EXAMINATIONS IN MEDICINE.

AN ENQUIRY INTO THEIR INFLUENCE UPON MEDICAL EDUCATION AND THE BEST METHODS OF CON- DUCTING THEM.

Read at the Second Pan-American Medical Congress, Mexico,
Nov. 16, 1896.

BY C. H. ALDEN, A.M., M.D.

ASST. SURG. GENERAL U. S. ARMY, PRESIDENT ARMY MEDICAL SCHOOL,
WASHINGTON, D. C.

My subject, that of examinations for medical men, can not fail to have engaged the attention, the very earnest attention, of each one of us at some period of our career. All of us have undergone the trial. Some of the younger physicians present may even now have recently passed through some such ordeal or are about to do so, and none of us are so old as not to have lively recollections of our experiences in this regard.

It has been said that the present is an age of examinations. They have without doubt become greatly multiplied in recent times, and the reason is not difficult to find. The rapid expansion of the bounds of human knowledge leading to widened and prolonged preparation for the professions, especially that of medicine; the institution of the Civil Service, aiming to fill offices by merit and not by favor; increased competition, have all naturally led to more numerous and severer tests of proficiency and fitness.

The attainment of the degree of Doctor of Medicine and entrance upon the practice of the profession are guarded among all advanced peoples and civilized nations by a careful examination into the qualifications of the candidate. Nor would we have it otherwise. The student and candidate of today becomes the practitioner and teacher of tomorrow, and while the former feels the pressure of the ordeal he is undergoing, the latter feels the importance both to the body of which he is a member and to the community at large of thoroughness and care in the selection of those who are to be admitted to the responsibilities and duties of the practicing physician.

The subject of examination needs to be looked at from two points of view, the point of view of the candidate and that of the examiner, and they are naturally very different. The examination presents diverse aspects as regarded by the two classes most directly interested. Much of the strain experienced by those undergoing examination for medical positions is unavoidable because inseparable from the circumstances under which the examinations are held. The candidate can not divest himself of the importance to his future career of the result at stake. He is perhaps competing for the degree which is to mark his entrance into the profession and to which he has devoted years of hard work; for one of the much sought hospital appointments with its opportunities for professional improvement; for some municipal or State position

with its fixed and certain compensation; for license under the State Board, or for entrance into one of the National Services, the Army, the Navy, etc., which service may have for him special attractions. The candidate can not forget the importance of the occasion, and this necessarily makes it a most anxious one. It comes, too, usually at an age when calmness and self-control have not yet been acquired and are hardly to be expected.

Nor, it must be remembered, does all the strain and labor fall to the share of the candidate. The examiner has his full share, if he faithfully execute his most delicate and responsible duty. As we shall see more particularly hereafter, his part requires careful preparation as well as the exercise of patience, tact and sound judgment.

Let us look into the methods of medical examination now in use. Let us inquire how they can be best adapted to fulfill the end in view, to accomplish the purpose for which they were instituted, the selection of competent men, and how, while fulfilling adequately this purpose, unnecessary strain and labor upon the examiner and examined may be avoided. Our investigation may, it is hoped, clear up some misunderstanding on the part of those presenting themselves for examination as to its scope and their true relation to the persons who are conducting it. If this can be done and the two parties concerned be put more *en rapport*, a highly desirable result will be effected.

The examinations of the undergraduates in medicine and those held at the end of his course for his degree, first claim consideration. Of late, both in this country and abroad, the view has been advanced that these medical examinations as now conducted have an injurious influence upon the preparation of the candidate for his future work, that they lead to the habit of cramming and memorizing facts as laid down in books. It is said that the importance of examination has become so much exaggerated that the student thinks the thing to be attained is passing the examination rather than the acquirement of sound knowledge and practical training; that even if facilities for practical work are given the student, his mind is ever on the necessity of preparation for the examination ahead, rather than on the careful observation of the clinical cases and of the prosecution of the practical work at hand. It is feared that the present system loses sight to some extent of the true function of medical instruction, which is not so much to fill the student with knowledge as to train his mind, his hand and all his senses, and to bring him into actual contact, under guidance, with the diseases, injuries and emergencies that he may hereafter be called upon to treat.

Jonathan Hutchinson, late President of the Royal College of Surgeons, has pointedly drawn attention to this in his address before the Liverpool Medical Col-

lege in October, 1895, on examinations as an aid to education. He says:

"The scope of the examination in prospect has been all-powerful in determining that of the previous course of study. 'This I shall want'; 'that I shall not be asked,' have been the ever-present motives in the selection of subjects for reading and thought. Whatever was deemed not likely to be questioned about has been ruthlessly put aside, whatever its intrinsic interest. The demands of the examiner set the pace of study, and the breadth of the examination determines the narrowness, or otherwise, of the student's education."

Mr. Hutchinson advocates, in order to reduce the evils of which he complains, the substitution of written for oral questions, and the institution of objective or practical examinations as far as possible. He makes the rather novel suggestion that the written questions should not be prepared by the examiners nor at the time of examination, but carefully framed in advance and published in volumes, the number of questions to cover the ground very extensively and to be largely in excess of the needs of any one examination; that from these volumes the desired questions be selected. He thinks this system would lead to more patient and careful testing of qualifications; since examiners are usually very busy men and can not give sufficient time to this important task. He further advocates the so-called divided examinations; the examinations being held along through the student's course and not crowded into one short period at the close.

Mr. T. Pridgon Teale, F.R.C.S., Member of the General Medical Council of Great Britain, introduced a resolution at a meeting of that body in June last advocating a change in its methods of examination. He supported it by some forcible remarks upon the need of reform. He stated that the number of rejections had been doubled in the last twenty years, and the stringency of examinations greatly increased, and that these rejections brought no corresponding advantage to the profession, while they added unnecessarily to the time and expense required to pass the ordeal. He believes that examinations are too exacting and that unsuitable questions are asked, that the examinations are too hurried and hence an element of chance has been introduced, that "good men fail to pass and unfit men, from a talent for cramming, manage to answer questions a little too well to justify rejection." He dwells on the interference with clinical work and practical training which results from the necessity for preparing for these numerous examinations. "Students," he says, "are overworked and badly worked."

Mr. Tobin of Dublin, in an address delivered at St. Vincent's Hospital, 1895, speaks in a similar vein.

Sir William Stokes describes the examination ever impending and kept in constant mind by the student as "the sword of Damocles."

Articles have appeared in some American journals drawing attention to this subject. A writer in the *New York Medical Journal*, June 20, 1896, says: "Examinations are directed too much to finding out what a man's stock of memorized facts amounts to and too little to finding out how far he has learned the art of studying by himself and how well qualified he is by natural gifts."

It may be that the evils complained of do not exist to the same extent in the United States as in Europe, yet the remarks of the eminent physicians and teach-

ers quoted give valuable warning of dangers to be avoided, and suggest possible improvements of our methods.

Let us consider the most important points as to methods used. Although my remarks on this subject are naturally based on experience gained on boards of examination of young medical men applying for admission to the medical staff of the army, they will for the most part, it is believed, be applicable to medical examinations in general. I desire to say briefly here that the method pursued in the army examinations have been evolved from long experience of the department, examinations having been held from a very early period of its history. Although they are not perfect nor all that could be desired, still they combine, it is believed, the most important elements, are practical as well as theoretical and accomplish the ends in view quite as satisfactorily as can perhaps be expected under existing circumstances.

In the first place it is important that the scope of a medical examination shall be so arranged as to determine the fitness of the candidate for the particular position or duties in question and not for any other. The examination for the degrees is designed simply to test the candidate's thorough acquaintance with the branches taught in the college curriculum and to ascertain if he has availed himself faithfully of the practical advantages afforded him. Examination in outside or preliminary branches should come at the beginning of his medical career, though it too often is not required at all. Neither in this nor in the examination for hospital appointments is it desirable to go into the literary or physical qualifications of the candidate.

The conditions are different as regards the medical staff, and these conditions are sometimes not understood by medical gentlemen applying for admission. The service may require exposure to extremes of heat and cold and to great fatigue, and the young medical officer must be thoroughly able to do duty under all circumstances. The government in appointing a medical officer takes him for life, if he desires to stay and is worthy of being retained, and it is essential that he shall be not only sound in health at the time, but free from any defect or incipient disease that is likely to disable him and render him useless and a burden upon the nation. A very considerable number of candidates find themselves thrown out by the physical examination who might be spared the expense and trouble of presenting themselves had they appreciated the necessity of a thoroughly good physique. Persons have been known to present themselves for examination with gross defects such as hernia, ankylosed joints, mutilated hands and serious defects of vision and hearing.

The preliminary examination of candidates for the medical staff in subjects of general education, such as arithmetic, geography, history and literature, has sometimes excited surprise. It seems to some not only unnecessary, but almost an indignity to subject a medical man to such an ordeal. It is to be remembered, however, that the army examination is practically open to all graduates and that the possession of a degree in medicine does not, under the present system of medical education in the United States, guarantee the amount of liberal cultivation or even of general information, which all will agree is essential for a scientific man. The army medical man becomes the associate of educated men, of officers who have

been trained at West Point, and it is clearly important he should be a man of equal culture.

The preliminary examination referred to is intended to ascertain this and does not require special preparation. It is not too much to ask, for instance, that the candidate shall be able to add and subtract fractions and understand the rule of three, that he shall have at least some knowledge of his own country and of the more important geographic features beyond these limits; that, for instance he does not locate Plymouth Rock on the coast of Virginia, nor the city of Vera Cruz on the coast of Peru; has a generally correct idea of the origin and course of the Mississippi River and can locate the Mediterranean Sea, etc. He ought not to complain if required to give at least a general idea of the most important events in the history of his country and of the world, such as the Declaration of Independence, the war of 1812, the reign of Queen Elizabeth of England or the battle of Waterloo. To say, as a candidate has been known to do, that at the great engagement referred to, George Washington was in command of one of the opposing armies, is certainly hardly allowable. Of literature, too, the candidate is expected to have such a knowledge as a gentleman acquires in ordinary reading. He should at least know the names and chief works of prominent authors. Certainly a physician can lay no claim to be an educated man if he knows nothing of Shakespeare, of Milton, of Cervantes, of Molière, of Schiller, of Prescott, of Longfellow, etc., and yet such ignorance is occasionally found among candidates for the medical staff.

If the medical colleges of the country held a preliminary examination before matriculation and required a certain standard of general education to be attained, as some colleges now do, and as it is hoped all eventually will, this inquiry into the preliminary education might be waived in the case of applicants for the army medical service. The day will probably come when a degree in the arts may be required of all candidates as is now done for entrance to the Johns Hopkins Medical College, but at present it is not possible.

It is much to be desired that the time of the examiners and of the candidates should not be taken up by such non-medical branches, but devoted to medicine and surgery alone. As a step in this direction the applicant for the army medical staff is now allowed, if he desires it, to take his physical and preliminary examination at some military station near his home under the supervision of the post medical officer. A considerable number of applicants are thereby saved unnecessary expense and disappointment.

The plan of dividing the examination for the medical degree, already practiced, it is understood, in some countries of Europe and in Mexico and Cuba, and now coming into use in the United States, so that examinations are held during the course instead of being crowded together at the end, is believed to be a good one. Medical education now extends over so large a field and so long a period that such division of the examination seems almost necessary. It has the advantage of giving more time and therefore more thoroughness to each examination and lessens the strain upon the candidates. In army examinations it is impracticable to any great extent, but the preliminary examination referred to, held near the candidate's home, partially carries out the idea.

The question of the relative value of written and

oral examinations is one that has received much attention and excited much discussion. In former times the oral was the usual method, but in late years as competition has increased and the necessity for closer scrutiny has arisen the written examination has come more and more into favor. There can be no doubt that the written examination has many advantages. It is in many respects a fairer test, as thereby the candidate is placed more at his ease and is better able to show what he knows than under the excitement and hurry of oral questioning. It largely eliminates the element of nervousness and puts the diffident man and the confident one more nearly on an equality. It affords the best means of determining the comparative merits of several candidates who may be examined together, since all are given the same questions. Granting these advantages to the written method, the oral examination can not, for army examinations at least, be wholly abandoned. By it the examiner is brought into close personal contact with the candidate, can insist on direct answers to his questions, can ascertain if the applicant is certain of his answers and his reasons therefore, can better estimate how much he simply remembers and how much he carries with him for use, can test his presence of mind and thus better judge the young man's capacity for the work he may be called on to do. A combination of the written and oral methods is for the reasons stated the best, and is now practiced in the examinations for the army.

The way in which either mode of examination is carried out is perhaps of more importance than the choice between them. It is highly important that the questions, either written or oral, should be planned with great care. It will not do to leave their preparation until the time of the examination, as they are then apt to be hastily and carelessly framed and to repeat too frequently questions already asked. It may well take almost as much pains and time for the examiner to prepare his written questions as for the candidate to answer them. The art of question making is by no means a natural gift or one that can be taken up by any one without study. It costs time and labor to select questions so that they shall well cover the various divisions of the subject, and to frame them so that they shall be clear and promptly understood by the candidate, call for exactly what the examiner desires to know and not invite too discursive writing whereby the candidate may try to hide his ignorance of the main point. A good plan is to prepare, for weeks in advance and at one's leisure, numerous written questions extended over a wide field so that all the important branches of the subject may be represented and then at the time of examination to select and arrange a set containing the desired number.

No advantage is seen in the plan adopted in some medical examinations of placing before the candidate a number of questions from which he is allowed to select and required to answer a certain percentage. The privilege of such selection favors the candidates least well prepared and in a competitive examination prevents any exact judgment of the relative merits of the written answers.

The examination by oral questions requires equal care exercised in a somewhat different way. The examiner should prepare himself beforehand and have by him a memorandum of the topics upon which he intends to question. If he does not do this he is sure to repeat himself. The examiner's favorite questions

soon become known to intending candidates and are specially prepared for. The greatest tact is necessary in the conduct of an oral examination, a tact born of right feeling but attaining its highest development only by cultivation. The questioner's manner should be calm, quiet and courteous, have no appearance of hurry, and it need hardly be added he should avoid anything like trying to show his own superior knowledge or the candidate's ignorance. His object is to find out what the person under examination knows and to do this must put him under the circumstances most favorable for finding out. A great deal depends upon the way the oral examination is opened, upon the first question. A first question misunderstood may so confuse and puzzle the young man that it may be impossible to get anything intelligible out of him. The questions should be clear and definite, and generally, at first at least, call for brief and definite answers. To begin, as an excellent surgeon but tactless examiner has been known to do, by asking the candidate, "What do you know about the brain?" is simply to render the candidate almost incapable of reply. A wise plan is to spend a few minutes in general inquiries on matters not directly connected with the subject of examination and, if possible, to get the candidate fairly entered upon it, without his being conscious of beginning.

Of still greater importance is the subject of the practical or objective examination as it has been called as distinguished from the examination by written and oral questions. The development of the practical side of medical education, and the greatly increased attention paid to laboratory and clinical work in the curriculum of our medical colleges is a source of just pride and congratulation. We recognize now that it is not enough for the medical student to listen to lectures, he must not only be told what to do and how to do it, but trained in doing it under the instructor's guidance. Yet it is probable that our tests of his practical ability have hardly kept pace with the facilities afforded him for obtaining it and that professional examinations still bring out rather what a candidate remembers than what he can do. It is manifestly impossible, from the want of time and other circumstances surrounding an examination, to make actual practical tests of the young physician's ability to deal with all the conditions and emergencies which he may encounter hereafter. The examination by questions must necessarily still be largely depended on, yet it would seem possible to test his practical acquaintance with laboratory work, and to ascertain how he can diagnose and treat disease and injuries at the bedside, and perform operations on the cadaver, to a greater extent than is now practiced.

No one is now allowed to present himself for examination by the Army Medical Board unless he has at least one year's hospital experience or its equivalent in private practice. Practical tests are therefore an essential part of the work of the Board, the candidate being required to examine patients at the bedside, and his method of diagnosis and treatment carefully scrutinized. The performance of operations on the cadaver is also required. It has not infrequently happened that an applicant for the medical corps has passed successfully the written and oral examinations but has shown at the bedside or in the operating room such unreadiness for practical work as to cause his rejection.

This paper can hardly close without some sugges-

tions for the special benefit of the person who is under examination.

First as to the candidate's preparation. It may be said that a thoroughly qualified physician needs no preparation; still the candidate, if he has time, will prudently look into the requirements as far as he may be able to discover them. It is generally easy to do so, as these requirements are often fully made known in advance and sample questions published. He should then endeavor carefully to meet these requirements, to supply his defects and honestly to qualify himself not only to pass the required examination but for the career he hopes to enter upon. This is a very different thing from cramming to answer the questions that may be propounded. Special instructions and special courses so far as they add to the candidate's knowledge and his practical skill are good and valuable. If their purpose is simply to enable the candidate to pass an examination, to stuff him full of the answers to questions that are known to have been asked by previous boards and may therefore be asked again, without reference to his general training, they are bad and useless. The tendency of most persons who make a business of preparing candidates for examinations is to train too fine, so to speak, to magnify the importance of their help by crowding the student with a mass of minutiae and valueless detail, neglecting the general principles and wider knowledge which is not only of the first importance but more likely to be of use at the examination.

In presenting himself for examination the candidate should stand squarely on his own merits; an introduction to a member of the board is well enough but voluminous and extravagant recommendations do harm rather than good. It is well known that they are to be had for the asking and have therefore but little weight. Reliance upon such outside influence is apt to make the examiner think it is needed. Politics and social influence have no weight in determining the candidate's success or failure. Let him enter the examination with a determination to do the best he can and to appear exactly as he is without pretence or exaggeration. Let him remember the old proverb. "One can take out of a cask only what has been put into it," or as the Spanish forcibly put it, "La cuba siempre huele del vino que contuvo." It is true there are constitutionally timid men, but knowledge and practice give a confidence which nothing else will.

Further, let him not delude himself with the idea that success depends on luck and not on merit, for in proportion as he cherishes that opinion will sound preparation be neglected. He may have full reliance upon the fairness of the board, and should disabuse himself of the thought that examiners are unfriendly or are trying to puzzle him. It is quite the contrary. The board can have no possible object in rejecting a worthy candidate. The very object of their appointment is to obtain, not to exclude men.

The questions given out, especially those requiring written answers, are usually framed with care and demand definite answers. Their purport should be studied carefully and exact answers given without guessing or hedging. A diffuse reply upon some side topic to cover up ignorance upon the main one, is a waste of time and deceives no one. The candidate will as an honorable man accept no aid from comrades or memoranda, even if he is not prevented from doing so.

A serious mistake often made by gentlemen under examination is that of studying hard just before and during the intervals of the examination. The man who during examination week sits up all night to supply his supposed defects not only does not add to his stock of permanent and useful knowledge but usually brings on such a state of nervous confusion and strain that he can not call up the knowledge he actually has. It is of the first consequence for success under an examination, especially a prolonged examination, that the candidate should have a clear head. Overwork at the time of examination, largely self-imposed as I have indicated, is by no means a small factor in the failure of well-trained and promising candidates.

The points to which I would in conclusion draw especial attention are as follows:

That medical examinations as now conducted often have an injurious effect upon the student's preparation, leading to cramming and interfering with practical work.

That for life positions, such as the army medical staff, an examination into physical condition is necessary; and under the existing requirements of medical colleges, in general education also; that examinations should be held at the close of instruction in each subject and not altogether just before the degree is given.

That in the examinations by questions, both the written and oral methods should be practiced, each having distinct advantages, and that the preparation of questions requires great care.

That practical tests of the candidate's readiness for his future work are of the highest importance, being probably still too much neglected.

That the preparation of the candidate should be for the position rather than for the examination, that he should rely on his own merits and not on influence, trust to the fairness of his examiners and avoid all extra work at time of the ordeal.

FRENKEL'S TREATMENT OF ATAXIA BY MEANS OF EXERCISE.

BY BOERNE BETTMAN, M.D.

PROFESSOR OF OPHTHALMOLOGY AND CLINICAL OTOTOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO.

Heiden, Switzerland, situated 2,500 feet above the sea level, overlooking the beautiful Lake Constance and the five cantons bordering it, formerly had the reputation of being a whey cure. It became especially popular through the annual visits of Albrecht Von Graefe, the so-called "Father of Ophthalmology," who sought rest and recreation among its peaceful hills. A horde of patients and medical disciples followed in his wake, so that it soon became the Mecca for oculists and afflicted ones seeking their aid. Its excellent location, its salubrious climate and its hotel facilities induced Dr. Frenkel to select it for his field of work during the summer.

During a seven weeks' sojourn at Heiden this summer, I had an opportunity, through the courtesy extended me by Dr. Frenkel, of observing daily his new method of treating locomotor ataxia due to tabes dorsalis. So excellent were some of the results obtained under my personal observation, that I thought it would interest American physicians to know of Frenkel's method of correcting one of the most annoying disturbances of tabes; the one, at least, which interferes most seriously with the ordinary routine of life, namely, the ataxia.

A vast number of therapeutic measures have been introduced to combat the disease. They have been summarized by such universal writers as Leyden and Erb as, the "mercurial treatment (which, in Erb's opinion, ranks first in importance, since over two-thirds of 700 cases of tabes dorsalis reported by him were due to syphilis); treatment by internal medication, as for instance silver nitrate; injections of animal extract à la Brown-Séguard; thermal baths such as Oeynhausien, Nauheim, Kissingen, Aix; hydrotherapeutics; sea baths; Kneip's cure; massage; electrotherapeutics; nerve stretching of Langenbach; suspension, introduced by Motschutkowski; orthopedic treatment of Hessing," etc. The mere fact that so many methods of treatment are in vogue, is sufficient proof that none is satisfactory, and this is the conclusion that is reached in the above mentioned monographs.

Frenkel, realizing how few were the cures effected by all the methods used, disregarded the disease proper and turned his attention to the correction of its most annoying feature. The method which he has so scientifically evolved is the result of an observation made during the treatment of one of his tabetic patients. At the first examination, the patient was unable to correctly perform the simple test of stretching out both arms and with closed eyes bringing the tips of the extended index fingers together. Much to Frenkel's surprise, at the second examination, a few weeks later, the patient performed the test admirably, and upon inquiry stated that he had repeatedly tried the movement at home. Frenkel related an amusing incident to me which bears on the matter in question. A now well-known professor of nervous diseases carefully prepared his maiden lecture and selected a number of tabetic patients to illustrate various ataxic movements. He inadvertently told the patients what special purpose they were to serve. The demonstration was a perfect failure, owing to the efficient manner in which the patients had overcome the ataxic movements through constant practice days before the lecture was delivered. The reason of the unsuccessful demonstration dawned upon the professor after hearing of Frenkel's method.

The thought that naturally arose in Frenkel's mind after observing his patient was: If one symptom due to incoördination can be cured, why not every one?

In the *Semaine Médicale*, March 25, 1896, appeared an article on "Cerebral Exercise," in which Frenkel states: "One of the fundamental properties of nerve tissue is to retain impressions made upon it. When these same impressions are frequently repeated, a permanent change is wrought in the nervous apparatus, which in the domain of association of ideas is translated as memory and in the domain of motor functions calls forth coördinated movements. It is thus that the physiologic rôle of habit, exercise, education is explained."

Coördination is acquired only after years of practice. Every single movement of the body is learned. We are born with a complete set of muscles, but how to use them each one must learn. The various movements of our body, even the simplest ones, call into play certain muscles and groups of muscles. Their harmonious action, directed by the senses, may be called "coördination" or coördinated action. Through practice this harmonious action, this coördination, can be increased to a marvelous degree. We need only cite the homely examples mentioned by Frenkel and Hirsch-

berg. The infant learning to walk; the child to play piano; the juggler; the tight-rope walker. The infant in his first attempts to walk is decidedly ataxic. The tight-rope walker performs his, to us less agile persons, difficult feats, only after having learned to bring into harmonious action the numerous groups of muscles required, directed by the different senses. Beginners in the art of writing, of dancing, of rope walking, are ataxic compared to experts.

All movements are controlled by the sense of sight and the muscular sense. The oftener any action is performed the more perfect its execution, and the more mechanical it appears. Finally the controlling influence of the sense of vision and the muscular sense is lost sight of, and the movement is termed automatic, as for instance writing, walking, playing an instrument. When, however, one of the controlling influences is disturbed or impaired, as for instance the muscle sense in tabes, the movements lose their *finesse*, become coarse or incoördinate. The other sense, that of vision, is called into play to enable the patient to gauge his movements to this means. It is well known that an ataxic person becomes more so when the controlling influence of vision is excluded by closing his eyes.

The ataxia of tabes is accounted for by Leyden,¹ by a loss or impairment of the sensibility. Erb and Charcot attribute it to a primary lesion of the center of coördination itself or its paths.

Frenkel believes that a mental or psycho-motor element plays an important rôle in coördinated movements, consisting of the idea of the act, the voluntary effort necessary to accomplish it, and the consciousness of having effected it. This being, according to Frenkel's idea, the physiologic action of coördination, he bases his therapeutic reëducation upon the same principle. By a series of graduated exercises the patient, by calling into play certain groups of muscles, stimulates certain nerve centers in which these movements originate, thus giving rise to what Frenkel terms *gymnastique cérébrale*.

Frenkel assumes that in but very few cases of tabes, an entire destruction of the sensory tract of the cord ensues. In the great majority of cases there are still bundles of the sensory fibers intact, whose functions have probably been annulled through a temporary pathologic change or by lack of use. Be that as it may, stimulation through gymnastics is intended to revive and possibly intensify their action. Leyden terms Frenkel's treatment compensatory treatment.

Attention is called to the great influence of the will power. This plays an important rôle in all exercises, and must never be lost sight of, either by the physician or by the patient.

Frenkel distinguishes three kinds of movements, 1, simple contractions of the muscle, such as extending or flexing a finger; 2, simple coördinate movements, more complicated movements than the first mentioned ones, such as placing in turn the tip of each finger on thumb nail of the same hand; 3, complicated coördinated movements, as writing, drawing.

These three kinds of movements must be practiced every day. The various exercises performed by Frenkel's patients are described by Hirschberg, who supervised their execution under Frenkel's instruction, at the Salpêtrière.

Before detailing them it may be well to sound a note of warning. These exercises are expected to be

performed with the greatest exactness and with a constant expenditure of will power, and are thus extremely fatiguing. Consequently the patient must be restrained from over-doing even if he feels no consciousness of fatigue (I will touch on this later). Patient must rest a few minutes, if not longer, between all exercises. The simplest exercises are first tried, the more difficult ones later on. It stands to reason that exercises are chosen to meet the individual needs of each patient. There are two classes of exercises, those performed in and those performed out of bed.

In bed, the patient is called upon to flex, extend, abduct and adduct each leg separately and then both simultaneously. The knees and hips are likewise exercised. The patient is asked to place the heel of one foot on the big toe of the other foot. Place heel upon knee of the other leg and then slowly travel from the ridge of the tibia toward the ankle. Exercises are made alternately, first with one leg, then with the other one, with open and with closed eyes. These exercises are attempted over and over again, every morning a half hour, with frequent rests between times. Patient is encouraged to persevere until he succeeds.

The exercises in the turning hall are repeated twice a day, a half hour in the morning and again a half hour in the afternoon.

1. Patient is placed with his back to a chair, heels together, then seats himself slowly in the chair and is then made to rise in the same careful manner. No cane is used. If patient can not stand an attendant is placed at either side of him to support him if necessary.

2. One leg is placed at an ordinary walking step in front of the other, and then placed with great exactness back into its original position. Same exercise is then performed with other leg. The patient, if necessary, supports himself with a cane or otherwise.

3. Walks three paces slowly and with precision.

4. Rest in standing position, one foot before the other; with hands placed akimbo he flexes his knees and slowly raises himself again.

5. Patient, as in exercise number 2, advances one foot, then returns it to its original position, and then puts it one step behind the other one. This exercise is usually a very difficult one, requiring as it does a great deal of balancing power.

6. Walk twenty steps as in exercise number 3.

7. Number 2 performed without a cane.

8. Stand without a cane, with feet placed together and hands on hips.

9. Stand without a cane, feet separated; various movements with the arms, grasping objects, forcing back outstretched hand of physician, etc.

10. Maintain same position as in number 9, flexing trunk forward, backward, to the right and to the left.

11. Exercise number 9 with feet together.

12. Exercise number 10 with feet together.

13. Walk along a painted line on the floor, patient supported by a cane.

14. Same without a cane.

Exercises for the fingers and arms are also employed, based on the above mentioned principles. The author of this method of treatment has invented a number of inexpensive apparatus. I will mention one or two. Balls of different sizes are suspended by strings. The balls are set in motion and the patient is requested to grasp between finger and thumb a given one. A board containing a number of holes in which are fitted

¹ Frenkel, Münchener Med. Wochenschrift, No. 52, 1890.

violin keys or stops is placed before the patient. He is ordered to remove and replace certain specified numbered stops. He holds the hand behind the head and at the word of command slowly or rapidly executes the desired movement. The original position of the hand excludes the controlling influence of vision. An endless variety of similar exercises can be introduced to meet the requirements of every case.

I saw several tabetics practicing the parade-march step. One patient, while walking briskly the length of the hall, had chairs and other obstacles put into his path. To avoid these he had constantly to change his position as though he were walking in crowded streets. Regularity, slowness, precision, are the important features of these exercises which the physician impresses on his patient.

It is not my intention to detail cases recorded in literature in proof of the efficacy of this method. Suffice it to say that men like Leyden, Erb, Raymond and Hirschberg, and others, speak of it in terms of highest praise, and report a number of cases of practical cures of the ataxia.

Leyden² says: "To my mind, it is only in this or some similar manner that one will attain the best results possible in the therapeutics of tabes."

I will, however, briefly recount a few general impressions I received while almost daily observing the patients at their exercises. Most of the afflicted individuals were chronic cases, some having made the round of many of the noted neurologists in Europe. All were from the so-called better class of society, professors, judges, military officers, officials and business men. Probably the most striking effect after a few weeks treatment was the revival of the patient's hopes. Men who had been confined to roller chairs for years, who had needed the aid of attendants to dress and to retire, developed a surprising amount of energy and spirit when they realized that they could again perform simple movements without aid and coordinately. This state of mind aided materially in furthering their progress.

A number of the better informed patients realized that the treatment was only intended to cure the ataxia, but it was just this feature of the disease which had prevented them from following their vocation and from finding enjoyment in life; and the visible improvement gave them new hope, at least for some relief, if not the entire cure of the ataxia. The moral influence was great. The confidence of the patients was restored. Instead of continually seeking the aid of an attendant or a cane they began attempting things themselves.

On my walks from the hotel to the turning hall I was often accompanied by a strong looking, young Serbian. Repeatedly I had found him seated before the hotel waiting me. He was a tabetic patient, but walked quite well with his cane. One day we met Dr. Frenkel when entering the turning hall; he chided the Serbian for waiting for me, explaining to me that the patient had once fallen, and ever since had been afraid to walk alone. The presence of an infant at his side restored his confidence. A few weeks later the patient's confidence in himself was so much restored, that I often met him taking long walks only supported by his cane.

The time required before any improvement is visible, varies greatly, depending naturally, firstly, upon

his condition and secondly, upon the temperament of the patient. I have in mind a patient 45 years old, who when I arrived at Heiden spent most of his days in a roller chair and could with difficulty, supported by a cane, drag his legs one hundred paces. After four weeks he walked the length of the long turning hall unsupported by his cane. Another patient who had been lifted bodily out of his roller chair and carried up the steps into the hall, and had there been supported through the exercises, by means of a broad belt which had been fastened about his body and to which handles had been attached, so that the attendants might hold him up, walked up the steps of the turning hall, six weeks later, supported only by his cane. Another case was an old and feeble man who after three months practice in Paris performed all the feats in a most perfect manner. He walked along a painted band on the floor, four or five inches broad, backward and forward and never overstepped the borders. He stood perfectly rigid on either foot, the other one flexed, without losing his balance. He fenced with an opponent, readily assuming the various attitudes. He danced a polka at a ball given at the Freihof hotel. For a more detailed account of other cases I refer you to the literature.

The patients after having mastered the details of the exercises are supposed to continue them conscientiously in their own homes.

Frankel placed at my disposal a manuscript of a paper soon to be published in the *Berliner Medicinische Wochenschrift*. In this, he accounts for the purported failures of his method of treatment, by attributing so-called failures to two causes:

The faulty selection of exercises for individual patients. As stated in the beginning, it is a matter of greatest importance to begin with with simplest exercises, and then adopt them to meet the individual needs of each case. The second cause of failure is attributed to patient's loss of sense of fatigue. Owing to the destruction or interruption of the centripetal nerve path, the patient, having lost his muscle sense, is no longer conscious of fatigue. Consequently if not forced to rest, he will do too much and greatly injure himself. *Over-taxation must never take place*, in every instance must be carefully avoided and guarded against. After exercising patient ought to rest for an hour or two, ought never immediately attempt long walks.

When a relaxed condition of the muscles and tendons exist, massage and other gentle stimulation is resorted to.

Frenkel has recently called attention to an heretofore unmentioned symptoms of tabes hypotonus. This is manifested by patient's ability to make more than normal exercising with his limbs.

A normal individual lying flat on his back, can but lift his legs so that it is at right angle with the trunk. A tabetic patient of high degree, brings the leg nearer the trunk. I saw a photograph of an exaggerated case of hypotonus; the patient was an inmate of the Salpêtrière and could place his straightened leg on his trunk, so as to make it touch the shoulder. Hypotonus is due to the relaxed conditions of the tendons of the joints.

There are but very few contraindications to treatment and exist only in cases where the atrophy of the muscles, disease or deformities of the joints render the use of limbs impossible.

Frenkel objects to gymnastics and turning for

tabetic patients and in evidence of the dangers attending each exercise, quotes a number of cases of fractures resulting therefrom.

In conclusion I need hardly state that the above is merely a sketch of the new method of treatment of ataxia due to tabes. For the benefit of those who desire fuller information, I affix a complete list of articles bearing on the subject, which have appeared up to date.

ETIOLOGY, PATHOLOGY AND DIAGNOSIS OF APPENDICITIS.

BY C. E. RUTH, M.D.

PROFESSOR OF DESCRIPTIVE AND SURGICAL ANATOMY, KEOKUK MEDICAL COLLEGE; PROFESSOR OF CLINICAL SURGERY IN ST. JOSEPH'S HOSPITAL, KEOKUK, IOWA.

If we would correctly estimate the tendencies of appendicitis it will be through an understanding of its etiology, pathology and diagnosis. As the varying anatomy and relations of the appendix have much to do with the origin, course and recognition of appendicitis they should receive some consideration. The appendix is an organ absolutely without function. For this reason nature is attempting to rid herself permanently of its presence. At the present rate it will be many generations before it is accomplished, and until then physicians must continue its study. All organs without functional activity have less resistance to abnormal processes than those which are functionally active.

Every conceivable position is occupied by the appendix, but usually its base is in the right iliac fossa. Its tip may be anywhere that its length, from one to six inches, may enable it to reach. In the female its proximal opening into the cecum is said to be somewhat larger than in the male. Thus, other things being equal, the woman has a little better chance of recovering than the man with appendicitis. We usually find the appendix is as strictly an intraperitoneal organ as any part of the small intestine, or we may find that the serous coat of the cecum stretches over its proximal third or half, while the balance is intraperitoneal. The serous investment of the cecum may be continuous with the iliac fossa, directly across and in front of the appendix, and in that way comes only in contact with the anterior surface of the appendix and the latter really has only two investing coats, mucous and muscular, and is consequently extraperitoneal. Its drainage is often against gravity and around sharp angles, obstructed by pressure and position with a muscular wall usually less developed than any other part of the intestinal tube. The longitudinal bands on the ascending colon are directly continuous over the cecum to the appendix and are there-

fore the most important guides to finding the appendix. Lack of this simple anatomic point may compel a long search for this little organ, which should be instantly followed to its cecal attachments, where inflammatory processes have not destroyed this landmark. The cecal attachment of the appendix is usually on a line between the anterior superior iliac spine and the umbilicus, and about two and one-half inches from the spine. The appendix has a mesentery of its own of varying extent.

When its mesentery extends entirely to the appendix tip the nourishment for the organ is the best possible. Frequently the mesentery extends but a short way and the distal portion receives only such blood supply as can be carried by the coats to the distal end. Thus should sudden swelling occur from any cause the tense peritoneal investment at once strangulates the distal end and favors perforation and the passage of pathogenic bacteria, if not immediate gangrene of the entire distal portion beyond the mesentery.

The caliber of the tube is normally so small that no great amount of swelling of mucosa is required to produce complete occlusion. The peritoneal investment is tense but will permit of great distention if the pressure from within comes on very slowly, but if rapid it yields by rents occurring at one or various points. Stercoral calculi are the principal foreign bodies now recognized as etiologic factors in the production of appendicitis. To these add the anatomic disadvantages under which is placed the extension by direct continuity of all forms of inflammation from the colon, mechanical pressure from fecal accumulations in the ascending colon, and in the female extension of inflammatory processes from uterine adnexa; we have nearly the sum total of appendicitis etiology.

Pathologic varieties. Its pathology is: 1. That of the ordinary cecal and colonic troubles by continuity of tissue due to digestive disturbances of all kinds. These are usually primarily of the milder or catarrhal variety. 2. Ulcerative, in which one or more or all of the coats may be lost at one or many places. 3. Obliterans, which is simply a variety of the ulcerative. 4. Gangrenous.

The catarrhal may occur without leaving behind it any appreciable lesion or may lead to either of the other forms.

Where ulceration or gangrene does not occur there would seem to be in every case a lowered vital resistance with great liability to recurrence of other attacks. So marked is this tendency to recurrence, even in the mildest cases, that hardly any physician considers a case of catarrhal appendicitis is cured unless three or four years have passed without attack.

This lowered resistance in the appendix would appear in these cases to be analogous to that found in the catarrhal inflammations found in pharyngeal mucosa rather than to gross anatomic lesions.

The ulcerative form may follow in the wake of the catarrhal by pressure depriving the mucosa in various ways of its blood supply or by direct action of an irritant. This process may remain limited to the mucosa and in its repair cause the third variety, obliterans, by adhesions of the walls of the tube. Should this begin at the distal end, repeated attacks, if perforation or migration of septic material does not occur, will effect a cure by obliteration. Should it occur at the proximal end the same result is still possible but not likely, for the septic material caught beyond the point of occlusion can by no plan, except abscess for-

mation, be evacuated unless the neighboring lymphatics be for a long time loaded with septic materials constantly liable to destroy life by abscess rupture. When the case progresses in this manner to complete obliteration by either plan, a recognized rare occurrence, the cure is complete and permanent.

When the ulcerative process is slow, whether the appendix be *intra-* or *extra-*peritoneal the general peritoneal cavity is protected as a rule for a considerable time by inflammatory exudate, but when rapid the general peritoneal cavity may be involved in twelve to forty-eight hours. Slow progress of the inflammatory process favors the development of tolerance by the peritoneum in the neighborhood of the trouble.

Gangrene, whether involving a considerable portion of the appendix or but a very small area, is usually due to sudden deprivation of its blood supply, because of its absent or limited mesentery or to pressure necrosis, either of which may permit the passage of the most virulent infection to the peritoneal cavity in a few hours before sufficient time has elapsed for inflammatory exudate to throw out a protecting barrier of any kind. Rapid swelling of the appendix may so weaken all the coats that a serous exudate between and within them favors the culture and passage of pathogenic bacteria and septic material which may produce general and usually fatal peritonitis without solution of continuity in any coat of the organ. The recognition of the colon bacillus in many internal organs without any appreciable lesions has compelled caution in attaching so much importance to it in lesions about the appendix, as has been given it in the past. We should justly consider it of secondary importance in inflammatory trouble about the appendix and its presence due more to accident than as a causative factor (Welch). They are prone to collect in parts already invaded by other organisms, or weakened by injury. If the appendix be *intra-*peritoneal it is, other things being equal, more liable when inflamed to produce an abscess that will be followed by general or local peritonitis. It is also in its earlier stages easier of surgical access.

When the cecum and appendix receive an extension of the peritoneum from the colon to the iliac fossa on their anterior surface, abscesses forming about the appendix are almost sure to be *extra-*peritoneal and may spread great distances, dissecting up the peritoneum, going down into the pelvis, up behind the colon and well across toward the median line, and still show but little tendency to rupture. Appendix abscesses so placed cause no inflammatory, agglutinating exudate to be thrown out into the peritoneal cavity and the intestines are consequently free from adhesions. The intestines are carried up in front of the tumor and may give at all points tympanitic resonance. At the base of the appendix where the mesentery diverges to encircle the organ there are in all cases properly but two coats, and a very large number of abscesses which form about the appendix have their apparent connection with the appendix only at this point, and are for that reason usually approachable *extra-*peritoneally.

This is probably one of the reasons why it was so long before the influence of the appendix was discovered in the production of the purulent accumulations in and about the cecum. The perforation of the two inner coats may occur at any point and yet the inflammatory perforation products be carried under

the serous coat the entire length of the appendix in the loose connective tissue space between the diverging layers of its mesentery to the much greater loose connective tissue space about the appendix and cecum, where the pus may burrow almost without resistance till large accumulations take place as in the *extra-*peritoneal variety above mentioned.

Diagnosis.—If the pathology of appendicitis here given may seem obscure and confusing, it will be vastly more so when the diagnostician undertakes to clinically recognize these varieties. In fact we may say at the outset that the diagnosis of appendicitis is usually fairly accurate, but the diagnostic differentiation of its pathology is not yet possible. Pain is always present at the beginning of appendicitis, but is often remote from the location of the appendix. Frequently the pain is severe about the umbilicus, but the local tenderness will correspond to the position of the appendix and is usually midway between the anterior superior spine and the umbilicus. The muscular tissue of the abdominal wall early gives evidence, in increased resistance to manipulation, of the presence of trouble in the right iliac fossa. The pain may soon fix itself in the right iliac fossa. Nausea and vomiting are almost always present as an early symptom, but may permanently disappear within twenty-four hours without other amelioration in the patient's condition. Neither the presence of constipation or diarrhea aids us in the diagnosis of appendicitis, unless the latter be sufficient to empty the alimentary canal and aid in the palpation of the abdominal contents. Tenderness in the right iliac fossa may be said to be always present. Palpation of the appendix without considerable enlargement of the organ or abscess formation is rarely possible. It should, however, always be attempted, and by placing the fingers of the right hand upon the abdomen and making steady, firm pressure downward just to the outer side of the umbilicus, draw the hand downward and to the right toward the iliac spine, and as the spinal column, external iliac artery, psoas muscle, appendix, etc., are successively crossed a lateral motion of the hand parallel with the long axis of the body should be made, so as to detect any abnormal condition of each tissue or organ before it is allowed to escape from under the fingers.

A distinct tumor is rare before the third day. Dullness is not found if the appendix is behind the cecum (Shrady). Fluctuation does not occur until suppuration is far advanced. Examination of a large appendicular abscess must be made with caution to avoid rupture, especially in the case of a large tumor with evidence of pronounced sepsis, when the tension is so pronounced as to overcome or to have greatly retarded its blood supply and the temperature has fallen to or near normal. The patient feels almost well, the physician is led to doubt his diagnosis and to advise the patient and his friends to delay radical measures. This is the calm that so often precedes the fatal storm. When the blood pressure was so great or the abscess tension was so great as to limit absorption of septic material into the system, the blood supply was also reduced and the vitality of the abscess wall so low as to prevent further exudation to strengthen weak points (Harris), and palpation must be very gentle or entirely interdicted because this choking of the blood supply from the abscess pressure having stopped the formation of plastic exudate for the protection of the general peritoneal cavity, rupture is

imminent. Careful attention to the history and examination should enable one to readily differentiate appendicitis from psoas abscess, morbus coxarius, renal and biliary colic, tubal and ovarian disease, intussusception, carcinoma of the colon and cecum, typhoid fever and floating kidney. Peri-nephritic abscess occurring on the right side might readily deceive one as to its origin. The mistake, however, would be of no moment, for the indications in each would be practically the same. When pain is produced in the right iliac fossa by pressure on the left side of the abdomen we should be suspicious of appendicitis.

To sum up the diagnostic symptoms upon which we must rely to recognize appendicitis I mention: 1, pain; 2, nausea and vomiting; 3, tenderness and muscular resistance in the right iliac fossa; 4, palpation, tumefaction, fluctuation; 5, septic manifestations.

OF WHAT USE IS SURGICAL TREATMENT IN OVARIAN NEUROSES?

Read before the Nebraska State Medical Society, at Lincoln, Neb.
May 19, 1896.

BY A. F. JONAS, M.D.

PROFESSOR OF CLINICAL SURGERY IN THE OMAHA MEDICAL COLLEGE; SURGEON TO OMAHA DEACONESS HOSPITAL, ETC.
OMAHA, NEB.

The term *neurosis*, as commonly used by the profession, has an indefinite meaning. It may mean a pain, severe or slight, of a "neuralgic character." It is often applied to irregular functional disturbances, as for example, the gastro-intestinal functions, which may be perfect to-day, less so to-morrow, violently disturbed the next day, and normal the fourth, without any assignable cause. Neurosis may mean emotional manifestations, for example, irritability of temper, explosions of unprovoked grief, attacks of epileptiform convulsions, such psychic disturbances as melancholia and maniacal conditions. Ecstasy, delirium, hallucinations and trance have been called by that convenient term. It is often applied to that indefinite symptom-complex, known as neurasthenia, or more popularly called hysteria. In short, no matter what the train of symptoms may have been, when it seemed impossible to find structural changes due to inflammatory processes, acute or chronic, or when it could not be shown that there existed an atypical cell proliferation in the form of a neoplasm, or other new formation, it has been the custom to speak of it as neurosis, or a neurotic condition. When there has been observed pain, aberration of glandular or organic function; psychic or mental disturbances, convulsive manifestations, without discernible organic structural changes, that much abused term, *neurosis*, has been found of great convenience.

Under the modern system of specialism, when each organ has its special custodian, whose sole duty seems to be to stand as a guardian angel over that which he has selected and adopted, it seems clear to each specialist that this long train of neurotic symptoms, are nothing more nor less than reflexes (another term used with so much delight, and no more understood than the other), beginning in that particular organ which happens to be the pet of a given specialist. There is such a strong tendency for every specialist to attempt to look into the human body, through his own little speculum.

The ophthalmologist, if he can find nothing visible

by external inspection or ophthalmoscopic examination, discovers slight errors of refraction or accommodation, and in that, a reflex neurosis which explains that headache, the disinclination for work or pleasure.

The otologist is sure to find the origin for vertigo and fretfulness in the ear.

The rhinologist is positive that the dyspnea and its accompanying train of symptoms, originate in the deflected septum, spurs, thickened turbinated tissue and post-nasal adenoids.

The lung and heart specialist is inclined to ignore what the aforesaid authorities have diagnosticated, for he hears through his stethoscope sounds that explain all.

The gastro-intestinal authority finds matters very plain. He removes the stomach contents after giving a test meal, and with reagents and microscope, and possibly, if he be well advanced and properly equipped, he may employ the gastroscope, and the gyromele. He indicates to you as plainly as the writing on the wall, what is at the bottom of the trouble.

The orificial specialist is positive, beyond all powers of argument, that all neuroses, and even appendicitis, begin in the external orifices.

The gynecologists, and nearly one-half of the physicians of our cities are professed gynecologists, never fail to trace an ache, or pain to the pelvic organs. The uterus and its adnexa are centers, which, to their minds, control every function in a woman's body. Every ache and pain is a neurosis, and when located in a region remote from the pelvis, is a reflex condition. Under the head of neurosis, according to our enterprising and pushing gynecologist, is included a wide range of disorders, and I fear, a multitude of sins.

When we view this vast subject from the standpoint of the true gynecologist (not the six weeks' policlinic fledgeling, but I mean the earnest, honest, broad minded, careful, painstaking, scientific gynecologist, whose specialty is the culmination of a wide experience as a general practitioner, and whose skill as a specialist is the outcome of a long and large experience at the bedside), we soon find that we must eliminate the larger portion of nervous manifestations, from our consideration, as diseases originating strictly from the organs of generation which are frequently denominated as ovarian neuroses.

Under the caption of ovarian neuroses, we may include all such affections as are characterized by primary pain or other disturbances, referable to the ovarian regions, unattended by inflammation or any ascertainable structural lesion.

If we adhere strictly to this definition, we will find that the vast majority of the gynecologic cases that come to us, are of a neurotic character. The pelvic distress and hypersthesia, local or diffused, is in a large portion of cases, unaccompanied by structural change. Nearly all these cases complain of distress involving, one, and in some cases, nearly every vital organ in their bodies.

For convenience of description, in our discussion we may adopt the classification of Baldy: 1, neurasthenia; 2, hysterio-epilepsy; 3, psychoses-insanity.

The more modern, more esthetic, and possibly more scientific appellation, neurasthenia, has largely displaced the term hysteria. The latter has become to be regarded as a reflection upon the mental balance of the sufferer, and is often means a forfeiture of sympathy on the part of her friends. But to designate the long and variable train of nervous and mental

disorders, as neurasthenia makes her an object of solicitude and the tenderest care from the side of her friends, and stamps the doctor, in the estimation of all concerned, as a skillful diagnostician and a profound physician. While hysteria and neurasthenia are described under separate heads, still when we study their symptomatology we find that both have much in common. We find in hysteria (Webber) "an almost innumerable variety of symptoms, which may be analyzed in a general way into signs of increase, diminution, or perversion of various nervous functions. It is commonly classed as a functional nervous disease, and has no recognizable pathologic anatomy. Postmortem investigation gives no clue to the morbid process."

For neurasthenia (James J. Putnam) we find "certain states of the nervous system of which the anatomic basis is unknown, but which is characterized on the one hand by lack of vigor, efficiency and endurance, affecting usually a large number of nervous functions, and on the other hand, by signs of active derangement, which in part seem to occur as positive symptoms, and in part are due to failure of the mutual control which the different parts of the nervous system afford each other in health."

When we make a critical analysis of the cases that come to us for treatment, we find that nearly two-thirds of them belong under the above headings. Their subjective symptoms are innumerable, their objective signs, aside from feebleness and palor due usually to too close confinement and inactivity, are few. Among the endless subjective symptoms, a few usually predominate and are referred to some special organ, and in these progressive days, when pelvic organs have met with such terrible onslaught and have been so persistently directed to the pelvis, the poor sufferer being a woman, naturally thinks of those organs which make her such. She seeks comfort and advice from the specialist, and he being ambitious and anxious to distinguish himself, and being imbued with the idea that the culmination of all skill is in blood, seldom fails to find something in the pelvis, that, to his mind, solves the entire condition and offers him opportunity for sanguinary achievements. If he does not find a laceration of cervix uteri or perineum which need repair, it is a metritis, that must undergo the ordeal of curettement, and if not that, a thickening in one or both broad ligaments, which means chronic salpingo-ovaritis, and if he be an up-to-date specialist, he can invariably diagnose adhesions; or he finds adherent flexions and versions. The diagnosis having been completed a grave prognosis made, an operation is urged as the only means of cure, and often the only possible means of saving life, for blood he craves, and nothing short of blood will appease his craving. The frightened patient gives her consent. Elaborate preparations are made; a half dozen or more colleagues are invited to witness the marvelous feat. The operator clad in spotless gown, in his sterilized hand he holds aloft a gleaming, keen-edged knife. He calls *time*; with a sweep or two of the knife the peritoneal cavity is open; two fingers are rapidly thrust into the sacred recesses of the pelvic cavity; an unoffending ovary and tube, a marvel of perfect anatomic form, is drawn forth and instantly pronounced cystic; it is tied off by a specially devised method, cut away and the pedicle dropped. The same procedure is followed on the other side. To vary the condition and to give proof of his wonderful knowledge of morbid structure,

he unhesitatingly pronounces the second ovary (which really does not differ from the first) to be scirrhotic. Abdominal wound closed by a new method, dressing applied and the time-keeper announces the startling information, "*seven minutes!*" A triumph of modern surgery and individual dexterity! Patient is put to bed, recovery uneventful, discharged, *cured* on the fourteenth day. Cured, did you say? By that you mean that her neurasthenic manifestations have vanished. Did you ever see one of these chronic sufferers cured in fourteen days? When Lawson Tait only a few years ago published his remarkable tables, of a hundred or more cases in a table, and we found that 98 out of 100 cases were discharged cured, you and I, in our verdant simplicity imagined that when he said *cured*, it meant to be relieved from all pain and distress, and the departed bloom of youth had returned. And when we found that our cases had not been cured in six months or a year, and some were even worse, it slowly dawned upon us, that "*cured*" in published statistics, meant a survival of the surgical ordeal only. When we examined the appendages removed by the aforesaid seven minutes operation, we found that what we had been taught to be normal, unruptured Graafian follicles had suddenly, according to the aforesaid operator, become cysts. The old sites of the ruptured follicles had become evidences of a "fibrous condition," which was proof positive of scirrhotic. The Fallopian tubes were open at both ends and otherwise so perfect as to delight the teacher of anatomy who is in search of normal specimens to demonstrate to his class. One well-known surgeon, after he had removed the uterine appendages, found that what the textbooks describe as sites of newly ruptured Graafian follicles, an ulceration of the ovaries. Who has not seen several pairs of such ovaries with open Fallopian tubes, with beautifully branching fimbriæ, exhibited before medical societies, as the result of a half-day's labor. You and I have no hesitancy in pronouncing them to be normal, and we ask why were they taken out? The answer can always be anticipated. "Why, she had ovarian neuralgia;" the "cystic" and "scirrhotic" condition caused reflex neuroses!

We have often wondered why operators in comparatively small towns have such a large proportion of pus tubes among their abdominal cases. Recently we had some light thrown on this point by an operator, who, in a country district where specific infection is a rarity, removed in ten minutes uterine appendages identically like those described in the foregoing seven-minute operation. The operator carefully squeezed the Fallopian tube from its fimbriated toward its uterine end, and succeeded in pressing out of it a very few drops of fluid that had a very slight opaque appearance; instantly the diagnosis of pyosalpinx was made. The microscope was superfluous with a surgeon who possessed such microscopic vision.

If we could examine all the specimens removed from cases in the many reported "series" where the mortality is small we would find a large proportion to be those of absolutely normal uterine appendages. Have you taken pains to follow the subsequent history of these cases? You will find that a large proportion, the majority of them, are not benefited. Many have been made worse. Why? If these cases had been carefully investigated, the conclusion would have been forced upon the operator that the local pain was only a *local expression of a general nervous condition*. In these cases we sometimes have persistent pain in the

stomach, liver, heart, lungs, head, arms and legs. Why not extirpate or amputate one or more of these occasionally. But the resourceful gynecologist promptly decides that the pain in these various organs are of a reflex nature, which take their origin in the womb or ovaries. Poor maligned organs, "more sinned against than sinning!"

A few years ago I had occasion to do a successful Morton's operation in a case of metatarsalgia in the left foot of a young married woman. The uterus had been faithfully painted with silver nitrate solution twice a week for several months by a "gynecologist," under the supposition that the pain in the foot and calf of the leg was a uterine reflex.

About a year or more ago I was visited by an unmarried lady, who had suffered for several years from general nervous debility, probably due to over mental strain and deficient physical activity. She had some pelvic pain, somewhat exaggerated during the menstrual period; she had undergone much local treatment of the form termed "uterine tinkering" by Lawson Tait. She was referred to me for operation because drugs, which had been given chiefly in the form of high potencies, $1 \times 500,000$, had not cured her. On bimanual examination the pelvic organs, which could be unusually well palpated, were found to be absolutely normal. Her chief complaint was gastro-intestinal disorders, obstinate habitual constipation. These had been regarded as due to reflexes. She was advised to return, with a written opinion, to her physician (who had given her no treatment but had referred her to me). She failed to follow my advice; she sought another operator, who promptly removed her ovaries and tubes, collected a large fee and discharged her *cured*. A few weeks ago she appeared in my office again. A nervous, fretful, emotional, broken down woman. No, hardly a woman, for that which distinguished her sex had been taken from her, without any compensation for her loss. If her tubes and ovaries had undergone structural changes, as the result of disease, she was unsexed already, and to have removed them would have given her health, but to remove her normal uterine adnexa the surgeon is directly responsible for the aggravated neurosis. As she sat in the chair bemoaning her fate and denouncing her surgeon, she cried: "If I had only followed your advice! What shall I do? What shall I do?" I have seen many such cases, and I am sure other doctors have seen similar cases that have been operated on. My personal experience in abdominal work began when pelvic surgery, aside from the removal of large ovarian cysts, was in its infancy. Shortly after the field had been opened by Beatty, Tait and Hegar, for the removal of diseased uterine adnexa. We all of us looked to these men for guidance. While their lists of cases were long ones, the information they conveyed was imperfect and meagre and referred only to the immediate results of the operation. Little or nothing could be learned regarding the ultimate outcome. We were compelled to learn much by our own experience, we had no precedents established as we have today. In my anxiety to relieve suffering I frequently operated on cases belonging to the class under discussion, but the ultimate outcome was usually so unsatisfactory that with accumulating experience with each succeeding year I refused to operate on cases that I would have advised surgical procedure in the preceding.

I unhesitatingly declare that all cases in which no

structural changes in the pelvic organs can be made out, should not be subjected to operation, and in cases where under mistaken diagnosis the abdomen is opened and the appendages found to be normal they should not be removed, no matter what the local subjective symptoms. The experience of such men as Gill Wylie, Boldt, Howard Kelley, Charles Noble, Baldy and many others, has shown that no benefit can be expected, but the cases are often made worse.

Trachelorrhaphy.—An operation which in popularity stands next before salpingo-ovarectomy is trachelorrhaphy. A minor operation which every tyro can do, and illustrates the ready credulity of the average patient. It brings the operator as large a fee as the average abdominal section, and has established the reputation of many a man as a "fine surgeon," who would shrink from an ordinary amputation.

Every laceration, however slight, must be repaired, upon the assertion that nerve endings are adherent to the cicatrix, which if they have not already produced, soon will cause a neurosis and innumerable reflexes. This operation, when done according to the indications laid down by Emmet, is useful, but as usually done is useless in four-fifths of the cases, as proven by the results.

Hystero-epilepsy.—According to Charcot and his pupils, hystero-epilepsy "is distinctly a symptom of hysteria, and in no way confounded with epilepsy, when it assumes its typical form." . . . "The seizure is usually preceded by a change in disposition, perhaps for some days, and more directly by an aura, abdominal or epigastric, which affords the patient time to seek a position of safety. The attack proper is divided into four periods: 1, the epileptoid; 2, the period of contortions and great movements; 3, the period of emotional attitudes; 4, the period of delirium" (G. L. Walton). "During the intervals between the attacks the patient suffers from incomplete hysteric hemianesthesia, ovarian hyperesthesia and other hysteric symptoms . . . The aura, which is in the nature of a globus hystericus, seems to proceed from the affected ovary. The patient shrieks and falls insensible, and tonic spasms result; this is quickly followed by clonic spasms and these are succeeded by muscular relaxation, stertorous respiration and coma. The second stage (phase des grands mouvements) consists of movements which are rhythmical or disordered, and which are sometimes violent and ludicrous. The next stage (phase des attitudes passionelle) is marked by a rapid succession of attitudes and gestures which suggest the term phase of *lubricity*. Hallucinations of terror, sorrow, joy, etc., follow. The paroxysms may recur frequently and may be provoked by slight pressure upon the ovarian region on certain hyperesthetic spots; sudden and firm compression of the ovary will sometimes arrest a paroxysm" (Foster).

Charcot and his followers believed that this affection had its origin in the womb and its appendages. This view seemed confirmed by the observation that the attacks often became worse during the menstrual period. When abdominal section became a comparatively safe procedure, surgeons did not hesitate to drag forth and remove tubes and ovaries that were often models of anatomic perfection. Occasionally a case was benefited and sometimes cured. These were reported with all the extravagance of which the English language is capable; and many more were reported before sufficient time had elapsed to note if

the case had even been temporarily benefited. One of the blots of this progressive period in medicine is the premature report of cases.

But what became of the fifty that were not benefited and not reported, but were permitted to wend their miserable way, unpublished and uncured? Hence those of us of more limited opportunities and less experience were led into the error of holding up to our distracted patients a light of hope that burned a short while, then flickered feebly and went out. Have you ever experienced the despair that follows hope, the darkness that succeeds a dazzling light?

My own experience comprises eight cases. When we study these cases we find, in all, the attacks were aggravated during the menstrual period. In seven the attacks occurred between the periods. In one only during the period. In six the attacks could be brought on by compression of one or both ovaries. In the one case where the attacks occurred during the period only, a complete cure has been effected. In one case, that of a married lady, mother of eight children, the attacks sometimes numbered two or three during an hour. After five years, I was informed that she seldom has more than one convulsion during twenty-four hours, "but that they are very much milder." We see she is not cured. The chief benefit that has been derived is that she can not propagate any more of her kind. In the remaining six cases we imagined for a time that they were improved, but gradually relapsed into their former condition.

When we take into consideration that some of these cases recover spontaneously, we wonder whether those which are seemingly benefited by an operation might not have recovered without one. My own limited experience is not encouraging. On consultation of recent literature I find the results of those operators of large experience is no more encouraging, and I find that the weight of opinion is in favor of surgery only in such cases where the attacks are confined *entirely* to the menstrual period. In all other cases it is worse than useless to operate.

Even the insane woman has not escaped the enterprising abdominal surgeon. He studied his cases profoundly and selected carefully such in whom the mental disturbance seemed worse during the menstrual period. They were often reported improved immediately after operation, but we have been kept in the dark in reference to the ultimate outcome. My own experience has taught me that it is an exceedingly hazardous procedure to operate on man or woman who has exhibited unusual mental "peculiarities." It has been my misfortune to have had four cases of post-operative insanity. The immediate recovery in all the cases was uneventful. Convalescence had practically been completed when mental disturbance appeared. Without any evidence to the contrary, I feel that we are not justified in doing salpingo-ovarectomy on the insane women, except for organic changes, no matter how aggravated her condition during the period, if she is not perfectly sane during the inter-menstrual time. In cases where insanity occurred only during the flow we might expect recovery after inducing a premature menopause by operative interference. You ask why in the face of this evidence do men continue to mutilate women for functional disorders? We may answer:

1. Inexperience and mistaken diagnosis. No man should begin pelvic work until after many years of general practice, until he has served a long appren-

ticeship with an experienced diagnostician and operator, so that he may avoid the pitfalls into which those of us have fallen when there were no precedents to guide us. The opportunity for acquiring diagnostic skill in our large medical centers is almost unlimited, but it requires time and patience to acquire it. The great trouble about our post-graduate teaching is, that somehow, although the opportunities for becoming proficient in diagnosis are abundant, the student returns to his chosen field with his head full of technique and not enough of diagnostic landmarks.

2. The desire to do many abdominal sections and to show a low mortality ratio in his reports. At this time nothing is more tiring and time-robbing in our society meetings than to report a long series of abdominal sections, each case differing from every other in the list. A surgeon who aims to do many laparotomies always does many useless ones. Such a surgeon takes his own reputation solely into account, irrespective of what benefits his patients may derive. His policy is a short-sighted one. His selfishness predominates in all his work. His many needless operations will in the end cost him his reputation, for which he has so zealously and short-sightedly labored.

3. The prospects of a good fee. The man who is prompted chiefly by a fee (and we know of such) is unworthy of the confidence of his patients and his fellow practitioners. He should be relegated to that oblivion from which he came.

4. The pleadings of the patient. Who can sit unmoved when the poor suffer who has exhausted many methods of treatment without relief appeals to you as a surgeon. I have often found that it required more courage to refuse an operation than to do one. Surgeons should lay sentiment aside at such a time and look the stern facts in the face and decide accordingly.

5. The fear of losing your patient, that she may go to another surgeon. Have the courage of your convictions, state them frankly and plainly and in the end you will be the gainer; subsequent patients will place confidence in your opinion.

We have endeavored to point out what must *not* be done for these cases. And now more than ever, the great question confronts us. What can we do for these unhappy beings?

Experience has shown us that the surgery of the present is a failure. We must seek in other directions and for other means which may offer a hope of relief. We have seen that the majority of these cases with functional disturbances are inactive physically and mentally; they are anemic, have muscular atony, poor circulation, gastro-intestinal distress, especially obstinate constipation. It has been my practice for years to insist on some form of physical exercise. If the case is too feeble to do this alone begin with the aid of an assistant, who aids in the various passive and active movements, followed by massage. Later, various forms of gymnastics; then riding, walking in the open air. But the difficulty has been the patient soon ceases to be interested and she returns to her old condition. Of late I have succeeded better. I have prescribed that fascinating and popular modern innovation, the bicycle, one of the most useful machines invented in the last century. In nearly every case the patient has forgotten her medicine and her doctor, and goes wheeling merrily along, with new interest, new plans for life and happiness and better health.

In this dissertation, it has been my aim to call attention to some of the abuses in our profession. If I have been severe in some of my statements they have been prompted by motives for the improvement of surgery. I have not spared myself. I have frankly spoken of my failures in the hope that my small contributions might, assist us in the future to avoid a useless method and search along new lines. As broad and progressive surgeons we must become, first of all, diagnosticians, not along special and narrow lines, but must be willing to give the time to study and learn the nature of all diseases to which the body is heir, and all possible means for their proper recognition. The gynecologist, especially, should have a most thorough knowledge of neurology, gastro-intestinal diseases and affections of the urinary tract. Unless we are thus prepared we will be blunderers, groping mostly in the dark, and our therapeutics will be solely experimental. I am confident, however, that even now we have at our command the means which can and will remove from our profession the stigma of an inexact science. Much has been done for the cure of woman's ills in the last decade. We have only begun to find means for the relief from suffering in her who is the better, nobler and kinder half of humanity: She who is man's inspiration, his joy and his hope.

EXTRA-UTERINE PREGNANCY.

Read before the State Medical Association of Missouri, May 19, 1896.

BY T. F. PREWITT, M.D.

Professor of Principles and Practice of Surgery and Clinical Surgery, Missouri Medical College; Surgeon to St. John's Hospital and Infirmary, etc., St. Louis, Mo.

In fulfilling the functions for which the sex was created, no accident more dreadful can befall a woman than that of extra-uterine pregnancy. She may have reason to suspect that pregnancy has occurred, but in that fact she finds nothing to excite apprehension of the future. On the contrary it may kindle in her bosom the fondest aspirations of motherhood; the instincts of maternity may arouse in her heart the tenderest emotions and visions of that supreme happiness which fill the soul of the mother, when, having passed the period of probation, she clasps her firstborn to her breast with rapture. Should she already have been a mother, there is nothing different from past experiences and she has no dread of the future. Soon the inevitable catastrophe comes, it may be with the suddenness of the lightning's flash; an agony of pain, collapse and death. It may be all so sudden and violent that no chance of rescue is offered. Yet this is not always so, not even perhaps in a large proportion of cases. The clinical history and certain significant symptoms often serve to warn the practitioner, and woe to his patient if they are not quickly heeded and promptly acted upon. He is confronted with a grave responsibility and if he fails to grasp the situation or misinterprets the symptoms, a life is sacrificed.

Six cases have fallen under my care. Of these, two died and four recovered. Not the least instructive of these are the two fatal cases, both of which I believe would have recovered had I not followed the teachings of the time, which I am now convinced were erroneous.

The first case I have given somewhat in detail because the clinical history is obscure, and I believe I did not adopt the course best adapted to secure the recovery of my patient.

Case 1.—Mrs. G. C., aged 43 years, mother of four children, the youngest of whom is ten months old, was taken on Oct. 28, 1890, with severe pains in the pelvis, and I was sent for. I found that she had menstruated at the fifth, sixth and seventh month after her last delivery although still nursing her child, but for the last three months had missed her periods. During this time she had had no symptoms to induce her to believe herself pregnant, except the failure of the menses to appear. Upon making a digital examination I found the uterus somewhat enlarged. I could feel no swelling or enlargement outside of the uterus. I ordered quiet and anodyne enemata, which relieved her. On November 5, I was called in haste to see her, the husband stating that she was suffering greatly and was quite faint. I found her crying out in an agony of pain located in the pelvis, her pulse feeble, her skin cool and pale and in a condition of partial collapse. I could feel no swelling or tumor outside of the uterus but a soft fullness in Douglas' cul-de-sac. The pain, when the finger was brought in contact with the roof of the vagina, was excruciating. She vomited once or twice. The diagnosis was tubal pregnancy with rupture of the sac with hemorrhage into the pelvis. I proposed abdominal section, to which they readily consented. The hygienic surroundings were very bad, but with the aid of Dr. H. S. Brookes and two medical students, I proceeded to make an incision four inches in length. Upon opening the abdomen a quantity of blood gushed out, confirming at once the diagnosis. The sac was found connected with the right Fallopian tube. The mass was brought up and the pedicle tied with a double ligature. The tumor was then cut off. The pelvic cavity was then freely douched with hot water and Thiersch's fluid. The greatest difficulty was experienced in removing the clots, which came away in large quantities. When it was supposed that all had been removed further exploration revealed additional clots firmly adherent to the intestines, which had to be picked off with the fingers, doubtless leaving many others. A drainage tube was placed to the bottom of Douglas' cul-de-sac and the wound closed. The woman was placed in bed in good condition and Mr. Koch left in charge. The patient was comparatively quiet up to five o'clock next morning when he left, and having no regular nurse she was left alone. The next morning I found that she had deranged the dressings leaving the wound uncovered and the tube had been nearly forced out by her rolling and tossing about the bed; this could only be imperfectly replaced. I made an attempt to replace the tube in which I only partially succeeded. At 6 p.m. of the following day the temperature was 101 F., pulse 143. Later the septic symptoms became more pronounced and she died.

Case 2.—Some four or five years ago I was called in consultation, and learned from the attending physician the following history: The woman, about 30 or 40 years of age, had missed one menstrual period. The day previous to that upon which I saw her she had gone to the basement of the house and while there was seized with a sharp, cutting pain in the pelvis accompanied by faintness. After a short time she went up stairs and was again seized with severe pain and faintness compelling her to send for her physician. He found her suffering greatly, with rapid pulse and symptoms of collapse. He gave her anodynes for the relief of the pain and enjoined quiet. The next day, he sent for me. The patient had rapid pulse, great prostration, abdomen distended, but with marked dullness in the suprapubic region. I diagnosed tubal pregnancy with rupture of the sac and large extravasation of blood and suggested operation. There was some delay in operating, which was done after dark and with a poor light. On opening the abdomen the blood spurted out. I fished up the ruptured sac as rapidly as I could and tied it off. I sought to get rid of the large amount of blood in the abdomen by washing it out with hot water, using eight to ten gallons for the purpose. I gave it up in despair of getting the abdomen clean, as clots continued to be found adherent to the intestines, which could only be removed by the fingers. Putting in a drainage tube, stitching up the wound and applying antiseptic dressing, the patient was put to bed, hot bottles applied and other measures taken to bring about reaction, but all to no purpose, as she failed to rally and died in the night.

I received the next day a journal in which a practitioner had had a case precisely similar. Having opened the abdomen and removed the ruptured sac, he found the patient's condition such that it was necessary to terminate the operation at once if he wished to get her off the table alive. He hastily removed with his hands as much blood as he could, closed the wound and put the patient to bed, and fortunately she rallied and recovered.

I have not forgotten the lesson and have done no *flushing* since in these cases.

Case 3.—Mrs. M., aged 35 years, mother of four children, had missed one period and suspected herself pregnant. About ten days after she should have been unwell she was seized with pain and faintness. When I saw her the pulse was quickened but of fair volume; the abdomen in the suprapubic region tender, more marked upon the left side. There was bloody flow per vaginam. No enlargement of the uterus could be recognized, but there was great tenderness in the pelvis, most marked upon the left side. I advised operation and performed it the next morning. Blood issued from the abdomen as soon as the peritoneum was opened. The tumor formed by the sac was pulled up out of the wound, a Tait ligature applied and the mass removed. A rent in the sac showed the source of the hemorrhage. The pelvis was sponged out and the wound closed. An uninterrupted recovery followed.

Case 4.—Mrs. K., aged 25 years, had never been pregnant. Had missed one period and about a week after was taken with pain in the pelvis and a vaginal flow. In spite of the measures instituted by her physician, the flow continued, accompanied by pain, for three weeks, when I was sent for. I found extreme tenderness in the pelvis, more marked upon the left side. No tumor could be felt, but a soft, baggy fullness. I diagnosed tubal pregnancy, with slight rupture of the sac, and advised operation. The next day I operated. I found a sac larger than a hen's egg with a slight rupture and about a pint of blood in the pelvis. The tumor was drawn up out of the pelvis, a Tait ligature applied, the blood sponged out and the opening closed. The patient recovered and three months ago was delivered of a healthy child at full time. Mother and child doing well.

Case 5.—Mrs. H., aged 30, mother of one child. On the 27th day of June, 1895, two weeks after she should have been unwell, she was taken with severe pain, some faintness, followed by the appearance of a bloody flow from the vagina. I was called and explained to her my fears of an extra-uterine pregnancy, but as the symptoms subsided in a few days I thought I might be mistaken. Mrs. H. having suffered from constipation, resorted to the use of an enema. While upon the commode she was seized with violent pain and great faintness. I was immediately notified and found her pale, with cold extremities, feeble pulse and pain. I explained to her that an immediate operation was necessary. An abdominal section was made: blood presented at the opening in the abdomen and two fingers pressed into the pelvis detected the sac connected with the right Fallopian tube. This was tied off, the blood sponged out and the abdomen closed with silkworm gut. Patient recovered.

Case 6.—Mrs. P., aged 30, mother of one child. Had a miscarriage about one year ago. Menstruated last, Dec. 29, 1895. Toward the latter part of January, having passed her menstrual period, she had nausea, slight enlargement of the breasts etc., and believed herself to be pregnant. About the 8th of February, 1896, she went to Indiana. While on the train she became unwell, the flow stopping and recurring without cause and accompanied with much more pain than usual. The flow continued for nearly three weeks. On February 27 she ate rather heartily. Soon after she was seized with acute pain in the region of the left ovary. This was accompanied by nausea, vomiting, feeble pulse, faintness and pallor. Dr. T. A. Martin of St. Louis was summoned, who kindly furnished me with notes of the case. "Three days after the attack, I saw her in the condition above noted, pulse very feeble and faintings occurred upon the slightest exertion. The abdomen was tympanitic and extremely tender upon pressure. Diagnosis: Tubal pregnancy, rupture of sac, internal hemorrhage and peritonitis. I did not see her again until March 29. I found her still pale, pulse 110, temperature 101.5 degrees F., abdomen tender and dark blood constantly being discharged from the vagina. I could detect a slight swelling occupying nearly the center of the abdomen, extending slightly above the pubes and seemingly attached and continuous with the fundus of the womb." I saw the case with Dr. Martin on the first of April. A distinct tumor could be felt a little to the right of median line and in front of uterus. At short intervals severe pains would come in left pelvic region and extend down left leg.

The next day, assisted by Drs. Martin, Geitz, Schlueter and Henke, I opened the abdomen in the median line. Extensive adhesions from recent inflammation were found. The sac was found in front of the uterus, the latter crowded back into the pelvis. Some adhesions of the omentum to the tumor required tying off and some effort was necessary to detach the sac from the surrounding parts and to drag it up and tie it off with the Tait knot. Considerable blood was found in the pelvis and the rent in the sac from which it had escaped was plainly visible. The fetus was found escaping from the hemorrhagic mass which filled and protruded from the rent in the

sac. Some of the blood clots in the pelvis had undergone changes so that they scarcely looked like blood. The pelvis was sponged out with iodoform gauze and closed with silkworm gut. Recovery took place without any untoward symptom.

It will be seen from a study of the cases I have reported that the clinical history presents a striking similarity. Given a woman who has menstruated pretty regularly, who has had some endometritis (mucous), who has passed the menstrual period a week or ten days, who may or may not have experienced some of the usual symptoms of pregnancy, such as morning sickness, enlargement of breasts, etc. Let such a case be taken with a sharp, cutting pain in the pelvis, accompanied by great faintness and followed by a menstrual flow and possibly by recurring pains of threatened miscarriage and associated with such tenderness upon digital examination as to suggest a pelvic peritonitis, and we have the strongest grounds for making a diagnosis of extra-uterine pregnancy, with rupture of the sac. Should we hesitate to act upon these symptoms and conclude to await further developments, we shall find within a few days a repetition, more pronounced, of these symptoms—violent pain in the pelvis, faintness and collapse, weak pulse, great restlessness, extremities cold, sighing respiration—in short, the symptoms of hemorrhage added to shock caused by the rupture of the sac.

Unfortunately the practitioner may be confronted at the very outset with these alarming symptoms and may find his patient almost *in extremis* when called in to see her, no pulse or one scarcely perceptible, cold, clammy skin and profound collapse.

The practitioner is justified when called to a case of a woman who has experienced a violent pain in the pelvis, with great faintness, bordering upon collapse, and who, he finds, has missed one period for a week or more, who finds extreme tenderness in the pelvis upon palpation, who also finds in connection with these symptoms those simulating a possible threatened miscarriage, he is justified in making a diagnosis of extra-uterine pregnancy, and it is his duty to perform celiotomy and rescue his patient ere it is too late from the imminent danger with which she is threatened. He must not allow himself to be misled by the symptoms simulating miscarriage. Miscarriage in a healthy woman who has never miscarried before, can often be traced to some cause. Nor does it come on suddenly with such violent pain and threatened collapse.

Then too, the principles of modern surgery are applicable here as well. It has crystallized almost into an axiom in abdominal surgery that sudden, violent pain in the belly, emphasized in its significance by marked general disturbance, is warrant for, if it does not demand, an exploration. As Tait says, "Absolute accuracy of diagnosis in the abdomen is very far from being possible; only the ignorant assert that it is and only fools wait for it."

Even if there be a lingering doubt in his mind as to the accuracy of his diagnosis by reason of some missing link, it is still his duty to explore the pelvis and find out the trouble, since it is certain that some serious accident has happened, the consequence of which can be rectified by immediate operation.

An exploratory operation *per se*, under proper anti-septic precautions, adds nothing to the danger of the situation, while the threatened danger of his patient is too great to permit of hesitation.

In those cases where the symptoms which confront the practitioner are those of profound collapse, it becomes a question as to what course to pursue. Shall he operate at once at the risk of extinguishing the feeble spark of life, or shall he wait and endeavor to secure reaction, partial at least, before doing so? In my opinion, the latter course is the wiser. He should remember, however, that the shock is primarily due to the rupture and that the collapse is prolonged and deepened secondarily by the internal hemorrhage. As soon as there is some return of the pulse he should open the abdomen, seek for the sac, ligate close to the uterus and remove it, thereby stopping all further hemorrhage.

It was formerly advised to wash out the blood, insert a tube and drain. I believe this bad practice. In the first case I report, had I been content with simply sponging out the pelvis, accurately closing the wound, the uncovering of the wound would not have been followed by infection, and the patient would probably have recovered.

The practitioner should then sponge the abdomen as rapidly as possible with aseptic gauze, and having removed all that he can readily get rid of without prolonging the process, should close the abdomen without drainage.

The blood left is not septic and will be absorbed, and all the more readily, too, if the peritoneum be not disturbed by the flushing. If the patient has lost a great deal of blood and the abdomen is full of it, as in the second case I have reported, no amount of flushing will remove it all, and precious time is lost in the attempt. All that can be readily removed by the hands and by sponging, should be quickly cleared out, the wound closed and the patient put to bed. Hot bottles and strychnin, digitalis and whisky, should be resorted to hypodermically as may be necessary to sustain the heart's action and favor reaction.

It has been my fortune to meet with one case of abdominal pregnancy where the fetus had reached full term before its death. The case was brought to me in 1885 with what was supposed to be an ovarian tumor. I found a tumor which extended transversely from the left lumbar region to beyond the median line, and from the brim of the pelvis below to the margin of the ribs above. She had had it for fifteen years. Lately she had complained a great deal of colicky pains and troublesome constipation. The colicky pains had been so distressing that she had become addicted to the use of morphin to relieve them, and this in turn had promoted the constipation. The tumor had a very hard and smooth surface with somewhat irregular borders. Over the surface of the tumor there was dullness at some points, resonance at others. After explaining to her that it was very doubtful if it could be removed, I proposed an exploratory incision, to which she assented. I found that the omentum and small intestines were adherent to it; in fact, it seemed imbedded in them. It presented a somewhat broad, flattened, smooth surface which looked like bone or cartilage. Suffice it to say that it was clearly inadvisable to attempt its removal. The wound was stitched up and healed by first intention. Great irritability of stomach persisted, her strength failed and she died two weeks after the operation. A postmortem examination was made and the bones of a fetal skull at full term was found, with traces of the legs and arms. In connection with the left ovary there seemed to be a piece of the bone of an arm.

Between this and the mass above there was no apparent connection whatever. Evidently there had been a tubal pregnancy of left side with rupture of the sac, the fetus having survived the rupture and continued to develop to full term in the abdomen, when death ensued.

Two other cases have fallen under my care, both of which I believe to have been tubal pregnancy with rupture.

Mrs. H., aged about 35 years, mother of five children, had eaten a hearty dinner including corn. In the evening she suffered from considerable disturbance of the bowels. While in the water closet she was taken with violent pains in the abdomen, with great prostration, vomiting, etc. When called to see her the next morning, Sept. 9, 1895, I found her almost pulseless, cold, clammy skin, suppression of urine and great tenderness of abdomen. There was also some bloody discharge from the vagina. This condition deterred me from attempting an operation. She never rallied, and died on September 14, five days from the time of the attack. No autopsy.

Mrs. D., aged 26, mother of three children. Had one miscarriage between the first and second child. Had passed her menstrual period some four or five days when the flow commenced, which she regarded as delayed menstruation. This continued for four days. November 15, 1895, it stopped suddenly. She supposed she had taken cold, especially as she had some pain. On November 18 she was taken with severe pain in the left pelvis which "doubled her up," as she expressed it, accompanied with some faintness and also diarrhea. I saw her in the afternoon. There was still pain, tenderness very great upon digital examination and upon suprapubic palpation, with quickened pulse, etc. I mentioned my suspicion of extra-uterine pregnancy, and suggested laparotomy, which she emphatically declined. In the meantime there was a return of the bloody flow. She had some fever for a few days, temperature reaching 103 F. and pulse 130. The flow continued for about three weeks. She gradually got better. Some fullness and great tenderness in left pelvic region, and which has not yet, May 21, entirely disappeared.

That some accident happened in this case, I think, can not be questioned. The clinical history, symptoms and subsequent history point to extra-uterine pregnancy.

MODERN METHODS OF TREATING THE MAXILLARY AND OTHER SINUSES OF THE CRANIUM.

Read in the Section on Dental and Oral Surgery, at the Forty seventh Annual Meeting of the American Medical Association held at Atlanta, Ga., May 5-8, 1896.

BY W. XAVIER SUDDUTH, A.M., M.D.

FELLOW OF THE CHICAGO ACADEMY OF MEDICINE,
CHICAGO, ILL.

Pathology.—The diseases to which the sinuses of the head are liable are many. The most common, however, are empyema, tumors and necrosis of the walls from syphilis, mentioned in the order of their importance and frequency of occurrence.

Empyema antri is a suppurative condition and arises in the maxillary sinus, in a large proportion of cases from infection through dental abscesses, although the records show a considerable number of cases that can be traced to the extension of disease from the nasal cavity. In some instances the local inflammation undoubtedly arises from occlusion of the osteum maxillare by polypi or inflammation and decomposition of the retained secretion of the cavity walls. The most common cause of obstruction of the natural outlets of the antri is nasal polypi situated around the opening. The final result in any case is suppuration within the cavity of the antrum.

In chronic empyematous conditions of the antral cavity the lining membrane is generally found to be thickened and spongy in character, the caliber of the

cavity in some cases is considerably reduced thereby. In not a few cases necrosis of the bony walls, results from the internal disease.

More or less intense neuralgias following the course of the nerve supply, together with sympathetic affections of the eye, resulting through the intimate nerve supply or caused by pressure of the inclosed pus upon the floor of the orbit, which also forms the roof of the antrum are found. These conditions are generally unilateral as empyema of the antrum is seldom bilateral.

Symptomatology.—The symptoms may be divided into two classes dependent upon whether there is occlusion of the osteum maxillare or not. In most cases it can also be said that the difference in symptomatology depends upon whether the disease arises from a dental or a nasal source, as occlusion of the osteum maxillare is most commonly, if not entirely, found accompanying the inroad of the disease from the nasal cavity.

Where obstruction of the natural outlet exists, there is a greater or less accumulation of matter within the cavity, with consequent pressure upon contiguous parts and more or less marked facial neuralgia. In some instances where the empyematous condition becomes chronic, necrosis of the osseous walls, most commonly on the nasal side, results and a copious discharge occurs into the nasal cavity. When the quantity of pus is large and does not find free outlet it may produce absorption of the orbital plate and infiltration into the tissues about the eye, in some cases producing glaucoma by involving the optic nerve.

In other instances the frontal sinus of the same side becomes involved as do also the sphenoidal sinuses, accompanied by marked supra-orbital neuralgia.

In empyema antri, without closure of the osteum maxillare, there is a more or less constant discharge of pus from the affected side, especially when patients lie upon the opposite side, a position seldom assumed because the discharge annoys them to such an extent they can not sleep. As a result of the constant discharge of pus into the throat, more or less interference of the general health follows. Dyspepsia and poisoning of the whole system results, which is indicated by a decided cachexia especially noticeable by the yellow appearance of the conjunctiva.

Diagnosis involves a differential consideration of the symptoms present in empyema of the several cavities of the head, including the diseases of the nasal fossa.

As pain is one of the constant symptoms, we use that as the first basis of comparison.

The diagnosis may also be established by exclusion, beginning with the maxillary sinus. Many different ways have been advocated to establish a diagnosis of empyema of the antrum. The simplest method is that of tapping with a curved hypodermic needle, through the nasal membrane, making the puncture in the inferior or middle meatus, and directing the point of the needle backward and downward. If there is pus present it may be accurately ascertained by such means.

Not every case of empyema antri should be opened, and great care should be used in making a diagnosis. Acute cases seldom come into our hands, by reason of the fact that nature restores the parts to a bearable if not a normal condition, and this fact should teach us a lesson regarding surgical interference in acute cases.

Transillumination has been advocated by some, but

has failed in the hands of even the most expert specialists when put into actual practice. I have used it in several cases but with indifferent success. In one case it was used before tapping and drawing off a considerable quantity of pus, and then again afterward, but no noticeable difference in the appearance could be observed.

The one remaining condition to be differentiated from suppuration of the antrum is fetid ozena. Rhinoscopic examination will, in all cases, establish the diagnosis, as in the latter condition the disease of the mucous membrane will be readily observed, and, in all probability, found to be bilateral; while empyema antri is, in a large per cent. of cases unilateral.

The greatest difficulty in the diagnosis is found where complications arise by reason of several of the cavities being diseased at the same time. These cases do not come to the dental practitioner for treatment as often as they pass into the hands of the nose and throat specialist. Empyematous conditions of the antrum are generally of a purulent nature from the beginning, by reason of the fact that the cause generally lies in the discharge of a collection of pus from an alveolar abscess into the antrum.

Treatment of these cases is best directed from within the oral cavity, although the same methods may be adopted of introducing a tube through the nasal septum as before described. This is preferable to sacrificing a fairly good tooth or even trephining the outer plate in the region of the canine fossa. The latter should invariably be done, if the patient, for cosmetic reasons, objects to having the tube exposed upon the face, for if it is introduced through the outer plate it may be entirely concealed within the mouth. The method to be adopted is as follows: Select a trephine and a flexible rubber catheter of the same caliber, No. 7 or 8 being the size I generally use, and place them in an antiseptic solution.

Have the patient rinse the mouth thoroughly with a borated soda solution or listerin; dip the trephine in carbolic acid solution 5 per cent, or inject the tissue in the region where it is intended to insert the instrument with a 4 per cent. cocain solution and then make the opening and apply first dressing through this; then insert the tube, which should be ligated to a band or clasp that had previously been made and cemented to a conveniently located tooth. A short piece of tube or piping should be soldered to the band before putting it in place. The rubber tube should be about three or three and one-half inches in length, so as to enter the antrum from one-half to three-fourths of an inch and leave two inches outside. The free end should be kept plugged with a soft wooden pin, so as to prevent the saliva and air from entering, both of which may become a source of infection.

After placing the tube, the antrum should again be washed out thoroughly with a biborate of soda solution, the fluid to be introduced through the tube and allowed to flow out through the natural opening into the nasal cavity, the patient being instructed to incline the head forward. If the opening is found to be closed or too small to permit the fluid, on which the pus freely floats, to pass out, then a freer opening should be made. After the cavity has been thoroughly cleansed by the soda solution, a 3 per cent. pyrozone solution should be introduced and permitted sufficient time to disintegrate the remaining pus, if any, after which as a final dressing some bland antiseptic, such

as a well diluted listerin, should be thrown into the cavity, and allowed to remain.

If the patient is told to lean forward when the washing out process is begun no part of the discharge will pass into the mouth or throat, a point that will be greatly appreciated. In like manner tubes may be inserted into all the cavities of the cranium and the cavities should be washed out two or three times a day. By aid of the tube this may be done by the patient or some member of the family and the case need not be seen by the practitioner more than twice or three times a week at the most.

If there is any odor at the second sitting, perman-ganate of potash should be substituted for the listerin, for a few days. As soon as the quantity of pus becomes lessened, then a stimulating antiseptic should be substituted. I do not know any that is better than sozo-iodol and its compounds. Sozo-iodol and bismuth in acute cases, sozo-iodol and mercury for sub-acute, and sozo-iodol and zinc for chronic cases. These should be used in the strength of about one-half grain to the ounce of distilled water. All solutions should be warmed before using, including the H_2O_2 , which may be done by placing the vessel containing the fluid in a dish of hot water.

If neuralgia follows the washing process, it is generally indicative that the astringent solution is too strong.

A DISCUSSION ON ANATOMY OF THE ANTRUM OF HIGHMORE.

Read in the Section on Dental and Oral Surgery, at the Forty-seventh Annual Meeting of the American Medical Association at Atlanta, Ga., May 5-8, 1896.

BY M. H. FLETCHER, M.S., M.D., D.D.S.
CINCINNATI, OHIO.

The two following quotations are from the discussion on a paper by the present author, entitled "What a Dentist saw in Examining 500 Crania," read before the Mississippi Valley Dental Association, April 18, 1895.

Dr. J. E. Cravens; "I believe that if the Doctor had examined the skulls in the living subjects he would have found his proposition a mistake. I believe that nature never pushed the apex of a tooth root into the Highmorian cavity, without a bony protection, however thin. She never completed the apex of the root of a tooth in the mucous membrane alone."

Dr. H. A. Smith: "I doubt very much the entire absence of bone. If the position taken by Dr. Fletcher is true it may account for certain lesions, phases of facial neuralgia. I doubt very much if the root of a tooth ever penetrates the antrum. You must have a thin covering of bone. The bone of the antrum is proliferated by its own periosteum, and does not depend on any tissue of the teeth. If you take those skulls and examine the roots of the teeth you assume that they never had a covering of bone, but they may have had, even though it was as thin as paper. If you examine those skulls, where the bone is denuded it is so thin that in the dry state it falls away. An observation made on a dry skull is not conclusive. If it is true that the roots will penetrate the antrum it will account for a great many of those cases of facial neuralgia."

These criticisms were brought out by the following statement made in the paper referred to:

Dr. M. H. Fletcher: "As to diseases of the antrum, it seems to me that these people were remarkably

exempt, when we consider that they could have had no surgical or medical attention, and also that about 25 per cent. of them had abscessed upper molars. This fact is significant when it is claimed by the majority of authors that diseases of the antrum come more frequently from this class of teeth than from any other source. This series of examinations show that out of the 252 cases of abscessed upper molars, only 12 perforated the antrum. This would seem a remarkably small number and indicate that abscessed teeth do not cause antral trouble as often in comparison with other causes of inflammation of this cavity as most authors maintain they do."

My reasons for believing that the teeth may often be affected by diseases of the antrum are strengthened by considering a certain feature of the anatomy of the parts, mentioned by Gray, and omitted by most other anatomists, that, "in some cases the floor is perforated by the teeth in this situation." I found this to be the condition in twenty cases, showing that about 4 per cent. of persons have, normally, nothing covering the apices of these teeth but mucous membrane (I wish to say that the statistics on this particular point are not accurate, on account of the inability to see into the antrum, in an unbroken skull). Many skulls were broken, however, so that the examinations could be thoroughly made on this point, as well as others, and when they were not broken the sense of touch was used to determine the presence of bony processes, septa and the general form of the cavity, and the normal openings above the teeth, as far as possible. It was also observed that these normal openings occurred where the floor of the antrum was comparatively flat, and not where there was a conical process, and that these cases where the conical processes occurred were almost invariably covered with a considerable thickness of bone.

These conditions being present, it would seem a natural result when the mucous membrane of the floor of the antrum becomes broken down, for the blood and nerve supply of teeth (so perforating the floor) to be interfered with, and possibly entirely destroyed, since the apical foramen of the teeth must be exposed to these destructive influences. In cases of occlusion of the osteum maxillare and other openings into the nose, the antrum may become tensely engorged, and under this condition if there be no bony covering to the apex of the teeth, it would be more or less driven from its socket and become very sore to the touch.

It is my belief that if accurate statistics could be had they would indicate that the exciting causes of diseases of the antrum is ten to one in favor of intranasal disorders. I make this statement, taking into consideration the large per cent. of teeth that are known to perforate the bony floor of the antrum, for my observations also show that a much larger number of teeth are denuded of bone on the buccal surface of the alveolus, hence, the large preponderance of abscessed teeth which discharge in this locality, a place where one familiar with the disease invariably looks for a fistulous opening. In this situation, if the bone is not entirely absent in some spot, it is so thin that it offers to internal pressure the least possible resistance of any other part of the sockets of the teeth.

During the discussion of the paper referred to I corrected the statement that "These cases have, normally, nothing covering the apieces of the teeth, but mucous membrane." The words mucous mem-

brane should read soft tissues, meaning periodontal and mucous membrane.

I was led to the above statement from the fact that many instances were found (about 4 per cent.) where the apices of the teeth perforated the bony floor of the antrum, having no bony covering, and by close examination it seems clear to me that this condition obtained during life, especially since one case was found among the recent specimens of the Army Medical Museum when the skulls and recent specimens were being examined.

Within the past few weeks I have examined twenty more recent subjects on this point as well as others, and found a case where nothing but soft tissue covered the apex of a buccal root of a first molar. These two cases show that such a condition does obtain during life, and furnish a good foundation for the belief, that when skulls are found with no bony covering to the apices of the teeth, that during life they probably had no other covering than soft tissue.

Since writing the paper referred to, three cases of empyema of the maxillary sinus have come under my observation, none of which were in any way traceable to disorders of the teeth, but in each one the exciting cause was intranasal; thus adding to the evidence that the trouble is due in the larger number of cases to intranasal disorders, as claimed in former papers.

Illuminating these cavities by the mouth lamp, is a most valuable adjunct to diagnostic symptoms; the three cases referred to, all threw the diagnostic shadow.

THE TECHNIQUE OF RESECTIONS OF THE SKULL.

BY ALLEN DEVILBISS, M.D.
TOLEDO, OHIO.

Surgical work should not be undertaken until the nature and location of the disease is first determined. In a limited number of cases it may be advisable to remove portions of the cranial bone or bones for explorative purposes. Localization of cerebral functions has made it possible in certain cases to make an accurate diagnosis. There are large portions of the cortex, that the functions of are not understood, but the sensor motor area, the visual area, the speech area, the auditory area, and the areas of sensations of smell and taste are known, and these facts in connection with the various symptoms will generally guide to a correct idea of the nature and situation of the lesion.

Trephining may be performed for the removal of foreign substances, spicula of bone, depressed bone, blood clot, the opening of an abscess, the removal of cysts, excision of tumors, for the relief of intracranial pressure, for drainage, etc. Any one of the conditions just mentioned may be the cause of epilepsy, insanity, paralysis, or most any of the brain lesions with which we have to contend.

While I do think that we should not hasten to operate in all cases, yet we must remember there is danger in delay. Delay of surgical interference in recent fractures has often resulted in death or brought about conditions that make death preferable to life. We should not hesitate to open the mastoid cells when there exists an abscess. If done early, it is sure to prevent further mischief, but if left alone quite a proportion go on to infection of the lateral sinus, meningitis or abscess of the brain. The suc-

cess of cerebral operation depends upon every detail of aseptic surgery being carried out to perfection.

The marking off on the scalp, for the fissures of Rolando and Sylvius, is necessary in many cases and should be done before giving the anesthetic. To accomplish this, various rules have been given. Owing to the difference in shape and size of the head no land marks can be taken that are constant in their relations to the fissures, but are sufficiently so for surgical purposes. The plan that I have used is principally one of my own, and I think, it is quite definite and not complicated. I use a flexible metallic tape for measuring, and tincture of iodine for marking. First, measure from the glabella over the top of the head to the occipital protuberance, half of the whole distance plus one-half inch back will correspond to the upper end of the fissure of Rolando; mark this point, then place one end of the flexible measure upon the point marked, and carry it along the side of the head down to the angle of the mouth. Make a mark by this line at a point, three and one-half inches from the mark on the median line. The imaginary line

FIG. 1.—1, Glabella; 2, Nasion; 3, Inion.

between the points marked will lie over the fissure of Rolando except at its lower portion which is more vertical. To find the fissure of Sylvius place one end of the tape at the lower end of the nasal bone, carry it along in line with the external angular process of the frontal bone to a point three-fourths of an inch below the parietal eminence; then make a mark at a point one and one-fourth inch back from the external angular process. From this point count off four inches and mark. A line drawn from one of these points to the other will correspond to the fissure of Sylvius. The anterior limb of the fissure is about two inches behind the external angular process. By continuing the Sylvian line to the median line we form a junction at the point where lies the parieto-occipital fissure.

All the areas now known can be located with a definite relation to these three fissures; hence no further rules are necessary. With the landmark made for the fissures and the patient anesthetized, we are ready to make the incision through soft parts.

This may be done with one stroke of the knife. We are now ready to make the initial opening through the bone to the dura. This can be accomplished in several ways. After trying the various devices used, I prefer to use a small-sized cone-shaped trephine, three-eighths of an inch on its face, which makes an opening of sufficient size to allow the easy passage of the lower jaw of the forceps down to the dura. Its advantages over other trephines are: 1. Its centering point can be held in position until placed upon the part to be operated upon, and when it has cut deep enough for fixation, the centering point may be removed. 2. The central opening being carried twice the length of the cutting cylinder with a recess above the cutting part to allow the bone button to be shoved up through and fall out, which makes it easy to clean.

FIGURE 2.

While most operations can be made by the hand trephine, the advantage of drills used by power will be readily seen, especially in cases of mastoid diseases, where there are symptoms of cerebral disease, yet the symptoms are not distinct enough to warrant

FIGS. 3 and 4.

the initial opening to be made direct, the mastoid being first opened and then extended as far as is found necessary.

I have one small drill for making explorative openings, also for enlarging them. It widens from the

FIGURE 5.

point up and has a cutting edge on its end and side. This causes it to lock and stop when the point is ready to pass through the bone; there being no more bone to cut with the point, the side of the drill is pressed into the wall of the hole. This stops its revolving just when the hole is completed, or when there is only a thin sheet of bone not thicker than writing paper left, which may be pushed out with a probe-pointed drill, or cut out with a stop drill by holding it back so that it can cut but little at each revolution to prevent its locking. In this way, the first opening is made without danger of wounding the tissue beneath the bone. When using this drill it is best to instruct the person furnishing the power to

stop turning as soon as the drill locks. By so doing there will be no unnecessary strain upon the cable. I also have one side-cutting probe-pointed drill that I use wherever there would be danger in wounding tissue by the one with the sharp end. They do the work in less time than it can be done with the chisel or gouge and without jarring. They are now machine ground and are very accurate and will not heat if run at a proper speed. The harder the bone the less speed should be used. The same law that governs the speed in drilling metal applies to the drilling of bone. When the initial opening is made directly through the skull bone to the dura and I wish to enlarge it, or cut a slot out or make a trap-door, I use a bone-cutting forceps that I have devised for this purpose. It will cut a slot in any direction desired. The lower jaw shoves the piece cut off out through the upper jaw, leaving the edge of the bone smooth next the dura. The under-surface of the lower jaw being round and smooth serves as a dural separator. The leverage is such that there is no difficulty in biting through. After the slot is two inches long, it is best to take

FIG. 6.—1, Point of Initial opening; 2, Fracture line. Forceps should be turned at each end of fracture line as shown.

side bites so as to make an opening large enough for the lower jaw to pass through and not go back to the place of beginning. It can be made aseptic, as its parts separate by removing the thumb screw. I use a jaw that cuts one-eighth of an inch. Some prefer one only one-sixteenth inch so as to have bony union instead of fibrous.

The lower jaw is made so that it does not fit closely the opening in the upper one. By having a little space left it clears itself better and yet leaves the bone smooth next the dura. There may be slight nicking of the external surface of the bone, which is immaterial. I have used the lower jaw flat upon its face and also deeply cupped. I find that this makes but little difference in regard to the smoothness of the surface or the ease with which it is accomplished. I have used it many times and I find no bleeding from the diploe. It is prevented on account of the way it shoves the bone out. When making a trap-door brain operation of sufficient size to cover motor

areas, situated along the fissure of Rolando, say two by three inches, I have adopted the following plan: Make an opening at the center of the upper end of the portion to be turned over; then take the forceps and bite out piece after piece until the point to be fractured across is reached; then turn the forceps in the direction of the line to be fractured and take a bite or two; next cut out from the central opening to a point where the other end of the fractured line is to be, take a side bite or two in the same manner as done upon the other side. This leaves the part to be fractured across weaker than at any other point and can be easily broken. Next take a vectus and lift or pry it up and break it over. After completing the work necessary within, the flap may be returned. The fractured end may be placed even (or up, if need be, to increase intracranial room), and the rough surface of the fractured parts will hold it in place, if pressure be maintained until it is put in proper position. The semi-circular or horse-shoe-shaped bone flap with soft tissues attached and continuous with the scalp at its base which contains the blood supply for the parts,

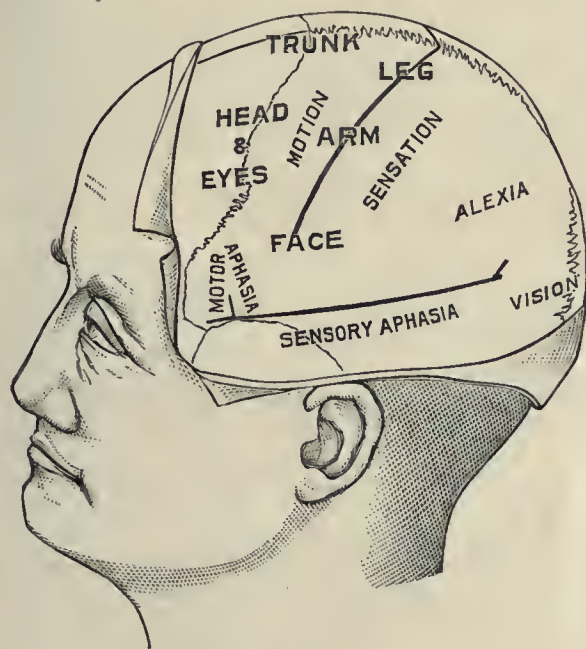

FIGURE 7.

are to be preferred to any other procedure except in recent fractures; no extension of the incision should be made in the direction of the line of the fracture, nor is it necessary to do any chiseling or cutting of any kind of the bone along the line to be broken. The connection between the soft parts and bone should be disturbed as little as possible.

For operation upon flat bones there is no other instrument equal to the forceps that I have described to you, whether it be by skilled or unskilled hands. In unskilled hands it is certainly safer than the chisel and mallet, for the reason that when the instrument is placed in position to bite, it shoves the dura out of the operative field, and by its use the injurious effects are prevented that may occur from the blows when the chisel and mallet are used.

When using it I prefer to take the lower handle in one hand, the upper one in the other, so that I can carry the bit up or down at will, and place firmly its stem against the bone, in this way a full bite can be taken out each time. A large trap door can be made

in from five to ten minutes. That there are more permanent cures made by this plan of operating I have described, I can not say, but I can say that death and other bad results from shock incident to the prolonged use of the mallet and chisel may be prevented.

Many surgeons have used it in making craniectomies and proved its usefulness; but this is not its only field, it extends to thoracoplasty and laminectomy and all bones that are thin enough to come within its jaws.

When in Chicago recently I found this instrument in use in several of the schools.

CATAPHORESIS.

Read in the Section on Dental and Oral Surgery, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1895.

BY HENRY W. GILLETT, D.M.D.

NEWPORT, R. I.

The primary facts upon which the present practice of cataphoresis are based were first discovered, nearly forty years ago, by Dr. B. W. Richardson. The development of practical results from these facts has been slow, but the past five or six years have added much to the general knowledge and application of them.

The fact that the galvanic current does, under proper conditions, carry with it into the tissues of the body, fluids and the substances they may hold in solution, is now sufficiently well known and accepted. The practical realization and use of this fact has not been general for numerous reasons, but now that the principles of the process are becoming more widely understood, it seems quite probable that some of the most important applications of this method of medication will be in the treatment of the oral tissues.

The dentine of the human tooth, which, for generations, we have been wont to consider practically impenetrable by drugs, has, by reason of our better understanding of the process of cataphoresis, changed its relative position, and may now be considered one of the tissues easily penetrated and influenced by drugs.

The very fact that has made it impossible for us to cause absorption of drugs into dentine, namely, its comparative non-vascularity, is an aid when we apply them by cataphoresis. Into a very vascular tissue it is difficult to feed a cocaine solution with sufficient rapidity to produce a deep effect, because the blood current washes it away and spreads it through the system. In dentine this does not occur.

There are material differences necessary in the apparatus to be used with success for treating sensitive dentine, and that which may be used for other tissues. For some subjects almost any voltage of current may be used if it is choked down in quantity; but a large percentage of the subjects who most need the aid of this method will be found too sensitive to the effect of the galvanic current to allow of its use on sensitive dentine, unless the apparatus is so arranged that the voltage may be reduced to a very low point at the start, and gradually increased, in small steps, to a point where it will be efficient in producing cataphoric effects in a reasonable time. McGraw used the ordinary battery apparatus in 1888 for treatment of dentine, but gave it up because of crudeness of apparatus. With such apparatus it is necessary to either commence with the full voltage, or to add it in

steps equal to a whole cell (equal to about a volt and a half).

Recently apparatus has been described in the *International Dental Journal* for using the 110 volt current choked down in quantity, without modifying the voltage, and also apparatus for using a storage battery fitted to produce a twenty volt current, and choking the current from that. Methods and apparatus giving the same currents were used by your essayist in his early work in cataphoresis.

In order to extend the range of application for the method, an apparatus, since named a volt selector, was devised. The completed instrument has been called by the manufacturers the Geo. M. Wheeler Fractional Volt Selector, and it is the most suitable apparatus obtainable for making applications of electricity to sensitive dentine. When connected to the 110 volt circuit, it allows the operator to command at will any voltage of current, from less than one up to forty, in quarter volt steps, or by turning a switch, the voltage at command may run up to eighty in half volt steps. An instrument of the same type may be connected to sets of batteries, and any voltage from one extreme to the other of the set is at the command of the operator. There is a marked advantage in having this capacity to graduate the current to any desired voltage, since it enables the operator to begin with a current that any and all patients can bear without discomfort, and to increase the current very gradually up to such point as the individual patient may be found able to take without objection.

For a résumé of the prominent points in the history of the development of the use of cataphoresis, I would refer to a paper which was published in the February, 1896, number of the *International Dental Journal*, in which I drew largely from Bigelow's International System of Electro-therapeutics.

My first work was commenced with the belief that cataphoresis was possible in dentine. A few trials on my own teeth with the 110 volt current, choked with the ordinary rheostat, demonstrated the correctness of this belief. This first apparatus was tried in practice, and found usable for a few patients. It was modified so as to furnish a sixty volt current, which extended its applicability, but it was still not useful for general practice, and the voltage was further modified till it was demonstrated that the apparatus which would eliminate the difficulties which were met with, namely, pain and irritation, was one with the qualities mentioned above. An apparatus was accordingly made by which the voltage in the working circuit could be modified at will. This somewhat crude apparatus proved to be a practical office instrument. It was used for some months in my practice and proved equal to all cases for which it was needed, although there were some cases where the steps by which the current was added proved to be too large for the comfort of the patient.

Having brought the principle to a workable condition, it was handed over to a manufacturing company for development, and a successful instrument with many conveniences and improvements is the result.

Nearly all my work with cataphoresis has been in obtunding sensitive dentine. For this purpose I have generally used a strong cocain solution, 20 to 30 per cent., applied on cotton in the cavity of decay; the positive electrode, platinum tipped, being placed on the cotton, and the negative (ordinary wet sponge)

electrode applied anywhere on the surface of the body.

It is not absolutely essential that the rubber dam be used, but it is very desirable; also that any metallic fillings which are so placed that they may make good electric connection with the current, be insulated by covering them with some non-conducting material like varnish, wax or gutta percha. If this is not done, considerable pain from the current may be expected.

I quote some experiments from the article mentioned above:

No. 1. A 15 per cent. aqueous solution of cocain on cotton wound on positive electrode, applied to back of right hand, at a point where the sensibility to the prick of a fine instrument had been tested; the negative electrode wet with a salt solution, applied to the palm of same hand. One milli of a seventeen volt current passed for ten minutes. Result: Absence of superficial sensation, and I was able to pass an instrument through the skin without pain over the area covered by the positive electrode.

No. 2. A 15 per cent. aqueous solution of cocain applied on cotton to corresponding point and under the same conditions on back of left hand; no current used. At the end of ten minutes there had been no appreciable modification of the sensitiveness.

No. 3. A 10 per cent. salt solution, on cotton, on positive electrode, applied to another tested point on back of left hand, and negative sponge electrode wet with same solution applied to palm of hand. Current applied for ten minutes, reaching a maximum of thirteen volts and about four millis. There was so much pain and burning as to make this a disagreeable experiment to try. Result: Redness and irritation, but no effect upon the sensitiveness.

No. 4. A 15 per cent. aqueous solution of cocain on cotton was placed in a moderately sensitive cavity of decay in a tooth for fifteen minutes. No modification in sensitiveness took place.

No. 5. Same case; same day. A 15 per cent. aqueous solution of cocain on cotton, placed in another moderately sensitive cavity for ten minutes, with no resulting modification of sensitiveness.

No. 6. Rubber dam applied, and 25 per cent. aqueous solution of cocain applied on cotton to a very sensitive bicuspid cavity of medium size for twenty minutes, without the slightest effect upon the sensitiveness.

No. 7. Same cavity as No. 6. Rubber dam in place. A 25 per cent. aqueous solution of cocain on cotton in cavity; positive platinum electrode applied to cotton, and negative sponge electrode to the cheek. Electric current passed for thirteen minutes, beginning with a voltage of three, and attaining a maximum quantity of about two-thirds of a milli. Result: Absolute freedom from all sensation to the vigorous use of an excavator for removal of decay, and to the use of bur for forming ample retaining grooves in cervical and side walls.

No. 8. Sensitive buccal cavity in inferior third molar. Rubber dam in place. Positive electrode applied in cavity to cotton saturated with 20 per cent. sodium chlorid solution. Current applied for twelve minutes, reaching a maximum of eight volts and one milli. Much diffused pain resulting while current was applied, but no anesthetizing effect.

No. 10. Same cavity. A 15 per cent. aqueous solution of cocain instead of the salt solution. Current applied during eleven minutes, reaching a maximum of ten volts and about two-thirds of a milli. No diffuse pain, a very little in tooth. Result: A marked lessening of sensitiveness of whole cavity, and entire removal of it in a large part of cavity.

As a rule, this class of cavity requires longer applications than approximal cavities, and it is sometimes difficult to affect that part of the cavity which is out of the path of the current.

No. 11. Coronal cavity in left superior second molar. Quite sensitive. Placed in a .5 per cent. solution of sodium chlorid on cotton in the cavity and applied current for ten minutes, beginning with a voltage of less than one, increasing it to eight and a half at the end of the ten minutes. The milliamperemeter then recorded about a half milli. I was unable to work the current up faster because of the pain it caused. The sudden turning off of the current at the end of the ten minutes gave a very decided sensation (kick or kink, patients often call it) in the tooth. The sensitiveness of the dentine to the excavator had not been in the least diminished.

No. 12. Same cavity as No. 11. A 25 per cent. aqueous solution of cocain applied in this way, beginning with same voltage. After the first two or three minutes it was possible to increase the voltage much more rapidly, without undue

pain, than was possible with the salt solution, this fact being seemingly due to the beginning anesthetic effect of the cocain. At the end of eight minutes seventeen volts (or twice the quantity given in No. 11) was being administered, and with less pain. At the end of ten minutes there was no pain. The milliampere meter recorded about three-fourths of a milli. When the current was suddenly cut off, there was much less of the "kink" noted by the patient—another indication of deep cocain effect. Upon vigorous use of the excavator, the dentine was found *absolutely* free from all sensation. It should be said that this patient and the one for experiments Nos. 6 and 7 had never had the process used before, and that no explanations were made beyond the statement that I was going to try to relieve the sensitiveness, and that they should not be hurt.

"The results of these experiments may be summed up as follows: Ten per cent. aqueous solution of cocain applied on the positive electrode with a weak electric current for a few minutes will anesthetize the skin. A similar cocain solution applied for the same time without the current has no anesthetic effect. The same electric current without the cocain has no anesthetic effect. Cocain solutions of from 15 to 25 per cent. applied in sensitive cavities, for ten or twenty minutes, do not modify their sensitiveness. The electric current alone applied to sensitive dentine, sodium chlorid solutions of varying strengths being added to insure good electric connections, does not perceptibly modify the sensitiveness.

"Cocain solutions and the electric current applied to sensitive dentine, together, *do* completely anesthetize it; consequently the cocain is the active agent.

"It seems probable that the exhibition of other drugs may produce the same results, and I have other experiments preparing to demonstrate the facts. I hesitate less about reporting results with cocain without lengthy trial than with most other drugs, since, theoretically, it can do no possible harm to the tooth.

"The effect of the cocain in these applications does not seem to reach deeply into the dentine in most cases. By prolonging the application, however, the pulp may, in favorable cases, be anesthetized, even through a layer of dentine.

"It is quite often the case that a ten- or twelve-minute application will anesthetize the dentine deeply enough to allow the greater portion or all of the cutting to be done painlessly, but for deep grooves it may be necessary to repeat the application. In cases where there is much sensitiveness, and consequently much time will be required to prepare the cavity, I find the time required for applying the cocain is fully made up by the increased speed possible after the sensitiveness is under control."

I would also quote from the same some directions for making the application:

"I always apply the rubber dam, as it is difficult, and often impossible to prevent leakage of current through other tissues if this is not done. Any metal fillings which will be in contact with the wet cotton in the cavity or with the electrode must be covered. The current from a metallic surface into dentine is irritating and painful. I find Gilbert's temporary stopping a very useful material for this purpose. Wax or varnish will also do. In cases where I am working on an approximal cavity in one tooth, and a filling in the next tooth is too close to allow of its satisfactory insulation, I apply the rubber at first over the tooth to be worked upon, thus insulating it completely; or, if the rubber is already in place a second rubber may be applied over the tooth to be worked upon. The positive electrode should be of platinum as most other metals are affected by the current, and are liable to stain the tooth. These conditions being provided, be sure that your current is turned on. I always test this by touching the metal parts of the electrodes together, and watch the milliampere meter to observe the result.

"This selector is so arranged that when the needle is at zero, and contact of electrodes is made as described, about one milli will be recorded. Getting this result assures the operator that all connections have been made, and that the apparatus is ready. If, however, a larger quantity of current is indicated by the milliampere meter, it shows that the rheostat contact is not at the right place. This same proceeding would also serve to detect any break-down in the rheostat if it had occurred. Twenty seconds serve to assure the operator on these points, if his apparatus is conveniently placed. I then wet the negative sponge electrode with water or dilute salt solution. I place in the cavity a pellet of absorbent cotton saturated with a 20 to 30 per cent. cocain solution. I prefer not to have this cotton extend outside of the cavity, and to keep the solution confined to the cavity as much as possible. This concentrates the current in the part I desire to affect.

"The negative wet sponge electrode I usually allow the patient to hold. It is preferably to be applied about the face or neck, as near the tooth as is convenient. Having placed this and allowed the patient to take it, I apply the positive electrode to the cotton in the cavity, and begin slowly to increase the current by turning the large fiber knob of the rheostat head in the direction indicated by the needle which records voltage. The first consciousness of the current sometimes comes to the patient as the typical little "kick" or "kink" of the galvanic current, but it is a very small one with this selector. More often the patient is only conscious of an indefinite, gradually increasing pressure, and if the current is pushed too rapidly this may increase to pain. It is therefore necessary to watch the patient carefully, and to pause in the turning-on process as soon as the change in the eye of the patient indicates that he is beginning to feel the current to an uncomfortable degree. After the first experience, if cautiously managed, a patient will usually give the operator all necessary indications for his guidance, and allow him to keep the current up to a point just short of pain. After one experience with it, the sensation is readily borne, even by sensitive children of twelve or fourteen.

"As the operator pauses at the point where the patient indicates that the current is strong enough, or even turns back a little if there is too much current, it is well to assure the patient that any disagreeable sensation will subside promptly. It usually does this in from one-half minute to two minutes, and then the voltage may be increased slowly and gradually, with pauses long enough for any disagreeable sensation to disappear.

"Subjects differ very much in the amount of current they will bear without discomfort. It is usually found, however, that by very gradual increase, and by taking more time to reach the maximum in these sensitive cases, a sufficient amount may be applied, to any case, to attain the result of anesthetizing the dentine.

"It is my habit, as soon as I have opened into a sensitive cavity, to make an application lasting from eight to twelve minutes. If I have reason to expect difficulty with the case, I make the application longer. If the first application is not sufficient for all I wish to do, I repeat it later.

"I have some ten or twelve cases on record where twenty to thirty minutes have been needed to produce sufficient effect. These were all cases where both patient and operator felt compensated for the time spent. Most of them were either extremely sensitive teeth or subjects who could bear but little current, and several of these cases would have been all but impossible without the aid of this method. On the other hand, I had numerous cases where ten or even eight minutes had been ample time for successful results. Having reached a voltage likely to be sufficient, I allow it to stand at that point till the end of the application. Fifteen to twenty volts will usually be attained in seven or eight minutes. In many cases, with small cavities and little sensitiveness to the current, twenty-five or thirty volts may be marked in the same time. The higher voltage works more rapidly. At the end of the application, I usually break connection at the negative electrode, as there is less often shock in so doing. If the subject is very sensitive to the current, I turn the voltage down low before breaking connection. Having concluded the application, I turn off the current in the selector by means of the switch. This lever may also be used for concluding the application of current if you find no objectionable shock resulting. Then I test the cavity, and finding it all right proceed as usual, bearing in mind that the effect may not have gone as deeply as I wish to go with my instruments, so it is still necessary to watch for signs of returning sensitiveness."

No ill effects are to be expected from the application. In no case have I seen any symptom which would contraindicate the use of cocain and the current for sensitive dentine.

It has been proposed to utilize the anesthetic properties of guaiacol in this way, and combinations of guaiacol and cocain have been used with success. It is claimed that the use of guaiacol will reduce the time needed for the application to prove effective. Unfortunately, it has an unpleasant odor, and escharotic properties which lead to its being used with caution. It is to be hoped that the firm now at work upon this combination of drugs will succeed in eliminating its escharotic properties and in overcoming its odor. If this can be done, it will aid us, since the

time required for producing anesthesia of dentine is the chief objection to the practical use of the method, and this drug may probably reduce the time. It is quite possible that the drug is not sufficiently escharotic to work harm in the dentine, but it would seem desirable to use it with caution till more is known of its effects. With guaiacol and cocain it would be less necessary to use the rubber dam, and it would also be easier, with the escharotic properties eliminated, to produce effects on the gum if it were desired to use the method there. The combination has been used successfully for anesthesia in extraction, implantation, and skin surgery. On mucous membranes the subsequent sloughing is objectionable. On the skin it is said not to produce ill effects.

For bleaching teeth a 25 per cent. aqueous solution of H_2O_2 will prove successful if used as directed for cocain. The cotton in the cavity needs to be kept wet with fresh solution and stronger currents may be used than in living teeth.

When a commercial system is used as the source of power, it should be one that furnishes a steady current. A system subject to large intermittent demands upon it is not satisfactory in this respect. It needs also a well-appointed and well managed central station in order to be successfully used for this purpose; otherwise the irregularities due to imperfect machinery will be disastrous. Any primary or storage battery of sufficient capacity will do well. The manufacturers of the selector have made one to be used with a set of dry batteries that impresses me very favorably. It is certainly a most convenient form of battery, free from the objection of requiring constant care, and much less liable to injury than storage batteries. It is essential that the selector be fitted to go with the particular battery provided.

The most formidable objection to this process for the treatment of sensitive dentine is the time required. On this account, its best field is in the cases of extreme sensitiveness that require so much time and care for their preparation. I anticipate that the result of the general use the process is fast attaining will be the development of improvements which will reduce the time required.

EXPERIMENTS ON THE RUSTING OF INSTRUMENTS IN STERILIZATION BY BOILING.

BY EDMUND ANDREWS, M.D.
CHICAGO.

Every one knows that if steel instruments are sterilized by boiling in pure water, they become covered with spots of rust. It is usual to guard against this by adding to the water 1 per cent. of sodium carbonate. Some surgeons complain that this process gives no uniformity of result, their instruments sometimes coming out bright, and sometimes badly spotted.

As the rusting is a simple chemie process, the results ought always to be the same if the conditions are uniform. The following experiments were made to ascertain the effect of boiling under different conditions. A quantity of thin polished steel plates, each one inch wide and two inches long, were made for me by a cutler. These were washed well in ether, and then soaked in a bath of ether for some hours to remove all oily matter from the surface.

Also two plates of aluminium, each two inches square, were subjected to the tests, and two bright

scalpels, one with an aluminium handle and one with a German silver handle. These scalpels were selected to see if the presence of different metals in the same bath caused any galvanic action at the expense of the steel blades. For the same reason two plates of steel were laid on a plate of zinc and boiled.

Experiment 1. Two plates of steel were boiled twenty minutes in distilled water. They began to rust in two minutes, and in twenty minutes large elongated spots of black rust covered 30 per cent. of the surface.

Experiment 2. Several steel instruments were exposed to a steam bath over boiling water for twenty minutes. They came out much spotted with black rust.

Experiment 3. Two steel plates were boiled in Lake Michigan water, which is purer than ordinary Western well water, but contains small traces of chlorids and sulphates, being slightly "hard." The plates began to rust in two and one-half minutes. In twenty minutes about one-quarter of the surface was covered with small black spots.

Experiment 4. Two steel plates were boiled in water from a country well dug in the boulder drift. It was very "hard" water, owing to the presence of soluble chlorids and sulphates. In twenty minutes they were taken out and only one-twentieth of the surface was rusted, showing that hard water is better than soft for this purpose.

Experiment 5. Two plates were boiled twenty minutes in Lake Michigan water with 1 per cent. of sodium carbonate added. No rust at all.

Experiment 6. Two plates boiled twenty minutes in Lake Michigan water containing 1 per cent. of sodium bicarbonate. Not a particle of rust.

Experiment 7. Two plates boiled twenty minutes in very hard country well water containing 2 per cent. of green soap. Not a particle of rust.

Experiment 8. Two plates boiled twenty minutes in Lake Michigan water with 2 per cent. of green soap. No rust.

Experiment 9. Two plates boiled twenty minutes in Lake Michigan water with 2 per cent. of ordinary toilet soap. No rust.

Experiment 10. Two plates boiled twenty minutes in Lake Michigan water containing 2 per cent. of boric acid. Began to rust in two and one-half minutes. In twenty minutes there were many minute specks of rust.

Experiment 11. Two plates boiled twenty minutes in Lake Michigan water containing 1 per cent. of sodium chlorid. Twelve per cent. of the surface was rusted.

Experiment 12. Two plates boiled twenty minutes in pure Lake Michigan water, lying on a plate of zinc to test the galvanic effect. Twelve per cent. of surface rusted in large spots.

Experiment 13. Two scalpels, one with German silver handle and one with nickel plated handle, were boiled twenty minutes in Lake Michigan water with 2 per cent. of green soap. No rust.

Experiment 14. Plate of aluminium boiled twenty minutes in pure Lake Michigan water. A thin, delicate tarnish appeared on the surface.

Experiment 15. Plate of aluminium boiled twenty minutes in Lake Michigan water containing 1 per cent. of sodium carbonate. Copiously covered with blackish rust.

Experiment 16. Several aluminium articles soaked

in solution of bichlorid of mercury, strength 1 to 2,000. Surfaces marred and injured by the bichlorid.

Experiment 17. Two steel plates were placed in a small covered dish of melted vaselin and set for twenty minutes in a bath of boiling water. Not a particle of rust resulted.

These experiments yield the following conclusions:

1. Hot distilled water and steam rapidly rust steel instruments.

2. One per cent. solutions of soap and sodium carbonate almost perfectly protect steel instruments, provided they are completely immersed in the fluid.

3. If instruments lie in a shallow boiling-pan and are not fully covered with the protective fluid, and a cover or towel is laid over them, the portions projecting above the fluid will only get a steam bath and will rapidly rust. This is the accident which perplexes some surgeons, and leads them to think there is no uniformity about the action of protective fluids in preventing rust. The fluids themselves will not cause oxidation, but the steam rising from them will easily corrode steel.

There is one theoretical objection to the use of all these boiling fluids. Educated mechanical engineers say that the heat of boiling water somewhat impairs the temper of cutlery steel. This is no doubt true, yet they are not so badly softened as to prevent us from using them with good effect, and as the boiling seems to be a necessity, we have to put up with the slight injury done to their cutting efficiency.

2520 Prairie Avenue.

SOCIETY PROCEEDINGS.

Physicians' Club of Chicago.

A regular meeting of the Club was held Monday evening, Nov. 30, 1896, at the Victoria Hotel.

Dr. ARTHUR R. REYNOLDS in the Chair.

The subject for discussion was

THE WATER SUPPLY OF CHICAGO.

The Chairman in calling the meeting to order, said: Our subject tonight is "The Water Supply of Chicago." There is no subject in which the members of the medical profession of Chicago are so deeply interested, and there is perhaps no subject in which the taxpayers are so deeply interested, for it is true, or will be true at the close of this century, that the taxpayers of this community will have paid directly or indirectly to maintain the purity of its water supply \$100,000,000 since the foundation of the city.

It has been said that each human being is worth to the State \$5,000. Impure water has been credited with destroying a great many lives, and it has often occurred to me that in this public-health matter, looking toward the preservation and building up of the race, that in order to get the people to understand the importance of the subject, it is necessary for us to reduce the matter to dollars and cents. I can not tell you at this time how many lives have been sacrificed because of bad water and so can not compute the total cost. Our own water supply is sometimes good and sometimes bad. It is a matter of very great interest to Chicago to have the outside world think well of us, because this city is a commercial center and is well known all over the world. Indeed, when we were inviting the world to partake of our hospitality and to attend the Fair, it was one of the bugbears even beyond the Atlantic Ocean, that our water supply was bad and on this account a great many people that would otherwise have come to the Fair remained away. Medical journals across the Atlantic took the matter up and discussed our water supply with a great deal of interest, and pointed out the evils of our water system, while we ourselves had said nothing and have suffered in consequence. If our water is impure we should admit it at once, in order that proper measures may be taken to purify it. To start the ball rolling it gives me very great pleasure to introduce Prof. Carl S. Hallberg of the Chicago College of Pharmacy.

Prof. C. S. HALLBERG spoke to the text: "Water, air and

cleanliness are the chief articles in my pharmacopeia." (Napoleon.) He said: As long as we have at the head of our municipal government men who know nothing about the importance of those matters for which they are engaged, taking care of the public health, we never can expect a better condition than we have at the present time. As for the subject of water; the newspapers have ridiculed the proposition of the Health Department to boil the water regularly every twenty-four or forty-eight hours, and one journal has even suggested that we get an automatic health department that would simply announce to the public every twenty-four hours, "boil the water," and that would be all that is necessary. However much we may ridicule the condition of the water in Chicago, anyone that has any knowledge of the service water in the large cities in this country, particularly in the East and Southeast, must agree with the statement that the water of Chicago, however bad, is better than it is in any other large city east of us. It is only in the cities west of us that the water supply is perhaps purer. To consider the best methods of purifying water is a large subject, and I shall only briefly touch upon it, for the reason that there are other gentlemen here who have made water supply a specialty. There are three methods of purifying water:

1. *Filtration.*—Filtration resolves itself into any process which will remove the finely suspended insoluble particles. We may carry that process to such an extent as to also remove whatever microorganisms or organic matter the water may contain. As to whether or not filtration will purify ordinary water, such as our Lake Michigan water, is doubtful. In the first place we must remember that the filtration from the service pipes, that is for domestic or culinary purposes in small quantities is one thing, while the attempt to filter all the water which goes through the service pipes is another thing. It is quite possible to purify water if we attempt to do so in small quantities for domestic purposes, provided we take extreme care, giving it constant and unremitting attention. Filtration, as you doubtless know, is dependent upon the attraction that solid matter has for other solid matter. When we pass a liquid charged with more or less solid matter through a porous solid, such as animal charcoal, which is a mass of minute pores, by capillary attraction the solids, and particularly in this case, organic matter, are attracted and retained in the pores, while the clear water is allowed to pass through. For small operations we might choose various media through which to pass water which will not only rid it of the grosser impurities that it may contain, but will also carry off the microorganisms themselves. But we must remember that just as soon as this particular medium becomes charged to saturation with the insoluble matter, or with microorganisms, from that time on the process can be no more effective, and that is an objection to all forms of filtration of whatever kind; in filters made from sand, charcoal or silicious matter in any form, or burnt loolin, made into cylinders and the water passed through by pressure as in the Chamberlin-Pasteur period, and then their usefulness is at an end. Then, in many instances, the filters may require to be regenerated, burnt out, when they will again be free from organic matter and effective and be used again. In a larger way it is doubtful whether or not, for a city like Chicago, water can be purified by filtration. I might refer here to the conclusions based upon filtering apparatus used in three or four of the largest German rivers, because we have no details from any others, such as the Elbe, Oder, Neckar and Spree. The various cities situated on these rivers, such as Breslau, Berlin, Altona and Stüttgart, have filtering apparatus attached for purifying the water. But it is found by referring to the standard work of Koenig, that there are more impurities in the water served to those cities on the German rivers that have filtering apparatus attached than any other cities which do not have any filtering apparatus. This may not be conclusive testimony, but The Waterworks Technical Society of Germany a couple of years ago, after investigating the matter, reported that it must be remembered that the microorganisms in a filter settle to the bottom of a filter. The manner in which these filters are constructed is to have a depth of from five to six feet of various fineness of sand, gravel and stones. For example, beginning with a layer of fine sand, then coarser sand, then gravel and coarser gravel on top of that and finally pebbles. A bed like that, 300 meters square, representing 90,000 square meters area, would filter about one hundred million gallons of water every twenty-four hours. The bacteria are found to accumulate and to grow under the bed of the filter. In the beginning the water runs through in an impure condition, but after a while a sediment forms and a rather thick impervious coating over the porous bed, which retards mechanical impurities and lessens largely the number of bacteria. However, the question has yet to be solved whether or not a

filtering apparatus, constructed in this manner, is sufficient to purify the water on so enormous a scale as would be required for a large city like Chicago.

It is possible by the use of upward filtration that the growth of bacteria might be prevented. This is a phase of the subject which has as yet not been fully investigated.

2. *Distillation.*—Another method of purifying water consists in distillation. In distillation, if proper care be taken to reject portions which are loaded with ammonia and the various gases which the water contains, and in not carrying distillation beyond a certain limit, we can obtain under proper condensation absolutely pure and sterile water. Distilled water does not keep unless exposed to air, when it may be protected against infection from bacteria by stopping the container with absorbent cotton. Distilled water is not suitable for potable purposes, not only from the lack of the gases but of the salts which it is necessary to have in the water in order to make it palatable, an aid for digestion, and to allay thirst. If distilled water is aerated and the gases are supplied we can secure palatability to a very great extent, but such will not keep as well as water which has not been sterilized or distilled, which has certain salts in it, particularly nitrates which prevent the accumulation and growth of bacteria. For that reason we believe the only practical method is that of precipitation.

3. *Precipitation.*—The method of precipitation for the purification of water seems to be upon the whole, wherever the quantity required is not too great, the most satisfactory. The ordinary impurities in water are alkalin salts, calcium, sodium, magnesium, and those derivable from the organic matter directly or indirectly, such as ammonia and its compounds. There are several substances which upon the addition to water are split up and form new compounds. Of these are the sulphate of aluminum, and the double sulphate of aluminum and potassium. When alum in solution is added to water, according to the proportion of impurity in the water to be gotten rid of, the aluminum sulphate is split up and forms aluminum hydrate. The sulphuric acid radical which is eliminated combines with the calcium and forms the sulphate of calcium or gypsum. Both of these substances are as insoluble as any substances we have. They are heavy. They go down. The aluminum hydrate spreads as a flocculent precipitate over the surface of the water and as it goes down it carries both the finely suspended and organic impurities with it. After the water has settled for twenty-four hours we may obtain the purified water by decantation or by syphoning it. Filtration perhaps would be most reliable in many instances. It is a fairly practicable, inexpensive and convenient process. The alum must be the potassia-alum; ammonia-alum will not answer the purpose. The quantity of alum required is from 5 to 10 grains to one gallon of water; ordinarily Chicago water requires 8 grains to the gallon. By this process you purify the water and leave it otherwise as it is. You do not change the water from its natural condition, except that you eliminate those impurities which are undesirable, and I believe for operations in small cities it is the most feasible, practical method.

There are a great many substances used for precipitants, and there are regenerative processes. Calcium permanganate can be used as a precipitant, and with it gases can be removed. We have also the dried basic phosphate of sodium for this purpose, the precipitate forming the phosphate of calcium, which can be collected and used for fertilizing purposes. I believe there is a scheme on foot abroad where the phosphate of sodium is used and the residue sold for the purpose of fertilization.

There is a system of filtration through pumice stone which has been saturated with ferric hydrate. The water is allowed to pass through and the ferric hydrate combines with the impurities and renders them insoluble. Neither the medicinal solution nor the tincture will answer. The solution of ferric chlorid, on account of containing free acid, added to water forms ferric hydrate which causes a flocculent precipitate to spread over the water and carries the impurities with it.

We are inclined to think that precipitation in conjunction with filtration is the most feasible method for purifying water that is used for domestic purposes and in public institutions. We admit, however, that we have never given these waters any biologic examination because we do not think it is necessary; I believe that when we can determine by chemic methods that water is absolutely pure, it is unnecessary to subject it to a biologic test. A biologic test does not always indicate the purity of water. Water should be examined chemically first, and then as a corroborative test it should be examined biologically.

In conclusion, Mr. Chairman, I wish to say that not until some method is devised whereby that putrid mass of filth which floats into the river from the abattoirs is stopped or modified, will Chicago ever have good water.

F. W. REILLY, M.D., Assistant Commissioner of Health, read a paper on

RELATION OF THE MEDICAL PROFESSION TO THE WATER SUPPLY OF CHICAGO.

The history of the efforts to secure a pure water supply for Chicago is inseparably connected with that of the medical profession of the city. Forty-seven years ago Dr. N. S. Davis arrived in Chicago in the height of the cholera epidemic of 1849. Before the epidemic was over he had traced the relationship between the greater incidence of the disease in certain localities and the use of water from surface wells, and at once began an agitation for pure water from the lake. During the summer of 1850 he delivered a course of lectures on the sanitary conditions of the city and pointed out the means for their improvement. The plans he then suggested for a pure water supply and for its necessary complement—the proper disposal of the sewage of the city—are the basis of all that was done toward these ends during the subsequent forty years. One immediate result was the passage of an act, Feb. 15, 1851, incorporating the Chicago Hydraulic Company, the foundation of our present system of water supply.

Only the merest mention may be made of those who followed the initiative of Dr. Davis and persistently pointed out the evil effects of impure water and urged measures for preventing the pollution of our source of supply. The roll would include the names of almost every man prominent in the profession in the early days, Brainard, Egan, McVickar, Boone, Paoli, Ross, Lyman, Holmes, Byford, Hollister and their colleagues, among whom may be especially noted Dr. James Van Zandt Blaney, who, while the writer was an assistant in his laboratory in "Old Rush" in 1855-56, made the first chemico analysis of Lake Michigan water; Dr. Hosmer Allen Johnson, subsequently a sanitarian of national reputation, and Dr. Edmund Andrews, whose report on the erysipelas epidemic of 1863 was a scathing indictment of the municipal indifference which had allowed the river to become an open cesspool, with here and there an independent pollution, which he describes with grim humor, as answering "every purpose for the increase of medical practice in general and of erysipelas in particular."

To no other member of the medical profession, however, if to any other citizen, does Chicago owe so much in this connection as to the late Dr. John H. Rauch. Indefatigable as were his labors in the cause of medical education and far-reaching as were their results during his lifetime, his efforts toward the solution of the sanitary problems of Chicago were of even greater and more direct importance to the prosperity and the health of this community. The work that he did lives after him in the parks and boulevards of the city; a direct result of his monograph on "Public Parks; Their Effects upon the Moral, Physical and Sanitary Conditions of the Inhabitants of Large Cities, with Especial Reference to Chicago." It lives after him in the suburban cemeteries which now receive the city's dead, without offense or menace to the living; the result of a paper read before the Chicago Historical Society in 1858, entitled "Intramural Interments in Populous Cities and Their Influence upon Health and Epidemics." His work lives after him in the present drainage and sewerage system, which he so persistently urged, and concerning which, in his report, as sanitary superintendent, to the Chicago Board of Health in 1869, when the average death rate for twenty-five years had been over thirty in the thousand—he wrote as follows:

From the results of drainage and other sanitary measures carried on in this city, it may be inferred that the judicious expenditure of money for sanitary purposes is a sound maxim of municipal economy, and from past experience I am satisfied that the mean annual death rate can be reduced to 17 per 1,000 by continuing in force the present sanitary and drainage regulations, thereby making Chicago one of the healthiest cities in the world.

In his presidential address before the American Public Health Association he cited this prediction, together with other passages from his reports and papers, with the following comment:

I introduce these quotations simply to show that sanitary science has made sufficient progress at the present time to admit of the supreme test which science falsely so-called can never endure—that of verification by subsequent experience.

Dr. Rauch fortunately lived to see the verification of his prophecy "by subsequent experience." The year before his death, in March, 1894, the mortality rate of the city was only 16.9 per thousand of its population, a fraction less than that which he had asserted, twenty-four years before, was attainable if the plans originally formulated by Dr. Davis in 1850 should continue to be carried out.

And Rauch, too, was a prophet not without honor—save among his own people!

Basis of the sanitary waterway and drainage channel.—He lived, however, to see also the fruition of his efforts for the protection of the water supply of the city in the advanced

stage of work on the great sanitary waterway and drainage channel. In his annual report for 1869, he foreshadowed, in a general way, the plan now in progress for the ultimate disposal of Chicago sewage and consequent protection of the water supply, and from that time until work on the sanitary waterway was actually begun he continued to accumulate facts and present arguments, which were finally successful.

Probably no other one demonstration had more weight in determining the adoption of the present plan than that developed in the study and collation of the results of Prof. J. H. Long's analyses of the sewage contents of the Illinois and Michigan Canal and of the waters of the Illinois River as far south as Peoria, made in the summer of 1886. These analyses were part of a plan projected by Dr. Rauch, and carried out under the direct supervision of the writer, for an investigation of the water supplies of the State, with especial reference to the progressive decomposition of sewage in running streams, first between Chicago and St. Louis and subsequently in other Illinois water courses.

The collation of Professor Long's analyses between Bridgeport and Peoria enabled me to show that more than one-half the sewage pollution of the canal disappeared before reaching Lockport; nearly one-third of the remainder was lost in the next four miles, or 33 miles from Bridgeport; while at Channahon, 48 miles from the city, no trace of sewage was detected. These results were so unlooked for that Dr. Rauch hesitated to accept them. Water analysts had asserted that the self-purification of a polluted stream was impossible—as one phrased it, "no river in the world is long enough to purify itself after it has once been contaminated with organic matter." In his article on "Water," in the Reference Hand Book of the Medical Sciences (Vol. vii, p. 714), that distinguished authority, Surgeon Charles Smart, U. S. A.—with whom the writer was associated, together with Deputy Surgeon-General John S. Billings, U. S. A. and Col. George E. Waring, Jr., in the sanitary regeneration of the city of Memphis after the terrible yellow-fever summer of 1878—makes the following comment touching this matter:

"These statements would be of immense importance were they sustained by collateral evidence; but, unfortunately, those analysts who have had much practical experience in following the track of sewage in its passage down stream, will recognize in these results: 1. The analysis of a fresh and turbid sewage at the starting point, the solid particles of organic matter giving a high rate of impurity; 2, the analysis of a partly sedimented sewage as those particles disappear from the water; and, 3, the dilution effected by the Desplaines river."

To this I felt constrained to make the following reply in the "Preliminary Report to the Illinois State Board of Health on the Water Supplies of Illinois and the Pollution of its Streams," April, 1889:

"For the benefit of those analysts who have had much practical experience in following the track of sewage in its passage down stream' it should be stated that: 1. The analysis itself, showing 12.6 parts of free ammonia per million, is that of anything but a fresh and turbid sewage, at the starting point; on the contrary, it is a sewage in an advanced stage of decomposition. 2. 'Sedimentation' in a current with the velocity of that in the Illinois and Michigan Canal is a physical impossibility, and this entirely apart from the influence of the passage of boats. 3. It is expressly stated in the text quoted by Dr. Smart that there was 'no dilution of the contents of the canal,' which contents were the sole subject of the various analyses at Bridgeport, Lockport and Joliet; as a matter of fact, the Desplaines river above the point of junction with the canal had ceased to exist as a watercourse during the period of observation—which was one of unprecedented drought—and the contents of the canal were undiluted from any source after leaving Bridgeport."

The demonstration and its deductions were of such obvious—such "immense importance," to borrow Dr. Smart's phrase, that the analyses were repeated in the winter of 1886-7, again in the summer of 1888 and still again in the spring of 1889, with substantially similar results in every case.

In 1892 Professor Pettenkofer caused a similar investigation to be made of the River Isar, which receives the sewage of Munich. Within a mile below the point at which the Isar receives the Munich sewage the *beggiotoa*, or sewage fungus, was found growing in abundance; it was still found at Ismaning, between seven and eight miles below; but the last traces were found at Garching, ten miles below Munich. After a ten or twelve miles' flow the Isar so far purifies itself from sewage that its waters no longer support the *beggiotoa*. The chemist analyses gave similar results, while Pettenkofer himself reports that he found 198,000 bacteria to the cubic centimeter at the

mouth of the sewer and only 3,600 at Freising, twenty miles below. He distinctly asserts that sewage is decomposed in running streams and is rendered harmless in a few miles' flow.

It may be added that bacteriologic investigation fully supports Professor Long's chemist analyses and the combined chemist and bacteriologic examinations of Professor Pettenkofer. Dr. Adolph Gehrman, Director of the City Laboratory, who has probably done as much practical work in water bacteriology as any other man in the United States, made a special study of these waters from the south branch of the Chicago River to a point just below Peoria, during September, 1894. One of the chief objects of his study was the typho-coli group of bacilli. The difficulty thus far unsurmounted of identifying the Eberth bacillus in the water supply of any large city lends especial interest to this group. During 1892 Dr. Gehrman isolated seven organisms resembling the *B. typhosus*, but each gave some variation from the typical, either in growth or on potato or as to gas production. As a result of this study and of the work in 1894, under the direction of your Chairman, Dr. Reynolds, then Commissioner of Health, Dr. Gehrman found that, while the bacilli of this group will live in sewage contaminated water a variable time, the evidence is that they do not tend to multiply in such water but disappear after a longer or shorter period. He found them in the sewage-contents of the Illinois and Michigan canal and in the Illinois river at every point between Chicago and Peru. At Hennepin they had entirely disappeared and were not again detected anywhere below that place until after Peoria was reached. They were not present just above the city, but were found in abundance just below, after the river had received the Peoria drainage and sewage. At Lockport the specimens showed 930,000 bacteria, including the *B. coli communis*, in each cubic centimeter; at Henry the number had diminished to 5,500 per cubic centimeter, with none of the coli-typhoid group present.

In short, it may be accepted as an axiom that running streams tend to purify themselves; they always have done so and will continue to do so when not too highly charged with organic matter; that is, charged beyond the powers of the bio-chemic process continually operating in nature—the action of sunlight and oxygen and of the inconceivable myriads of microorganisms that live on organic matter, break it down and finally leave it inert and innocuous. This might have been argued *a priori*, but for the dogmas of the earlier water analysts who for years based all their conclusions on the results of chemist determinations to the exclusion of the bacteriologic.

A prolonged study of the composition of Chicago sewage finally led to the conclusion that a dilution of 20 to 1, in a stream with a velocity of one and a half miles an hour, would be sufficient to cause a disappearance of pollution in a flow of less than twenty miles. It is upon this theory that the dimensions of the drainage channel are based.

Unfounded fears of St. Louis and the Valley.—It has been recently announced from St. Louis that the Eberth bacillus has been found in water taken from the mouth of the Illinois River at Grafton, and that it was positively identified—probably by a tag or label—as a genuine Chicago product. Our professional brethren in that city who are moving heaven and earth, including the Federal Government, to stop our drainage canal lest the Chicago bacteria affect those which they themselves propagate, and our colleagues in the Illinois Valley, who are concerned lest the Illinois River be affected as a source of water supply, should pluck up heart of grace from the above cited demonstrations.

The contribution of the Illinois River to the drinking supply of St. Louis via the Mississippi River will, after the drainage canal is in operation, be incomparably better than it is now. As for the Illinois itself, its waters are naturally not potable and have long since been abandoned by many of the valley towns as a source of water supply. Its sources are largely in marshy areas, whence it becomes highly charged with organic matter; it is malarious, readily stagnates, and has scarce enough free oxygen to support fish life. With the contribution, through the drainage canal, of from 300,000 to 600,000 cubic feet of water per minute, chiefly from Lake Michigan, with its excess of oxygen, not only the navigable and economic, but the sanitary conditions of the river will be immensely improved. Mr. L. E. Cooley, who has already addressed the Club on this subject, recently suggested to the writer that the profitable disposal of sewage may, after all, lie in this direction. Fish will not live in the Illinois above Morris, sixty miles from Chicago, nor for twenty to thirty miles below Peoria—beyond which distance the stream purifies itself so that fish are again found. U. S. Commissioner Bartlett reports that in 1893 11,000,000 pounds of fish were taken from the other stretches of the river—a more profit-

able crop, as Mr. Cooley puts it, than any garnered from the prairies of the State, acre for acre.

Section 20 of the Sanitary District Act reads as follows:

"Any channel or outlet constructed under the provisions of this act, which shall cause the discharge of sewage into or through any river or stream of water beyond or without the limits of the district constructing the same, shall be of sufficient size and capacity to produce a continuous flow of water of at least two hundred (200) cubic feet per minute for each one thousand (1,000) of the population of the district drained thereby, and the same shall be kept and maintained of such and in such condition that the water thereof shall be neither offensive or injurious to the health of any of the people of this State, and before any sewage shall be discharged into such channel or outlet, all garbage, dead animals, and parts thereof, and other solids shall be taken therefrom."

It will be noted that the degree of dilution shall not be less than 200 cubic feet per minute for every 1,000 inhabitants, and it *must* be as much more as is found necessary to keep the channel in a condition "neither offensive nor injurious to the health of the people of the State." Furthermore all solid animal or vegetable matter shall be taken out of the sewage before it is discharged into the channel. With these conditions maintained it is believed that fish will live in its waters throughout, except at sewer mouths or in the vicinity of special pollution. It is certain that they will be restored to the full length of the Illinois River, to convert the wastes and refuse of every town upon its banks into a palatable and profitable food crop, thus furnishing an ideal solution of one of Chicago's sanitary problems—the prompt and inoffensive disposal of its sewage and the consequent protection of its water supply.

Certain squeamish individuals, with highly imaginative stomachs, have objected to this proposition as nauseating. But wherein does the conversion of waste organic matter into finny food differ from its conversion into vegetable food? These very persons are among those who strenuously and obstructively labored for the disposal of our sewage by broad irrigation and sewage farming. Yet plant life fed upon sewage is not less a scavenger of earth than is fish life of water.

Alternate plans for the disposal of Chicago sewage.—I was asked to say something tonight about the alternate plans for the protection of the water supply from sewage contamination and about underground water supplies.

Only two other plans have received serious consideration—one for the construction of a huge tunnel out into Lake Michigan off Hyde Park, into which all the sewage of the city should be gathered and discharged on the bottom of the lake. This monstrous proposition, it is hardly necessary to say, was *not* conceived by a Chicago physician. It was seriously advocated, however, by a prominent Eastern engineer, who was imported to tell us what to do to be saved. Thousands of dollars were spent in attempts to show its feasibility and it was finally abandoned only when its minimum cost was seen to be at least \$37,000,000, with an annual expense of \$2,500,000 more for maintenance. Its monstrous character will be better appreciated when it is known that the relatively few lake-emptying sewers now discharge an equivalent of 1,500 tons of solid organic matter into the lake every year, and this has already covered the lake bottom with a bed of filth to an undetermined distance from the shore—analyses made last month, October, show traces of its pollution twelve miles east of the Chicago Avenue pumping station.

The other project was for land disposal of the sewage by filtration and irrigation. This was also abandoned after prolonged study and expensive investigation. Its minimum cost was estimated at \$58,000,000, with fixed charges of \$3,000,000 per annum, and it would further have required the consent of the State of Indiana, since the nearest suitable body of land extends into that State. The Commission, appointed in 1886, spent a year's time and between \$70,000 and \$80,000, chiefly in efforts to find arguments for the recommendation of one or the other of these projects, but was finally and reluctantly compelled to take up the plan already well digested and generally approved by Chicago physicians.

Such adverse criticism of this plan as is still met with is generally found, on examination, to be due to misconception of its character and purpose. Its essential purpose is to keep Chicago's sewage from polluting Chicago's twenty-odd miles of lake frontage, and the lake itself, from which its water supply is drawn. This is a sanitary necessity, even though every drop of Chicago's drinking water should be filtered or otherwise purified—as it will have to be unless relief is speedily afforded through this channel and its essential complement, the intercepting sewers. In character, it is a new tributary to the Illinois River, with a less degree of organic impurity than

any other of its tributaries, and destined to materially improve the sanitary conditions of the entire Illinois Valley—the "great malaria preserve" of the State, as it has been called.

Chicago's underground water supplies.—There is not so much to be said tonight concerning the underground water supplies as there seemed to be when the subject was first talked over with your Chairman, who was, as he expressed it, "fascinated with the idea."

In the winter of 1885-86 I thought I had made a very valuable discovery. Mr. Cooley, Mr. Ossian Githrie and myself, as a sub-committee of the Main Drainage and Water Supply Committee of the Citizens' Association, appointed to investigate and report upon measures of relief for conditions which were even worse than the present, had submitted in September, 1885, our joint report embodying the three essential features of the project now being prosecuted. We were, however, still independently pursuing our investigations in search of pure water.

Late in the fall of the year 1885, my attention was attracted to the wells sunk into the fissured Niagara limestone which underlies the city, covered by a blanket of impermeable blue clay, and the study resulted in the publication of a series of articles, the first of which appeared in the *Morning News* of Jan. 27, 1886.

A recently published communication from Gen. Sooy Smith, one of the newly appointed Water Commission, in which he now advocates the same views, led me to look into the matter again, and I have materially modified the enthusiasm with which I once urged the substitution of vertical tunnels, a few hundred feet deep into the unpollutable underground supplies, for the horizontal tunnels of two to four miles long out into the lake.

Briefly stated, there are three water-bearing strata under Chicago; first, the fissured Niagara limestone, reached at a little over 100 feet from the surface and having a depth of about 700 feet; second, the St. Peter's sandstone, immediately beneath, with a thickness of about 200 feet; and third, the Potsdam formation, separated from the St. Peter's by a non-water-bearing stratum some 300 feet thick. Wells sunk into the Niagara now furnish about 20,000,000 gallons a day, and as much more is obtained from the Potsdam at a depth of more than 1,200 feet. The maximum capacity is, however, probably already reached. The first Potsdam or artesian wells flowed above the surface, but every additional well now affects the level of the existing wells, and all now require pumping; this is also true of the shallow or Niagara wells. There still remains the St. Peter's sandstone, which is water-bearing throughout its whole mass, but not, in the opinion of Mr. Thos. T. Johnstone, Engineer of the Sanitary District, in a sufficient degree to render it useful as a source of supply for a large city. Mr. Johnstone, to whom I am indebted for this recent information, suggests, however, that perhaps the St. Peter's might be fed artificially from Lake Michigan by driving shafts into it from the bottom of the lake. It is also possible that the Potsdam would yield more abundantly from a greater depth, though Mr. Johnston tells me that below 2,000 feet the water is too rich in salt to be used for drinking purposes, whilst as to the fissured Niagara he says that "sufficiently extensive explorations only can determine finally whether natural tunnels are available; but the general facts known are not sufficiently encouraging to lead to a belief that useful results would follow."

Unappreciated public services of the medical profession.—I will detain the club only a moment more. The Relation of the Medical Profession to the Water Supply of Chicago is typical of its relations to every effort for the betterment of the conditions of life in this community. And these relations are at last becoming recognized—though slowly—by the community, as shown by the following tribute to the profession from a local historian, himself a non-professional. Prefacing a chapter on the medical history of Chicago, he says:

"When negligence permitted the condition of the city to become unhealthy in the extreme, an invitation to epidemics, the physicians persistently sounded the alarm that ultimately caused the citizens to demand of the authorities purification and the establishment of sanitary laws and officials. The system of sewerage adopted by the city was substantially a mode suggested by a physician. The method of drainage was that promulgated by a physician. And when the tardy measures taken to cleanse the city had proven utterly ineffectual and the cholera appeared, those who had so persistently advocated precautionary measures demonstrated that they knew not only how to warn against a foe, but also how to fight it; and with unremitting zeal, with unswerving fidelity to the afflicted and with the most complete self-abnegation, the physicians of Chicago cared for the sufferers. Of all the bright pages of Chicago's history there is none that glow with brighter

luster than that whereon are emblazoned the names of those physicians whose assiduity in attendance upon cholera-stricken patients caused them to forfeit their own lives."

To this it may be added that the medical profession is the only one of a secular nature whose members persistently labor to reduce the demand for their own services. All sanitary progress, every advance in the field of preventive medicine by which the causes of disease are removed or disarmed, by which, in the language of Edmund Parkes, "growth is rendered more perfect, decay less rapid, life more vigorous, death more remote," and therefore and perforce, the field of curative medicine is abridged and the remunerative practice of the physician grows less and less—is the result of the physician himself.

Speaking of the development of the science and art of preventive medicine, Sir Benjamin Ward Richardson, just deceased, says: "It is not a science, it is not an art separated necessarily or properly from so-called curative medicine. On the contrary, the study of prevention and of cure proceed well together, and he is the most perfect sanitarian and he is the most accomplished and useful physician who knows most both of the prevention of disease and of the nature and treatment of disease." This lofty sentiment we openly and sincerely applaud, while a still small voice in the privacy of home or office confronted with the monthly bills, asks who pays and who gets paid for preventing disease, from the treatment of which alone are fees now derived?

This is, of course, a very sordid and ignoble query, but sooner or later it must be answered. You, gentlemen of the Physicians' Club, assembled tonight to show your interest in the subject of a pure water supply for Chicago—whereby you won't be bothered with treating typhoid fever and other remunerative lingering intestinal diseases—may take this proposition home for further consideration: Preventive medicine and curative medicine are logically antagonistic so long as the public pays only for curing disease. When the long-eared animal comprehends that it is more economical to pay for its prevention than its cure the physician will be properly appreciated and properly compensated for services which he now not merely renders gratis, but to the detriment of his only recognized sources of income.

Dr. ADOLPH GEHRMANN followed with remarks upon

THE LOCAL AND DOMESTIC PURIFICATION OF WATER.

He said: I beg leave to make one or two remarks concerning the reasons why the quality of the water supply of the city of Chicago changes so often as it does, before saying anything as to the different methods of local purification. We have twenty-seven sewers and two rivers emptying directly onto the lake front. The Calumet River always flows into the lake; the Chicago River usually flows in the direction of Bridgeport, but oftentimes its flow is toward the lake. When such conditions are present as will carry sewage into the lake, or in an unusual quantity, the water supply becomes bad. If we have a dry season the sewage which is poured into the lake is mostly cared for near shore by the natural agencies of purification and the absorbed oxygen which is in the lake water. At such times the current of the Chicago River is in the direction of Bridgeport.

A condition which will sometimes aid in bringing about local conditions of impurity is the direction of the wind. A strong westerly wind will lower the level of the lake to a considerable degree and the rivers will flow strongly toward it. Surface water will be blown out from shore, as any one may see at 35th or 22nd street, where sewers discharge. Here a grayish streak extending out from the mouth of the sewer will be seen. Sometimes it can be seen for a distance of two miles. It is distinct and separated from the rest of the water and is produced by the wind not ruffling the greasy sewer water. The grayish streak passes in the direction in which the wind is blowing. If we have a strong southwest wind, contamination of the north cribs is more marked. If we have, on the other hand, north winds, and especially northeast winds, which blow the water south along the lake shore, we have contamination of the south cribs. When we have a period of heavy rain combined with westerly winds, sewage will flow into the lake to an unlimited extent and the most serious contamination results. It varies with the conditions. At such times we have taken samples out as far as twelve miles and found no marked improvement, except in the last two samples in one series and in the last sample in another series.

As far as the local purification of water is concerned, it is simply an expedient wherever it is undertaken. To me it seems about like this: Some local method is used when the citizen himself believes he must have some method of purifying his water supply. But if all the people in a locality believe that the water is bad they immediately set about to

remove or avoid the general contamination. If the water supply of a town is admittedly bad it behooves the people, in their households and other places, to resort to whatever means of purification they can have until a general pure supply of water is brought to them. We can place the various methods of purifying water under headings according to their value and their ease of application.

The first is boiling the water. This is by all means the simplest, and as far as disease-producing germs are concerned, especially those of typhoid fever, it is the best. The only great obstacle to it is the length of time which the water requires to be boiled. The period for boiling should be thirty minutes, but the chances are people often desire water when the supply is exhausted and will not wait the time of boiling a new quantity. Then the matter of cooling water after it is boiled is another consideration. Distillation does give us perfectly pure water. But owing to the absence of salts the water is not as good for use. A pinch of salt may be added to it and to some extent this fault can be overcome.

In regard to the question of purification by filtering and by boiling. When one comes to figure the expense for a year, and the amount of gas required daily in a household, or the quantity of coal used, to boil or distill a certain quantity of water, he will find that it is quite an item of expense, equal to the cost of a filter. A friend said to me some time ago, "How is it you are in collusion with the gas and coal companies?" I was astounded. I could not see what he meant at first. He said, "Why you are instructing the public to boil their water, using gas or coal."

The matter of local filtration is one of considerable interest and one that has a great many sides to it because of the great number and variety of appliances which have been suggested for the purpose. We may view the question from two aspects: 1, the purification of water from a sanitary standpoint; 2, the purification of water simply by removing the bacteria which are contained in it.

With reference to purification by filtration from a sanitary standpoint, when we take into consideration the storage of the water, most of the water delivered by filters will be ruled out, because the water becomes contaminated if it is in storage tanks, the number of bacteria will increase, and on account of the number of bacteria the water would be classed as not being potable or sanitary.

As regards filtration for bacteria, they will be removed by any material which is dense enough or has pores smaller than the diameter or size of the bacteria. However there are two facts in regard to the removal of bacteria by a filtering medium. One is the direct removal which may take place by a good many substances, and the other is the "growing through" of the bacteria through the filter. If a filter has been used a length of time and bacteria are crowded into the pores, they gradually grow along these spaces; that is to say, the bacteria adjust themselves to the spaces and after a time appear on the filtered water side of the medium. The growing through depends upon the degree of organic matter that is present and the temperature at which the filter is kept. If there is less food, and the temperature is lower, the filter can be used with less danger of this than if the reverse is the case. Every filter should have a ready means of cleansing the medium for filtration. A filter which is new will work satisfactorily; but after it has been used a short time it will be found that the condition is gradually one of increasing impurity in the water delivered from it. The organic constituents increase in the water and if the filter has been used a considerable time it will be found that bacteria will grow through and appear in the filtered water. Self-cleaning filters are of no value. The medium is to be one which can be renewed entirely, or which can be taken out and regenerated by some method of dry heat or steam, or by some chemical process.

Methods of precipitation, as Professor Hallberg has said, are of value in some instances. I can simply mention two other procedures that have been advocated to a considerable extent, not, however, for the purpose of precipitation, and dragging down the bacteria, but for their direct action upon the bacteria. Fluorid salts are known to have considerable germicidal action and are recommended for use in water in one in ten thousand strength, but I have found they are not efficient except when given in the proportion of one in one thousand, so that the fluorids are of no value at all unless given in proper strength. One part per thousand is not poisonous to animal tissue.

The use of the coal tar preparations, such as saccharin, have been recommended for the same purpose. The saccharin gives an unusual taste to the water which is not agreeable and it does not act as efficiently as has been claimed for it. However, I have not experimented to any extent with this substance

Precipitation by the use of alum or other substances which brings about a flocculent precipitate and causes settling is a very good means of purification, but it is difficult to carry out the method. The purification is always left to some person about the household to manage and the amount of precipitant which is added, or the method of application of the chemical, or the means of drawing off, is not completely and accurately followed out, so that the results are not surely as good as they should be. The same is true of any method of filtration. The filter is usually left to be managed by the cook or some one about the kitchen. The tube may be clean to start with, and the apparatus filtering properly, but some part of the apparatus may become loose; some unfiltered water may escape through the filter. The filter may be properly constructed, but when the filtering medium is replaced in the filter some water may overflow into the chamber for the filtered water, or a crack may be produced that is unnoticed at the time, consequently there will be an increased amount of filtration brought about by such an accident. This would indeed be looked upon by the cook as being a great advantage on account of the filter acting a little more quickly. She would consider that the filter had been very effectually cleaned. It is as necessary to have expert care for household filters as it is for large filtering plants.

I will simply say again that the methods that are used for local purification of water are excipients which are to be used simply for emergencies. What we all need is a pure water supply, and we should attain it by whatever means and whatever cost we can. We should, however, take our neighbors into consideration and to some extent, at least, do what we can toward avoiding any danger to them.

Mr. CHARLES E. KREMER also discussed the subject.

The Chairman then introduced Mr. JEWELL, who said: The filtration of water in all of its forms is a subject to which I have given special study, and inasmuch as the water supply of Chicago is giving so much trouble now, if some comparison with the work which is being done in other cities will be acceptable, I will be pleased to tell you briefly what is going on in other cities in this country. The City of Cincinnati has appropriated \$6,000,000 by authority of the legislature to improve its water supply.

The City of Philadelphia has been discussing the question of filtering its water supply for the last three years, and it is only about three weeks ago that an appropriation was made by the Council of \$3,000,000 to be spent in filtering the water supply of that city. They have discussed the subject of going out of neighboring water sheds to get water, and of sinking wells and of resorting to various other methods, but after investigating the subject very carefully during the last three years, they have decided to filter the water as the most practical and best means.

The City of Scranton, Pa., has just passed an ordinance to construct a filtering plant. The City of St. Louis, Mo., had a bill up for second reading before the Council at its last meeting having for its object the appropriation of \$3,500,000 to filter its water supply. About five million of dollars a number of years ago was appropriated to improve the quality of the water. The settling tanks in the new pumping station have been in use for almost two years, but are unsatisfactory.

The City of Louisville is also going to filter its water next year. A filter has been located at the pumping station of the Louisville water works, to be operated for one year, and at a cost within the limits of acceptability. It has a capacity of 250,000 gallons a day. The filter is run day and night.

There are practically two methods of filtration on a large scale. One is known as the bed system, the other as the mechanical system of filtration. The bed system is the one to which Professor Hallberg referred as being in operation in Europe, and is unsatisfactory. The American system is the mechanical system of filtration, and American filters are even being sent abroad. They are in operation in France and Germany.

There is a filter in operation at Wilkesbarre, Pa., with a capacity of 15,000,000 gallons of water a day, and also one at Elmira, N. Y., with a capacity of 6,000,000 gallons per day.

Dr. NICHOLAS SENN—The subject under discussion tonight is so foreign to my line of thought, that I shall occupy your time but for a moment. There seems to be a wrong idea among the public, and to a certain extent among the profession, in reference to the disease-producing qualities of germs which contaminate pure water. Some of the remarks made here this evening seem to point in the same direction. I was very much astonished when Dr. Reilly referred to an epidemic of erysipelas that prevailed here, and which was attributed by no less an authority than Professor Andrews to impure water. We all know, from bacteriologic research, that it is absolutely safe

to drink pure cultures of the microbe of erysipelas without any danger of contracting the disease, because the microbes of erysipelas can only exercise its pathogenic properties when introduced into the vascular tissue of the body. It is not the pathogenic microbes which infest the intestinal canal that are always dangerous, but the microbes that are produced by such diseases as cholera and typhoid. The only disease that can be traced in this city to impurity of the Lake Michigan water would be, if any, typhoid fever, because we know all other microbes with which we have to contend here do not produce intestinal infection. I have been very much interested indeed by the speeches that have been made this evening. I have learned a great deal about water. I am somewhat disappointed in not having heard, however, so far as Chicago is concerned, more said about the prevention of the contamination of our water than the purification of it. Our citizens are paying water taxes and are supposed to receive pure water, and I believe if disease could be traced to impure water furnished by the city, the city could be held responsible. The completion of the drainage canal will, I trust, do away with further contamination of our water supply.

Dr. CLARK W. HAWLEY—I have had an instance of pure water contamination come to my notice within a week in the city of Aurora. They had an epidemic of typhoid fever there this year. They have been tapping the same vein as is found here for artesian water, and when the season is favorable they have plenty of such water. Every case of typhoid fever they have had within the last six months has occurred among people who drink nothing but well water, and not a single case of the disease has occurred among families who use the artesian water. There can hardly be a better demonstration of the necessity of pure water. One of the physicians of Aurora told me this within a week, that "Every case so far has been fully investigated, and all of the cases of typhoid that have occurred have been using water from wells." The cities of Joliet, Ottawa and Aurora, and those along the Illinois river are afraid of being contaminated by the sewage system that is going to take place and they must begin to supply themselves with water from other sources than those they at present have.

I was quite surprised to hear that as the water went down the Michigan Canal it improved, or it was pure at eight or twelve miles out. If any of those who made the report had lived as near to the canal at a hundred miles out as I have, I do not know what they would think. I know the water at Ottawa is an abomination, and I do not see how the water can be made better when a canal emits such a stench as they get there. Of course, I am not disputing the facts of chemist analysis. I am speaking from nose experience only, because I have lived in that neighborhood and know the canal there is foul indeed. The reason I do not know.

Dr. S. C. STANTON—In the summer of 1878 I selected for my graduating thesis in college, "The Distribution of the Sewage of Great Cities, with Especial Reference to Chicago." To procure data I was allowed, through the courtesy of the Commissioners of the Illinois and Michigan Canal, passage on one of their boats from the Illinois River at Peru to Chicago, and secured samples of the water of the canal at twenty-five points between the Illinois River and Lake Michigan, taking three samples at each point, one from the surface, one from three feet below the surface and one from the bottom of the canal, or, at least, six feet below the surface. These specimens were taken above and below towns on the line of the canal, above and below feeders, and at various points in the Chicago River and the lake at the mouth of the river. The results of the analyses of these specimens of water were practically identical with those Dr. Reilly has detailed, namely: That at Summit, eight miles from Bridgeport, the water of the canal contained very little organic impurity. Below every large town there was a marked increase in the amount of organic impurity, and so much so that below Joliet the water contained almost as much organic impurity as at Bridgeport. Below feeders there was again a marked diminution of the amount of impurity, and, as a rule, within four miles below towns the water showed only a slight amount of pollution. These results in graphic form are in the possession of the Sanitary District.

W. M. H. WILDER, M.D., Secretary.

Chicago Pathological Society.

Regular Meeting, October 12, 1896.

(Concluded from page 1346, Vol. XXVII.)

PRESENTATION OF SPECIMEN.

Anenecephalus et Acrania, by Dr. JOSEPH B. DE LEE—This specimen is a fresh one, and as I thought it would be of interest to the members of the Society I brought it with me. It

represents an anomaly which is not so uncommon. It comes from a woman, 30 years of age, who, twelve years ago, after three days' labor, bore a small child. She has a contracted pelvis of the justo minor type, and is to a certain extent rachitic. Labor commenced Saturday night at 8 o'clock and by Sunday night at the same time no progress had been made. At 11 o'clock Sunday night the pains were strong and expulsive, but still no progress in labor. In making an examination I could determine the back, and heart tones to the left side, and introducing my hand into the vagina I came upon something which I thought to be the vulva of a female child. I found two lips between which was a depression and on each side of which were two hard lumps which I judged to be the tuberosities of the ischii. Further examination revealed an ear alongside of this, and my previous diagnosis had to be retracted. Continuing the examination my finger ran around the head of this monster, the head of which I succeeded in delivering. The shoulders, however, refused to come in spite of traction which was kept up for twenty minutes, aided by Kristeller expression. Examination also showed the cervix tightly contracted around the neck of the fetus. The larger part of the resistance came from the narrow pelvis. I performed the operation of section of the clavicles, known as cleidotomy, and introduced by Phenoceno last year. Under the guidance of four fingers, with a strong pair of scissors the clavicles were divided, the chest fell together, and came through without any difficulty.

The nature of the anomaly is apparent. It is a monster in which both the cranial vault and the brain are missing. This little pad which you see consists of hemorrhages, some brain tissue and vessels. The technical term for this monster is anencephalus and acrania.

As to the cause, there are three theories. One is that the medullary canal does not close properly and therefore the cerebral vesicles are not well developed. Another is that acute hydrocephalus in the first two months of pregnancy causes dilatation of the cerebral vesicles and subsequent atrophy. A third theory is that the head fold of the amnion becomes united to the thin membranous covering of the brain, the primordial cranial vault at some period in the early weeks of pregnancy, and the inflammatory adhesions produce this deformity by inhibiting the growth of the brain.

PRESENTATION OF CASE.

Tricuspid Regurgitation, by Dr. JOHN A. ROBISON—The case I wish to show you illustrates the difficulties which we sometimes encounter in making a diagnosis of valvular disease of the heart. I thought the case would come in nicely with the discussion on Dr. Herrick's paper.

The patient has been examined by a great many doctors from time to time, but I will not say as many different diagnoses have been made, but quite a number of them have been made. The stumbling block seems to be whether this patient has disease of the right side of the heart or not; in other words, whether he presents a lesion connected with the tricuspid valve, and there have been more physicians who have said that there is no disease of the tricuspid valve than there have been those who have taken the opposite view. We find present in this case undoubted evidence of disease of both the aortic and mitral valves. In the first place, you will notice the character of the pulsations in the neck—the carotid pulsation. Secondly, if you feel the pulse you will get the Corrigan water-hammer pulse, which is greatly accentuated when you put the patient's hands up in this manner. Furthermore, a sphygmographic tracing gives evidence of aortic regurgitation. Listening at the base of the heart over the region of the aortic valves we hear a very soft, almost indefinable murmur with the first heart sound, which is carried slightly upward. We also hear a murmur during the first part of diastole carried slightly downward. Passing to the apex of the heart we hear a murmur at the apex, if my ear does not deceive me. This murmur does not increase in intensity as we go toward the axilla or to the left of the chest, nor do we hear it with the same intensity to the left of the spine as we do in front. Again, you hear a systolic murmur over the whole precordia, but as we travel from the apex of the heart toward the right, we reach a point here near the ensiform cartilage where the intensity of the murmur is greatest. I think if you had time to examine this man I could prove that to you very easily by using the stethoscope I have in my pocket. I have taken a piece of thin glass and glued it in the stethoscope, by means of which I eliminate the muscular sounds of the heart, and I hear simply the murmur. Placing this stethoscope over the apex we hear the murmur during the systole with distinctness, it not being carried upward toward the axilla or around the chest wall. In carrying it to the right toward the ensiform cartilage it

becomes more intense until we reach a point below the left border of the sternum, where we hear a loud murmur with each systolic contraction of the heart.

Another point I wish to call attention to is the fact that we have what I would call the venous pulsation in the neck, the pulsation being presystolic; and not only that, by placing the fingers at the junction of the jugular with the subclavian veins we get a pronounced thrill. My diagnosis in this case would be, judging simply from the primary signs of valvular disease, that this man has undoubtedly a tricuspid regurgitant murmur.

The patient, as I have previously said, has been examined by quite a number of physicians; some of them I see here tonight. They dispute that diagnosis. Of course, a case like this presents many difficulties. In the first place, we have an aortic regurgitation which has caused great increase in the size of the heart, so that the apex beat is below the sixth rib and to the left of the nipple to the extent of two fingers in breadth, and there is no doubt but what he has mitral regurgitation; but if this murmur were simply due to mitral regurgitation, why would not the sign of the propagation of the murmur which generally corroborates the diagnosis of mitral regurgitation be present? Furthermore, it is perfectly consistent with our present knowledge of pathology, as illustrated here tonight, that we can have coexisting disease of the tricuspid as well as of the mitral valves, and there is no reason why we may not have tricuspid insufficiency as well, and account for the fact that we hear this murmur in the region where tricuspid insufficiency murmurs are heard.

SELECTIONS.

Some Medical Emergencies; a Clinical Discourse.—Dr. Seymour Taylor, of the West London Hospital, in the *Clinical Journal* gives a practical talk about hyperpyrexia and the like that requires a therapeutic alertness.

1. **Hyperpyrexia.**—Of late years it has become fashionable to ignore the use of drugs in this condition. The argument has been urged that few medicines have any marked power in reducing temperatures unless the remedies are pushed to such extreme in dosage as to render them a source of danger. But is this really the case? I admit at the onset that I prefer the use of ice packs or the graduated baths. They are quicker in their action, they are easily controlled, and very few houses are without the means of applying either one or the other. But have we no drugs upon which we can depend when we wish to bring a highly feverish and therefore perilous temperature down to a region of safety? I will leave on one side quinin and the phenol compounds, since possibly they may come within the objectionable category which is marked as dangerous. But I will draw your attention for a few minutes to a common food, or drug if you will, which is somewhat neglected as a cooling agent. I refer to alcohol. Probably most of us prescribe it somewhat casually and carelessly, with no instructions as to exact quantity and the periods at which it is to be taken. But I am as certainly convinced as a man can be that when prescribed with intelligence, it is one of the most powerful remedial and restorative agents which we possess. My thoughts were first drawn to the subject of alcohol as a heat-reducing agent, by the refusal of a northern gamekeeper to take some whisky when we were exposed on a cold night; he simply said when I proffered him a flask, "No. It is too cold." These words sank deeply into my mind and caused me much anxious thought. A patient, a heavy and unweildy woman was suffering from typhoid fever in the third week. Her temperature was 105.6 degrees, a point above the danger line. She was quite insensible and was to all appearances about to perish from hyperpyrexia. It was impossible from the surroundings of the patient to administer a graduated bath, or even an iced pack. So we decided on giving alcohol in large doses. Between nine o'clock at night and nine the next morning our patient was made to take twelve ounces of good brandy, an ounce every hour. On the morrow I found her temperature down to 100.5 degrees; she was sensible and appeared astonished when she saw and recognized me as a strange doc-

tor, but was of course quite oblivious to the fact that I had visited her only about twelve hours previously. From this date she made an uninterrupted and good recovery.

2. Relapses in Typhoid Fever.—In a given number of cases of enteric fever a certain percentage of relapses will occur even if our diet-sheet be unimpeachable. But there are accidents of the disease, and errors of diet, especially toward convalescence, which may lead up to and actually produce a relapse, or a recrudescence. In the St. Thomas' epidemics we found a large percentage, indeed the majority, of relapses dated from either an action of the bowels after a period of constipation, or from the allowance of bread in the dietary. No matter what the remedy employed to relieve the constipation, whether it was castor oil or a simple enema, the risk was just the same—a rise of temperature dated from the evening of the day on which the bowels acted. The return of febrility might last two or three days, amounting to a recrudescence only, or it might constitute a fresh attack or true relapse. Only last autumn I saw two in which I was called to consult as to the cause of such cases, a sudden return of fever. In both cases enemata had been given and I was enabled to point out that the condition might be temporary only (of two or three days' duration), or it might develop into a genuine relapse. But bread is a far more fatal error. We learned this from the nursing sisters. I can not satisfactorily explain why it should be, but the most alarming and fatal relapses which I have observed were those which commenced on the day following an allowance of bread, whether it was given boiled with milk, or even as toast in the beef tea. I will only quote one case. An old friend of mine was attacked with typhoid and I saw him in consultation with his family doctor. Then I went away for a three weeks' holiday, being kept informed of his progress every other day. Toward the end of the disease I wrote to his doctor to ask him to exclude bread from his diet for at least another ten days. Three days after my return home I was summoned to his bedside and found all the symptoms of a well-marked relapse. The second fever was more severe than the first and he unhappily perished. Unfortunately, by some mistake a basin of bread and milk had been given to him on the day prior to the fresh rise in temperature.

3. Medication in Fever.—As regards drugs, I have no rule of thumb to lay down. But my practice has followed on Dr. John Harley's plan, to give small doses of gray powder three times a day. Whether the mercurial preparation acts as a partial antiseptic on the bowel, or whether by keeping up a gentle peristalsis and flow through the intestine, it obviates constipation on one hand and diarrhea on the other, I can not quite satisfy my mind. I can only tell you of results. Dr. Harley's death rate in hospital practice was extremely low, and I have had similar happy results by following in his footsteps. We have a remedy, which as a stimulant, is an exceedingly valuable, if neglected, one. I refer to musk. I formerly regarded musk as a disgusting remnant of a barbaric pharmacopeia. But I was induced to try it in a case where profound exhaustion with subsultus were present and when alcoholic stimulant was refused. The result was a happy recovery, and I have had reason to think highly of the preparation in some three or four subsequent cases. Then there is another experience which my note books have afforded me. A high temperature is always in itself a dangerous symptom. Wunderlich fixed the line of danger in typhoid at 105.5 degrees, I think. I would place it even lower, at 105. Those of you who meet with much typhoid take note of it and see how many cases recover which at any time present a temperature of 105 or upward. I do not say that recovery does not take place. I have known many cases get well after this high reading, but the general rule may be stated from a large number of statistics, that a patient who has at any time had a fever of 105, either during the primary attack, or it may be during a relapse, eventually dies.

4. Hemoptysis.—In my experience astringents are for the most part useless, and may even do harm. Suppose, for

example, we give tannin, by which the albuminous matter surrounding the intestinal vessels is coagulated, or suppose we prescribe sulphuric acid, by which watery exudation from the vessels is retarded, or by whatever method these astringents act, their final effect is the same; not only do we produce a lessened action on the bowels, but we at the same time, and thereby, bring about an increased tension on the vascular system in general, and so favor a continuance of hemorrhage rather than stop it. I protest I would rather prescribe a saline purgative. And even if these intestinal constrictants do exert an effect on so remote a region as a lung's apex, it can only be partial and evanescent. As a brother practitioner once put it to me: "It certainly does seem a long way round for the action of such drugs." To me a much more rational and scientific treatment is to give opium, the drug *par excellence*, which calms the nervous system, combined with digitalis. By these measures we speedily notice amelioration of symptoms. The patient is quieted, his pulse becomes better in tone, and cough, one of the conditions we wish to avoid, is lessened. Then, as a last resource, we can fall back on ergot. All these drugs can be easily given by the mouth, but in these days of pharmaceutical advance and refinement, it is at times advisable, owing to the rapid way they can be administered, to inject the remedies subcutaneously. We all of us carry hypodermic syringes about with us, and tabloids of compressed drugs take up no room in our pockets. I would ask those of you whom I may convince to try and note the effects of the above line of treatment. At any rate you have used remedies which act directly on the circulatory system, which you desire to have somewhat under your control. As a last criticism on the subject of pulmonary bleeding, I would discountenance the use of an ice bag. For me, at any rate, it is difficult to recognize any beneficial action from such treatment. I fail to grasp the notion that any good can accrue from the action of ice through the chest parietes (with its skin, its muscles and its bones), upon a summit of a lung which is not necessarily adherent to these parietes, and in which therefore the circulation is derived from an entirely different set of vessels. Further, it is hardly necessary for me to point to the discomfort to the patient which results from the application of a cold, heavy pad on a part in which tenderness is already a pronounced sign.

5. Whooping Cough with Convulsions.—I have in the last three years been called in consultation to four cases of whooping cough complicated by convulsions. The first case luckily enlightened me. Eclampsia was the serious condition for which extra help was sought. Immediately after my arrival the child had a severe attack of cough, but without any inspiratory "crow." This, however, was followed by convulsion. The diagnosis we arrived at was "whooping cough in its first stage," and that the convulsions were due to and consequent on cerebral engorgement from the cough. This view was confirmed three days afterward, when the typical "crow" was heard and the child developed symmetric black eyes from coughing. The patient's younger sister subsequently developed whooping cough, and being therefore allowed to occupy the same room, she, at my request, spent some time in cultivating a budding artistic ability and made a sketch of her sister's face. Now, the bearing of all this on our treatment will at first appear obscure. But to me the first indication was to allay the cough. We are taught that children, especially infants, bear opium and its derivatives badly. I must demur to this. One has only to give the proper dose and children tolerate it as well as adults. In this case, to the astonishment of my friend in attendance, I suggested morphia, and it acted like magic. I gave 1-50 grain every four hours, with instructions to watch its effect, and to discontinue it if the pupil signs became very pronounced. The paroxysms were less frequent, they were less prolonged, there were no more convulsions and the child made a rapid recovery.

"Vacation Colonies" in Switzerland.—It is now twenty years since this beneficent movement, known as the "Ferien-colonien," or vacation colonies, was set on foot in Zurich. It has been very considerably imitated in other cities of Europe to the manifest advantage of thousands of poor school children needing release from overcrowding and other slum influences. Consul Germain, in the *United States Consular Reports* gives a sketch of the rise of the work and the extent to which the colonies are utilized. He says: "These places are selected carefully and usually situated in the mountains, where the air is pure and good lodging and good strong food are provided for, free of all charges. The founder of these colonies is the well known philanthropist, Rev. W. Bion, a Zurich clergyman.

This gentleman was formerly a minister in the small, mountain canton of Appenzell, from whence in 1873 he removed to Zurich. He soon learned that the city air did not suit his five children, accustomed, as they were, to inhale the pure air of their native mountains. For several successive summers he made them spend vacation time in their former home, whence, after a month's stay, they regularly returned with greatly improved health and spirits.

This experience set him to thinking that, if his own children, who were better situated than many others in regard to care and food, derived so much benefit from a stay in the high rural regions, how much good would it do to his poorer neighbors. He first advertised in the daily papers that if he received suitable volunteer support he would begin his proposed work. An amount, a little less than \$500, was given him in the first year, 1876, and he sent forth sixty-eight children, divided into three different points in the canton of Appenzell. Each colony was allowed a vacation of two weeks. The physicians and some of the school directors of Zurich were among his earliest supporters. In 1886, he was able to send out forty-nine colonies, comprising 1,128 children; in 1895, the number of colonies was seventy-three and of children 2,198. In twenty years 21,728 children have received the benefits of these recuperation colonies.

The means of the managing committee not being enough, as a rule, to send all of the needy children to the colonies, such as show the greatest need therefor, on account of poor health, are selected, while those compelled to remain at home are provided with fresh milk and bread twice a day, morning and evenings, in order to compensate them somewhat for the loss of the vacation trip. They can thus enjoy a milk cure during vacation, lasting from three to four weeks, which proves very beneficial.

Close attention from year to year has been paid to the progress and results obtained from the Swiss colonies, so as to ascertain the direct benefits derived from these periodic summer vacations by the participants. Among the particular points closely studied are: Increase of weight of attending children, as compared with those remaining at home; general improvement in health, strength and purity of blood, especially of those suffering from anemia; visible improvement in intellect, as well as increased capacity and willingness to study, etc. The table below shows, after a close study made by the Zurich health officer and observed on thirty-four children, the condition of their blood before and after the vacation period, as well as at several later intervals:

Description.	Blood coloring.	
	Per mille.	Per mille.
1. Before departure to the colonies:		
Boys	748	725
Girls	756	722
2. Immediately after return:		
Boys	886	911
Girls	959	955
3. Two months after return:		
Boys	820	884
Girls	863	924
4. Four months after return:		
Boys	869	935
Girls	903	982

The children are always accompanied to the colonies by teachers or other interested adults and remain while there under constant supervision. Their lodgings, specially prepared for that purpose, are composed of large well ventilated bedrooms, dining rooms, and play rooms; in some of them, bath rooms, etc. The food is very nourishing and healthful, and consists of an abundance of milk and milksops, meat, vegetables, etc., and the location is such as to allow of daily walks and exercise in the open air in forests and meadows, offering at the same time, a beautiful view of Swiss scenery of mountains and lakes. In 1895, the city of Zurich sent 448 children

to nine colonies in the high regions of the cantons of Appenzell, St. Gall and Zurich, accompanied and marshaled by forty adults, most of them teachers, and it is said that this year's number will be greater.

One of the Zurich colonies, the "Schwæbrig," which is situated in the canton of Appenzell, has been bought and transformed into a regular sanitarium, where, in 1895, 208 children were cared for outside of the vacation time, between May and November. These children, on account of poor health, needed a longer recuperation and remained there from four to twelve weeks, or until they had recovered their health.

PRACTICAL NOTES.

Sterisol for Cracks in the Nipples.—The *Union Méd. du Canada* states that if cracks in the nipples are closed and covered with sterisol and a second coat applied in ten minutes, the child can nurse fifteen minutes later without inconvenience. No bandage is necessary.

Nutritive Value of Meat Broths.—Some dogs fed exclusively on meat broths, 500 grams, in Vulpian's laboratory, died at the nineteenth day, while others to whom water alone had been given, survived within one day as long, dying the eighteenth day—showing the negative nutritive value of meat broths.—*Gaz. d. O. e d. C.*, November 22, from *Bulletin de Therap* October 23.

Fractures of the Clavicle.—In case of irreducible fracture with much displacement, suturing is the only means of avoiding subsequent deformity and also troubles in the nerves and circulation. Fèvrier has collected forty-four observations of this treatment, all followed by recovery. In thirteen there had been nervous troubles which were cured by the suture. It must be made at once, before the neuritis has had time to develop, as otherwise it may be difficult to cure. The only inconvenience is the cutaneous anesthesia of the pectoral region, consecutive to section of the supraclavicular filaments of the superficial cervical plexus.—*Presse Méd.*, November 21.

New Stain for Differentiating the Bacterium Coli and Eberth's Bacillus.—Ramond has produced a stain with "rubine acid" which stains the bacterium coli red very rapidly, while it does not color typhoid colonies. It is prepared by coloring a tube of lactosed gelatin or gelose at 4 per cent. with a few grains of "rubine acid." It is then decolorized by adding, while warm, two drops of saturated solution of carbonate of soda. It is then filtered and sterilized. It replaces Elsner's gelatin advantageously, and owing to its extreme alkalization, is not favorable to the growth of other kinds of microbes.—*Bulletin Méd.*, November 11.

Formalin an Approximate Specific for Ringworm.—An interesting editorial note has appeared in *Guy's Hospital Gazette* calling attention to a recent paper by Mr. Alfred Salter, on the treatment of ringworm by formic aldehyde, or formalin. This treatment is now so well known in Guy's, and has had such a conspicuous success, that it should be part of the ordinary practice of every old Guy's man. There seems no doubt that it is the almost specific treatment for the disease, especially in obstinate and hitherto incurable cases. And yet this discovery arose from the annoying fact that the inventor's cultivations of the ringworm microbe were all killed one night through his having left the stopper out of the formalin bottle. So do fates at times turn good out of evil. *The Therapist* (London), November 15.

Treatment of Tuberculosis with the Salts Ordinarily Contained in the Blood.—Impressed by the fact that the animals whose blood contains the largest amount of salts are the least liable to tuberculosis, Stadelmann suggests that comparative immunity might be conferred upon human beings by increasing the

amount of salts in the organism. Analysis of the milk of the goat, which we know is comparatively immune to tuberculosis, shows .622 per cent. inorganic salts, while human milk contains .138 per cent., and the milk we know is a product of the blood. Reasoning from this premise that animals whose blood is rich in salts are not disposed to contract the disease, he administers salts to patients hoping to thus annihilate the predisposition. He has tried this treatment in many cases, principally in local manifestations, and announces that the bacilli disappeared from the sputa, and the other objective symptoms showed marked improvement. The salts he administered were sodium carbonate or bicarbonate, ten to forty grams a day. In a few cases he ordered also sodium phosphate, two grams, three times a day, with subcutaneous injections of sodium chlorid, .5 gram daily. While he does not consider his limited number of observations sufficient to determine finally the value of the treatments, yet his success to date induces him to recommend others to experiment with it as it is so simple and harmless and easy of application.—*Nouv. Remèdes*, October 24.

Statistics of Surgical Intervention in Perforation of Typhoid Fever.—There are thirty-three cases on record, with five positive cures. The deaths were usually found to have been caused by additional perforations. The sutures held, and Monod states that laparotomy in these cases must not be rejected, as it affords a last chance of recovery.—*Bulletin Méd.*, November 22.

Maternalization of Milk.—Eminent scientists have been experimenting to adapt the milk of the cow more closely to the needs of the human infant, and they have succeeded in maternalizing it, as it is called, to a most surprising degree. The milk of the cow is richer in salts and proteids than human milk with less sugar. The amounts of fatty substances are substantially the same. It is made to approximate human milk by the following process: The quantity of milk needed for the child during the twenty-four hours is poured into a graduated glass jar with a hole near the bottom, corked tight. The jar is then closed with a rubber cover over the top and set away in a cool place in summer and in a warm place in winter. In about four hours the milk separates into the cream and skim milk. A third of the skim milk is then withdrawn through the hole below, and with it a third of the salts and proteids. The milk is retored to its former volume by adding an equal quantity of water to which have been added lactose at the rate of 35 grams and chlorid of sodium one, for each liter. The jar is then well shaken and the contents poured into the sterilizers. If the child does not increase in weight with this according to the normal standards of growth, it is well to add one or two teaspoons of fresh cream each day. This process can be applied on a large scale simply by diluting the fresh milk with one-third of its volume of water, to each liter of which have been added 15 to 20 grams of fresh cream, 35 grams of lactose and one gram of chlorid of sodium.—Dufour in the *Rev. Mens. des Mal. de l'Enfance* for September, *Presse Méd.*, November 25.

Section of the Vas Deferens.—The discussion of this subject at the Congress of Urology held at Paris during October, resulted in nothing new, but a recent article in the *Lyon Méd.*, by Nové-Josserand, presents this operation in a little more favorable light. He states the results of his own experience in three cases, with a careful study of forty-three others. He ascribes the retention of urine and other troubles of the kind, to a vesico-prostatic congestion, which is relieved by section of the vas deferens, although this rarely affects the size of the prostate. This, however, is no longer considered essential to the success of the operation. The most positive, gratifying, and the most frequent result obtained is the improvement in the emission of the urine, which may become entirely normal if the retention has not been of too long standing. The pains and the tormenting desire to urinate also pass away, usually at once. Although the operation produces sterility,

the patient may retain otherwise the virile function. The unfavorable results, complete retention of urine and noticeable alteration in the general condition and mental faculties, are fortunately transient and not severe (*peu graves*). The operation is so slight that it requires no stay in bed, and even elderly and cachectic patients bear it easily. It has no effect on cases requiring cystotomy, nor where there are complicating tumors, calculi, peritonitis, pyelonephritis, etc., but it is especially indicated at the middle period of prostatism, when congestion dominates the scene, and leads to cystitis, hematuria and more or less complete retention of urine. Later also, in the presence of old prostatic deformations, it may render great service in diminishing the pains.—*Bulletin Méd.*, November 22.

Transient Amblyopia During Lactation.—In a recent number of the *Neurologische Centralblatt* appears a short abstract of a paper in the *Beiträge zur Augenheilkunde* by Dr. Karl Heinzel. He describes four cases of transient blindness occurring during lactation and traceable to interference with the functions of the nervous system. Such a condition, according to Dr. Heinzel, is apt to occur in otherwise healthy women. The first symptoms may manifest themselves before the birth of a child or during the early period of suckling, and consist of interference with the function of the eyes which may proceed to complete blindness. With the ophthalmoscope may be found evidences of more or less inflammation of the nerve. The duration of the symptoms extends over months and usually leads to a partial degree of optic atrophy with perhaps only a just perceptible interference with visual acuteness, and never to permanent blindness. The inference that lactation is in some way connected with the symptoms in these cases was arrived at by a process of exclusion.

New Method of Arthrotomy.—The results of resection in coxalgia are so far from satisfactory that Delagenière has been attempting to secure better, by a new method which has proved extremely successful in the two cases in which he has tried it. It consists in gouging the epiphysis, with drainage through the neck and great trochanter. He makes an incision similar to Langenbeck's, only descending lower on the thigh, about two centimeters below the base of the great trochanter, 15 centimeters in length. He detaches the fibers of the gluteus maximus to open up the pelvi-trochanterian muscles; pushes the pyriformis and gluteus medius to one side, and then incises the periosteum from the cotyle to the base of the great trochanter, around its internal and external surfaces. The capsule is opened freely with a T-shaped incision, and the condition of the articulation investigated. The periosteum on each side is loosened in order to work under it. He then cuts out a notch in the superior border of the great trochanter, extending it up to the neck, and proceeds to gouge the neck up to the head; the *évidement* of the head follows, and he is careful to remove the corresponding portion of the cartilage. The operation is completed by the *évidement* of the great trochanter, which he carries down a centimeter below its base in order to form a tunnel, with a regular downward slope, following the direction of the spur of the femur. A metal tube is then inserted in this tunnel, the inner end in the joint and the outer end fastened to the skin. This metal drain is left until recovery is complete. The two patients upon whom he has performed the operation had very grave suppurated coxalgia. All the symptoms rapidly passed away and prompt recovery followed. The advantages of this operation are its extreme simplicity, that the drainage of the diseased articulation and of the epiphysis is definitely secured, while the hip retains its shape and some of its movements. It also seems to be exempt from serious consequences.—*Presse Méd.*, November 21.

NOTE. It is doubtful if this method affords any material advantage over the method of temporary resection of the trochanter and gauze drainage.—ED.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, In Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the ASSOCIATION living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, JANUARY 2, 1897.

THE PSEUDO-DIPHTHERITIC BACILLUS.

The fact that the Klebs-Löffler bacillus is closely simulated by a non-virulent organism is well known, and it has been rather largely held that the latter is a variety or modified form of the former that for some reason has lost its special pathogenic qualities. Some observers have maintained that there are several kinds of diphtheria bacillus, while others have considered them all as practically the same, but differing in form and pathogenic power under different conditions. So far there has been no practical test of the virulent and the non-pathogenic forms but that by inoculation, a tedious and impracticable method under most circumstances in actual practice. Guinea pigs are not always available, and the test is most often made by the effects on the patient himself, with the result that for safety the physician concludes all cases, mild or otherwise, to be virulent, and if he is a conscientious practitioner, with modern views as to infection, etc., all the elaborate and troublesome details of isolation and disinfection must be carried out to their fullest extent.

The fact that has also been fairly well established, that many healthy individuals carry in their oral and pharyngeal tracts one or the other of these microbes, further complicates the question and leaves a rather uncomfortable uncertainty as to whether we are ever really safe from diphtheritic infections. The modern precautionary fads of individual cups in religious rites and elsewhere seem almost if not quite fully

justified to many minds by the discoveries in bacteriology and pathology of the present day.

To find some better means of reaching a certainty in the distinction of these two forms of organism that so closely resemble each other, and to thus add a little to the possibilities of human happiness that are being now daily encroached upon by bacteriology, is a result that every well-wisher of mankind ought to pray for, but as yet it seems a little too far in the distant future for our comfort. That attempts are being made to solve the problem may be a relief, and as evidence of this we have two recent papers in Dr. WOODHEAD'S *Journal of Pathology and Bacteriology* for December, 1896. In the first of these, Dr. E. A. PETERS, as the result of a large number of experiments and cultures, comes to recognize two types of pathogenic diphtheria bacilli, the long and the short, and two non-pathogenic; also a long form and the short or Hoffman bacillus. The long pathogenic form is the ordinary type, the short is less common and less virulent. The long non-pathogenic form is indistinguishable from the long virulent type, excepting in its effects, and they may therefore be classed together for practical purposes, where inoculation tests are not practicable. The Hoffman bacillus is common in ordinary sore throat and tonsillitis, scarlet fever, röteln, and in diphtheria in association with the true bacillus of that disease. It resembles the short form of the latter in its mode of growth, and to some extent microscopically, but Dr. PETERS holds that there is "no proof forthcoming that this bacillus is an attenuated form of the diphtheria bacillus, though the short diphtheria bacillus, when it becomes non-pathogenic, tends to resemble Hoffman's bacillus."

In the second paper Drs. COBBETT and PHILLIPS recognize two varieties of non-virulent organisms or pseudo-diphtheritic bacillus, which vary to some extent in microscopic characters and in their reaction with glucose. The typical Klebs-Löffler bacillus is long and shows several segments divided by narrow unstained (with methyl blue) or faintly stained intervals. Its reaction with glucose is acid. Of the two non-pathogenic forms, one that also has an acid reaction closely resembles the true virulent bacillus, while the other, *without this reaction*, differs in many respects, it is usually shorter, has in its early growth at least only one septum, its colonies on serum are whiter and more conspicuous, and the authors, finding no intermediate forms varying in virulence, are inclined to consider it a distinct species. It would seem to correspond with the Hoffman bacillus as described by PETERS as nearly as anything.

The practical deduction from the results of these two independent investigations would seem to be: With a long bacillus in sore throat, use every precaution; with a short one, test the glucose reaction. If further studies confirm these results and develop no

embarrassing complications, we have a valuable practical aid in our diagnosis of diphtheria.

Inasmuch also as all these separate forms appear to be occasionally found in the mouths of healthy persons, these observations do not throw special light on some of the questions of immunity, etc., involved. They are, however, very suggestive and valuable in many respects, and it is to be hoped mark a real advance in our knowledge of the subject.

THE AMBULANCE IN AMERICAN CITIES.

The *Nineteenth Century*, October, contains an article by Hon. DUDLEY LEIGH on the American system of ambulance service at the hospitals of our larger cities. He just points out the fact that in England the hand-stretcher is yet, as a rule, the only ambulance, although occasionally the old worn-out cab is brought into acquisition.

The idea of instituting horse ambulances, that should be summoned and sent out in cases of illness or accident with the same speed and regularity with which fire engines are called and despatched in the case of fire, originated in the year 1868 with Dr. E. B. DALTON, at that time the superintendent of the New York Hospital. Owing to a change in the disposition of that institution's property the suggestion was not acted upon at the time, but in the following year the Department of Public Charities and Correction approved of Dr. DALTON'S proposals and the code of rules he had drawn up, and in consequence an ambulance service was adopted at Bellevue, the Municipal or Free Hospital of New York. From that time forward the system has proved so useful and beneficial that it has gradually extended to all or nearly all the other hospitals in New York, as well as to many other cities in the United States, and has become an integral part of the hospital work, and numberless lives are saved by its agency, and by the speed with which help is brought to the sick and injured.

As has been mentioned before, the municipal or free hospital of New York is Bellevue, where the first ambulance service was adopted in December 1869. In that month there were seventy-four calls; in the next year the number was 1,466.

The following table will show the increase in calls from this time forward, not only in Bellevue, but in other hospitals which have adopted the system, and the year of their so doing:

NAME OF HOSPITAL.	YEAR WHEN SYSTEM ADOPTED.					
	1870	1877	1878	1879	1881	1892
Bellevue	1,466	1,217	1,606	1,888	2,282	4,858
House of Relief		1,155	1,253	1,321	2,293	3,216
New York			651	585	1,154	1,520
Roosevelt			273	291	352	1,675
St. Vincent				823	1,387	2,066
Presbyterian					387	1,730

In 1893 the total number of cases was above 20,000.

The ambulance service of New York City requires vehicles. With the exception of those of the muni-

cipal hospitals, these vehicles are under the management of, and maintained by, the respective hospitals, without any assistance from the municipal authorities. The service is controlled by three separate departments: the police, the health, and the commissioners of public charities and corrections. The police commissioners only exercise control in so far as the allotment of an area is concerned, from which individual hospitals receive casualty cases. The commissioners of public charities and corrections maintain and have special charge of and control over the municipal and public hospitals, but the private institutions are independent of their orders. But by arrangement between the hospitals, both public and private, and the commissioners and the police, all sick and injured persons may be taken to whichever hospital may be the nearest, the object being to insure the quickest possible medical or surgical treatment. The private hospitals enter into such an agreement because of the experience and practice it affords to the physicians and surgeons connected with them; indeed, so much has the ambulance service become a part of the New York hospital system that there is a great desire to secure an allotment of an area, so as to ensure a share of the accident and emergency cases that occur. No hospital, in fact, in New York could now be carried on without ambulances; a hospital without an ambulance would be without patients. The ambulance surgeons are not students merely but are sub-juniors of the hospital house-staff, holding the degree of M. D., and they give their services gratuitously on account of the experience they gain.

The ambulance used in New York is of the ABBOT-DOWNING type, and has a covered arched roof, room for the bed before mentioned, on which the patient can lie at full length, and for the surgeon and the various instruments and appliances he carries with him. The cost in New York is \$550, or allowing for the difference in the purchasing power of money in England and in America, about £85 to £90 in English money. The cost of maintaining an ambulance in New York is about \$920 to \$1,000 (£190 to £208), which may be considered equal to about £150 in England, this estimate including the wages and board of the driver, forage for the horse, and keeping the ambulance in repair.

The excellent example set by New York in regard to its ambulance service has been copied in its general principles by most of the big towns in the United States, though the systems pursued differ in various details. For instance, in Philadelphia, Norwich (Connecticut) and Chicago, the police have the chief charge of the service, though in Philadelphia other ambulances are maintained by private hospitals and institutions.

In St. Louis one ambulance is kept by the police and one at the Railway Hospital, while others are

maintained by their Department of Health. At Pittsburg twelve patrol wagons are used by the police for ambulance purposes, while at the same time all the hospitals in that city have ambulances ready. In Boston five of the general hospitals have six ambulances in use altogether, the municipal hospitals have three, while the police department has seven. In New Orleans the service is under the direction of the administrators of their Charity Hospital, which is supported in a manner that in one of its details would scarcely be recognized in this country.

Numberless lives have been saved, not only in New York, but in many other cities that have followed the admirable example it first set, by the speed with which the ambulances reach the sick and injured, bringing help that literally wrests back the sufferer from the jaws of death, as the last flickering spark of life is leaving the body. As, in the case of fire, the first few seconds or minutes are proverbially the most critical, so it is often in the case of accident or illness, and many lives are lost by injuries received in the streets of London and the other great cities of England, owing to the delay in reaching the scene of accident with a hand-stretcher, that might be saved were the New York system in universal use. And, if a conveyance is employed in any English town in the case of accident, what is it? Generally a four-wheeled cab or such-like unsuitable vehicle perhaps to convey the patient for a distance of several miles to the nearest hospital, when suffering from broken limbs, the cramped position necessary in such a conveyance causing the sufferer excruciating agony.

The police department, if it were so decided, might introduce and take charge of the ambulances, as the police do in Chicago and other cities of the United States. But probably the most satisfactory way of all would be for the London County Council to take up the matter, either by subsidizing the hospitals according to the number of ambulances employed by each, as in Brooklyn, or by working them by means of their own employes, in conjunction with the hospitals. The first plan of the two would probably prove the most satisfactory; but as to the details, it would be for the future to decide them. It has only been attempted in this slight sketch to draw some attention to what is being done by other countries in the alleviation of human suffering, and it seems impossible not to believe but that in the greater London of the future the same kind of system will ultimately prevail, by whatever means it is set in motion. And certainly, when ambulance wagons take the place of the present old-world stretcher, or the worn-out cab so often made use of in this great city, it will be a matter of wonder that, with all our many philanthropic schemes, and all our efforts to minimize the terrible suffering that flesh is heir to, we have so long neglected an example set us by far younger cities than our own.

THE EMERGENCY RATION OF THE ARMY.

Under the authority vested in him by Section 1146 Revised Statutes, the President has established an emergency ration for troops operating for short periods under circumstances which require them to depend upon supplies carried on their persons. This ration has been adopted after full consideration of the subject by boards of officers convened for the purpose. Forty-five officers, all men of rank, years and experience, served on these boards, the membership of which included 9 medical and 9 subsistence officers, 18 infantry, 6 cavalry, and 2 artillery officers, and 1 inspector general. The ration adopted may therefore be accepted as the best that can be provided by the knowledge and experience of the military men of this country.

The want of a special and distinctive emergency ration in our service has been a subject of discussion, particularly by line officers, since the time of the Franco-Prussian war, when so much was heard of the value of the iron ration of the German troops. In April, 1895, the Commissary General of Subsistence addressed a letter to the Adjutant General of the army, in which he invited attention to this want, and suggested the appointment of a board of officers in each of the eight military departments to consider and recommend a suitable ration. This suggestion was approved by the Secretary of War, and a board consisting of one medical, one subsistence, and three line officers was appointed in each of the departments. These emergency ration boards were in session during the summer and autumn of 1895. They communicated with the food manufacturing firms of the country and investigated samples of all kinds of concentrated food that could be procured. In some of the departments detachments of troops were sent out on field service to put the ration recommended to a practical test. When the reports reached the War Department a board of officers was convened in Washington, D. C., to examine the reports of the departmental boards and to consider such views and suggestions as the Major General Commanding the Army and the Commissary General might lay before it; also to make recommendations on the subject and to report upon the minimum amount of articles of food necessary to sustain a soldier in health and activity while in active service in the field for a limited period. The report of this board was approved and on December 5, 1896, the order establishing the emergency ration was published.

The consideration of an emergency ration by the military authorities led to popular anticipations of the discovery and adoption of some form of concentrated food which would sustain the vital energies under a heavy strain while having but little bulk and weight to incommode the soldier on his march. These anticipations found expression in the daily

papers and even in some of the medical journals. Kola advertisements fostered this idea. The practical men of the army found, however, that the advance of science has not yet enabled the human system to be independent of physiologic laws. They concluded that when work is to be accomplished by the human machine a certain quantity of the organic elements must be supplied; and as in emergencies hard service is generally to be expected, the principle was adopted that the emergency ration should contain as much of the food elements as is necessary to sustain the soldier under the maximum of physical strain. The conservatism and good sense of these military boards are shown by the manner in which they disposed of all suggestions of concentrated meats, pemmican, pastes, etc. It would be unwise to select as the staples of an emergency ration any article of food with which the soldier is not familiar, or which would make a material change in his dietary during the continuance of the emergency. The emergency ration, therefore, consists of a hard labor allowance of the ordinary articles of the soldier's ration. Saccharin is substituted for sugar, and tobacco is added on account of the difficulty sometimes experienced by troops in procuring the latter during the emergencies of a campaign. In another part of this issue we print a Summary of the Proceedings, Conclusions and Recommendations of the Emergency Ration Board, as a valuable contribution to the literature of food and dietaries.

THE JOURNAL ITSELF.

It is with great pleasure that we announce to our readers that the last year of the JOURNAL has been one of unwonted prosperity notwithstanding the continued stringency of the times, and that its growth has been steady and continuous. In the last three months the circulation has grown faster than ever before in its history. One reason for this has been the sincere desire of the members themselves to increase the strength of the organization, by inducing acquaintances to become colleagues, and another reason has undoubtedly been that the JOURNAL has furnished satisfactory material to the ASSOCIATION. Certainly its volume has never been so great. Exclusive of advertising pages, the JOURNAL furnished 1,364 pages quarto, the most part in closely printed type. No count is taken of advertising pages, title page nor index, and the index itself for these six months is of immense value. Three hundred and six members contributed original articles to the JOURNAL during the six months.

It is to be remembered, however, that many of the advertisers who were formerly giving formulæ, have ceased to advertise because unwilling any longer to publish them, and the losses of the JOURNAL on that account will be greater next year than in former years; but, notwithstanding, with the steady increase of mem-

bership, a movement which seems impossible that it can now be prevented by any change of sentiment, will probably counteract this. The character of the advertising carried in the JOURNAL has been made during the last volume to conform to the rule of the ASSOCIATION, which requires the formulæ of all proprietary medicines to be printed. With the encouragement that the past few months have furnished, let us all take hold of the work of organization in earnest. Let us have 10,000 members in this anniversary year!

CORRESPONDENCE.

Ether and Chloroform.

CHICAGO, Dec. 24, 1896.

To the Editor:—An article in the JOURNAL of December 19, by Dr. W. S. Caldwell, has been of great interest to me for several reasons. One reason is I do not agree with the conclusions drawn; but I am not prepared to combat them with statistics and cases and I will not take up the gauntlet on that score. In one place, however, Dr. Caldwell says "anesthetics are most skillfully given in large hospitals." I do not believe this statement is true. Anesthetics are usually (in hospitals) given by the junior interne during his first three months' service; though he may become quite skillful before his service in that department is over, yet for the greater part of that time he must be considered unskilled. Unfortunately, as a rule, he is given no instruction whatever and must get his skill by the hardest kind of experience and wholly at the expense of his patients. Even Dr. Caldwell credits one hospital surgeon with the statement that the interne "must kill a patient or two before he can get his hand in." Why not then employ an experienced man and require the anesthetist to get his experience as the surgeon does.

I wish to call particular attention to the Doctor's italics when referring to chloroform. They are as follows: "*Great care,*" "*trained and skilled,*" "*proper hands,*" "*proper precautions,*" "*more care,*" "*safer in skilled hands,*" "*properly administered,*" "*skilled.*" Here then we have his most emphatic arraignment of chloroform and his argument for ether. Any student, laborer, messenger boy, or member of the patient's family may safely (?) give ether, but chloroform requires a careful, experienced man; therefore he concludes chloroform should not be given. As well say that because it requires an expert to do a laparotomy, such operations should not be done at all.

But it is not my purpose to try to convince the ether givers of their error, but rather to use his paper as a text to plead the cause of the anesthetist. I do this, not with a desire to be regarded as a specialist in this underrated but very necessary branch of medical art, but rather because I happen to be familiar with the difficulties under which the anesthetist labors.

In fully 50 per cent. of the cases requiring an anesthetic, there is more danger to the patient in the anesthetic than there is in the operation which makes it necessary. If training and skill are exacted of the surgeon, why should they not be exacted of the man also who gives the anesthetic? The life of the patient is in many cases jeopardized as much by the one as by the other. In a large percentage of cases the skill required of the anesthetist in giving the anesthetic is fully as great as that required of the surgeon in doing the operation. This being the case, why is it that so many patients, and not a few surgeons, seem to think that the anesthetist is entitled to little or no compensation? The remedy lies with the sur-

geon. He too often tells the patient that the operation will cost \$100 or \$200 and that he will bring a doctor to assist and one to give the anesthetic. When the operation is done, he will say to the anesthetist, "You will get \$5 out of this when I get my pay." In that case the surgeon gets the first \$195 and the anesthetist gets the last \$5; or if five or six months have gone by, the surgeon has probably forgotten all about it and the anesthetist gets nothing. If there is any trouble about the bill and the whole of it is not paid the anesthetist's share is usually included in the unpaid portion.

To a young doctor in Chicago who wishes to learn surgery, it is a positive disadvantage to acquire a reputation for expertness in administering anesthetics. He is called upon to take this part in all cases where the work is wholly charity, and in many cases where all the work, except his, is paid for. Under such circumstances is it any wonder that the knowing ones decline this task and that the most unskilled are the ones on whom this great responsibility most often devolves? He considers the work he is doing as altogether unimportant and uninteresting and mechanically pours on the ether or chloroform, while his whole attention is concentrated on the operation. Is it any wonder that deaths occur under such circumstances? The vigilant anesthetist will not let his attention be attracted from his patient's condition for the fraction of a minute during the whole operation.

In the past two years and two weeks I have administered chloroform 161 times and ether once. Three times have I had respiration stop; twice in the case of smokers and once where too much chloroform was given. In all cases, by promptly removing the mask and using proper means, the patients were quickly restored. I will relate my experiences in the matter of compensation: For these 162 anesthetics I have received just \$327, an average of \$2.63 each. Many of these required that I leave home at 8 o'clock and kept me away till afternoon, usually carfare and sometimes railroad fare to pay. As a partial remedy to these evils, I would suggest that the surgeon state plainly to the patient that he can not do the operation alone, that he must have an assistant and some one to give the anesthetic, and that they must be paid. Then let these assistants send their bills in separately and take their chances with the surgeon on getting their pay. Then as the anesthetist will, in all probability, not see the patient again, a suggestion that he be paid in cash, would usually be complied with. I have such an arrangement with two surgeons for whom I frequently give anesthetics and I see no possible objection to it. Under no circumstances will I send in a bill for less than \$10.

On one occasion, about a year ago, I was invited to attend an operation. On my arrival I found the assembled doctors holding a consultation; the patient's condition was such that it was feared she would not survive the anesthetic and the man who was there to administer it refused to go on. The surgeon considered the operation imperative and he and the husband urged me to try giving her chloroform. I anesthetized her and during the operation she lay so quiet that she appeared to be dead; even the operator stopped two or three times to inquire whether all was well. The husband spent the time alternately weeping by my side and in the next room on his knees praying. When the patient was returned to her bed and we prepared to go the husband objected to our leaving until she regained consciousness, although the family physician had indicated his intention to stay. Eight times at monthly intervals I sent in my bill, and as regularly it was ignored. Then I sent a collector to see him; he told the collector that he did not invite me to his house. I came there of my own accord and he guessed that I would have to look to myself for my pay. He also said that I had "nerve" to send in a bill for a little thing like that; he supposed doctors were glad to do that for the experience they got out of it.

I gave chloroform to a woman, the wife of a business man

down town, and sent in a bill of \$10. After the lapse of considerable time she sent me \$5 with the statement that she had "consulted no less than a dozen of the most prominent doctors in the city and they all said that \$5 was the very highest fee ever charged for giving an anesthetic." I wondered whether these "prominent" doctors charged \$10 each for these consultations. On another occasion I received a message requesting me to come to a suburban town to give an anesthetic. On my arrival there I found the patient to be a doctor whom I had never seen or heard of before. The operator told me that the patient was a wealthy man and owned a good deal of business property in a prosperous city in Minnesota. I sent him a bill and got a reply in which he said he was "astonished beyond measure" at my sending him a bill; he said that he had never yet paid a doctor for professional services and intimated that he never expected to. I left home at 8 A.M. to go to this case, got back at 3 P.M. and paid railroad fare both ways. Of these 162 patients whom I have anesthetized, 61 paid something. But the patience of the editor and the space of the JOURNAL would both be exhausted before I could exhaust the reasons given by the other 101 for not paying anything. Yours very truly,

D. H. GALLOWAY, M.D.

200 Oakwood Boulevard.

Harvey Medical College.

CHICAGO, ILL., Dec. 18, 1896.

To the Editor:—At a recent meeting of the faculty of the Harvey Medical College the following resolutions were passed unanimously:

"That the licensing power to the practice of medicine in the State of Illinois be taken from the State Board of Health and given to a separate board of medical examiners.

"That a diploma from a medical school of good standing shall be a necessary qualification for examination.

"That the examination shall be in the English language."

A committee was appointed to confer with a joint committee of the State medical societies to assist in furthering the passage of the bill.

Does this look as if the faculty of the Harvey Medical College desire or intend to run a diploma mill?

BYRON ROBINSON, M.D.

PUBLIC HEALTH.

Insusceptibility to Vaccination, a Very Rare or non-existent Condition.—In the last report of the medical officer of the Local Government Board it was stated that among 88,875 successive vaccinations by the officers of the board, whether with humanized lymph or with calf lymph, no case of insusceptibility had been met with; that is to say, in no case of primary vaccination had the individual been vaccinated three times unsuccessfully. The statement has caused some expressions of astonishment, especially as it was accompanied by another to the effect that no less than 1,983 certificates of insusceptibility had been granted by medical practitioners in England and Wales during the last year reported on. There is, therefore, some interest in noting what has been the result at other than Government public stations, where, presumably, the operation has been performed with perfectly fresh—that is, unstored—lymph. We now note that Mr. O. Lowsley, public vaccinator for Reading, recently announced to the Reading Board of Guardians that out of 14,000 children whom he had vaccinated he had "never found a case of insusceptibility." Although "insusceptibility" to vaccination is admitted by law it really becomes doubtful whether it has more than a legalized existence.—*London Lancet*, November 14.

Practical and Inexpensive Methods of Disinfecting with Formic Aldehyde.—1. Spray: Wet wall, furniture, etc., all over and on

every side with a 2 per cent. solution of formic aldehyde and close the rooms for twenty-four hours. Sixty to seventy c.c. of this solution will disinfect one square meter. 2. Evaporation of cloths wet with formic aldehyde: Dip the cloths in a solution of a 35 per cent. solution of formic aldehyde, one liter to 500 grams of chlorid of lime, and suspend in the rooms to be disinfected for twenty-four hours. One cloth two meters square will disinfect eight cubic meters. Sixty to seventy square centimeters of this solution are necessary for each cubic meter. Formic aldehyde is especially adapted to the disinfection of books and furs. The price is moderate, but the eyes must be protected by special glasses, the nose and mouth by a double mask of cotton, and the hands by gloves into which vaselin has been well rubbed. These processes are recommended by Nils Englund in the *Hyg. Rundsch.*, page 306, as the most efficacious.—*Nouv. Remèdes*, October 24.

The Water Supply at the West Point Military Academy.—The Board of Visitors at the Academy has reported adversely upon the condition of the water-supply at the Academy, and strongly advise an attempt at purification by filtration.

At the present time work is in progress on a reservoir for the collection of the running waters of the Cascade and Crow's Nest stream during the season of their free flow, with additions, when necessary, from the round pond. The reservoir is intended to hold 75,000,000 gallons, and when finished will give the post a water supply assured as to quantity. It should be filtered before distribution, not so much for the improvement of its chemical character as for the removal of the particular cause of the periodic fever.

"In the United States we are not so careful to the purity of our water supplies as are the people of Europe," says the reporter, "and in consequence we have an access of typhoid, malarial and so-called typho-malarial fevers. The laws of Germany direct specifically the filtering of all surface waters before they are delivered for public consumption. In England and continental Europe, the filter bed is an integral part of the water system, when the water is not from a naturally filtered spring or deep well sources."

Dr. Joseph D. Bryant, physician to the President, and a member of the board, signed his name to the report.

Bacillus of Hospital Gangrene.—The *British Medical Journal*, December 6, has a very interesting article on the above subject based upon a paper by Dr. Vincent, in *Annales de l'Institut Pasteur*, September 25, in which he claims to have discovered the bacillus in question in forty-seven wounded cases returned to Algiers from Madagascar. The pseudo-membranous pulp covering the ulcer contained, in every case, a bacillus varying in length from four to eight micromillimeters and about one micromillimeter broad. It was straight or slightly curved, with rounded ends and irregular vacuolation; many were segmented. It was decolorized by Gram's method and best stained by thionin. The number in a preparation varied directly with the virulence of the case; the pulp from the worst forms resembled a pure culture of the organism. The bacillus was found to have great power of resistance to antiseptics; it was present in large amount in wounds which had been treated for ten days with iodoform and sublimate compresses. The number of cellular elements present varied inversely as that of bacilli, and in favorable cases numerous leucocytes and large uninuclear cells could be seen engulfing the microbes. In forty out of the forty-seven cases a spirillum was also present, usually in small amount, but in two instances outnumbering the bacillus. Vincent considers the latter the pathogenic organism of hospital gangrene; its most abundant seat is immediately beneath the layer of pseudo-membranous exudation, in which respect it resembles the Klebs-Löffler bacillus of diphtheria. The process evoked by it is necrotic and hemorrhagic, but its action, even in severe cases, is

mainly local, the internal organs suffering but little, though the connective and muscular tissues may be much disorganized. Inoculation of the pus from hospital gangrene into wounds artificially produced in animals, or its subcutaneous injection in man, led to no lesions, so that it had to be supposed that special conditions were necessary as adjuvant factors in the etiology of the disease. Inoculation into a rabbit suffering from general tuberculosis, however, caused the formation of an unhealthy wound containing large numbers of the gangrene bacillus and similar results were obtained by injecting this organism, mixed cultures of streptococci, colon bacilli, etc. These associated bacilli, if they developed in the wound, occupied a position more superficial than that of the specific germ. There are, therefore, two special factors necessary to the development of hospital gangrene in the human subject, a condition of inanition in the patient, and an association of the specific virus with other microbes. The bacillus also has but little action when alone, requiring the preëxistence of a gangrenous ulcer evoked by other organisms. It is the prevention of the growth of these other forms by means of antiseptics that has rendered hospital gangrene so rare at the present day.

The Duration of Life in the Medical Profession.—Dr. Haegler, chief medical officer to the General Insurance Company of Basle, has recently published an interesting essay on the duration of life in the medical profession. It has long been known that among medical men the duration of life is shorter than among the general population of a like age, and that clergyman, for instance, on an average live twenty years longer than medical practitioners. According to some old statistics of the kingdom of Bavaria only school-masters in rural districts have a less expectation of life than members of the medical profession, 75 per cent. of the latter dying before the fiftieth year and 90 per cent. before the sixtieth year of age. These numbers, however, seem to be exaggerated, for a new statistical work on the Kingdom of Saxony, by Dr. Geissler, states that 80 per cent. of the practitioners of that country, reached their sixtieth and 25 per cent. even their seventieth year. It is worth mention that medical mortality is very high, especially in the early years after entering on practice, and the life insurance premium to be paid by medical practitioners is on this account 10 per cent. higher than the general insurance rate. The excessive mortality in our profession is not only caused by infectious diseases, which medical practitioners are liable to contract, but also to over-exertion and the impossibility of securing regular seasons for rest and meals. Typhoid fever and diseases of the lungs (phthisis excepted) are very frequent as causes of death, while suicide is rarer than among the general population. It is generally recognized that the conditions of life prevailing among any particular class or section of the population have an important bearing on the occurrence of longevity in that class. In former times the services of medical men were but little esteemed; their incomes were as a rule very small, and consequently their average lifetime was short. Then came a period when the condition of the practitioner improved, and accordingly the average duration of life increased, but during the last ten or twenty years various circumstances, including the overcrowding of the profession, have combined to lower the standard of living, and there is thus reason to suppose that the duration of life will be correspondingly shortened.—*London Lancet*, September 12.

Increasing Demands upon Laboratories for Official Bacterioscopy.—In the *Boston Medical and Surgical Journal*, December 3, Dr. Francis H. Williams relates the bacterial history of an instructive case of diphtheria, with remarks showing the importance of having two or more negative cultures, before the patient shall have been released from quarantine. His case, A. B., a child, was taken ill with diphtheria, and his younger brother

and nurse were sent, for fear of contagion, to the house of a relative in another town. Soon after its removal the younger child complained of its throat. I was called in consultation, and although there was no membrane to be seen, and this did not appear until the following day; I found the bacilli directly in a cover-glass preparation made at the bedside, and the cultures showed them likewise on the following day. I also had cultures made from the throat of the child's nurse, although it showed no indication of diphtheria, and found bacilli there also. If the bacterial test had been applied before they left home, the bacilli would probably have been found then in the throats of both the younger child and nurse. They could have been treated immediately, which is of great importance, and the risk of carrying the disease in another household would have been prevented. The following case demonstrates the importance of the bacterial test during convalescence. The throat of this patient, D. C., was perfectly clear within a week after the injection of the antitoxin, but the bacilli lingered, as this record of cultures made in the Harvard Medical School shows:

April 25, positive.	June 13, positive.	July 21, positive.
28, positive.	16, negative.	25, positive.
30, positive.	18, positive.	28, positive.
May 5, positive.	19, negative.	Aug. 4, positive.
10, positive.	20, positive.	11, positive.
12, positive.	21, positive.	19, positive.
17, positive.	23, positive.	25, positive.
23, positive.	25, positive.	Sept. 1, positive.
26, positive.	26, positive.	9, positive.
30, positive.	28, positive.	15, positive.
June 2, positive.	30, positive.	22, positive.
5, negative.	July 2, positive.	29, positive.
7, positive.	7, positive.	Oct. 5, negative.
9, negative.	9, positive.	6, negative.
11, positive.	14, positive.	

The patient was able to be about within a short time, and yet was dangerous to others; in October cultures made from her throat were sufficiently virulent to kill a guinea pig in thirty-six hours. Dr. Williams, in commenting upon this and like cases, remarks that the laity do not realize that diphtheria is not usually transferred from one person to another except by actual contact through the hands or mouth, or by infected clothing, utensils, etc. The bacillus is not a motile one, and this disease is essentially one the germs of which are put into the mouth or nose by the hands. The slight annoyance which taking a swab causes an individual will be acquiesced in when it is understood that the disease is not, as a rule, a dangerous one when treated early. The cardinal point is to ascertain who are infected; and this can be done by means of the bacterial test, which should, of course, be followed by intelligent isolation and treatment. The application of this test to every member of the given "group" as soon as a case of diphtheria occurs, is made practicable by the excellent laboratories already established, and from the fact that the laity are becoming more and more appreciative of its usefulness. It should be applied to both nose and throat, and a second test should be made after a few days to those in whom the first was negative. A thorough use of the test would make unnecessary much of the quarantine that is so obnoxious and burdensome to many, and although it entails some expense, yet if looked at merely from a money point of view, it is cheaper in the long run. Unless the bacterial test is carried out systematically and intelligently, it will be necessary to continue to spend large sums of money for the care of patients who should not have been ill, and some lives will be lost that might have been saved.

NECROLOGY.

H. NEWELL MARTIN, M.D., formerly of Baltimore and recently of Burley in Yorkshire, England, died October 27, aged 48 years. Dr. Martin was a distinguished biologist, whose name was well known to English readers from his association with the late Professor Huxley in the authorship of the "Manual of Practical Instruction in Elementary Biology," published in

1875. He studied at Cambridge University and was for some time a fellow of Christ's College; he was also a Doctor of Science of London University. The greater part of his working life was, however, passed in America, where he for more than twenty years held the appointment of professor of biology at the Johns Hopkins University, Baltimore. While in America he wrote a work called "The Human Body," as well as several physiologic treatises, which obtained a wide circulation. He did some valuable work, and especially he discovered a method of maintaining the circulation artificially through the mammalian heart after its separation from the body, so that the effect of various conditions and the action of various drugs upon it could be ascertained without the complication which usually arises from its connection with the central nervous system. Dr. Martin was much beloved by all who knew him, and all physiologists will lament the early death of such a gifted and promising investigator.

GEORGE H. TAYLOR, M.D., of New York City, died December 9, in the 76th year of his age. He was born at Williston, Vt., and in his early life was a teacher in the common schools. Becoming interested in chemistry, he devoted his spare time to its study and later made a specialty of physiology. He was graduated from the New York Medical College in 1852 and at once began the practice of medicine in this city, where he had since resided. He became interested in the curative effects of massage and the Swedish movement cure and in 1858 visited Sweden. In 1864 he invented mechanical massage and subsequently established the Improved Movement Cure Institute, of which he was consulting physician at the time of his death. He was the author of a number of books and treatises on medical subjects. He leaves a wife, one daughter and a son.

JOHN DAVIS CASTNER, M.D., of Brooklyn, died November 13, aged 27 years. He was a graduate of the New York University, class of 1893, and for a time made his home at Newark, N. J., but about six months ago removed to Brooklyn, chiefly for the purpose of serving as ambulance surgeon at the Eastern District Hospital. A few weeks later he manifested pulmonary symptoms, tuberculous in character, in regard to which he was aware of a strong hereditary predisposition. It is not probable that his hospital work had any part in his infection by tuberculosis. He was a well informed young man, studious and industrious, with promise of a useful future.

PROFESSOR BUKA, of Berlin, has recently died in his 45th year. An eminent physicist, who has contributed materially to the utilization and improvement of the Roentgen ray.

PROFESSOR STRAUS, professor of experimental and comparative pathology, at Paris, in his 52nd year. He came from Strasbourg to Paris without friends or influence and succeeded in making a name and position for himself, by his enthusiastic devotion to science and talent for teaching. His work published last year on "Tuberculosis and its Bacillus," is his best monument.

MISCELLANY.

Emergency Rations for the Army.

Summary of Proceedings, Conclusions, and Recommendations of the Emergency Ration Board.

WAR DEPARTMENT, WASHINGTON, D. C., May 4, 1896.

The board met, pursuant to the foregoing order [Special Order No. 74, Headquarters Army, Adjutant-General's Office, March 28, 1896], on March 31, 1896, and after some discussion it was decided that all reports and correspondence submitted to the board should be carefully read by its members individually, in order that each should have a full understanding of the subject submitted to it before further proceedings were held. The board has held frequent sessions during the past month, as is shown by the accompanying daily record of proceedings.

The questions as to what should constitute such an emergency as to require the use of the emergency ration was first

discussed, and it was decided that in the opinion of the board "emergencies" are occasions on which, from any cause, the troops are mainly dependent on food carried on the person.

The emergency rations recommended by the department boards were then considered, in connection with various articles of food supply submitted to this board, as suggested components of an emergency ration, and with the various communications on these articles and on the general subject. It appears that of the eight boards, six recommended a hard bread, pure and simple, one a bread from whole wheat, and another a hard bread composed of one fifth oatmeal and four fifths wheat.

In the matter of meat, five of the boards recommended bacon, one dried (chipped smoked) beef, another a cooked beef, one-third of which should be fat, and a third board a meat compound composed of one part pork and three parts corned beef.

The reports of the department boards indicate a general belief that it would be unwise to select, as the staples of an emergency ration, any article of food with which the soldier is not familiar, or which would make a material change in his dietary during the continuance of the emergency; for articles of known value will give greater satisfaction, other things being equal, than those of unknown or unusual character, and change of diet is to be deprecated at a time when the energies of the soldier have to be sustained under conditions of strain.

This board concurs in these views, and therefore rejects the suggestion of a bread containing oatmeal, which although nutritious, palatable, and in other respects good, is open to the objection that, while it may be satisfying to individuals, the more familiar wheaten biscuit or hard bread is probably more acceptable to the majority of soldiers. It rejects, also, the bread made from whole wheat as known to be causative of diarrhea, and when tried, as was to be expected, it failed.

On similar grounds, this board rejects all suggestions of pemmican or meat pastes prepared from dried and powdered beef, although some of these make nutritious and palatable dishes when well spiced and highly flavored with extractives. It rejects the suggestion of corned beef and dried and smoked beef, because much of the extractives are lost and the albuminoids hardened in their manufacture, and the suggestion of canned cooked beef, because such meats are acknowledged by the canners to be flavorless unless there is present at least 35 to 75 per cent. of water, thus involving the transportation of that amount of innutritious matter in the ration. Many of the canned samples submitted to this board of stews, roast and boiled meats, etc., although otherwise good, are objectionable on this ground. The suggestion of peptonized or partially predigested meat is wholly at variance with the object in view in carrying an emergency ration which is to furnish to sound digestions the materials to keep them in function.

As all the department boards reported favorably on some variety of compressed soup to furnish a highly nitrogenous staple of the ration, and as the documentary evidence is strongly in favor of such an article, and as, moreover, this board has satisfied itself by personal experiment with regard to the preparation, palatability, and keeping qualities of certain of the compressed soups submitted, it concurs in the unanimous opinion of the department boards.

It was therefore decided that the three food staples of the emergency ration to be recommended for adoption should, in general terms, consist of hard bread, bacon, and some variety of compressed soup.

The board then proceeded to consider the character of the hard wheaten bread to be recommended as a portion of the emergency ration. It rejected the suggestion that any substance of a fatty nature be incorporated in the bread, as the evidence showed that such additions detracted from the keeping qualities of the finished article, and as, moreover, the bacon already recommended as a staple of the ration would furnish the soldier with the needful fat to be used at his pleasure. It examined certain samples of hard bread submitted to it, and concluded that the best sample was that which became soonest permeated when soaked in hot water. The sample which gave the best response to this test was one which was slightly aerated, its substance being evenly pervaded with minute or pin-point vacuolations. Its density was somewhat lessened by this porosity, so that, pound for pound, it would occupy somewhat more space than ordinary hard bread; but the board considered that this could be offset in great part by exposing the aerated hard bread to a higher degree of heat than is used in the baking of the ordinary bread; by this treatment weight would be lessened by getting rid of a small percentage of water, the percentage of the nutritive elements being thereby increased, while some of the starch would be converted into dextrins. The ready permeability of this biscuit would reduce to a minimum the number of cases of diarrhea that in field service so frequently originate in imperfectly softened and masticated

hard bread. It was the unanimous opinion of the board that bread thus permeable, and browned on the surface, would be improved in its keeping and nutritious qualities, and be more acceptable to the men than the present issue.

In conclusion, on this subject the board decided to recommend, as the hard bread of the emergency ration, that quality of bread which should form at the time the regulation issue of the Subsistence Department. The board, however, in this connection, desires to invite the attention of superior authority to the possibility of improving the quality of the ordinary hard bread ration on the lines indicated above.

The character of the bacon of the emergency ration was then discussed to determine whether it should be cooked or raw, or partially cooked, *i. e.*, sterilized, and whether it was advisable to have a selected bacon containing, for instance, a larger percentage of lean than is found in ordinary issues. As a result of a full discussion of these points, the board decided on recommending as the bacon of the emergency ration an uncooked bacon of the quality which at the time should form the regular issue of the Subsistence Department, preference being given to those cuts having the largest proportion of lean meat.

The board then proceeded to discuss the character of the soup-making material which it desired to recommend as a component of the emergency ration. On account of a deficiency of proteids in the hard bread and bacon already recommended, it was evident that this component should contain a large per cent. of this proximate element. This could be done either by incorporating powdered beef, or by the use of pea or bean meal. As a matter of fact, one or the other of these meals appeared to enter into the composition of most of the samples submitted to the board. Most of them purported to contain meat, and some showed the presence of fragments suggestive of dried beef as a constituent; but the proteids in the analysis before the board were not materially in excess of that which would be present were peas or beans the only component. All the samples before the board made excellent soups, but some required to be boiled twenty-five minutes, which is longer than is desirable in an article intended for an emergency ration.

The board has been unable to obtain from those who have manufactured compressed soups in this country as full information as is desirable. The details of the manufacture of these soups being trade secrets, it is impossible on a mere request to secure them. So far as known there have been but three firms in this country who have manufactured these soups, but the demand for them has been so slight that two of the concerns have suspended operations, while the third apparently carries but a small stock.

The board suggests that the attention of the Subsistence Department be directed to the elaboration of a soup-making material of the kind mentioned, and in the meantime recommends that pea meal be adopted for this part of the ration, as a palatable soup can be made from this meal when seasoned with finely chopped bacon, pepper and salt.

Cheese, suggested as a desirable article on account of its high proteids and calorific value, was rejected after a full presentation of the arguments pro and con, and chiefly because it appeared from the evidence before the board that the Subsistence Department had already made an unsuccessful effort to introduce it as an article of food for our troops.

In taking up the consideration of coffee as a part of the emergency ration, the claims of chocolate as a palatable, highly nutritious and easily prepared accessory, were discussed, but on motion it was voted down as failing to give that general satisfaction which is known to be obtained from the coffee ration. From the records it appears that seven of the department boards recommended coffee as a part of the emergency ration. This board concurs in the recommendation, as it believes coffee to be preferred generally in the United States to any other dietetic stimulant. But, inasmuch as tea is recommended by one board and as an alternative by another, as the leaves can be put up in a suitable form, have good keeping qualities, and are more grateful to some tastes than coffee, while the active principle and physiologic action are the same in both, the board recommends that tea may, when called for, be substituted for coffee in the emergency ration.

The board considered the efforts at concentration in the case of coffee to be practically failures, the solid extract having no taste of coffee, while the fluid extracts had more of the taste of chicory than of the aroma of coffee. It therefore decided on recommending that the coffee of the emergency ration consist of roasted and ground coffee berries.

Several preparations of the kola nut, with much manuscript and printed literature on the subject, including recent analyses made in the laboratory of the Surgeon-General's Office, were reviewed by the board; but it regards the whole of this sub-

ject as in the experimental stage and, as such, unfit for serious consideration in discussing the constituents of an army ration.

The question of sweetening the coffee or tea, as between saccharin or sugar, was then brought up for settlement. The department boards were divided on this subject. On behalf of sugar the evidence showed that beside its sweetening power it has a high calorific value. Against saccharin was its novelty; but on its behalf it was found that the practically immaterial weight of 4 grains possessed the sweetening power of 2 ounces of sugar; that it has been used for long periods in much larger quantities than would be needful in an emergency ration with no detrimental influence on health, and that its antiseptic property would tend to lessen the prevalence of diarrhea due to intestinal fermentations. After obtaining full information on these and other points connected with the subject, the board decided on recommending saccharin as the sweetening agent of the emergency ration. The main consideration which led to this decision was the desirability of having a nitrogenous proximate principle in each of the articles which contributed materially to the weight of the ration, and as sugar contains no nitrogen, it was believed that greater efficiency would be obtained if some article containing proteids were substituted for it in the emergency ration.

The advisability of including tobacco among the components of the emergency ration was then considered. It is true that tobacco is not a food; but it is used so generally by soldiers during campaigns for the restful feeling which it induces, that many men would rather go short on food than be deprived of their tobacco. Moreover, those habituated to its use suffer acutely from its deprivation, and as it is the object of an emergency ration to keep up the powers of the individual at their maximum for the time being on the smallest weight of food to be carried, it is argued that half an ounce of tobacco would conduce more to comfort while on short rations than would the addition to the ration of an extra half ounce of bread or bacon. While men who use tobacco always endeavor to provide themselves with it, experience shows that it can not always be purchased during campaigns, and particularly in emergencies; and to the argument that many do not use tobacco, the reply is brought forward that no man will find difficulty in disposing of his portion to others for an equivalent in some other article of the ration.

The board then proceeded to discuss the amount or quantity of the ration as a whole, and of its various components. For the convenience of its members in appreciating the value of propositions in this connection, it prepared the following table as the basis of its calculations:

One ounce of 437.5 grains.	Nitrogen.	Carbon.	Calories.	Protein.	Fat.	Starches.
	Grains.	Grains.		Ounce.	Ounce.	Ounce.
Biscuit . . .	10.71	183.5	107	0.156	0.013	0.734
Beans	15.96	173.1	98	0.232	0.021	0.574
Peas	15.13	161.6	92	0.22	0.0198	0.529
Bacon	6.05	273.6	203	0.088	0.733

The question whether the emergency ration should be a minimum or bare subsistence dietary or one possessing a high potential energy, was then discussed at length. In this discussion it became apparent that the board was unanimous in the opinion that when emergency rations are issued to troops, it is to be expected that serious work is ahead of them, and that a ration of high calorific value is needful to sustain them under these conditions.

The board recognized that the difference in weight between that which is generally accepted as a standard diet for any ordinary man under ordinary conditions of labor, and the ration which will sustain the soldier under emergency calls to unusual strain is only a few ounces, and the experience of its members authorized the belief that the high condition of the men, resulting from full diet on such occasions, would be bought cheaply by the carriage of the extra ounces on the person. Moreover, the board appreciated that if the emergency did not call for any unusual strain on the physical powers, or if from any cause it became needful to economize during the emergency, the extra ounces of a ration based on a maximum requirement could be withheld from consumption to constitute the ration of a period in excess of the face value of the emergency issue.

Guided chiefly by these considerations, the board decided that the emergency ration should contain as much as the proximate principles of food as is necessary to sustain the soldier under the maximum of physical strain.

It was then decided that the amounts of the various components should be as follows:

	Ounces.
Hard bread	16
Bacon	10
Pea meal	4
Coffee, roasted and ground, with 4 grains saccharin	2
(Or tea, one-half ounce, with 4 grains saccharin.)	
Salt64
Pepper04
Tobacco5
Net weight, with coffee	83.18
Net weight, with tea	31.68

It is recommended that the Subsistence Department supply suitable bags in such numbers as may be necessary, for carrying the roasted and ground coffee, and the salt and pepper; also a tough paraffin paper for use in wrapping about bacon when carried on the person; also that the pea meal be issued in compressed cylindrical package.

The nutritive value of this ration is as follows:

	Protein.	Fats.	Carbohydrates.	Nitrogen.	Carbon.	Calories.
				Grains.	Crains.	
16 ounces hard bread	2.496	0.208	11.744	171.96	2,936	1,712
10 ounce bacon	0.88	7.33	60.5	2,795	2,030
4 ounces pea meal	0.88	0.0792	2.111	60.52	646.4	368
Total	4.256	7.6172	13.855	292.98	6,318.4	4,110

In determining the quantity of the components of this ration, the board gave due consideration to the various dietaries for hard work, as stated by those who are generally cited as authorities on the subject. In general terms, such dietaries consist of 30 ounces of water-free food having an available energy equivalent to about 4,000 calories. The emergency ration recommended provided 4,110 calories from 25½ ounces of water-free food. This greater food value from a less weight of material is obtained by an increase in the fat of the ration as compared with that of the standard dietaries. It must be remembered, however, that these dietaries are not intended for temporary, but continuous use. They express the views of the physiologists and scientists concerning the waste of the system under conditions of hard labor, and concerning the quantity and character of the food elements needful to completely repair their waste. The emergency ration is not intended for continuous use. It is intended to be used only occasionally and for short periods. The necessity of having it in the exact proportion of the proximate principles required by the system is not imperative. The objective in its construction should be the largest food value in the smallest weight. Fat has an available energy of more than twice that of an equal weight of the proteids or carbohydrates. The amount of fat assimilated by the system varies not only with the conditions as to heat and cold and rest or labor, but also with the quantity of carbohydrates in the diet. If the carbohydrates are not to be had, fat in excess of that ordinarily assimilated will be utilized by the system. Any deficiency in the proteids and starches of the emergency ration recommended above is offset by the higher calorific value of the fatty element. The fat, however, can not take the place of the proteid principles in the repair of the muscular system. This has to be considered from another point of view. A standard dietary for hard work should have at least 4.4 ounces of the proteids, equivalent to about 300 grains of nitrogen, for the average nitrogenous waste of the system amounts to about this quantity. The standard diet calls for a larger proportion, but it is questionable whether this is not a concession to meat-eating habits rather than a necessity of the system. The emergency ration above recommended gives close upon the quantity needful to repair muscular wastes. Should there be a deficiency it could be made up by meat issues when the emergency is at an end.

The board is called upon to report upon the minimum amount of articles of food necessary to sustain a soldier in health and activity while in active service in the field for a limited period. In considering this subject the board recognized that the wear and tear of the human machine involved in the mere act of living, i.e., in keeping up the vital processes and in sustaining the heat of the system at its normal degree, required the expenditure of a certain amount of energy. To supply this energy a corresponding amount of food must be introduced into the system, and this amount is usually spoken of by physiologists as subsistence diet. The quantities are stated somewhat differently by different authors. The lowest figures are those of Playfair, who calls for 14.5 ounces, of which 2 are protein, 12 starches, and 0.5 fat, containing 138 grains of nitrogen, 2,975 of carbon, and having the available energy of 1,758 calories. The board believes from the evidence before it, and as the outcome of its discussions on this subject, that men in well-fed

and healthy condition at starting can undergo the ordinary fatigues and hardships of an active campaign for at least ten days on the equivalent of a subsistence diet, such as that given by Playfair, and without any impairment of health resulting from the temporarily restricted diet. Hence, if the emergency should require economy in the use of the emergency ration, the men could be put upon a limited dietary, so that in the direst emergency, rations for five days might be made to last ten. The troops would individually suffer loss of weight by having to supplement their deficient dietary from their own tissues, but repair in sound men would be effected by a few days of rest and full diet.

The board considered from its experiments that emergency rations for five days should be the maximum number of rations to be carried on the person of the soldier. In emergencies of less than five days the troops should be required to carry the full ration for the number of days stated. In emergencies of longer duration the commanding officers may direct economy in the use of the ration, so that the five days' rations may be made to last for any number of days not exceeding ten. From their character as issued the articles of the ration are susceptible of accurate subdivision, by which means they may be used with any degree of liberality between a minimum of subsistence diet and a maximum emergency of hard labor diet.

Respectfully submitted,

CHAS. SMART, Major and Surgeon, President; C. A. WOODRUFF, Major and Commissary of Subsistence; E. A. GARLINGTON, Major and Inspector General; L. A. CRAIG, Captain, Sixth Cavalry; W. C. BROWN, First Cavalry, Recorder.

WAR DEPARTMENT,

SURGEON-GENERAL'S OFFICE, Washington, May 5, 1896.

Sir:—I have the honor to forward herewith the summary of proceedings of a board of officers convened by paragraph 3, Special Orders No. 74, Headquarters of the Army, Adjutant-General's Office, March 28, 1896, "to consider and recommend a proper ration for troops operating in emergencies."

Accompanying this will be found the daily record of proceedings and its appended papers.

Respectfully,

CH. SMART, Major and Surgeon, U. S. A., President.
The ADJUTANT-GENERAL, U. S. ARMY, Washington, D. C.

[First indorsement.]

WAR DEPARTMENT, October 6, 1896.

Respectfully referred to the Major-General Commanding the Army for remark. DANIEL S. LAMONT, Secretary of War.

[Second indorsement.]

HEADQUARTERS OF THE ARMY, Washington, Nov. 11, 1896.

Respectfully returned to the honorable the Secretary of War. The report of the board as contained in the summary of its proceedings is approved, and the adoption of the recommendations contained therein is advised.

NELSON A. MILES, Major-General, Commanding.

[Third indorsement.]

NOVEMBER 21, 1896.

Approved. DANIEL S. LAMONT, Secretary of War.

[Fourth indorsement.]

HEADQUARTERS OF THE ARMY, Washington, Nov. 24, 1896.

From the Major-General Commanding to the Adjutant-General for publication, with the orders and instructions to carry it into effect.

SAM'L BRECK, Ass't Adj.-Gen.

General Orders, } HEADQUARTERS OF THE ARMY,
No. 49. } ADJUTANT-GENERAL'S OFFICE,
Washington, Dec. 5, 1896.

1. The following order has been received from the War Department:

WAR DEPARTMENT, Washington, Dec. 5, 1896.

Under the authority vested in him by section 1146, Revised Statutes, the President hereby establishes an emergency ration for troops operating for short periods under circumstances which require them to depend upon supplies carried upon their persons. Its component parts are as follows: Bacon, 10 ounces; hard bread, 16 ounces; pea-meal, 4 ounces, or an equivalent in approved material for making soup; coffee, roasted and ground, 2 ounces, or tea $\frac{1}{2}$ ounce; saccharin, 4 grains; salt, .64 ounce; pepper, .04 ounce; tobacco, $\frac{1}{2}$ ounce.

DANIEL S. LAMONT, Secretary of War.

2. The Secretary of War directs that this emergency ration be resorted to only on occasions arising in active operations when the use of the regularly established ration may be impracticable; that, although its nutritive qualities permit its use on half allowance, it will not be so used except in cases of overruling necessity, and never for a longer period than ten days; and that not more than five days' emergency rations be carried on the person at one time.

3. By direction of the Secretary of War, the Subsistence

Department will provide tough paraffin paper for wrapping the bacon; will furnish hard bread in grease-proof packages, the pea meal in cylindrical packages, and the coffee, tea, saccharin, salt, pepper and tobacco in suitable packages.

By command of Major-General Miles:

GEORGE D. RUGGLES, Adjutant-General.

A Liberal Mayor.—The Earl of Derby, who is the Mayor of Liverpool, does not draw his \$10,000 worth of honorarium, but causes it to be passed over to the support of charitable objects, chiefly to hospitals and dispensaries.

New Process of Wood Engraving.—The wood is coated with varnish and the design drawn on this. The acid bath is made of four parts sulphuric acid, one part bichromate of soda and six parts of water. The impression is said to resemble closely aquafortis engraving.—*Nouv. Remèdes*, October 24.

Cessation of the "Union Medicale."—After fifty-one years of dignified existence, the *Union Médicale* ceases its publication with this year. The three principal editors, Richelot, Richardière and Eugene Rochard, join the editorial staff of the *Bulletin Médical*.

Rodent Ulcer; a Genuine Case.—At a surgical clinic a few days ago, before a class in the Harvard Medical School, a patient was shown who had a wound on the thigh caused by the bite of a rat. The instructor having asked the class for a diagnosis of the case, one of the students replied promptly, "rodent ulcer."

Mirror Speech.—Grasset reports a similar case to that of the child mentioned in the *JOURNAL* December 19, page 1307, who reversed the syllables in speaking. In his case it was a woman affected with hysteria major and since insane, who reversed the letters of the entire words, pronouncing them as if spelled backward with absolutely amazing rapidity and correctness.—*Progrès Médical*, December 5.

The New Element "Lucium."—The discovery of a new element to which is given the name "lucium," has been announced by M. P. Barrière. It has been found by him while investigating monazite sand. It is related to the other rare elements found in monazite and is distinguished from cerium, lanthanum, didymium, thorium, zirconium, yttrium, ytterbium and erbium by its chemic reactions. Mr. Barrière's announcement is confirmed by several other competent chemists. Its atomic weight is given as 104.

Aerial Convection of Typhoid Fever.—An epidemic of fever at Rheims among the dragoons was first traced unmistakably to the dust stirred up by their evolutions and Uffelmann's experiments demonstrate that the dried typhoid bacillus, as also the cholera microbe, can be disseminated in the air, and thus alight in dust on articles of food. Similar experiences are reported from Belgium as the cause of the present slight epidemic at Tirlémont. These facts tend to show that the water supply is not always to blame in epidemics of typhoid fever.—*Journal d'Hygiène*, October 29.

Double Monsters.—The *Journal des Sciences Méd. de Lille*, the organ of the Roman Catholic University, has been devoting considerable space lately to a study of this subject, in order to determine whether baptism should be administered once or twice to a double monster. It concludes that there are always two embryos, hence two souls, but that sometimes one dies in the uterus and its body becomes therefore merely an appendage of the other, a parasite, which of course does not require baptism.

International Congress at Moscow; Program of Surgical Section.—

1. Treatment of septic wounds. Address by Braatz of Königsberg.
2. Non-operative treatment of neoplasms, especially with sero-therapy.
3. Cerebral surgery in tumors of the brain and Jacksonian epilepsy; Bergmann of Berlin.
4. Surgery of the lungs, especially in pulmonary cavities; Tuffier of Paris.
5. Treatment of strictures of the esophagus and rectum, results

obtained by the different methods of intervention; Czerny of Heidelberg. 6. Syphilitic and gonorrhoeal arthritis; Ollier of Lyons. 7. Prosthesis of the lower member (consecutive to arthritis, paralysis, congenital luxation of the hip and amputations): Dollinger of Buda Pesth.—*Bulletin Médical*, December 2.

Photographing Concave Objects in Relief and Vice Versa.—A paper or plaster cast is taken of the object and this is photographed upside down, with the sensitive plate also reversed. In this way a negative of the cast, which is a negative of the object, is obtained and this when printed, by some optical illusion, produces exactly the effect of the original object, probably owing to our habit of seeing things lighted from above.—Moussard in *Nouveaux Remèdes*, October 24.

Model Crèches.—The importance and necessity of crèches (infant nurseries) for the children of working women are so generally recognized now that the municipality in some towns establishes crèches as it does public schools, under the supervision of the mayor. There are seven suburbs of Paris thus supplied with municipal crèches and the town of Roubaix has two fine ones that are considered models in every respect. The model crèches, however, are few and far between. A recent communication to the Acad. de Méd. states that there are only six in France that comply with all the requirements of the model crèche in regard to the location, building, sterilization of the milk and not too long delay in using the milk after it has been sterilized, with a suitable isolating room. Three of these six are municipal establishments (Roubaix and Tourcoing). Many have no garden, playground, piazzas nor yard. Every person connected with a crèche should pass a preliminary examination before a competent committee. At Gentilly the personnel is selected by competitive examination.—*Bulletin de l'Acad. de M.*, November 24.

Tick, or Texas Fever, in Australia.—Texas fever has assumed alarming proportions in northern Queensland, is reported to exist in western Australia, and its further spread is greatly feared by all the Australian colonies. It first appeared in Queensland in 1891, brought by cattle from the northern territory of South Australia. From them and other infected cattle introduced in 1894, the disease spread slowly at first, but latterly in a comparatively rapid manner. The bullock teams and drift stock from the northern territory and the western portion of northern Queensland to the boiling and extract works on the Albert and Norman rivers carried the disease in a southerly and easterly direction to a number of herds in that part of Queensland, inflicting very serious loss; but, as a rule, the losses were not so heavy in the country some distance back as on the coast. The whole of the gulf country from east to west, following generally the twenty-first parallel, has been strictly quarantined since November, 1895, and although this has to a certain extent stayed the spread of the disease, it has not proved thoroughly effective. When Queensland was found to be so badly infected, the legislatures of all the other colonies passed acts providing for their safety. The introduction of cattle, horses, sheep and dogs, also unsalted hides from Queensland, is prohibited absolutely by some colonies, and in others is permitted only after thorough inspection.—*U. S. Consular Reports*, November.

"Society for the Reconstitution of the Family."—The Acad. de Médecine of Paris proposes to bestow a medal upon the founder of this society, Mad. Hervieu, a midwife of Sedan, in view of the marvelous results accomplished by it already, with such small financial outlay. Its aims are similar to Governor Pingree's potato patch scheme. It supplies poor families with a plot of ground and seeds to cultivate it and during 1893, its first year, it assisted thus twenty-one families, representing 145 persons, at an expense of less than a dollar each (3 francs, 67 centimes). The results surpassed all expectations, as the

families not only supported themselves from the products of the land, but they sold enough to afford them an income. The next year fifty-four families were assisted and a coöperative society was formed of fifteen of the younger members of the families, about 16 years old, who each contributed one franc a month. With this amount land was rented, seeds donated, and at the close of the year the members of the little society had by their labor earned enough money to have each a savings-bank book with 50 francs to his credit. Branches of the society are also established at Brussels, Besangon and Montreuil-sur-Mer, which report similar results. The amount of land allotted to each family is 8 verges or roods for a family of two, about 104 square meters, as a verge equals 13 square metres; 10 verges for three; 12 for four to six in the family, and above this up to 20 verges. Land is selected that the family could purchase later if desired. The society also takes under its moral protection and guidance any child inscribed at birth on its records and keeps it in view throughout its after life. Any one can join the society by paying 50 centimes a month.—*Bulletin de l'Acad. de Méd.*, November 24.

The Pasteur Institut Under Fire.—The *New York Medical Journal* quotes with gusto an accusation against the Parisian Institut, fathered by the *Paris Medical Journal*. The complainant, a veterinarian named Eloire of Amiens, made use of the virus of Dr. Danysz, an attaché of the Institut, who he said had "with the usual flourish of trumpets" put on the market said virus for the extermination of rats and mice. Eloire's trials were made "conscientiously," but were failures. He thereupon launches an attack upon the other products of the Institut designed to be used as preventives of diseases of animals which have proved equally inefficacious. This is not the first time, he says, that there has been reason to complain of the products of the establishment founded by the lamented Pasteur. The chicken-cholera "vaccine" was only the starting-point of gross errors, and they have returned to it. The rabbit cholera made a complete failure in Australia in the hands of Loir, a pupil and relation of the master, and last year the anthrax "vaccine" caused Eloire very serious disappointments, so that the mortality in the herd kept on after the inoculation quite the same as before it. Eloire promises to recur to this interesting matter at some future time. In the meantime he remarks that the preventive inoculation of rabies leaves so much to be desired that it is not worth while to insist on it. As for the Danysz viruses, he says, they are a continuance of the unfortunate series of uncontrolled preparations sold for their weight in gold and not worth a nail. He protests that he is far from denying the discoveries of the illustrious master of French science; on the contrary, he says he is one of the constant patrons of the "vaccine-mill," and it is precisely in this capacity that he finds the products of the institute too often lacking in the quality that one has the right to expect in articles obtained from such a source. The above is the gist of the attack upon the successors of Pasteur, and if we were to stretch a point in the use of critical language, we would say that it looks like "small business." However, even the best of us are not harmed by being stirred up occasionally; and perhaps Drs. Roux and Duclaux will find this counter-irritant of the Amiens veterinarian an incentive to even greater care, better etiquette. This appears to have been open to review to an avoidance of commercialism, in a word, to the purely scientific attitude of their illustrious teacher. Upon his memory none of these complainants have returned to throw any of their adverse or pessimistic observations; the work of Pasteur has thus far passed unchallenged by these writers to whom we have above referred.

Communications and Evidence as to Abortions.—The statutory law of Iowa is that: "No practicing attorney, counselor, physician, surgeon, minister of the gospel, or priest of any denom-

ination, shall be allowed in giving testimony to disclose any confidential communication properly entrusted to him in his professional capacity and necessary and proper to enable him to discharge the functions of his office according to the usual course of practice or discipline. Such prohibition shall not apply to cases where the party in whose favor the same are made waives the rights conferred." Under this provision, two or three important questions were raised in the case of *State v. Smith*, decided by the supreme court of Iowa, Oct. 9, 1896. The defendant, a lady physician, was being tried on a charge of having produced a miscarriage on a pregnant woman. After she had treated the case for nine or ten days, according to her testimony, to prevent a miscarriage, and finding the head of the fetus in the vagina, and believing that a miscarriage could not then be prevented and that the obstruction must be removed, and having no instruments, she sent for another physician, who refused to have anything to do with the case, advising that nature be allowed to take her course. This second physician was called as a witness and asked to state what he saw and did there in the presence of the defendant. The patient waived any question of privilege and consented that the testimony of the witness might be fully given. This the defendant objected to on the ground "that the things he saw and the conversation he had with this defendant, upon the occasion of the visit mentioned by him, were confidential and that the knowledge he obtained upon that occasion was obtained in his capacity of a physician." The communication in question was not from the patient, nor did the relation of physician and patient exist between the witness and her, says the supreme court, as he declined to have anything to do with the case. The prohibition of the statute, it therefore holds, was not in favor of the patient and she could not waive the same. The prohibition of the statute, the court goes on to state, is not limited to communications with the patient, but applies to all communications of the character indicated in the statute, from whatever source, and is surely applicable, in all its force, to communications between physicians attending or consulting in the same case. At the same time, the court holds that as it was evident from the undisputed facts and testimony of the physician called in that the communication of the defendant physician to him was for an unlawful purpose, and had for its object the commission of a crime, it was therefore not privileged under the statute. The court further holds, in this case, that as there is no provision in section 3864 of the Code for punishing a pregnant woman upon whom criminal miscarriage has been produced, as it has never been held in that State that she is subject to punishment, and as the courts of many of the States have held that she is not an accomplice, and that corroboration of her evidence is not required to sustain a conviction, it will not require such corroboration, and affirms a conviction of the defendant here.

The Case of Marin Le Marcis.—In the year 1601, before the high court of Normandy, at Rouen, one Marie le Marcis was charged with creating a scandal, in that having for twenty years been dressed as a woman, she had called herself Marie and wished to assume man's dress and to marry another woman, the widow Jeanne le Febvre. After hearing the depositions of the principals, the court ordered that le Marcis be examined by two surgeons; a second visit was made by a physician, an apothecary and two more surgeons. Both these committees reported that the individual in question was undoubtedly a woman, whereupon the court condemned Marie le Marcis to do penance barefoot before the Church of St. Savior and afterward to be burned alive. Le Marcis appealed from this sentence, so a third commission was formed, consisting of the "oldest doctors, surgeons and midwives exercising in that city." One of the six doctors, two surgeons and two midwives making up this committee was Maistre Jaques Duval, to

whom we owe an account of this *cause célèbre*. Jean Riolan, the celebrated anatomist and physician to Marie de Medicis, claimed that all dwarfs, giants and people with six fingers and others of nature's freaks should be put to death to improve the race. The majority of the committee seemed to be of his opinion, for Duval complains that they stood aloof with their hands in their pockets, while he carefully examined the case manually and visually. As a result of his examination he concluded he had to deal with a "gunanthrope" or as we call it, a hypospadiac. Although the rest of the commission dissented from Duval's views, the court of appeal sided with him and the prisoner was released. Maistre Duval having his attention attracted by this *lusus nature*, set to work to justify his opinion in this case and if possible to collect similar cases. After a decade of investigation he gave his researches to the world.¹ As might be expected from the times, the work is a queer mixture of credulity and erudition. A picture of the author, aged 56, is found in front, dressed in the quaint garb of his day. He has a benevolent face and a high forehead furrowed by thought, and although the artist has represented one eye as much lower than the other, we feel certain this is a mistake. After passing in review the anatomy of the male and female genitalia, with some very creditable cuts, the author treats of normal labor, the Cæsarean operation and care of the newborn child. The last third is taken up with an account of hermaphrodites, the man who had horns growing from his head, the man who was born with the golden tooth, etc., together with a detailed account of the le Marcis case, with his examination. The work is liberally garnished with quotations from Juvenal, Ovid, Martial, Horace and from contemporary writers, as Bauhin and Paré, which prove the author to have been a man of much learning. Maistre Duval finishes the work by casting the horoscope of Marin le Marcis, who was born Oct. 15, 1579, and proves to his own satisfaction that the conjunction of the planets at his birth was under the influence of the malign Mercury and the sad Saturn, but that joyous Venus finally rescued him. This was not M. Duval's first incursion into the field of letters, for he had previously published two works.² His account of the Marcis case led to a controversy with Riolan and to a fourth work.³ One wonders what was the after-history of Marin and Jeanne, whether they were married and lived happily ever afterward, or not. All honor to Maistre Jaques Duval, Escuyer, Seigneur d'Ectomare and Houel, who rescued a fellow-man from premature cremation and has transmitted an account of his deed to posterity.

Changes in Maryland Law as to Practice of Medicine.—Sections 54 and 56 of Article 43 of the Maryland Code of Public General Laws, entitled "Health," sub-title "Practitioners of Medicine," are amended by chapter 194 of the Laws of 1896, which also adds four new sections, numbered 61, 62, 63 and 64, to said Article. Section 54, as amended, provides that every person who was practicing medicine in the State on or before June 1, 1892, shall be entitled to be registered as a physician or surgeon, or both, upon making application to the president of either board of State medical examiners, the application to be in writing, sworn to, and state that the applicant was a duly qualified, lawful practitioner of medicine, in good standing, actually engaged in the practice of such profession in the State, on or before such date. Any president of such board, to whom an application is addressed, may in his discretion make inquiry and examine witnesses under oath as to the truth of the statements contained in such application, for a permit to be registered; and if the president of either of such boards of

³ Réponse du Discours fait par le Sieur Riolan contre l'histoire de l'Hermaphrodit de Rouen, 1615.

medical examiners shall act upon such application, and shall refuse the same, then no president of the other of such boards shall entertain or act upon any application of such applicant for such permit. A permit is to be signed by the president and countersigned by the secretary of the board, and then registered by the clerk of the county where the applicant resides, or with the clerk of the circuit court of Baltimore, if he resides in that city, a certified copy of registration under the seal of the court being made legal evidence of such registration. But the provisions of this act are not to apply to those practicing medicine in the State prior to June, 1892, and who registered prior to July, 1894. Section 56 is amended by making it apply only to physicians who "shall hereafter come" into the State; by omitting the condition that they shall "have been practitioners of medicine or surgery for more than ten years prior to the date of the application;" and by extending the application of the section to any physicians or surgeons from other States "having a certificate or license from a board of medical examiners of any State where the requirements for practice are equal to those required by the board named in this article." Section 61 provides that any citizen of Maryland having information which causes him to believe that any person has been heretofore wrongfully and improperly registered as physician or surgeon, or both, may petition to the court wherein such registration was made, that the name of such person be stricken from the registry of physicians. Upon the filing of such petition, the court or one of the judges thereof shall pass an order requiring the person therein mentioned to answer the same under oath, on or before a date to be named within thirty days from the date of such order, and to show cause, if any there be, why the prayer of the petition shall not be granted. If no answer is made within the time, or one adjudged insufficient is made, the court shall order the name stricken from the registry. But if the allegations of the petition are properly denied, the issue thus raised shall be heard and determined by the court, subject to the right of either party to demand a jury trial. Moreover, the decision upon such petition shall have no force and effect in any criminal prosecution under this article. Section 62 enacts that the term, "Practicing Medicine or a Practitioner of Medicine," when used with respect to the qualifications of a practitioner or applicant to be registered under this article, shall be construed to mean the "practice of medicine" as a profession or means of livelihood, and by one duly licensed or registered. To this is added the very confusing sentence: "If a license or register by law at the time when such practice is alleged or claimed, or by one otherwise duly qualified to practice medicine, if other qualifications were required by law at such date." Perhaps it was intended to follow after a comma, "(if a license or registration was required) by law at the time when, etc." Section 63 makes it the duty of the secretary of either or both of the State boards of medical examiners to inquire into all violations of law under this article, and to institute all proceedings, or prosecutions thereof, and all expenses incurred by any secretary of either of such boards hereunder, shall be paid out of the funds acquired by or belonging to such boards respectively. Section 64 provides that the said board of medical examiners shall have full control over the expenditures and disposition of the funds collected from the fees and charges authorized to be made under the terms of this article; and shall fix and allow such compensation as they may deem proper for service rendered in the performance of the duties required by this article of members of said board or others, with the full power also to allow and discharge all proper expenses of said board, and any surplus to dispose of as said board may deem for the advantage of the practice of medicine in the State.

Washington.

MEDICAL SOCIETY.—At the meeting of the Medical Society held on the 16th instant the President, Dr. Samuel C. Busey, read his annual address entitled "1896 an Epoch in the History of the Medical Society of the District of Columbia." Dr. Busey made mention of the important medical legislation which had been secured through Congress, mentioning specially the medical practice act, the act regulating the incorporation of

medical colleges in the District, and the act relating to the testimony of physicians in courts of law in the District. He also touched on the important legislation in matters now pending before Congress affecting the District of Columbia, viz.: The omnibus sewer bill, the reclamation of the extensive flats about the water course, which at present causes so much preventable disease, and the creation and location of a contagious disease hospital. He further recommended the publication at Washington of a medical journal which would show the immense amount of valuable medical literary work done here in the different societies and medical and scientific departments of the local and general governments. Dr. Busey's untiring efforts in the interest of the Society and its members has made the Society the grand Society which it is today. The annual election of officers takes place on Jan. 4, 1897, and the indications are that Dr. Busey will be reelected President by acclamation. He has already served the Society as its President four terms.

DENTAL SOCIETY BANQUET.—The Washington City Dental Society had its thirteenth annual meeting and banquet on the 22d instant.

WASHINGTON OBSTETRICAL AND GYNECOLOGICAL SOCIETY.—The 255th meeting of the Society was held on the 18th instant at the residence of Dr. Wm. P. Corr. Dr. H. B. Deale read the paper of the evening, entitled "Intercurrent Infectious Diseases of Pregnancy."

Detroit.

DETROIT MEDICAL AND LIBRARY ASSOCIATION.—At the regular meeting of this association, Monday, December 14, Dr. E. Christian, Superintendent of the Pontiac Asylum, read a paper on "Bases for the Study of the Insanities," in which he said that there were four avenues open to us at the present day through which we may approach the study of the insanities: 1, the doctrine of localization of functions in the cerebral cortex; 2, the doctrine of three evolutionary levels of the C. N. S. and the application of the doctrine of evolution and dissolution of functions according to certain definite laws; 3, the doctrine of the "neuron," the unit of nervous and psychic function; and 4, the method of comparative and sociologic investigations, by which light is chiefly thrown upon the various types of degeneration. The first and last methods are well known to most students. A brief study of the second and third will be of interest. In lower animal life, the spinal system includes the gray matter of the spinal cord as far forward as the oculomotor nucleus. Next in order of evolution lie the middle centers, more definite in function than in anatomic limits. They are also sensori motor. On the motor side, they include the two central convolutions, extending along the longitudinal fissure above as well, and include the marginal convolution and also the striate bodies. On their sensory side, the greater part of the temporo-sphenoidal lobe, the gyrus fornicatus and the inferior parietal lobule are offered as fairly well representing the area receiving sensory impressions. Activities are here more complex, less organized and less automatic. The highest centers are situated in the pre-frontal and occipital regions. The activities here are the least automatic. The elements are still sensori-motor, but here we find the seat of consciousness. We have thus divided the nervous system of the animal kingdom into a lowest and highest middle center. Hughlings-Jackson says insanities are dissolutions of these different levels. Using the effect of alcohol as a means, we have first a loss of certain faculties. Later, when dissolution proceeds, the pronounced characteristics of the individual are altered, even so far as to become contradictory. Such results are attributed not to stimulation, but to the suppression of highest levels and the uncovering of levels more and more automatic, now free from inhibition of higher levels. In the case of a mental action accompanying epileptic paroxysms, the same phenomena of "letting go" of lower levels on account of more or less dissolution of higher levels are recognized as

in existence. Delusions in regard to self, which arise in mania or melancholia, are explained on the theory that this dissolution of a higher level does not go on uniformly, but that islets are left here and there of uncontrolled activity, comparable to those which cause dreams in sleep. Neuron is a unit of psychic and nervous force. With the first rudiments of the nervous system we find these sensory and motor neurons. With the acme in the scale of the nervous system, we have an intermediary system of the neurons develop. Thus we have three elementary neurons, the sensory, the motor and the connective. Eight types of nerve cells are recognized in the cortex. The cells of the gray matter which were formerly divided into six layers, are now divided into but four, the molecular layer, the ambiguous layer, the long pyramidal and the polymorphic. The pyramidal and ambiguous cells are the oldest in the process of the evolution of the cerebral cortex. In the newborn and young, and while the individual cells of the various cortical layers have already reached the completion of their numerical growth the individual neuron has by no means reached the acme of its evolution. The cell increases in size and processes and also in amount and complexity of its anatomico-physiologic connections. The material pathologic bases of the insanities furnished us by the neuron theory arrange themselves into two groups; the first arising out of alterations or defect in the early evolutions in brain and mind, such as has just been referred to; second, lesions in the protective or nutritive mechanisms. In concluding his researches, our author says: The whole of the above body of neurologic and pathologic evidence together with recent experimental work, show that in the early stages of the insanities there is a profound nutritive and dynamic failure of the nerve elements of the brain, which finds expression in the insanias, the melancholias and the commencing loss of memory, easily induced mental fatigue; and that the pathologic facts ascertained, in so far as they afford us any light, force on us the conviction that we are dealing with serious nutritive and dynamic changes in a central nervous organ; a conviction which must profoundly influence the clinical and practical treatment of insanity in the future more than it has in the past.

THE MT. CLEMENS HOME FOR INVALIDS.

THE MT. CLEMENS HOME FOR MEDICAL AND SURGICAL INVALIDS.—The property for the erection of a hospital for the treatment of such cases as go to Mt. Clemens and who need medical or surgical treatment, for which the hotels do not supply the necessary facilities, was bought about four years ago by Dr. C. C. Yemans of Detroit. The site is a very desirable one, being healthy, well shaded, well watered and with pure drinking water of a uniform temperature the year round. Work was commenced late in the summer for a building 50x200 feet, two stories in height and so constructed as to give the best possible service with the least running expense. The foundation has now been completed and the executive building is ready for occupancy. The building includes exercise rooms for gymnasium and other amusements for the separate

sexes. Not long ago it became apparent that there was not sufficient capacity in the State for the care of nervous diseases, and it was therefore determined to finish the building with a view to caring for such cases. The site consists of eight acres of land. It is healthful, well drained and well calculated for a launch for all kind of exercise and sport, such as football, tennis, etc., within the bounds of its own property. The location is a height on North Avenue, just far enough from the center of business to be quiet and secluded. The building is on the old colonial style of architecture, presenting a home-like and beautiful outline, the whole outfit costing from \$30,000 to \$32,000. It is expected that the building will be completed and ready for occupancy not later than June 1, 1897. Up to the present time the enterprise has been carried on by Drs. Donald McLean and Yemans. It will now become a stock concern at \$40,000 capitalization. It is thought no better location could be selected than Mt. Clemens, especially since it is connected with Detroit by rapid railway, bringing the hospital and the city of Detroit within an hour and a half's time of each other. Mt. Clemens is known to be one of the prominent watering places in America, having a full and elegant service of bath houses and hotels. This enterprise is entered into for the purpose of establishing a pure and simple hospital, with no effort on the part of those interested to supply mineral baths, trusting to those already there for any such needed auxiliary, as they are equal to any bath houses in the world. The hotels are adequate for the comfort and convenience of all who need only hotel service. The hospital is soliciting the patronage of those who are unable to get the required service at the hotels.

THE WEEKLY REPORT OF THE HEALTH OFFICE show 97 deaths last week, of which 48 were children under 5 years of age. There were 53 new cases of diphtheria, with 47 now sick. There are at present 39 cases of scarlet fever and 60 cases of measles. There were 14 deaths from diphtheria. Births during the week 92, of which 45 were males.

THE WAYNE COUNTY MEDICAL SOCIETY, at its regular meeting, Thursday, December 17, listened to an interesting paper by Dr. Charles D. Aaron, entitled "Chronic Dyspepsia and Chronic Catarrh of the Stomach," it being one of the series that the Doctor had read before the different medical societies of the city.

THE PUBLIC SERVICE.

Army Changes. Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from Dec. 12 to 26, 1896.

Major Clarence Ewen, Surgeon, extension of leave of absence granted on account of disability is still further extended until Jan. 24, 1897, on account of disability.

First Lieut. Benjamin Brooke, Asst. Surgeon (Ft. Thomas, Ky.), leave of absence granted for seven days is extended twenty-three days.

Change of Address.

Bonner, Horace, from 11 S. Ludlow St. to 119 S. Ludlow St., Dayton, O.
Kellogg, G. M., from Chicago to Keokuk, Iowa.
Norton, J. J., from Monroe City, Mo., to Biloxi, Miss.

No. 2.

ORIGINAL ARTICLES.

COMPULSORY VACCINATION; SHOULD IT BE ENFORCED BY LAW?

Read before the New York Medico-Legal Society, November, 1896.

BY CLARK BELL, Esq., LL.D.

PRESIDENT MEDICO-LEGAL CONGRESS,
NEW YORK.

[From advance sheets Medico-Legal Journal.]

This subject came recently before the Medico-Legal Society in the city of New York, introduced by a paper presented by Dr. Montague R. Levenson, in which his position was mainly an assault upon vaccination itself.

Most laymen and the majority of the medical profession have been educated to accept vaccination as a reliable, safe, and the only preventive remedy, to insure against smallpox, and without especial examination the world has accepted the remedy discovered by Jenner, whose centennial has just been celebrated by all the world, even in Japan.

It was not considered quite the proper way to meet the issue in a controversy pro and con, as to the merits of vaccination for this reason, and the issue was broadened and widened so as to embrace this issue:

"Conceding the utility and efficacy of vaccination as a preventive against smallpox should it be made compulsory?"

Owing to the recent agitation in England as to compulsory vaccination and the recent adverse report of the Royal Commission and to the fact that it was alleged to be in contemplation to engraft the idea of compulsory vaccination into the new charter now being formed for "Greater New York," I decided to take the views of some of those best calculated to know the facts germane to such a discussion; and being quite ignorant myself of how the lymph now in general use was obtained, and what supervision or precautions were observed as to its genuineness and purity, I addressed the following letter to boards of health in all the neighboring States and cities and to men eminent in the profession, as to the issues, and especially as to the subject of compulsory vaccination *per se*:

MEDICO-LEGAL SOCIETY,
SECRETARY'S OFFICE, No. 39 BROADWAY,
NEW YORK, Nov. 14, 1896.

My Dear Sir:—I have the honor to enclose a notice of our next meeting and dinner to be held on the 18th of November, instant, and would be glad to see you present and to take part in the discussion of the fourth question on the programme.

4. Conceding the utility and efficacy of vaccination as a preventive against smallpox should it be made compulsory?

May I also ask you to advise me in time for use on that occasion if possible, if not as soon as you can, upon the following additional subjects:

1. What lymph do you use in vaccination and how obtained?
2. Is that lymph obtained by inoculating the calf with the virus of smallpox or from any lymph thus originally obtained?
3. With precisely what lymph is the calf vaccinated and how was that lymph originally obtained for use upon the calf?

4. What supervision is exercised by the board of health, or any public official, over the character, quality and manufacture of the lymph employed in vaccinating the calf, as to its efficiency and genuineness?

5. What security have you that the lymph you use, or that they employ on the calf, is pure?

An early reply will be esteemed a favor,

CLARK BELL.

I submit some of the replies I have received and which were most of them submitted to the Medico-Legal Society in that discussion.

George B. Fowler, M. D., Health Commissioner of New York City, replied to the question as follows in a letter to the Secretary:

My Dear Sir:—Your communication of the 30th, relative to my replying to a prospective paper before the Medico-Legal Society, by Dr. M. R. Levenson, in which he assails "compulsory vaccination," is at hand. This board is not in favor of "compulsory vaccination" and never has been. It is acting under the State laws when it assists the board of education in securing the vaccination of pupils and teachers. So thoroughly has this coöperation been carried out that in the last ten years, during which three epidemics of smallpox have occurred in this city, not a single pupil or teacher connected with the public schools has been reported to this department as suffering with smallpox. The reason the board of health does not believe in compulsory vaccination is because it is believed that such a statute would result in antagonism to the work, which would defeat the object it has always secured in the way of gratuitous and voluntary vaccination and the comparative immunity from smallpox for which this city is noted.

I therefore do not see any reason why I should defend the position that Dr. Levenson proposes to take in this paper.

Yours very truly,

GEORGE B. FOWLER, Commissioner.

Dr. Moreau Morris, M.D., Health Department New York City, replied as follows:

Dear Sir:—To the question, "Compulsory vaccination, should it be enforced by law?" I would respectfully answer, that for a general State law, negatively, but for local purposes in cities or villages having a population of 1,000 or over, where large congregations of school children especially congregate, there should be compulsory vaccination as a precedent to school admission.

The experience of other countries and in this city in suppressing the spread of smallpox, by carefully selected vaccine virus introduced into the human system by proper antiseptic means, seems to set the seal of its legitimacy for public policy and universal protection beyond all question. The public protection is paramount to any and all private interests.

Respectfully yours,
MOREAU MORRIS, M.D.,

Prof. Eugene Foster, Dean of the Faculty of the College of Georgia, replied as follows:

My Dear Sir:—Pray pardon my failure to earlier make reply to your letters of September 28 and October 1. Great press of business, together with several absences from the city, has prevented earlier attention to the matter. I very sincerely appreciate the compliment extended in asking me to submit a paper on vaccination to be read on the third Wednesday of November in reply to one to be presented by Dr. Montague R. Levenson. I could not do justice to the subject of vaccination in "a short paper." I have written exhaustively upon this subject in my article on "The Statistic Evidences of the Value of Vaccination," which was presented at the Jenner Centennial at the recent meeting of the AMERICAN MEDICAL ASSOCIATION in Atlanta. This paper you will find in a series of articles which were published in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION. If this paper does not produce sufficient evidence to satisfy a reasoning man as to the safety and

efficiency of vaccination I could not consent to waste time in arguing the question with him. In my positions on the question of vaccination, I am sustained by almost every reputable medical man in the civilized world. I do not attempt to argue the good policy of compulsory vaccination; this is a question entirely separate and distinct from its efficiency and safety and many of the best members of the medical profession seriously doubt, if indeed they are not actually opposed to, compulsory vaccination. I have had the article above referred to reprinted and will in a short time send you a copy of it if you desire me to do so.

I very greatly regret that I did not know that the copy of the Berlin Report of the Consul General, referred to by you, was not preserved by me, that is, the original received from Surgeon General Sternberg; it was included among the manuscript turned over to the printer with the balance of my article read at the Jenner Centennial.

I will be very glad to have you send me Dr. Levenson's article, as promised in yours of October 1, for the reason that I do not now receive the transactions of the Medico-Legal Society as I formerly did. I am

Very truly yours,
EUGENE FOSTER.

Col. W. P. Prentice, counsel for the health authority, replied as follows:

Dear Sir:—I have the honor to acknowledge your letter of the 2nd inst., with its invitation "to prepare" for the meeting of the Medico-Legal Society, on November 18, my views upon the following theme, "Conceding the utility and value of vaccination as a preventive, should it be made compulsory by law."

There can not now be said to be any open question subject to concession in the first clause of your theme, in my opinion; but as the Register of Scotland reported in 1874, "there is but little of that unreasonable opposition to the practice of vaccination" remaining, and the recent report of the Parliamentary Commission of England, of which Lord Herschell was the chairman, following similar reports in Germany and other States, closes the discussion for the present, exhibiting the impracticability of opposition. This result adds strength to the argument for the indirect methods of securing vaccination. I have elsewhere in my book on "Police Powers," discussed this question more at large, and have given reference to many cases, including those which have maintained personal liberty where the public health was not directly endangered. At page 132 this statement was made: "Compulsory vaccination has been instituted in several countries and by the laws in several States in respect to minors. City ordinances regulate it, but the indirect method of excluding children not vaccinated from schools and factories, or in case of immigrants, insisting upon quarantine, and the offer of free vaccination, with the constant supervision of the health officers, are more effective."

This opinion I still maintain, and in common with many others, have not ceased to regret the unwise proceedings which have been occasionally undertaken, in defense of health and sanitary laws, weakening their proper force. The court of appeals' decision in 1895, matter of Smith, (146 N. Y., 68) brings up the sound rule to govern such cases, viz.: That "where a right to restrain the citizen in his personal liberty, or to interfere with his pursuit of a lawful avocation is claimed, to sustain the claim it must appear very clearly, not only that the right has been conferred by law, but that the facts exist justifying its exercise. The validity of the law is not so much called into question as the right to enforce its provisions," the opinion says, and again uses words which I would adopt. "I think no one will dispute the right of the legislature to enact such measures as will protect all persons from the impending calamity of a pestilence, and to vest in local authorities such comprehensive powers as will enable them to act competently and effectively." Little can be added to the lesson of this judgment, and I believe we have at present sufficient laws, if they are duly administered and properly enforced.

I remain with great respect,
Yours truly,
W. P. PRENTICE.

Sir Frederick Bateman, of Norwich, England, writes:

UPPER AND GILES STREET, NORWICH, NOV. 4, 1896.

My Dear Sir:—You ask my views on compulsory vaccination. It so happens that this question has much engaged my attention and I send you a pamphlet in which, at page 5, you will see my mature views on this subject. With kind regards,
Yours faithfully,
FREDERICK BATEMAN.

The pamphlet referred to is the annual report of the Asylum Union for 1895, by Sir Frederick Bate-

man, which can not, for want of space, be given, but the summary will be of great interest, which is as follows:

I hold that any individual who from his obstinacy declines to avail himself of the protective influence of vaccination, and thus risks not only his own life, but that of his innocent neighbor, is just as much liable, or ought to be, to punishment by law, as he who knocks his neighbor down, or picks his pocket; and I maintain it is a wicked crime for persons in the broad daylight of the nineteenth century, from obstinacy or ignorance, to refrain from being vaccinated and from having their families similarly protected.

As hypotheses and mere opinions have but little influence, I wish to support these remarks by some documentary evidence in reference to the results of vaccination. During a period of sixteen years, 5,797 cases of smallpox were admitted into the smallpox hospital at Highgate. Of this number 2,654, or nearly one-half, were unprotected by vaccination; of these, 996 died, being 35.5 per cent. Now just mark the reverse; of those properly vaccinated—and I lay great stress on the word "properly," because otherwise these statistics might be pulled to pieces—just under 1 per cent. died; so here you have 35.5 per cent. dying of the unvaccinated, and less than 1 per cent. of the vaccinated.

The latest scientific views as to the value of vaccination may thus be summarized:

1. Vaccination properly performed in infancy, affords an almost complete protection against smallpox up to the period of puberty; but it is important to bear in mind that vaccination is a surgical operation, and should be performed in a satisfactory and careful manner; for many of the supposed failures are in reality due to the careless way in which the operation has been undertaken.

2. That in the few instances in which vaccination may fail to impart absolute protection against the smallpox, it nevertheless, in the majority of instances, modifies the course of the disease, and renders it less fatal, as was strikingly exemplified in the outbreak at Hackford.

3. That at puberty, re-vaccination is strongly to be recommended, and that, as a rule, such re-vaccinated persons may be regarded as permanently protected, although in an epidemic of smallpox, it may be a wise precautionary measure to submit them again to the process of vaccination.

The importance of the subject, and the fact of the recent outbreak of smallpox in this Union, must be my excuse for dwelling at such length on the efficacy of vaccination. The arguments for the necessity of it have been much strengthened by the remarkable discoveries recently made in connection with bacteriology and the antitoxin treatment of disease, discoveries which have been hailed with acclamation in all parts of the civilized world; and I unhesitatingly and emphatically assert that the sanitary authorities will be neglecting their duty, in the face of all this, if they do not resolutely and unflinchingly put into operation the compulsory clauses of the Vaccination Acts.

C. S. Lindsley, M.D., secretary of the State Board of Health of Connecticut, replied as follows.

Dear Sir:—In your courteous invitation to me, on September 1, to prepare a paper "in support of vaccination," there is not a word about "compulsory." In your favor of September 10, you speak of my proposed paper, "defending compulsory vaccination." Defending vaccination and defending compulsory vaccination are two quite different things. I am not an advocate of compulsory vaccination. I am positively opposed to it, but wholly on the ground of expediency. The people of this country are too thoroughly imbued with a sense of personal independence to submit patiently to personal compulsion. The attempt would excite hostility to vaccination that does not exist at present, and would hinder rather than promote the cause of vaccination.

I have received this morning another notice, with an invitation which I regret to say I shall not be able to accept, by reason of other engagements.

Lack of time obliges me to reply briefly to your numerous questions, although they cover enough for a small volume. I will answer them as you have numbered them.

- Q. 1. Ans. Sometimes humanized and sometimes bovine virus.
Q. 2. Ans. No.
Q. 3. Ans. From a previously vaccinated calf, and originally from a cow or heifer with vaccine disease.
Q. 4. Ans. In most States there is no legalized supervision.
Q. 5. Ans. My only security is the known care and precaution which are observed by the best producers, except when I

use humanized lymph, and then my own personal knowledge of the health of the subject from which it is taken.

Very respectfully, C. A. LINDSLEY.

Dr. Samuel W. Abbott, secretary Massachusetts State Board of Health, replies:

Dear Sir:—In reply to your kind invitation to be present next Wednesday, I should like very much to be there, but it is impossible.

In reply to your questions:

1. I invariably use vaccine lymph from the calf. There is no objection, however, to the use of human lymph, provided you know that it comes from a healthy source.

2. The original source of the disease in the cow is undoubtedly some exposure to smallpox infection. Experiment has definitely settled this point. The term "spontaneous cowpox" has often been used in this country and abroad in connection with this subject. No progressive physician, however, at the present day, would for a moment admit the use of such a term. Infectious diseases have an origin, and that origin is an infectious disease of the same kind. As a matter of fact, the term is simply used as a catch-penny dodge for lining the pockets of some particular producer of vaccine lymph. I have seen and examined very many cases of cowpox in the cow occurring in large dairies, but these invariably occurred during the progress of epidemics of smallpox, such as those of 1880, 1872 and previous years.

3. Calves are vaccinated either with lymph from other calves or with lymph from healthy children. The latter method is quite as efficient as the former, and is recommended by the very highest authorities in Germany, where this whole subject has been treated in the most scientific manner.

4. Very little supervision is exercised in this country over the production of vaccine lymph. The State Board of Health of Minnesota maintains a small plant and produces lymph of a reliable quality. In my opinion, all vaccine production should be under the supervision either of State or National authorities.

5. The only security now given is the guarantee of the producer.

Finally, the principal fault in vaccine production in this country is due to the fact that the whole question has been treated commercially instead of scientifically. It is, however, pleasing to know that the movement is tending in the right direction.

Recent inspection of vaccine establishments has undoubtedly effected considerable reform, but there is abundant room for more. Too much reliance should not be placed upon bacteriologic inspection of vaccine products made upon a few specimens. No good sanitarian is willing to pronounce upon the quality of a sample of water from the chemist analysis alone, but finds it necessary to have a thorough knowledge of all the surrounding circumstances. The same is true in regard to vaccine production. A well managed establishment under careful supervision, and conducted upon the best principles, may be depended upon to furnish a good product.

The best argument for compulsory vaccination is the present condition of Germany, which has been practically free from smallpox for the past twenty years, in consequence of thorough enforcement of the law. Most of the deaths in Germany from smallpox, in three years, have been those of recent unvaccinated immigrants from Russia, France or Italy.

The Imperial Board of Health of Germany has just issued a publication, entitled "Smallpox and Vaccination," which presents very fully the history of the subject, together with much that is valuable with reference to present conditions in that country. Many conditions are presented which do not reflect creditably upon the condition of the neighboring countries, and show that the prevalence of smallpox in these communities is inversely as the thorough manner in which vaccination and re-vaccination are conducted.

It appears from this document that, in the five years (1889-1893), the death rate from smallpox in the German Empire was only 2.3 in each million inhabitants, while in the neighboring countries it was as follows:

In France	147.6	per million.
In Belgium	252.9	"
In Austria	313.3	"
In Russia	836.4	"

Or, in other words, had the same rates of mortality from smallpox prevailed in Germany as existed in each of these four countries, there would have been a loss by death from smallpox, respectively, of 7,321, 12,584, 15,558 or 41,584, according to the country with which the comparison is made. These figures speak for themselves. It is no wonder that the compiler, in

closing the volume, pays a glowing tribute to the memory of Jenner and expresses the hope that "the number of those who look back upon this day (May 14, 1796), with thankful hearts, may continually increase." Yours respectfully,

SAMUEL W. ABBOTT.

Benj. F. Lee, M.D., secretary State Board of Health of Pennsylvania, replies:

Dear Sir:—The matter of which you request information from me to be used in the discussion at the meeting November 18, is of so much interest and importance that I take the liberty of replying to your communication. As a portion of my answer, I send you a copy of *Public Health* for July last, and refer you especially to page 145, on which, and the six pages following, you will find a very full statement of the methods pursued at the Lancaster vaccine farm, the product of which I use exclusively and do not hesitate to recommend.

With regard to questions 4 and 5, I would say, that the State Board of Health makes frequent inspections of this establishment at unexpected times, and that both the precautions taken and the result of the bacteriologic tests, as well as the clinical evidence, convinced me that pure lymph is used in propagation and is dispensed from this establishment. I have the honor to be,

Yours very truly, BENJ. LEE.

The extract to which Dr. Lee refers, is from the report made June 15, 1895, by Robert L. Pittfield, M.D., Assistant Bacteriologist Pa. State Board of Health to the committee on preventable diseases of that Board, published in the new journal called *Public Health*, vol. 1, No. 3, p. 145, and relates to the Lancaster County Vaccine Farms, of Marietta, Pa. A description of the method employed in the vaccination of the calf is given in detail as follows:

11. Vaccination of animal.

a. Description of method.—The animal is strapped to the V. piece with girths, and then is swung over on back, the spinal column does not rest on the table, a space in the cushion accommodating it.

b. Point of selection for vaccination.—The point selected is the scutcheon over the biceps muscle and sometimes anterior to the udder and on the back, but it is considered best by Dr. Alexander to use the scutcheon.

c. Area of scarification.—The area of scarification is about the size of a half dollar, and six to eight are made on each leg.

d. How scarified.—The animal is carefully washed with bichlorid solution, twice shaved and washed, dried with a clean towel, and then scarified with knife previously sterilized. The lymph from the spades is carefully rubbed in.

e. What preparation given the hands. Clothing of operator.—Operator washes his hands in bichlorid, and is dressed in a clean suit of white duck, and every precaution is taken by the operator to keep his person clean.

f. Character of seed used.—The seed used is preserved on spade points in a refrigerator, where all other vaccine matter is preserved.

12. Maturity of vesicle and time of removal.

a. Temperature at highest.—102½ degrees to 104 degrees F., taken twice daily.

b. Removal of lymph.—The operator is guided by the areola about the vesicle, as to the proper time to remove the lymph, also by the temperature. The proper time for removing the lymph is from 5-7 days, depending upon circumstances. The crust is hard to keep in place and is convex rather than concave as in the human subject.

13. Food and water.

a. Regarded by operator.—These play a very important part in the development of the disease. If the least musty food or unpalatable water be given, the animal may refuse to eat or drink for from twelve to twenty-four hours. This will frequently result in an abortive condition of the vesicle. Plenty of good and fresh water is absolutely necessary if you desire a lymph that will give the greatest perfection of development and the least inflammatory action.

b. Character of food used.—Corn chop and bran (half of each by weight), mixed with cut hay in a concrete mixing box, which can be kept clean and will not sour readily, have given them the best results, next to forage crops, of which they use cow-peas and oats, green wheat and rye, clovers, Hungarian millet, and fodder corn. Food from a silo they are unable to use, as it requires from two to three weeks to get the animal accustomed to it, and changing them every thirty days renders it to them an impossible food.

c. Water supply.—Water works, having three large reser-

voirs arched over in the hill-side and supplied with water from two sources; one from the roof water and the other forced by a wind pump from a well 77 feet deep; this water is river water filtered through a sandy loam. All the water from these reservoirs, used for watering stock, operating uses and cleaning purposes, is first filtered through brick, then through Pasteur plates arranged in reservoirs. These reservoirs are located sufficiently high to enable the tapping of water throughout the establishment. They are also connected with the town supply. The cattle are watered by turning water into their troughs, which are lined with galvanized iron. This insures them a much more ample supply than the use of buckets in the hands of employes.

14. Preparation of vesicle.—This is done on the 7th day generally, care by means of a knife.

a. Cleansed.—The parts around the vesicle are cleansed with a solution of bichlorid and are then washed with water.

b. Removal of crust.—This is accomplished with great care by means of a knife, and the parts under this are sponged with sterile water and sponge until all the pus has been washed away.

c. Care taken with vesicle.—The vesicle is carefully cleansed and the lymph, as it exudes, is gathered from the base of the vesicle by means of sterile brushes and applied to the points. The points are not touched by the operator with his hands or person at any time.

d. Application of lymph to points or tubes.—The lymph, by means of brushes, is painted on the points held in wooden clamps holding 50 each.

e. Collection and preservation of seed.—This is collected upon spade points and preserved in refrigerator.

f. Fluid lymph.—Is collected from the cleansed vesicle and mixed in 30 per cent. to 50 per cent. glycerin. It is collected by a scalpel from the vesicle and flows from it into a receptacle previously sterilized. It is then run into capillary tubes.

15. Care of points and tubes.

a. Preparation of naked points.—These are soaked in alcohol and placed on a screen and then a lighted match ignites all the alcohol. They are then placed in a hot air sterilizer for an hour at 150 degrees C. This double procedure is unnecessary.

b. Sterilization of points and tubes.—This is accomplished in a hot air sterilizer.

c. Packing of points.—After the points are inoculated they are dropped from the frames into clean jars, and from these they are packed into glass bottles. There is a minimum amount of handling with the fingers in this operation.

d. Crusts are sold but not advertised.

e. Lymph tubes sufficient for one vaccination are filled by capillary attraction. Other tubes, containing enough for 10, 20 or 50 vaccinations, are filled and corked at one end, the other end is drawn to a point, the lymph is caused to exude by pressing in the cork.

16. Bacteriologic control.—No bacteriologic control is given, but bacteriologic principles bearing upon aseptic sterilization are carefully followed out. Great care is evinced in this direction and much effort has been spent to render the product as clean and aseptic as possible.

Bacteriologic examination of vaccine products.—In common with these of other places, those of Lancaster County Farms were purchased in open market and submitted to the same method of analysis previously described.

Number of bacteria on vaccine points and in fluid lymph:

Product	Gelatin	Agar at 75 degrees
One point	175	
One point		175
One drop fluid lymph	0	

Summary.—This is an admirable establishment in every particular. No objections could be found in so far as hygienic arrangements go; the farm is thoroughly drained and the interior of the buildings scrupulously clean. The animals seemed well fed and of excellent breeds. The habitual and thorough testing with tuberculin in every animal, in conjunction with the physical examination, is a step in the right direction. It seems a needless precaution to filter water, and to burn off the points before sterilizing them. The excellent bacteriologic showing of the product, purchased with the others in a large drug store, is an index to the hygienic condition of the cattle and the pains taken in removing the lymph to keep it aseptic.

The report of Dr. Robert L. Pittfield from which I make some extracts of matters germane to this discussion in addition to that part of it cited by Dr. Lee, is of great interest. I quote from Dr. Pittfield's report to the Pennsylvania State Board:

"There are a number of problems to be discussed in dwelling on the propagation of vaccine lymph. These concern the elim-

ination of the diseased cattle from the healthy; the sterilization of the points, hands, instruments, etc.; the care of the vesicle; the preparation of the skin; and the aseptic removal of the lymph.

At but two of the stations visited was tuberculin used; in two, the animal was killed and examined before the lymph was sold. The possibility of infecting points with anthrax bacilli exists, since in many localities cattle are often affected with this disease. At no establishment could we learn of any precautions against such a possibility. In many establishments malignant edema and tetanus bacilli might find their way to the vesicle and thence to the points and tubes, because dust in large quantities abounds in the incubating stables. This is especially true in those farms where the hayloft is directly above the stables, as dust from hay and manure is well known to contain these germs, and such dust could easily filter down directly upon the vesicles. Cases of gangrene and tetanus following vaccination have been reported.

In many places simple cleanliness is sadly neglected; but in others, however, the principles of asepsis and antiseptics are rigidly observed, and lymph from such establishments should be used in preference. Sterilization of the hands, instruments and apparel is a great advance in the right direction, as is a similar treatment of the points and tubes.

The sale of crusts, because of the pus and dust contained in them, should be forbidden by law. Some operators not only render the fresh skin aseptic by scrubbing and antiseptics, but also carefully, clean the base of the vesicle, after the removal of the crust, with antiseptics. If this does not interfere with the taking qualities of the lymph, it is an excellent procedure. In some places we found that the pus layer, for such it is, was not regarded by the operators as pus. In fact, some regard it as a particularly strong lymph and charge their points with it. Such points should not be used. Microscopic examination of this substance reveals pus organisms in large quantities, also typical pus cells.

Points should be placed in frames and carefully sterilized, and after this they should not be handled at all. The application of the lymph to the points by means of a sterile brush is an excellent procedure. It is not only economical, in so far as time and saving of lymph go, but it is also scientific. The individual application of the point to the vesicle irritates it. The point is likely to be contaminated by the fingers, and the drying of these points on dusty, unsterile plates is antiquated and unscientific."

The following is my view of the subject as expressed at the meeting alluded to:

The lateness of the hour, and the presence of other duties which are imperative upon us in completing nominations for the annual election, compel me to abridge my remarks to a consideration of the propriety of compulsory legislation, conceding the utility and efficacy of vaccination, and that the virus is properly prepared and the vaccination carefully conducted.

Upon the law of the matter I am disposed to concur with the views of Col. Prentice.

In case of a threatened epidemic where the safety of the lives of others and general immunity from the spread of the disease was the question, the State it may be claimed would have a right to interfere against the private and individual right as in the case of a conflagration, in tearing down a building in its path to save others beyond it.

It seems to me that enough has already been disclosed in this discussion to make the State hesitate in assuming the extraordinary power of compulsion over an individual protest.

There are well authenticated cases of terrible results, of health permanently ruined and life rendered not alone valueless but horrible by vaccination.

If it should be claimed by the sufferer, that the physician who operated (or the State if compulsory), was liable in damages for the injury it would be impossible to meet or deny the justice of such a claim.

It seems to be true that there is no State or official supervision over the manufacture or sale of the vaccine matter now in universal use, and this, where vaccination is compulsory, is inexcusable neglect. The manufacture is at present a purely commercial and business matter, and it is very doubtful whether the courts would sustain the enforced vaccination of a citizen against his will, without the State itself assumed the responsibility, not alone of the purity of the virus, but of the outcome of the administration.

Those American officials who are in a situation to be best informed upon upon this subject, like Dr. Fowler, C. S. Lindsley, Moreau Morris and others are unwilling to favor making vaccination compulsory. Even while conceding and asserting, the power of the State they doubt the wisdom and propriety of

such a law, and on a view of the whole ground, I incline to that view.

The state of the public mind is such, and so great is the doubt and distrust of so large a portion of the educated classes (not the ignorant or prejudiced alone) that it would be very unwise to attempt to legislate compulsory vaccination, without the State at the same time charged itself with responsibility in all cases as well with the purity of the virus used, as against any unfavorable result to the vaccinated.

It is worth our while to consider whether in the face of the Report of the Royal Commission adverse to compulsory vaccination we should hesitate, before we decide—in the absence of any epidemic especially—to enforce by statute such an encroachment upon the personal rights of a citizen as compulsory vaccination with its attendant risks would or might entail, against and over his protest, which might come from the enforcement of a compulsory statute. Again when we consider the views of such men as Dr. Samuel Abbott, Dr. Benj. Lee and especially criticize the careful report of Dr. Robert J. Pittfield to the Board of Health of Pennsylvania in which he reports a careful and critical examination of a large number of the establishments engaged in the manufacture of vaccine virus, that in the major part great carelessness and negligence exists as to the purity of the product; and that no official supervision exists anywhere over this manufacture, should we not consider, in view of the imminent risk to the citizen from the use of improper and injurious virus, that some legislation should protect the citizen, if the enforcement of compulsory vaccination shall be legalized, from the serious consequences following the use of impure virus by the State officials?

GUNSHOT WOUNDS OF THE KIDNEY. REPORT OF TWO CASES.

Read before the Central Wisconsin Medical Society at Beloit, Wis.,
Sept. 29, 1896.

BY CHAS. H. LEMON, M.D.
SURGEON TO ST. MARY'S HOSPITAL.
MILWAUKEE.

Gunshot wounds of the kidney, the history of more than thirty years demonstrates, are among the rarer lesions that come under the surgeon's care. These organs by reason of their deep location escape the accidents that so frequently happen to the other abdominal viscera. Their importance to the human economy, their anatomic peculiarities and relation to the other viscera, the difficulty of making an exact diagnosis at the time of injury before an operation is undertaken or thought advisable, give to the history of individual cases a distinct interest, and will in time make the duty and responsibility of the surgeon clear, as additional light is shed upon this class of lesions in the operating room as well as at the postmortem table.

Long before the era of antiseptics the necessity of providing free drainage in wounds of the kidneys was emphasized by Larrey and Dupuytren. The wisdom of this procedure was unrecognized or unheeded by the surgeons during the war of the rebellion. Of the seventy-eight cases of gunshot wounds of the kidney reported in the surgical history of the war, but twenty-six cases recovered. All were treated upon the expectant plan; no incisions for the purpose of exploration were made.

Perhaps we can not form a correct estimate of the dangers which, though present in a small degree today, confronted the men who tried to solve the problem of life and death for the victims of kidney lesions

which come under their care, often with complicated injuries, in the preaseptic era represented by the surgery of our civil war. The accumulated experience had taught in addition to the fact that adjacent viscera were often wounded, that these penetrating gunshot wounds, unlike incised wounds of the kidney, were not likely to be followed by urinary infiltration of the retro-peritoneal tissues. This experience which has been corroborated since, demonstrated that in gunshot wounds "the eschars lining the tract, protect the parts until a limiting wall of inflammatory exudate has taken place." Therefore in cases which in the beginning presented no urgent symptoms, it is not to be wondered at that the surgeons feared less the infiltration of urine and the formation of abscess than the more urgent and dangerous sepsis which too often followed the making of large incisions.

In this connection I would call attention to the fact that some of the complications of these wounds of the kidney were wounds of the stomach, spleen, liver, diaphragm, intestines lungs and spine. Such cases were usually rapidly fatal as can be well imagined, from shock and hemorrhage. I think that in the history of the cases that I shall relate I will convince you that the diagnosis must often be extremely doubtful and the symptoms misleading in many of these cases which shall be treated in the future, and that more often will the surgeon resort to exploratory incision to settle the question rather than rely upon being able to accomplish at the end of twenty-four or forty-eight hours what could be done with much less risk and a better prognosis within, say, a few hours at most subsequent to the reception of the injury.

We are so accustomed to the graver operations upon the kidney that are being made today that we are apt to forget that the first nephrectomy as a deliberately planned operation was made as recently as 1869, by Gustav Simon of Heidelberg, and that the operation of nephro-lithotomy was first performed by Morris in 1880. These two men have immortalized themselves by their work upon the kidney alone. The monograph published by Morris in 1844 is a classic that commands the attention of the student and has been quoted by every text-book and author who has written a line since upon the surgery of the kidney.

To those who are interested in the treatment of gunshot wounds of the kidney I would commend in addition to this book the admirable and exhaustive paper read by Professor Keen before the American Surgical Association this year, and published in the August number of the *Annals of Surgery*. He has tabulated all the cases of traumatism of the kidney that have been reported since 1878. In this list are nineteen cases of gunshot wound of the kidney, and there are given in a table the name of the operator, the nature of the injury, the treatment, operative or non-operative, the result and a short comment. Of these nineteen cases ten recovered and nine died.

With these few remarks as an introduction, I take pleasure in relating the following two cases, employees of the Milwaukee Electric Railway & Light Company, which came under my care.

Case 1.—On the night of June 4, 1896, during the recent strike of the employees of the Milwaukee Electric Railway and Light Company, as an electric car was making its way from a suburb of the city of Milwaukee, the car was fired upon from ambush, by unknown persons supposed to be sympathizers with the striking employees. Both the motorman and the conductor were struck by flying bullets, the latter being wounded in the thigh by a bullet which lodged under the skin on the

outer aspect of the right knee. This bullet, which I removed an hour or so later, was of 32 caliber. The motorman, Jno. B. aged 27, white, a Canadian by birth, was struck in the back, about 2 inches to the left of the spinal column and opposite the second lumbar vertebra, by a ball which passed upward, inward and forward and lodged somewhere in the anterior aspect of the chest, under the costal arch. The shock of the wound brought the man to his knees, but he still maintained his hold upon the controller of the motor and turning on the full current, the car struck a tree which had been thrown across the track and swept it out of the way, and amid a fusillade of bullets the motorman brought his car out of danger, with the conductor lying wounded on the floor. He ran the car fully a mile before anyone could relieve him, and was conveyed as quickly as possible to the Johnston Emergency Hospital, reaching there about 10 P.M.

At the time of admission the temperature was normal, the pulse 72, respiration about 30. The man showed little evidence of shock. The only thing in his condition that was particularly noticeable was a look of anxiety. No blood escaped from the wound in the back and I was inclined at first to the belief that no serious damage had been done by the bullet. A slight probing of the wound showed its direction to be upward and inward, and thinking that possibly the kidney might have been injured, I asked him to pass his water, and he replied that he could not. I then catheterized him and drew off about a quart of bloody urine. Some ten minutes later the catheter was again passed, and the urine which was drawn was heavily mixed with blood and clots. A priest having been sent for at the man's request, I asked Drs. Sperry and Purtell to see the case in consultation.

Knowing that the kidney was wounded, from the presence of hematuria, and being in doubt as to the character of the injury the kidney had sustained, an exploratory operation was deemed advisable and a lumbar incision decided upon. With some difficulty, owing to an accident to our bullet probe, the left kidney was exposed by an incision along the track of the bullet. Upon reaching the perinephritic tissue a considerable amount of clotted blood and urine was found, which upon being removed disclosed a wound in the inferior convex border of the kidney sufficiently large to admit the finger. A long probe being introduced into the wound could be passed sufficiently far to demonstrate that the ball had not lodged in the kidney, and as the direction of the wound was such that I felt certain the pelvis of the kidney had not been perforated on its anterior border, no further exploration was made. The ball had traversed the inferior portion of the kidney and approached closely its pelvis.

The hemorrhage into the wound, though not rapid, was constant, and I plugged the ragged tear which the eye could see, with a strip of iodoform gauze, bringing it out at the upper anterior aspect of the wound. I sutured the deep structures of the back with catgut in layers, providing a gauze drain in addition to the kidney drain, along the track of the bullet at the inferior and posterior angle of wound, the suturing of the skin and underlying structures being made between these drains.

During the twenty-four hours subsequent to the reception of the injury a considerable quantity of urine and blood was discharged through the wound which decreased in quantity during the second day and ceased altogether on the third day. The dressings were changed several times during the first forty-eight hours and some idea may be obtained of the amount of urine which escaped through the wound during the first two days, by noting the fact that the amount of urine drawn from the bladder the first day was but 26 ounces, the second day 31 ounces and the third day 47 ounces, this being the day the urine ceased passing through the wound. No suppuration occurred in the wound. A few days later the gauze was removed from the bullet track, allowing the track to heal and the second piece of gauze leading down to the kidney was gradually withdrawn, the wound being completely healed at the end of four weeks. The temperature curve was of no special moment, reaching its highest point, 100.8 degrees, thirty-six hours after the injury from which it gradually declined until the tenth day, when it reached the normal point. The highest pulse rate was 110 on the third day. The respiration deserves special notice, remaining for forty-eight hours subsequent to the injury between 36 and 42 to the minute. The catheter was used for three days, and ergotol in 15 minim doses was given for three days every four hours. In addition to this, owing to the fact that the man was suffering from a declining gonorrhoea, acetate of potash in 15 grain doses was given three times a day, and the bladder washed with a saturated solution of boracic acid. The day following the injury, the symptoms, which were of no moment at the time of injury, assumed an alarming character. The man complained of pain in the right iliac region, the

abdominal muscles were rigid, his expression was anxious in the extreme and I feared that in making the lumbar operation I had overlooked a possible perforation of the intestines. By the third day the symptoms had improved, the bowels had moved successfully and the blood which had continued mixed with the urine in considerable quantity with the presence of clots began to decrease in amount, and at the end of ten days had ceased altogether.

Little else than milk was given for diet for three weeks and the man when discharged from the Hospital at the end of four weeks was considerably emaciated and left the city to recuperate at his home in Michigan. I regret to say that owing to an excessive amount of work incident to the strike, I neglected to make a microscopic examination of the urine, the only notes being those of the record sheet, which show that while pus persisted in the urine for two weeks, at the time of his discharge the urine was clear. The patient spent the greater part of the summer on a farm in Michigan and I saw him the other day, looking well and strong, completely restored to health, his only complaint being of an irritation from the probable presence of the bullet in the left chest wall.

Richard R., Case 2.—Wound healed in ten days.

Case 2.—Richard R., aged 25, German, single, white, of splendid physique, was shot by accident with a 32 caliber revolver at three feet distance, Aug. 17, 1896, 9 A.M. The person handling the revolver stood somewhat to the right of Mr. R., and the ball struck him in the anterior chest wall about two inches to the left of the nipple line. Mr. R. complained of no pain at first, walked to the rear of the building and sat down on the outside steps. As I was not at home, the case was first seen by Dr. Hamilton, who had the man removed to St. Mary's Hospital, where I saw him in consultation about an hour later. At this time the patient's face wore an anxious expression, he complained of severe pain in the right iliac region, his abdominal muscles were rigid, the respiration was rapid, pulse accelerated and he was sweating profusely. The man complained of no pain in the chest, there was no cough, no hemoptysis, and no abnormal dullness over the right side of the chest that could be made out by percussion. The area of liver dullness was normal. Being in doubt as to whether the bullet had penetrated the chest wall, it being impossible to insert a probe after

a careful disinfection of the wound, I made a small incision with the bullet hole as a center, and found that the bullet had struck the upper border of the ninth rib, tearing off a small portion of the periosteum and had penetrated the parietal surface of the pleura. A further exploration being deemed inadvisable, the wound was packed with iodoform gauze and the patient put to bed to await developments.

At 2 p.m. the man was restless with a temperature of 99.6 degrees, pulse 72, respiration 84. He had passed no water and could pass none. Although he was suffering from an acute gonorrhoea, I catheterized him, as I for the first time suspected that the kidney had been wounded. Twenty-four ounces of bloody urine was passed at this time. Twenty minutes later, I again passed the catheter and drew off two ounces of urine heavily loaded with blood. With the consent of Dr. Hamilton, I asked Drs. Purtell and Sperry, who had assisted me in the first case, to see this case also. The man was anxious to have the bullet removed if possible and consented to an exploratory operation of the kidney. From the fact that the pain complained of was upon the right side, I inferred that the right kidney had been wounded, notwithstanding that the person who did the shooting stood to the right of Mr. R. and that the wound of entrance was to the left of the nipple line. What direction the bullet took after entering the chest and what deflected it, whether it was a vertebral body, or a rib posteriorly, we had no means of ascertaining. The wound of the rib anteriorly was but slight, being upon the upper border, and we inferred at the first examination that the bullet had either gone upward into the chest or passed directly backward. The man being chloroformed, I made the usual incision in the right groin, parallel with the last rib, to expose the kidney. Upon reaching the fatty tissue surrounding the kidney, I found a wound showing that the ball had passed through it, and I could trace the track of the bullet with the finger for a short distance in the iliac fossa. The kidney was thoroughly exposed and freed from its fatty capsule over the inferior portion and a careful exploration of the kidney between the thumb and finger showed the wound of exit through the kidney to be a ragged hole, easily admitting the index finger on the posterior surface of the kidney, about its center, one inch external to the renal pelvis. Unlike the first case, no clotted blood was found around the kidney and there seemed to be little or no extravasation of urine. Dr. Hamilton and Dr. Purtell each palpated the kidney. The hemorrhage being slight, I was satisfied that no serious damage had been done to the kidney substance, and I did not feel justified in further separating the kidney from its bed to examine the wound of entrance into the kidney, and I at once proceeded to close the wound without irrigation, having first packed a strip of gauze into the wound on the posterior surface of the kidney, bringing it out at the anterior portion of the lumbar incision. The deep structures were sutured with catgut in layers and the skin with silkworm gut.

The after-treatment in this case was similar to that in the case already described. Ergotol for the first few days, with the citrate of potash.

During the forty-eight hours subsequent to the reception of the injury, the urine was bloody and contained clots of blood. On the fourth day in the forenoon there was considerable blood in the urine without clots, and after this neither blood nor clots. The urethral discharge due to the gonorrhoea was profuse for a few days. As the pus had been carried into the bladder at the time of the first catheterization, the bladder was washed daily with warm water and boracic acid. No pus appeared in the urine until the thirteenth day. The amount of pus decreased steadily until the twenty-first day. Afterward it could be detected only by the microscope. I made a uranalysis on the fourteenth day, with the following result: Reaction, acid; specific gravity, 1020; pus; blood (traces); hyaline casts, a few epithelial casts; albumin, marked.

A uranalysis at the end of the fourth week showed: Reaction, acid; specific gravity, 1020; albumin, none; blood, none; pus, traces; casts, none. The diet was restricted to milk and water for eighteen days.

On the seventeenth day the temperature, which had not exceeded 100.8 degrees, suddenly rose to 102.6, owing to the onset of an attack of epididymitis on the

right side. On the following morning the temperature dropped to 98.8. Three days later a second rise in temperature to 101.6 occurred, with an increase of the epididymitis, and from this time on it decreased until the twenty-first day, when it reached the normal point and remained there. In this case, as in the former case, the respiration was accelerated; for more than two weeks it remained between 34 and 36 to the minute. The pulse was normal with one or two slight exceptions, during the entire convalescence.

Mr. R. left the hospital at the end of four weeks, and at the present writing he is rapidly regaining his lost strength.

A fact worthy of notice in both of these cases was the rapid emaciation which took place during the first three weeks. Case 1 lost forty pounds in weight in three weeks, and Case 2 lost fifty-eight pounds.

The regaining of weight after being placed on general diet and allowed to exercise was almost as rapid, Mr. R., Case 2, having gained nineteen pounds in two weeks.

Another fact deserving of mention is that both men were suffering from gonorrhoea at the time of injury, and notwithstanding the introduction of the catheter, neither of them developed a cystitis. The pus in the urine in Case 2, of which I have a more exact record, did not appear until the thirteenth day. It was evenly mixed with the urine when voided and resembled that so frequently seen in cases of pyelitis.

The absence of pus in the urine for more than ten days subsequent to the injury and its appearance subsequent to that time, may, I think, be attributed to the sloughing incident to the process of repair in the kidney itself. This supposition is strengthened by the observation that at times the urine was free from pus, at others quite heavily loaded with it.

The wound in the anterior chest wall, which was packed at the time of the accident, was sutured by Dr. Hamilton on the fifth day, and healed by primary intention.

On the third day I dressed the lumbar wound, and noticing that but little exudation had taken place and that the presence of urine could not be detected, I withdrew the gauze with which I had tamponed the kidney, and allowed the wound to close. Primary union took place and I removed the stitches the tenth day, the wound being completely closed.

The record of these two cases, similar in many of their details, examined from the post-operative standpoint, seem to present conflicting conclusions as to the indications for operation.

The symptoms presented a few hours subsequent to the reception of the injury in each case were misleading as an indication of the character of the lesion sustained. In Case 1, in which the kidney sustained the greatest damage and in which at least one-third of the urine secreted in the forty-eight hours after the operation was passed through the lumbar wound, the patient at the time of operation showed little evidence of shock, complained of no pain, and apparently had suffered but slight injury. These symptoms, however, during the next twenty-four hours were replaced by those of grave character, so much so that I feared the intestines had been wounded, and that the man was developing a general peritonitis.

From conclusions drawn from a study of the cases reported during the war and subsequently, I am convinced that without operation providing for free drainage in the lumbar region, that this case would have been either fatal from extravasation of urine and

the formation of abscess in the retro-peritoneal tissues, or at best have recovered after an illness of long duration.

In Case 2, the symptoms at the time of the first examination were of an alarming character. Twenty-four hours subsequent to the operation the patient was resting quietly, complained of no pain and was in every respect in splendid condition, having passed no urine through the lumbar incision. This case I believe might have recovered without operation, as at the time of operation we found no extravasated blood or urine in the peri-renal tissues. Yet without operation we would have remained in the dark as to the character of the lesion and would be without evidence that the ball, failing to make its exit from the body, had not lodged in the kidney itself.

I have been impressed by a study of these two cases with the fact that beyond a knowledge that the kidney has been wounded made evident by the hematuria, in a gunshot wound of the kidney, we can form but little idea from the character of the early symptoms as to the extent of the damage that has been done. I, of course, will except an injury which severs the large vessels leading to or from the kidney in which the evidences of internal hemorrhage would manifest themselves very early. In both of these cases, after a careful deliberation, I made a lumbar incision to the kidney for the purpose of exploration, believing that from the direction of the bullet in the one case, and from the known position of the person who did the shooting in the second case, that the other abdominal viscera had not been wounded.

The comparatively uneventful recovery made in each of these cases, demonstrates that the operation, if it were conducive of no good, at least did no harm.

In this connection I can but quote the words of Professor Keen in the article above alluded to, in which he says: "If the surgeon has reasonable evidence that the kidney has been probably traversed by a ball (and all the more so if it is certain that it has been so wounded) and the patient is evidently in grave danger, as shown by the general symptoms of internal hemorrhage and by the physical signs of a large lumbar hematoma, or of intraperitoneal bleeding, I take it for granted that all of us would recommend an exploratory operation with a view of determining the extent of the injury to the kidney and the proper treatment."

The question whether a case of gunshot wound of the kidney shall be treated by the operative or the expectant plan is one that in most instances will be difficult to decide. The indications for early exploratory incision, with or without nephrectomy, have been most admirably stated by Professor Keen in his recent article cited, and I would refer you to it for counsel.

Notwithstanding the rarity of this lesion, it is one that may confront any of us without a moment's warning and I have reported these cases at length in the hope that something may be added to the meager knowledge we already possess upon this interesting subject; or at least that the report of these cases may stimulate further research into the literature of the subject. Notwithstanding the fact that I failed to find the bullet in either case, I believe that a better prognosis can be given to each of these young men from the knowledge that we possess, that the kidney was not a receptacle for the bullet.

I trust further that I have demonstrated in both cases that when in doubt as to the advisability of

operating, we can be comforted by the knowledge that an aseptic exploration of the kidney under chloroform anesthesia adds little or no risk to the patient.

THORACOPLASTY IN AMERICA AND VISCERAL PLEURECTOMY, WITH REPORT OF A CASE.

Read in the Section on Surgery and Anatomy, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY ALEX. HUGH FERGUSON, M.D.

Professor of Surgery in the Post-graduate Medical School of Chicago; Surgeon to the Post-graduate Hospital, Cook County Hospital, Cook County Hospital for the Insane at Dunning, Charly Hospital and Chicago Hospital; Member of the American Medical Association, British Medical Association, Chicago Medical Society, etc., etc.

When I forwarded the title of my paper to the Chairman of this Section, I had no idea but that I should now have several interesting cases of Schede's operation performed in America to lay before you. Being disappointed by a personal research of the periodicals published in this country, I applied to the American Bureau of Medical Literature, at Washington, D. C., and in due time I received the following reply: "We have been unable to find any case of Schede's operation performed in America." There is no doubt in my mind but that this major operation has been done many times in this country, though not reported. Thoracoplasty, as first done by Schede, is an heroic measure for the otherwise hopeless cases of chronic empyema. It consists in the removal of the chest wall, that is the ribs; intercostal muscles and parietal pleura are extirpated, then curettage of the visceral pleura is done, and the raw surface of the large flap raised external to the ribs is allowed to come in direct contact with the bound down lung and its pleura. The external incision is very extensive and horseshoe in shape, extending in a sweeping curve from the vertebral border of the scapula downward to the lower ribs, and then upward to the nipple or beyond it in front. Whatever may be the cause or causes of the empyema, some cases there are which survive the aspirations, the pleurotomies and permanent drainage, or the resection of a portion of one or of several ribs, as advised by Estlander. In spite of all these procedures a few cases are not cured, and these urgently plead for relief from the foul, purulent material constantly pouring out of their side, and day by day vitiating and weakening the already overburdened constitution. Upon being confronted with one of these cases, too much stress can not be placed upon a thorough examination of the various organs of the body, particularly the lungs, for if these be markedly tubercular, no operative procedure should be undertaken. When the opposite lung is in a good healthy condition, even though the compressed one manifests signs of consolidation and breaking down, an operation may be advised, provided the patient be otherwise in a condition to stand it. If the sputum be free from tubercle bacilli, even though amyloid degeneration be quite obvious, and the person able to be about, thoracoplasty should be done. The assertion made by Schede, that amyloid degeneration and tuberculosis does not contraindicate this operation, is true within certain limits, and this the author verified by his results. A practical clinical observation, that is, the disappearance of the signs of amyloid degeneration of the internal organs, when the cause was

removed by operation, was a well known one to surgeons in pre-antiseptic days, occurring in those cases making a speedy recovery from the operation without much or any suppuration. It was observed by Rahlmann and Kubly that after partial extirpation of amyloid conjunctival tumors, the portions left became completely absorbed. (Thoma, Vol. I, p. 397.) We may conclude that an improvement of a diffuse amyloid degeneration caused by an empyema will begin to occur just as soon as the formation and discharge of pus is prevented. The condition of the kidneys is important. There may be albumin in the urine, signs of organic disease of these organs; but under what conditions are we to say that a case is operative or not

lander's operation, a suppurating cavity persists, complications are imminent, and there is not the slightest hope of recovery without further interference. Such a case has invariably been ineffectually treated by 1, aspiration; 2, pleurotomy, drainage and irrigation; 3, resection of one rib for more efficient drainage; 4, Estlander's thoracoplasty, curettage, packing with gauze and frequent irrigations. Just as soon as it is recognized that the cavity has no tendency to become obliterated by these procedures, the earlier Schede's operation is performed the better, and should a cure be not effected by it within a reasonable time, then visceral pleurectomy is the climax of operative procedures to which we shall resort. The following is

FIG. 1.—H, heart; L, liver; A and B, the two incisions.

on this account? We so often break through all rules, and yet our cases recover, when the apparently diseased kidneys would seem to contraindicate an operation, that a hard and fast rule does not obtain. More risks can be taken in amyloid or waxy kidney, provided we are able to remove the cause of such a degeneration. The amount of urea in the urine is the more valuable from a prognostic standpoint. The dangers ahead of a person suffering with a profuse suppurative discharge and fever are 1, septicemia and pyemia; 2, amyloid disease, and 3, tuberculosis, all of which may be obviated by a timely operation.

The indications for Schede's thoracoplasty are very clear. The chest wall has not collapsed after Est-

lander's operation, a suppurating cavity persists, complications are imminent, and there is not the slightest hope of recovery without further interference. Such a case has invariably been ineffectually treated by 1, aspiration; 2, pleurotomy, drainage and irrigation; 3, resection of one rib for more efficient drainage; 4, Estlander's thoracoplasty, curettage, packing with gauze and frequent irrigations. Just as soon as it is recognized that the cavity has no tendency to become obliterated by these procedures, the earlier Schede's operation is performed the better, and should a cure be not effected by it within a reasonable time, then visceral pleurectomy is the climax of operative procedures to which we shall resort. The following is

the report of my case of Schede's thoracoplasty for chronic empyema, which was greatly improved by it, but not cured, and then I performed an extensive visceral pleurectomy with an excellent recovery.

Case.—Wm. C. A. Clements, age 40, farmer, entered the Post-Graduate Hospital July 3, 1895, suffering from a large chronic empyema of the left side, discharging pus profusely.

History: The family history was good, with the exception of the death of a sister from consumption. Personal history excellent; never had any illness before May, 1894, when he was taken down with pleurisy, which resulted in his present condition.

Present illness: On May 22, 1894, pleurisy of the

left side set in with considerable severity, effusion followed, which was aspirated June 23. At this time there was no fever, nor chills, and he was able to be out of bed. There was marked dyspnea and considerable discomfort, both of which were increasing. A watery fluid was removed (according to his statement) and great relief was experienced, which however was only temporary, for on the fourth day a new train of symptoms were ushered in. A distinct rigor followed by a high fever, with much thirst, etc., was then experienced, which was several times repeated. From this time till August 10 following he was very ill, and his friends had little hope of his recovery. An anesthetic was administered, the chest wall opened and a portion of a rib was resected to establish permanent drainage. This afforded marked improvement in his physical condition. His appetite returned, he gained in flesh and was able to walk around once more. The suppuration continued, the lung did not expand and the chest wall was quite a distance from it, between which a large cavity existed. The drainage became inefficient. Three subsequent operations (Sept. 9, Dec. 10, 1894,

through a rubber tube in the fistula. A probe could be passed into an enormous cavity to the first rib above, the diaphragm below and straight inward a distance of 10 cm. Moist râles and bronchial breathing could be heard over the apex and borders of the compressed lung. The right lung was apparently in a normal condition. A microscopic examination of sputum failed to find the bacilli of tuberculosis. The liver and spleen were not enlarged.

SCHEDÉ'S THORACOPLASTY.

Operation.—On July 6, 1895, Schedé's operation was performed by me before the post-graduate class. A U-shaped incision.

Upon raising the flap, a stout, sharp retractor fastened under the border of the scapula did good service in exposing the ribs. The periosteum of each rib was cut through longitudinally. One after the other was then stripped with a periosteal elevator and cut through at each end with bone forceps, through the neck at the vertebral end of the fourth, fifth and sixth ribs, the rest not so far back; and near the costal cartilages at the other ends except the eighth, whose costal cartilage was removed *in toto*. A perpendicular incision was then made through the intercostal muscles, and parietal pleura into the empyemic cavity, from the diaphragm to the second rib and then each half of this musculo-fibrous structure scissored away at the angle of its reflection with the visceral pleura in front and behind as closely as possible. It was then found necessary to excise 5 cm. of the second rib in order to clean out the apex of the cavity (Fig. 2). Throughout the whole operation the hemorrhage was insignificant. The thickened pleura was curetted and freely scissored, the whole cavity packed with iodoform gauze, the skin flap allowed to fall upon it, and two rows of cutaneous sutures put in, one anteriorly and the other posteriorly, leaving the lower aspect unsutured for drainage and access. An abundance of antiseptic dressings applied, the patient put to bed and surrounded with hot-water bottles. He stood the operation well; the shock, though marked, was not profound; his pulse being 100, temperature 98 and respirations 26. The next day he was cheerful and in a good condition. The packing was removed on the third day and a smaller one substituted, which was repeated at the end of three more days, after which it was necessary to dress him every day. The skin wound healed by first intention, but pus formed in the cavity during the middle of the second week. Granulation tissue formed and gradually lessened the cavity. Once a week or so it was lightly curetted, with the hope of hastening the process.

During August he took pneumonia and nearly died. Prof. John A. Robson saw him then and gave an unfavorable prognosis. He, however, recovered slowly, and once more became master of the situation. He then gained rapidly in flesh and was soon sufficiently well to visit the parks. In spite of all our dressings, injections, curettings, etc., a long central sinus would not or could not close. Five months of this faithful treatment was surely enough, consequently I advised another operation.

Visceral pleurectomy.—On Dec. 12, 1895, I removed the thickened pleura over the lung and the whole pus secreting surface. The incision was made vertically the whole length of the sinus (Fig. 1, b). The pleura removed measured 17 cm., 5 cm. broad at the upper end, 7 cm. at the other, and from .5 cm. to

FIG. 2, A.—Ribs, intercostal muscles, and parietal pleura.

FIG. 2, B.—Cartilage of eighth rib.

and March 13, 1895) were performed by the local physicians, at which portions of the ribs were removed, but the suppuration with more or less pyrexia still persisted, and the chest wall had not sufficiently collapsed.

Condition on admission: He was a man of large, bony frame, slightly stooped and leaning to the left side. Height 5 ft. 11 in., weight 173 pounds, had lost about twenty pounds, but was not greatly emaciated. There was a hectic blush on his cheek, skin sallow and constantly perspiring. He had a loud, harsh cough, with a purulent expectoration, and the rushing of air in and out of chest wall could be heard before it was exposed. His temperature ranged from 99 F. to 101 F. Respirations 24; pulse 90; bowels regular; appetite fair; slight albumin in the urine, and he slept fairly well. A physical examination of the chest revealed a flattening of the left side, a fistulous opening between the sixth and seventh ribs in the mid-axillary line, thick creamy pus freely exuding

2 cm. thick, being thickest posteriorly. This was removed in two large and several small pieces. Fig. 3 represents what was removed as if in one piece.

In dissecting it off I tried to cut at the junction of lung and fibrous tissue. It was impossible to do this satisfactorily, and I had to cut through the peripheral layer of lung tissue. No sooner the upper portion of the lung was liberated than it so protruded through the external wound that I had to compress it with large gauze sponges before I could complete my pleurectomy, but at the termination of the operation the lung was collapsed, revealing an unsightly cavern in his side. The pleura removed was adherent

tysis for forty-eight hours. The amount of blood serum that exuded during the next four days was enormous, and beyond anything I had ever seen from any wound. The large dressings had to be changed daily, and even then the clothing around him was soaked. The granulation tissue that formed was very exuberant and vascular. It would bleed on the slightest touch. The cavity closed rapidly and February 19 he left for his home a healthier and happier man, though considerably deformed. His cough subsided, his pyrexia was gone, the skin assumed its normal color, the albumin in his urine cleared away, his appetite was excellent, and, in brief, his health was restored. The day before he left the city he was examined by Drs. J. H. Hollister, G. Fütterer, Byford, Bacon, Martin and others.

This leads up to the subject of

VISCERAL PLEURECTOMY.

The first visceral pleurectomy was performed in America with brilliant result. The honor is due to Dr. G. R. Fowler, performed on Oct. 7, 1893, and published in the *New York Medical Record*, Dec. 30, 1893. The second was done by Delorme, the third by Reclus, the fourth by Gallet and the fifth by myself. There were four cases reported up till April 1, 1896. The ages of the patients were 35, 26, 26 and 12. Two of them were males and two females. Estlander's operation had been performed in two of them and a pleurotomy in two. A fistula existed in all the cases,

FIG. 4.—Old pleuritic with secondary interstitial pneumonitis. A, younger granulation tissue; C, older tissue infiltrated; D, endarteritis obliterans; E, obliterated air vesicle; F, obliterating air vesicles; G, bronchus.

and a large cavity was present in three. Two recovered and two died. A brief outline of all the cases, including my own, is herewith appended. The pathologic anatomy of these cases has not been very fully given. I shall therefore only crave your attention while reporting that of my own case.

Pathology.—The manner in which the visceral pleura thickens, layer by layer, externally and by alteration of lung tissue internally, is very interesting and instructive. A study of the pathologic changes in this case proves how impossible it was for nature to supply sufficient nutrition to form enough granulation tissue to close the cavity.

Figure 3 represents the thickened fibrous visceral pleura that was removed. A strip of lung tissue is shown along the thin border and attached to it.

Figure 4 represents diagrammatically a transverse section of the thickened pleura and adherent lung tissue, showing the chief pathologic changes that have occurred. The microscopic sections demonstrating these points are as follows:

The outer surface of the specimen consists of rough, shaggy granulation tissue. Attached to the inner

FIG. 3.—The visceral pleura. A, lung tissue; B, posterior thick border; C, suppurating external surface.

to the pericardium and diaphragm as well as to the lung. Upon removing it the heart was so beautifully exposed that I yielded to the temptation of playing with it for a short time. In seizing hold of it gradually with my hand it appeared to avoid being grasped and fought, not unlike a little pig would do with its nose, being evidently excited. When left alone it went on with its wonderful, systolic, diastolic and rotary movements as if it never had been touched. The venous and capillary hemorrhage was considerable. The cavity was packed with iodoform gauze and the skin sewed over it, leaving a couple of inches open at the most dependent part. There was slight hemop-

surface there are remnants of lung. Cut section shows fibrous tissue with some waxy, glistening appearance.

Low power: Superficial surface. There is no epithelial covering in any of the sections that have

of blood vessels decrease, and an infiltrate of homogeneous material becomes more prominent. Deeper still a large number of blood vessels are seen in various stages of obliterating endarteritis. In some of them the lumen is scarcely apparent, while in the

FIG. 5.—Section showing A, Fig. 4. Thin walled blood vessels, embryonal cells, some infiltration with homogeneous material.

FIG. 8.—Section through G, Fig. 4. Cross section of bronchus lined by a single layer of ciliated columnar epithelium.

FIG. 6.—Section through D, Fig. 4. Some vessels obliterated, all with very thin walls; connective tissue of vicinity is old, laminated, wavy and abundantly infiltrated with homogeneous material.

FIG. 9.—Low power section through lung substance showing greatly thickened alveolar walls.

FIG. 7.—Section through F, Fig. 4. Alveolus nearly obliterated, lined as were nearly all the alveoli by cubical epithelium. In this vicinity are masses of epithelium lying in irregular masses in the middle of the connective tissue.

FIG. 10.—High power, same as Fig. 9, showing a typical chronic interstitial pneumonitis.

been made. Superficially there is an array of granulation tissue consisting of cells, fibers and a large proportion of thin blood vessels. As you go deeper the proportion of fibers to cells increases, the number

vicinity there are masses of concentrically arranged fibrous tissue, exactly similar to the vessels except that there is no longer a lumen. These whorls of tissue I interpret as blood vessels that have been entirely obliterated. In this zone can be seen col-

umns of tubical epithelium with no lumen; the remnants of obliterated air vesicles. As we go deeper into what is plainly apparent as lung structure we find gradations from the appearance just noted to be the air vesicle easily recognizable as such. These air vesical walls are thickened by an overgrowth of fibrous tissue that in places is even and in places is knob-like. There is considerable pigment within these alveolar walls. Occupying a portion of the air vesicle is an exudate. The blood vessels in these alveolar walls are thickened. A bronchiole of small size can be recognized.

High power: Superficial; typical granulation tissue, with a moderate infiltration of a hyaline material, is seen. As we go deeper matured fibrous tissue is found and the homogeneous infiltrate becomes more prominent. Some of the blood vessels show active proliferation of the endothelial cells; in others with very much thickened walls this proliferation is not so prominently seen. Here and there in these areas are irregular masses of degenerated epithelium, easily recognized, which are clearly representatives of former alveoli. Here also appear double columns of cubical epithelial cells, in which the epithelium is regularly arranged along its basement membrane; these are also remnants of obliterated vesicles. These vessel walls previously referred to are seen to be made up of concentrically arranged mature fibers. The thickening in the air vesical wall is due to increase in the connective tissue. The epithelium which covers it is everywhere cubical. The apparent exudate which filled many of the vesicles is now seen to be in part due to fibrin filaments, but in the greater part due to masses of epithelial cells lying loose in the vesicle. Many of these cells contain pigment. Cross section of the bronchus shows a typical bronchus of small size, lined by a single layer of ciliated columnar epithelium.

Microchemic means of differentiating the infiltrate were not employed. Sections stained for tubercular bacilli and other organisms were negative.

I am indebted to Dr. Evans for an examination and an accurate report of the pathologic specimen, and to Dr. Knapp for the micro-photographs.

REPORT OF CASES.

Case of G. R. Fowler, published in the *New York Medical Record* Dec. 30, 1893, p. 838. Female, aged 35 years; operation Oct. 7, 1893. History: May, 1886, fibroid phthisis was diagnosed. March, 1887, pneumonia of the right lung. Jan. 31, 1891, empyema diagnosed in right pleura. March, 1892, aspiration of about sixty ounces of purulent material. Four other aspirations were performed later. By June, 1891, permanent drainage was established. A rounded body could be seen through the fistula, which body moved with every act of respiration. Curetting and antiseptic irrigation having failed, the following operation was performed, for the wound had discharged almost continuously for the past five years. Operation: Elliptical vertical incision four inches long was made in the axillary line downward from the fourth rib, and in the flap was the orifice of the sinus. Three and one-half inches of the fifth and sixth ribs removed. A mass of cicatricial tissue was then exposed, through which the fistula passed. This was separated from the chest wall by blunt scissors. It was removed from the diaphragm as far as the median line, and was then by strong traction removed from the displaced pericardium. This part of the operation was assisted by working with the tips of the fingers, as paper cutters, and occasionally with blunt scissors. The mass was then lifted from the chest and last of all separated from the lung. Progress: Patient suffered considerably from shock, but soon rallied. Breathing was not much embarrassed, but the pulse was very frequent, because of the pressure made on the heart by the pledgets with which the wound was tamponed. After these were removed it became more regular and nearer normal.

Temperature never rose above 102 degrees, and was at that point only a short time during the first twenty-four hours. Cavity was irrigated daily with 1-1000 bichlorid solution, mixed with 5-1000 tartaric acid solution. Upon each irrigation the cavity was thoroughly dried out and tamponed with zinc oxid gauze. Recovered. Pathology: At last the cavity had so far diminished that instead of holding 32 ounces of fluid it held less than an ounce. When the cavity held only a drachm the irrigation was omitted and the wound allowed to close. Patient apparently well; gaining rapidly in health and strength. Can now do household work well. Chest wall is sunken to about an inch or an inch and a half below its normal level at the site of the costal resection. Normal respiratory murmur is present posteriorly down to the seventh rib, and anteriorly down to fifth rib. Complete flatness in area where the vascular murmur is absent. Apex beat is now to the left of the sternum. Remarks: Hemorrhage during the operation had been slight from the parietes, but during the separation from the lung bleeding was quite profuse, but ceased when the removal was complete. Hemorrhage throughout was controlled by sponges and pressure; only one ligature was applied and this was in an adhesion on the pericardial side of the mass. The removal of this cicatricial mass left a cavity in the lower three-fifths of the right side of the chest. The mass removed consisted of extremely dense fibrous tissue, with here and there bits of cartilage and osteoid tissue. The fistulous track is lined with dense areas of epithelial cells, beneath which are rudimentary sebaceous glands. No lung tissue in any part of the specimen.

Case of Delorme. Published in *Presse Med.*, Paris, 1894, p. 97. Male, aged 26 years. Operation Jan. 26, 1894. (?) History: Pleurisy, probably tuberculous, of the left pleura. Pleurotomy was practiced in September, and a discharging fistula resulted. The cavity was 15 cm. in its greatest diameter. Operation: A cutaneous flap was dissected up and a "trap-door" of the costal wall was made and turned back. A pocket was exposed which extended from the diaphragm to the pleural cul-de-sac in the apex. A thick resistant membrane covered the pericardium and the visceral pleura. This was incised over the lung and was found to be 1 cm. thick. The lung was freed from its attachment to this membrane, the cavity cleansed, trap-door replaced, the ribs sutured together and the wound closed. There is no mention made that the visceral pleura was extirpated, though such was probably the case, for Delorme mentions the advisability of extirpation of false membrane in empyema. Patient alive five days after operation. Remarks: Delorme is referred to by Gallet (*Soc. cit.*) as the original operator for visceral pleurectomy, and though no explicit statement is made that the visceral pleural membrane was excised in this case, the general trend of the article indicates that it was. Delorme, however, was not the first one to practice this visceral pleurectomy.

Case of Reclus. Published in *Presse Med.*, 1894, page 97. Male, aged 26 years. Operation Feb. 5, 1894. History: Puncture had been resorted to frequently. In November of preceding year pleurotomy had been performed and though benefited temporarily a fistula resulted. Operation: Rectangular skin flap, adherent by its postero-superior side over the sixth, seventh, eighth and ninth ribs. It is oblique from above downward and extends almost from the vertebral column to the sternum. These ribs were then resected for about two inches at the superior aspect of the wound and (the heavy dorsal muscles acting as a hinge) the anterior parts of these ribs with the corresponding muscles were reflected, after they had been cut loose anteriorly, superiorly and inferiorly from other parts of the thorax. The suppurating cavity exposed, extended from the costo-diaphragmatic sinus to the mediastinum and upward to the superior lobe. Its wall was a thick neo-membrane which was dissected with great difficulty from the pericardium and diaphragm and with less difficulty from the lung. During the removal the lung suddenly protruded from the thorax. Later, however, the lung contracted and when the operation was finished there was a larger cavity than before the operation, because of the removal of the membrane. Hence the trap-door was excised and the wound covered by a skin flap only. Patient never recovered from shock; died the same evening. Remarks: The operation lasted one hour and five minutes. Hemorrhage was very slight. Examination showed the intercostal arteries were filiform and atrophied. Postmortem, it was found much more serious lesions than had been imagined had occurred in the lung. The right lung was contracted in its inferior lobe, tuberculous in the superior one; the left lung was softened at its summit, and showed confluent tubercles throughout the rest of its extent.

Case of Gallet. Published in *Le Clinique* June 6, 1895, page 354. Female, aged 12 years. Operation March 19, 1894. His-

tory: Right pleura involved. Estlander's operation had been performed without effect, although both the parietal and visceral pleura had been curetted. Lung was much contracted and did not expand after the operation. Schede's operation; the visceral pleura was curetted, and a spiculum of bone, two inches long, removed from the pleural cavity. The wound tamponed for two days and then irrigated with boracic acid. The fistulae closed gradually. Recovered from the effects of the operation. General condition of the patient much improved and fistulae dry. Remarks: We can not state that the patient is radically cured. 1. In spite of all treatment, however ingenious, some cases of empyema are incurable. 2. This pulmonary decortication, advocated by Delorme, and first performed by him, is in the presence of some lesions futile and unavailing. 3. Schede's operation is an excellent resort when Estlander's has not caused sufficient mobilization of the thoracic walls. P. S.—No doubt a very small portion of the pleura on the lining was removed with the spicule of bone two inches long, but we could justly exclude this case from the list of visceral pleurectomies.

Case of Alex. Hugh Ferguson. Published in JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Jan. 9, 1897. Male, aged 40. Operation Dec. 12, 1895. History: Had pleurisy May 22, 1894. Aspiration June 23, 1894. Pleurotomy Aug. 10, 1894. Resection of ribs Sept. 10 and Oct. 12, 1894. Estlander's operation March 13, 1895. Fistula thoracoplasty (Schede's) July 12, 1895. Operation: Vertical incision exposed a fistula seven inches long, two and three inches broad. The visceral pleura dissected off the lung, cutting through lung tissue. It was adherent to pericardium and diaphragm. Lung protruded and heart freely exposed. Progress: Shock not severe. Out of bed on eighth day. Discharge very profuse. Granulation tissue very vascular. Rapidly closed, and he went home on Feb. 19, 1896, feeling very well. Cure complete. For the pathology see general description. Remarks: Hemorrhage considerable. It was venous in character. There was blood in the sputum for a couple of days after the operation. The cough ceased and he felt certain that he could assume work on the farm. The wearing of a shield was not advised.

P. S.—In a communication from Dr. Carl Beck, of New York, since the reading of this paper at Atlanta, Ga., he lays claim to having performed a pleurectomy prior to Fowler's case, regarding which he says: "I am not able to send you a report, as I have not published the case, but presented it to the German Medical Society; so that the only notice about it is contained in the secretary's minutes." I regret not being able to give due place to Dr. Beck's case, but I am not aware that it was one of visceral pleurectomy.

AUTO-INFECTION AS A FACTOR IN NERVOUS DISEASES.

Read before the Southwestern Iowa Medical Association, at Corning, Iowa, Aug. 20, 1896.

BY FREDERIC S. THOMAS, M.D.

PROFESSOR OF MENTAL DISEASES AND CLINICAL PSYCHIATRY, CREIGHTON MEDICAL COLLEGE, OMAHA, NEB.
COUNCIL BLUFFS, IOWA.

Clinical observers have described the characteristic phenomena of various neuroses; also of organic nerve lesions whose etiology can only be ascribed to auto-infection or intoxication resulting from non-elimination of the products of metabolism, or the absorption of ptomains arising from the action of the ever-present bacteria on the accumulations of retained excreta in the alimentary canal.

Alienists have frequently called attention to the relation existing between a constipated or sluggish condition of the bowels and melancholia, dementia and depressed intellectual powers. It is the opinion of the writer, that the ptomains or toxins and toxalbumins arising from bad digestion and faulty elimination are greater factors in disease than has yet been stated by writers on this subject.

For the purpose of bringing this subject before this society in such a manner as to elicit an intelligent

discussion, let us first inquire into some of the physiologic acts of the digestive tract. We learn that during digestion the albuminoids are acted upon by the gastric and pancreatic juices with the production of acid or alkalin albuminates, propeptones or hemialbumins, and ultimately peptones.

Normal gastric juice will digest albuminoids irrespective of the presence of bacteria. According to Flint, meat far advanced in putrefaction may be digested in a normally secreting stomach without serious deleterious effects upon the being; the bacteria being destroyed or rendered innocuous by the acid gastric juice. Interference with the function of the hepatic cells gives rise to an auto-infection which specifically reacts upon the nervous system, through non-elimination.

The liver produces more or less urea which is excreted by the kidneys. The bile which is essentially a secretion, is also decidedly an excretion. In so far as the biliary salts are concerned, they are manufactured by the hepatic cells and do not preëxist in the blood. The bile is thus a secretion, but the constant and invariable presence in the bile of cholesterolin classes it among the excretions. With the exception of the venous blood, crystalin lens, spleen and liver, cholesterolin is found only in the nervous system, which is the probable seat of its production. The blood loses cholesterolin in passing through the liver, yielding it up to the bile. Cholesterolin is converted into stercorin in the intestines, being thus entirely eliminated normally. It may accumulate in the blood when the liver cells are deprived of their eliminating function, giving rise to cholesteremia, a condition characterized by grave nervous symptoms allied to those in uremia.

When we consider ptomains, leucomains and the various chemic derivatives from fermentations, we see how important cell selection becomes in normal functional activities. While it is important that we should consider the process of digestion, as it represents the disposition of the food taken into the body, we must also take interest in normal excretion, as this represents the end-products of metabolic activity which are of no further use to the system.

Four channels, viz., the kidneys, intestines, lungs and skin, are made use of in this important process. As a rule, the gaseous waste products are excreted through the lungs and skin, the soluble solid bodies through the kidneys, the insoluble through the intestines. The gaseous products are mainly carbonic acid and water. Occasionally other gases, as hydrogen and marsh gas are present, formed in the intestinal canal by fermentation.

The more important bodies excreted through the kidneys are urea, uric acid, creatin, creatinin (all nitrogenous), phosphates, sulphates and chlorids; while by the intestines is excreted the excess of food undigested, together with the indigestible matter and the insoluble products resulting from the combined action of the bile and intestinal secretions. These products together constitute the outcome under normal conditions. If we consider these waste products of the body chemically, we find nearly all the nitrogen excreted from the kidneys and intestines.

The carbon and hydrogen, on the other hand (and a certain amount of organic matter), are excreted mainly through the lungs and skin, a small amount being found in the feces and urine. The remaining elements to be accounted for, viz., sulphur, phosphorus

chlorin, potassium, sodium, iron, lime and magnesium are found likewise in the urine and feces.

The most important nitrogenous bodies excreted are urea and uric acid, the former being the product of regressive metamorphosis by which proteid matter is changed by the action of the liver cells; the latter the product of a metabolism slightly different from that which leads to the formation of urea, undoubtedly one in which the spleen plays a part.

We have thus briefly recalled these physiologic processes only to refresh our memory along these lines, in order that we may better present pathologic conditions resulting therefrom. In such a consideration we must bear in mind that the function of an organ depends upon its structure. We are taught that "the structure of every cell and fiber of the body depends upon the quality and quantity of the material absorbed from the alimentary canal." An excess of food overwhelming the tissues and a deficient amount lessening the energy of every organ.

Toxic substances in the alimentary tract, whether introduced as such or developed from fermentation or putrefaction, deteriorates the structures and perverts its function.

Pasteur and others have shown that vast numbers of microbes capable of generating poisonous ptomaines and toxins, varying in their properties, are capable of producing most powerful poisonous effects. These poisons are produced in greater or less quantities subject only to the normal poison-destroying power of the liver, and the eliminating function of the kidneys. It has been asserted that "the great number of functional nerve disorders which are included under the general term neurasthenia, are all of gastric origin." Dr. Kellogg, in an article read before the Mississippi Valley Medical Association, says: "We see that special investigators in the etiology of disease are pointing toward the stomach as the starting point of the train of morbid processes which give rise, in each particular case, to a special group of morbid manifestations."

Dana asserts "that organic changes in the central nervous system are doubtless due to absorption of toxic substances produced by microbic processes in the alimentary canal." Since Murchison's series of clinical lectures in 1877, on the functional diseases of the liver, the accumulations of uric acid in the system, as pointed out by him, has become a recognized etiologic factor in lithemic conditions.

To present cases of auto-infection that should follow the foregoing introductory chapter, we can but present those of every-day occurrence, leaving a very large part of our subject without discussion. I present a few cases treated by the author during the last year, which will in a measure be illustrative of the subject under discussion:

E. T., aged 15; a well-nourished girl, inclined to inactivity and fond of reading many hours daily. When at school was at the head of her class and was far advanced for one of her age. At times was gloomy and irritable, crying upon the least provocation. Soon after would have an attack of migraines. The case was one that had exhausted the list of coal tar derivatives and other headache remedies without relief. An examination of the urine was made; specific gravity 1030 and uric acid crystals found. Salicylate of sodium as recommended by Haig, was prescribed with outdoor exercise, either walking or cycling, and with but little reading permitted. Patient occasionally takes a teaspoonful of alkalithia. Bowels kept open by a seidlitz powder when needed. She has had no return of her trouble for four months. This case was of easy diagnosis, viz., an accumulation of uric acid in the system, hence migraine as a symptom.

B. W., a man 46 years old, a very successful business man; has been treated for dyspepsia for years; is irritable at times, thin in flesh, suffers with flatulency and constipation. Is a medicine toper. Extremely jealous of his wife and is fond of slipping into the house at an unexpected hour, accusing her of intimacy with other men, yet her conduct is most circumspect. Complains much of headache and insomnia. An analysis of his urine was made and uric acid crystals were found; the urine clear when first voided, but becomes cloudy upon cooling with brick dust sediment; specific gravity 1028. Prescribed alkalithia and the salicylates and a trip to the mountains; bowels kept open with lapactic pills; he has improved much in health.

Mrs. B. P., married, aged 41, very fleshy and quite indolent in her habits; suffered with gastric and intestinal dyspepsia and cardiac palpitation and at times with a slight cystitis; had eczema once a year on portions of her body; complained occasionally of tenderness and stiffness in the metatarso-phalangeal joint of great toe of left foot; at times felt a soreness along the sciatic and pain in the intercostal nerves. Had been treated by one physician for dyspepsia, by another was told she had "chronic rheumatism." Her trouble was labeled "change of life" by her female friends. Had been given a course of "reduction of dislocated vertebræ" by an osteopathist. Her case was carefully studied and a chemic analysis of the urine made; uric acid crystals were found and a diagnosis of lithemia given. The patient was put upon a restricted diet composed largely of non-nitrogenous food, and exercise insisted upon; she was given large quantities of lithia water and an occasional teaspoonful of rochelle salts with bitartrate of potassa; a tonic of iron, quinin and strychnin was prescribed; at first a few doses of calomel were administered. She has improved much in health, her "rheumatic pains" have disappeared with her flatulency.

L. A., a married man, aged 36, a railroad employe. Began two years ago to suffer with attacks of indigestion and flatulency; at times had numbness of the extremities with some pain in back and loins; sexual function impaired; became depressed and would worry about trivial things; irritable at times and unsociable; performed his work with less interest and began telling his woes to comparative strangers. His sleep was disturbed and he suffered from headache; was constipated and flow of urine irregular, either scant and high colored or profuse and pale; lost weight and muscular strength; imagined he had heart disease on account of pain in the chest; was told he had diabetes; was also told he was becoming consumptive; was afraid he was losing his mind, and was not sure but he had locomotor ataxia; was constantly studying his own symptoms by the aid of a domestic work on practice. An analysis of urine was made and an excessive amount of urates found; specific gravity 1026. A diagnosis of neurasthenia given. He was required to visit my office but once a week and each time I made a thorough examination, both for the mental effect on the patient and to note any changes in his condition. His bowels were moved by a mercurial and salines, with plenty of water to keep them open ordered; tonics were given for a while; a shower bath with towel rubbing every morning required; a carefully regulated diet adopted and a cheerful mind enjoined. Faulty digestion, functional inactivity of the liver and the eliminating function of the kidneys were but improperly performed. As a result toxic substances were absorbed and the train of symptoms above enumerated ensued.

Considering the human body but an aggregation of cells, and cell groups normally functioning for the maintenance of the health of the individual, we realize the necessity of a normal equilibrium of nutritive factors, that they may resist the action of deleterious agencies. Men are not alike, nor are they at all times equally vulnerable to the action of bacteria. Heredity comes in for its share of theorizing, which in the light of modern research is defined as "a special vulnerability of certain cells or group of cells to morbid action."

Metschnikoff's theory of phagocytosis, and the theory that "certain albuminous constituents of the body possess a bactericidal power or a neutralizing effect upon the bacteria and their ptomaines," all point to the importance of normal functional activities within the body. From a study of the various systems of cells of which the body is composed, we

can with assurance point to those of the nervous system as the most vulnerable to the attack of morbid agents.

With the multitudinous array of symptoms seen in many forms of nervous disorders, how natural it seems for us to turn to the avenues of elimination in search for a source of infection. Then, surely, auto-infection is a factor in nervous diseases.

THE USE OF FORMALIN IN INFECTED WOUNDS.

BY A. L. CORY, M.D.
CHICAGO, ILL.

My attention was called some time since to the use of a mixture of formalin and gelatin in infected wounds. A German firm placed the mixture on the market under the name of "glutol." Formalin is mixed with gelatin, which forms a solid mass; this is grated, forming a fine gray powder, in which state it is sold, to be dusted on the wound as we have been doing heretofore with iodoform or boric acid. An American firm have recently put the same thing on the market under its proper name, "formal-gelatin." It was claimed for it that when pus was present the gelatin would gradually dissolve in the secretions and liberate the formalin, which is a strong disinfectant, and thus keep up a continual action while any of the powder remained. On trial I failed to realize the good results except in superficial injuries, for instance in two cases of scalp wounds. At the second dressing, 48 hours after the injury, the skin around several of the stitches looked quite inflamed and seemed about to suppurate, but on the application of the powder and fresh gauze at the next dressing, four days after, the wounds were found entirely healed. In cases where the infection was deep and pus already formed I could see no benefit from the powder. At this time I had under my care one of the nurses of Englewood Hospital who had been operated upon for appendicitis. The external wound had by some means become infected and I had opened it widely down to the peritoneum. In spite of all the measures I could apply, including the glutol, the wound surface continued to suppurate, and a pocket formed under the skin, beyond the wound but communicating with it, from which pocket I could press out at each daily dressing about two drams of pus. It then occurred to me to try the formalin in solution. Knowing it to be very strong, I without any special reason chose to make it of the strength of 1 to 200, formalin 3i, water ʒxxv. After the wound had been washed with sterile water until clean, I packed both it and the pus pocket with plain sterile gauze dipped in the above solution, and what was my surprise on the next morning to find no pus whatever. I again dressed it with the formalin, and at the end of another twenty-four hours removed it and dressed with iodoform, and the wound healed promptly without further formation of pus. At the same time I had under care a woman who had an Alexander operation for shortening the round ligaments, and in whom one of the wounds had become infected so that I had opened it widely for drainage. Two dressings of the formalin, 1 to 200, stopped pus formation, and the wound healed under iodoform without further suppuration. Since that time I have dressed all infected wounds, and we get many of them in railway surgery because of dirt ground into the wound at the time of the injury, with plain gauze

thoroughly wet with a solution of formalin 1 to 200, and have not had pus occur where the formalin could get to all parts of the wound.

I have had some wounds irrigated with the same solution, but do not get as good effects as where applied on gauze packed into the wound. In an amputation of the arm for railway injury suppuration occurred in the track of the drainage tube; here it was not possible to pack the entire tract with gauze, and irrigation seemed to reduce but not entirely stop pus formation. It would seem from my experience that the formalin must be held in place so that it may act on every part of the wound for several hours. In an acute case of gonorrhoea in a woman, as proven by finding the gonococcus in great abundance, I had the vagina thoroughly douched, then packed it through a speculum with gauze wet with formalin 1 to 400. This was renewed for four days in succession, and the gonorrhoea was cured.

My experience with the formalin has been so satisfactory that I desire others to try it and see if they can get the same good results.

I believe that with gauze dipped in the solution and the powder applied we have an ideal non-toxic dressing. With gauze wet with the solution packed in "pus pockets," and in gonorrhoea in the female applied on gauze, we can get better results than with any other dressing used at present by the profession. I would not expect as good results in gonorrhoea in the male, for there the formalin could not be retained long enough in contact with the diseased surfaces. In making my solutions I have used the formalin 1, as it is really a 40 per cent. solution of the gas called formaldehyde. I have continued the formalin as a packing material in my pus cases only long enough to stop the pus secretion. I do not know that it would be injurious, but knowing that it is being used as a fixative of fresh specimens for microscopic specimens, I have feared that its continued use would harden the granulations and delay the cure, so as soon as the suppuration has stopped I have used iodoform in powder and plain gauze as a packing to stimulate the growth of granulations.

4101 State Street.

TOBACCO AMBLYOPIA.

Read at the meeting of the Third District Branch of the New York State Medical Association at Auburn, N. Y.

BY F. W. HIGGINS, M.D.
CORTLAND, N. Y.

I shall make no attempt to present anything novel on the subject of tobacco amblyopia. It is a subject that has been much discussed during the thirty-three years since Jonathan Hutchinson first clearly connected failing vision with the inordinate use of tobacco. Still the pathology of the disease was not made clear until a dozen years ago and there is still much difference of opinion among writers upon the question of its real cause. But it is not even an attempt to clear up any one of these disputed points that I have had in mind in selecting this topic, but because I think that the ascertained facts in the case have been too much neglected by us as general practitioners. Until the ability to detect the condition is in the possession of the profession generally, it seems to me that many cases are bound to go unrecognized. Even if it is first diagnosed by the eye specialist, it can be best treated and its course followed by the family physician.

The diagnosis in this, as in any of the bedside cases we are called upon to treat, is of the first importance. Here, fortunately, it is not difficult if we keep its distinctive features in mind. If a person whom we know to use tobacco, therefore generally a man, who had used it moreover for several years, should complain of failing vision, for which he could find no help in spectacles, and affecting both eyes, we should have good grounds to suspect tobacco amblyopia. If then a rough test of the color fields of vision should show central scotomata for red and green, there could hardly be one chance in a hundred that we were mistaken in deciding that we had a case of this affection on hand. Of course the ophthalmoscope should be used, if for no other reason, to exclude other lesions. But I am one of those that believe that the ophthalmoscope should be used by every physician that is capable of using any instrument of precision, since it so often affords a clue to the general disease for which our patient is to be treated. *Tabes dorsalis*, Bright's disease and diabetes are only a few of the general diseases in which we may expect to derive some assistance from the ophthalmoscope.

The almost pathognomonic symptom is the central scotoma for red and green. A very simple and ready way to test this, when it is suspected, is to have the patient stand directly in front of you at a short distance, two feet for instance. One of his eyes is to be closed and with the other he is to look directly at your nose. A little piece of red paper is then to be fastened to the end of a penholder, or anything convenient, and from arm's length at the side to be brought slowly toward your nose. When the patient can first recognize it as red, you find that the object is at an angle of from 30 to 45 degrees from his eye. As the test object continues to approach your nose, suddenly there is a failure to recognize the color again. The object can be seen but looks simply dark, with no distinctive color. This small spot in which a person is color blind includes the fixation point and extends a short distance beyond it especially toward his temporal side. The same test with a bit of green paper will reveal the same scotoma, while other colors and white will probably be recognized. If the patient stand near a blackboard this field can be mapped out, and still more precisely by the perimeter, of which every part is equi-distant from the eye.

Such a typical case would be a man about 50 years old, who had smoked for many years. Chewing, working in a tobacco factory, or rubbing the gums with snuff may bring on the condition, but as a matter of fact, rarely do. The associated use of alcohol seems to act as a predisposing cause. Indeed, it seems to be proven that the chronic consumption of alcoholic beverages alone may cause an amblyopia indistinguishable from the one we are considering. Much of the literature on the subject has been of the nature of a discussion between those who believe that tobacco is the principal etiologic factor in the ordinary toxic amblyopia and those who would ascribe most or all cases to alcohol. The determination of the question is rendered the more difficult by the fact that most of those affected have used both narcotics to a greater or less extent. The English, following the investigations of Hutchinson, Nettleship and other English investigators, would claim that alcohol amblyopia seldom or never occurs. The French, in their intense loyalty to the published investigations of their fellow countrymen, almost

unanimously declare that alcohol is the sole cause of the retro-bulbar neuritis; that it causes sclerosis of the optic nerve as it does sclerosis of the liver. The Germans seem willing to allow both causes, as a result of their studies. The Americans have done too little original study to have a decided opinion on the subject. I think, however, that they admit both.

Often the observation is made that the patient can see better in the evening, or when the light is dim, than in broad daylight. A case is given of a coachman who could see the numbers on a house in the evening, but could not in the daytime. The pupil, however, is generally small and spasm of the ciliary has been noticed, which might require a strong light for the best vision.

If one makes an ophthalmoscopic examination he will discover, if sufficient care is used, that there is an atrophic appearance of the temporal quadrant of the nerve head. This bluish white color is hard to describe and drawings fail to give the delicate color change.

Within the last few years there seems to be a pretty general agreement as to the pathology of the disease. This to me forms a very interesting chapter. So long as it is found clinically that only the region of the macula and its immediate neighborhood are affected it would be expected that only a part of the fibers of the optic nerve would be found diseased. As a fact, this proved to be the case when sufficiently careful microscopic study of the nerve was made. A photograph of the section of a nerve near its peripheral extremity shows that the bundle of fibers lying at the outer and lower side and destined to supply the territory about the yellow spot is sclerosed. This change consists of a chronic inflammation with increase of the fibrous tissue lying between the nerve fibers, which by its subsequent contraction produces their atrophy.

A little farther back this bundle of fibers runs in the central part of the optic nerve instead of peripherally as before. The inflammation is often found to be most extensive near the optic foramen, where the situation of the bundle is entirely central. This fact disposes of the theory that the affection is primarily of the optic sheath and affects the elements of the nerve by pressure or extension. It is a primary nerve lesion.

Exceptional cases have occurred in which the central scotoma has enlarged until it has occupied almost the whole of the color field. In such a case we would have a condition of acquired color-blindness. It is easy to see how in such circumstances a railroad engineer or a pilot, who had successfully passed an examination for color blindness might become unsafe.

The kind of tobacco used may be a factor in the causation of the disease. It is found most among the poorer classes, because they use the cheaper, ranker tobaccos. It is found that the Virginia tobaccos contain two or three times as much nicotine as the Cuban or Maryland product. While it is probable that the other complex alkaloids and chemicals produced in the combustion of the weed are in part responsible for the effect upon the nervous system, still the percentage of nicotine in a sample in a general way measures its strength. The frequency of the affection seems to be greatest in England. In some clinics it reaches as high as 1 per cent. of all cases treated. Possibly this is due to the fact that more general attention has been called to the disease there, or it may be due to

the ranker sort of tobacco in common use. The very high import duty on tobacco and cigars in England does lead to the usage of a cheaper, stronger grade.

A very interesting case is given by Fuchs in which the same amblyopic condition was brought on by the long continued smoking of stramonium for asthma.

The treatment of tobacco amblyopia is very satisfactory because it is almost always successful. That is to say, it is successful where the conditions are carried out. The *sine qua non* is that the patient shall quit the use of tobacco absolutely. If one has a patient who would rather smoke than see, the prognosis is bad. Something might be done by smoking in the Turkish style, or greatly lessening the use of it and giving large doses of strychnin; but in the majority of cases no improvement is noticed until the last trace of its use is given up. Small doses of nuxvomica are recommended. Bromid of potassium may be indicated to quiet the nerves while undergoing the tantrums of breaking off the old habit. We are told, too, to give cathartics to take the place of the accustomed effect of the tobacco.

The progress of the case toward recovery may be measured by examining the size of the scotoma from time to time. It will be noticed, too, that as the conductivity of the tract from the retina to the brain centers is increased that the disability to distinguish the two colors, instead of being absolute, is only partial. At times in a favorable light, the colors will be correctly named in a hesitating manner. Entire recovery may be expected if the abstinence is continued. An ophthalmic examination may still show a paleness of that portion of the optic nerve, but vision will increase from $\frac{6}{60}$ to normal.

NOTE.—Several charts to illustrate the condition were presented.

DISINFECTION OF THE MOUTH A POTENT FACTOR IN THE TREATMENT OF LA GRIPPE.

Read in the Section on Dental and Oral Surgery, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY G. V. I. BROWN, D.D.S., M.D., C.M.
DULUTH, MINN.

In my capacity as a dentist, through dispensary and hospital practice incident to the study of general medicine, and by consultation with physicians in regular practice, who were particularly alive to the importance of the oral cavity in its relation to other disturbances, several conclusions have been borne upon my mind, which it is my desire to make the basis of this discussion.

1. That the disinfection of the oral cavity ought to be, and would be, if the necessity of it were sufficiently understood, as much a part of preliminary treatment of many diseases as the administration of a cathartic.

2. What is wanted to bring the dentist and the medical practitioner more frequently into consultation, as they ought to be, is not so much reports of remarkable cases, which, while they call attention to the possibilities of trouble, do not give an adequate idea of the frequency of mouth excitants of disease; not so much a theoretical digest of pathologic and bacteriologic processes; for given the state of things as they exist, the physician can supply all this for himself; but a plain statement of the facts of individual observation and experience as applied in relation

to particular diseases. Following this line, I desire to call attention to influenza, or la grippe as commonly called, in its relation to pathologic conditions of the mouth.

For fifty years this affliction has been recognized in periodical outbreaks, yet much of the real nature is still shrouded in mystery. We find, with some variation among authors, its description briefly to be as follows:

Definition: An acute, specific, infectious disease, characterized by great prostration and often catarrh of the mucous membranes, particularly the respiratory and gastro-intestinal tracts, with marked liability to complications.

Etiology: Comparatively unknown, notwithstanding exhaustive literature on the subject; believed to be due to the infection of the body by a specific organism, though bacterial examinations have usually shown pus organisms and diplococcus pneumoniae to be present. Symptoms are those of a marked infectious, or toxic, general constitutional disturbance of the body, with local lesions and symptoms; fever, languor, pain in the back, head, eye balls, bronchial disturbances, or catarrhal affections of the digestive tract, with perhaps nausea, diarrhea, etc., usually great depression of nerve force and spirits and a tendency to painful neuralgias of the trigeminus.

Complications and sequelae are the really formidable part and due for the most part to secondary infection, manifesting themselves in a variety of ways.

Diagnosis: Not usually supposed to be difficult, unless in a form resembling typhoid in its early stages, but differentiated later by pain in the muscles and catarrhal symptoms.

Prognosis: Favorable in healthy patients, dangerous in heart troubles and pulmonary diseases, or chronic nervous patients.

Treatment: Symptomatic, almost entirely phenacetin, antipyrin, quinin, strychnin and stimulants with morphia, when required, and good general care are the remedies most usually employed, with the usual variation of special advocates of other drugs. Thus we see from the clinical picture before us a disease, the characteristics of which are exactly those one ought to expect from quite common conditions of the teeth and gums, which by reason of the constant discharge of pus, must, and undoubtedly do, aggravate the symptoms.

In abscessed teeth, caries and necrosis of the jaws, as well as in pyorrhea alveolaris, we have the danger of direct infection, of reabsorption of waste products of toxic poisoning, and the constant passage of the pus germs through the alimentary canal along the mucous membrane surfaces, ready to ignite inflammatory or catarrhal processes wherever the lowered vitality of the part offers the least resistance. I do not think it an over-estimate to say that 90 per cent., if indeed not all patients, would have some pathologic oral condition, and a research of medical literature gives us almost nothing in regard to direct medication applied for the purpose of disinfecting the entrance portal of the infection.

We note the two most common forms to be bronchitis, with its serious complication, pneumonia, and catarrhal disturbances of the digestive tract.

Miller, in his "Microorganisms of the human mouth," referring to the experiments of Fränkel and Weichselbaum, who hold that the coccus of sputum septicemia is to be regarded as the most

frequent, if not the sole excitant of the lobar pneumonia, says: "If their view be correct, we may answer that in at least many cases the infection came from the mouth. The oral cavity serves as a gathering point for this microbe, which from time to time is carried into the lungs with the air, until at last, at some weak point, or the result of some slight inflammatory action in the lungs, through which the power of resistance is impaired, it obtains a foothold in the lungs themselves. For this reason, therefore, among many others, the neglected oral cavity offers a dangerous source of infection, which has by no means received the attention it deserves."

Mouth bacteria as excitants of nasal and pharyngeal troubles are too well understood to need more than passing notice and the same will, I think, apply to diseased conditions of the stomach, both catarrhal and digestive, which, over and over again, have been found to be the direct result of mouth conditions.

The other symptoms and sequelæ of this disease are simply such as might be expected from any toxic poisoning affecting the system from infection, varying according to the virulence and power of resistance of the individual case.

It is by no means intended to convey the idea that la grippe is purely and simply a result of oral infection, though, as we not unreasonably suppose, the secretions of the mouth are often a culture media for its specific organism; but there can be no doubt that many complaints arising solely from mouth disturbances are incorrectly diagnosed as la grippe, and that in such cases, as well as in the disease itself, much comfort, relief and benefit might be given to the patient during its progress, beside which many of the most serious complications might also be averted by the prompt, thorough and continued disinfection of the mouth, meaning thereby not only sterilization of the buccal secretions, but treatment or removal of any diseased condition that may exist.

It has happened repeatedly in my practice that patients have come complaining of all the marked symptoms of la grippe, perhaps while under the care of a physician for its treatment, with a foul odor from the breath, the mucous membrane of the tongue coated, more or less pharyngitis, and upon examination I have found a copious discharge of pus from the necks of the teeth, discharges from the fistulæ of apical abscesses or necrosis of the jaws, and by a removal as far as possible of the exciting cause, thorough cleansing of the teeth and medication in the form of sterilizing agents, aided by an antiseptic prescription to use as a mouth wash every hour the first day or two, and three times daily thereafter, have been given marked relief and shown improvement within twenty-four hours, with apparently complete recovery in a very short time.

One such had suffered from recurrent attacks, accompanied by chronic sore throat, a severe bronchitis, hacking cough and asthmatic attacks of considerable severity. All symptoms were marked, particularly the nervous depression and hopelessness.

Examination showed a chronic catarrhal state of nasal and pharyngeal cavities, with nasal polypus of considerable size. The oral cavity showed all the teeth more or less elongated, some having been lost, and on the right side, the outer wall of the superior maxillary was bulged out sufficiently to give a dis-

torted appearance to the face. As a preliminary step the care of the mouth was begun, it being understood that the polypus was to be removed and the treatment for the nose, throat and bronchials was to be taken up later.

Incision was made through the thin, bony covering of what appeared to be a sinus filled with thin light-colored fluid (though not connected with the antrum), but in washing out the cavity with hydrogen dioxide, bubbles were seen to ooze out around the neck of the right superior first bicuspid, and proved in fact that, though the pulp of the tooth was alive, a pyorrhea pocket communicated with, and had actually caused this apparently serious condition. Thorough local disinfection, drainage and cleansing of the necks of the teeth, care of the pyorrhea, by correcting malocclusion, an active exciting cause in this instance, and general disinfection of the mouth, repeated in the office daily for a number of days, augmented by a prescription for use at home, made such a general improvement in the patient that there was a general abatement of all the unpleasant symptoms, the despondency disappeared as she was able to go about and do her own housework, and the other treatment was considered unnecessary.

Another, a young man, having all the symptoms of disordered digestion, foul mouth, coated tongue, and troublesome but not severe pharyngitis, loss of appetite, intestinal disturbances, pains in his head and all over body very marked, pulse irregular, one or two degrees of fever, for which, curiously enough, his physician had been content with administering phenacetin, a depressant, to still further increase the already weakened and depressed condition, a treatment, according to good authority, that has probably killed, during the epidemic of 1889 and 1890, more patients than ever the disease alone would have done, was given the same treatment as in the preceding case, viz.: Thorough disinfection of the mouth, in which not only pyorrhea of long standing was encountered, but some abscessed teeth and necrosis, for which it was necessary to remove a sequestrum of bone. Immediate relief was given. Three days without the administration of drugs, were sufficient to put him quite on his feet again.

These two cases are typical of the principal forms of this disease, and illustrate as fully as could be done by a rehearsal of many similar cases that have come within my notice.

In using the term, disinfection, I have included the operative means necessary to accomplish the desired end, as well as the use of antiseptics. The former usually requires the assistance of a dentist, but the latter is quite within the reach of every practitioner of medicine, who, if as he looks at the tongue in the truly orthodox manner of physical diagnosis, will glance at its surroundings, and give along with the prescription for internal use, one for a simple mouth wash with good germicidal properties, he will certainly find the usual remedies unusually efficacious.

Dr. Kirk, in the *Cosmos* of November, 1895, speaks quite strongly upon this subject, and recommends the use of phenolsodique, adding the somewhat unusual procedure of holding the tongue and scrubbing its surface with a brush, to cleanse off the closely adherent furred coating. This I have not tried, though for a thorough cleansing, it speaks for itself. I begin, as is my custom with every case presenting in which the suppuration processes are apparent, by making the

patient rinse the mouth with a solution of mercuric bichlorid 1 to 1,000, with an equal amount of hydrogen dioxid, or in place of this, a strong carbolyzed solution, and continue the process two or three minutes by the watch. This serves the purpose of safety both to the patient and the operator. The local applications are governed by the nature of the case, and upon dismissing the patient, give the following prescription, which I have used a long time, and once before given before this Section:

R. Listerin	āā	ʒiij.	96
Glycerin		ʒiij.	12
Acidi carbolici			

Misce. Sig. Dilute one teaspoonful in one-third glass of water. Use as mouth wash.

This seems to be quite effective, and is satisfactory because, by reason of its simplicity, patients being familiar with the drugs, are able to use judgment in varying the strength, as necessity may require.

There are mouth washes galore, and I have no especial desire to go into the matter of their discussion. They must be strong enough to at least inhibit, if not destroy, the pathogenic organism, must be used constantly, and held in the mouth for several minutes consecutively, to be at all certain of effecting the desired purpose. As for other desirable qualities, these may undoubtedly be left to individual preference.

What is true of influenza is undoubtedly also true of many diseases, and if alone the practice of disinfecting the mouths of their patients could be freely established among those whose duties call them to the bedside, far-reaching benefit must undoubtedly result.

DISEASE OF THE ORAL CAVITY A POT- ENT FACTOR OF GENERAL DISEASE.

Read in the Section on Dental and Oral Surgery, at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY SHEPPARD W. FOSTER, M.D.

ATLANTA, GA.

The oral cavity in its broad range of function, in its necessity to the life and advancement of the human family, fills one of the most important offices of any organ of the body.

Serving, as it does, among other important functions, in the articulation of human speech, in vocalization, prehension, mastication, insalivation, deglutition, etc., it has constant employment from the induction of life to the last breath of old age. It plays equally an important part in both the sorrows and pleasures of life. And since its functions are so imperative, we can readily appreciate the fact that any pathologic condition existing here might with ease become manifest upon other organs.

We will call attention to some of the deleterious effects of first dentition. We know that this period covers the most critical span of human life, but it has been stated by eminent authority that the vast mortality of infantile life depends more on the conditions of the oral cavity than from all other causes combined.

When the development of the root of a tooth progresses more rapidly than the overlying tissues are absorbed, we have local inflammation. The gums become red, swollen, and highly inflamed and are very tender to touch. The secretions are much increased and the reflex pressure on the nervous and vascular supply augments the trouble, until we have the entire system involved. The child has grown

wakeful, restless and fretful; its cheeks are flushed; it refuses nourishment; the alimentary canal becomes more active, diarrhea being manifest, and if relief is not given, relaxation of the vital forces follows and we have nausea, vomiting, convulsions, paralysis and not infrequently death. Statistics show that a greater number of deaths occur from cholera infantum, entero-colitis, convulsions, infantile paralysis and laryngismus stridulus during the period of first dentition than at any other time of life.

Considering the anatomy of one of the largest and most complicated nerves of the human organism, that which supplies the teeth, the trigemini: A compound nerve varied in its functions, a nerve of special sense, common sensation and motion; the great sensitive nerve of the head and face; the motor nerve of mastication; its lingual branch the nerve of the special sense of taste, sending important branches to the ear and eye, anastomosing with many other nerves. It is not strange that we have remote lesions having their origin from this nerve.

A large percentage of neuralgia can be readily traced to some dental disease. The most numerous cases of reflex irritation are associated with these disorders. One of the most frequent is the continued attacks of auritis during the eruption of the sixth year molars. In almost all cases of reflex irritation, as the result of erupting teeth, the free use of the lancet gives immediate relief.

I have with me an unerupted, impacted central incisor tooth, which Dr. R. B. Chapman, of Troy, Ala., extracted from the mouth of a lady aged 25 years. She had suffered with neuralgia for several years. It had taxed her patience and the skill of the best physicians of her city and she had spent several seasons at different resorts, endeavoring to obtain relief, but to no avail. Finally, she came under the care of Dr. Chapman, who noticing the absence of the tooth, made a careful examination and located it with cutting edges pointing upward and almost protruding into the nasal cavity. He removed the tooth by making an incision at the union of lip and gum and with burrs and chisels removed the overlying osseous tissue and lifted it out of its bed. With the healing of the wound the neuralgia entirely disappeared and the general health was greatly improved.

I have also in my possession a left superior second molar which has interlocked with an impacted wisdom tooth, with coronal surface deflected backward toward the tuberosity of jaw. The patient had dull, heavy, gnawing pain for some years about the region of molar bone and auris, finally terminating in slight paralysis of the face from which she could not be relieved. The second molar having developed quite a large cavity which became painful, then she applied to have the tooth extracted. The operator was much surprised at bringing with it the unerupted wisdom tooth. Within a few weeks after this operation the paralyzed condition disappeared. We believe many conditions of like character are the result of nervous reflex irritation produced by dental disorders.

We frequently have recorded cases of amaurosis as the result of inflamed or dead pulps, or chronic catarrhal trouble induced by a diseased tooth, first producing an inflammatory condition of the antrum and spreading from thence through the nares and various sinuses.

In examining the mouths of many patients suffering with dyspepsia it has proven the exception when

the masticating powers have not been destroyed from one-third to five-sixths of their capacity. We know that bolting of food day after day will produce dyspepsia, gastritis, etc., therefore we must admit that if the inability to properly masticate is not the direct cause of this dreadful disease, it certainly accompanies it. Lower your vitality and you invite disease. The oral cavity is the commencement of our digestive tract. It is the antechamber to man's vegetative life and in this respect it is introductory to the stomach. Therefore it is reasonable to suppose that any lack of hygiene, or any pathologic condition that causes a deficiency of quantity or quality of the fluids which the food first meets when entering the mouth, is a hindrance to nutrition and undoubtedly makes its impression on the stomach.

Often when a patient presents herself for treatment she is anemic, debilitated, despondent and melancholy. The physician examines her and asks various questions, but can not locate the trouble in any special organ, so he says "nervous debility," or "breaking down of the vital forces," and the usual prescription of tonics, change of residence, etc., is advised. A careful examination of the oral cavity would reveal decayed and broken down teeth and suppurating sinuses, contaminating the air of respiration, vitiating the oral fluids, poisoning nutrition and consequently lowering the vital forces and breaking down the general health. This is not imaginary, but the real condition of the mouths of many of our patients.

It is rare that we find a consumptive without a typical case of pyorrhea, or at least pus exuding from around the necks of the teeth, and I have thought that inhaling the effluvia from these suppurating sinuses of the mouth might produce this fatal disease. This leads me to ask, What should be the relations of the physician and dentist? Should the dentist know more of medicine or the physician know more of dentistry? As to these propositions I think no medical college should be without a chair on the principles and practice of dentistry and our dental schools should teach more of general medicine and surgery.

THE TECHNIC AND PATHOLOGY OF THE PERIDENTAL MEMBRANE.

Read in the Section on Dental and Oral Surgery, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY VIDA A. LATHAM, M.D., D.D.S., F.R.M.S.
CHICAGO, ILL.

Dental histology and pathology are yet in the embryonal stage, less advanced, perhaps, than any other kindred subject. With the exception of a few, we can not claim special micro-workers. Little encouragement is given to prosecute the subject. The technic is difficult and unsatisfactory at the best, and our schools are content to teach the subject in such a brief elementary way that a student graduates in dental surgery with but a slight knowledge of the barest facts concerning the structures that compose the teeth. It is needless to urge that this is wrong, such a fact is self-evident. An exact knowledge of structure always aids in understanding the function of a part, and is absolutely essential to a clear idea of its diseases and to rational treatment. If we do not know the arrangement of enamel, we are in danger of splitting the tooth in chiseling. We can not tell

what agents are absorbed if we do not know the composition of the dentinal tubules, or the action of bacteria and their septic products on the surrounding structures of the root. Precise information on the histology and chemistry of the teeth would solve many of the curious problems we meet in the practice of our profession.

So far as I can find by consulting text-books on micro-technic, little or nothing is said of technic in dentistry. A few ideas are scattered here and there through our journals. Works on dentistry dismiss in few lines the peridental membrane and its structure, position and the modes of obtaining sections for study. When looking over some mounts of teeth I was surprised at the different appearances presented, some showing extensive pathologic features and some interesting conditions. To obtain normal peridental membrane is not easy. Some authorities state that it is found on all extracted teeth, while others say it is not present unless some pathologic process exists. Certainly in the majority of healthy teeth after extraction the roots are always free from any tissue, or what might be considered periosteal tissue. In carious teeth, especially those which have had some periosteal inflammation or irritation, we can easily find thickened membrane. A recent study of several thousands of sections of carefully selected teeth has convinced me that in the case of normal teeth, after extraction, it is difficult, if not impossible, to demonstrate the presence of peridental membrane; whereas in carious teeth, particularly those with periosteal inflammation, a thick layer of peridental membrane is always present. Therefore, I am in favor of considering sections from such teeth pathologic material.

In studying the development and relations of the peridental membrane, sections were made of teeth of animals, fetal and matured, including serial sections of one and of both jaws, to show the relations of teeth and membrane *in situ*. So far as I have pursued this work it has been anything but satisfactory, for the following reasons:

1. It is difficult to secure good specimens of membrane.
2. When obtained, it is hard to preserve the membrane in a normal condition and to cut sections from it.
3. Sections show poor results from staining, as the effect of some acid reagents prevents the securing of sharp definition and contrast.
4. Even with good teeth, it is difficult to secure the membrane *in toto*, as the paraffin sections are very liable to become brittle or curl up.
5. Much important material is lost by decalcifying agents and the irregularity of their action.
6. It is difficult to obtain maxillæ with teeth *in situ* which are fresh enough for examination.

Dr. Black' says: "The time the tissue remains in the embedding material must only be counted by minutes, never by hours; and if, after its removal and placing the tissue in water, it does not swell out to its normal proportions in every part, which failure may be detected after sufficient experience by its appearance, it should be cast aside and a new effort made." This statement is open to question, if we may trust our workers of technic. Poor results are too often occasioned by hurried embedding and infiltrating with the penetrating and clearing agents. If once the material has been properly and thoroughly hardened when fresh, the paraffin ought not to cause

¹ Periosteum and Peridental Membrane, pp. 18 and 19.

shrinkage. Tissues may be cut fresh in gum, ether and aniseed oil, but with these methods we expect more shrinkage. Personally, I prefer to use weak decalcifying agents for a number of days, instead of strong solutions for a short time, as advised by Dr. Black; for I believe if the material has been carefully fixed no bad shrinkage will result.

The absence of any concise discussion of this department of odontologic science in current literature is much to be deplored. So far, there is only one small compilation on the subject, and this deals chiefly with the methods for general histologic work, rather than with the methods suitable for dental microscopy. Further original investigation is much to be desired. The best way is to secure some tissue and harden portions of it in various ways, recording every particular; and then, by measuring, estimate the amount of shrinkage, the action of the hardening agents on the cells as regards the distinctness with which they show and their behavior in relation to staining agents. The previous generation of investigators have left us enormous labor in correcting their errors, for they dogmatized upon observations of tissues profoundly altered or modified in course of preparation. All the science of modern histology with its many warnings and precautions, is one great safeguard for avoiding these errors in the future. To save the tissue elements which so readily distort after death, we must secure an immediate preventive, viz., fixation. This may be done by chromic acid, Flemming's solution, Carnoy's modified by Van Hook and Ohlmacher, osmic acid, bichlorid of mercury, gold trichlorid or absolute alcohol. Fixing is especially necessary in preparing the embryonal material. When it contains cartilage, bone or dentine we may use the same fixative, but must follow it by a decalcifier. It must stay long enough in the fixing agent to harden properly and then be thoroughly washed till testing shows it acid-free. (This is not the case with certain special formulæ, which require acidity to stain well.)

The question of imbedding then follows. I obtained the best results with the freezing microtome if each section was carefully worked out. In some cases, however, it is probably necessary to use the paraffin or the celloidin method, and this particularly concerns the embryonal material. In using paraffin, even though decalcified till soft, the teeth invariably became so hard that only a few sections could be obtained from each sample. It was especially hard to avoid "crinkling" so that thin and perfectly flat sections could be made. To obtain sections of the hard and soft tissues together, the method of Drs. Lavis and Vosmaer, now better known since elaborated by Weil, is one of the best, although requiring much time and patience. Chromo-nitric or chromo-hydrochloric acids are good. Picric acid is good, but very slow in its progress. The following are a few of the most successful formulæ: Fresh teeth were dropped at once into

1. *Müller's fluid.*

2. *Chromic acid, 1-6 per cent., 2 parts; alcohol 1 part.*—These were changed constantly, kept in the dark, then thoroughly washed and decalcified in different solutions. It was here that such contrasting results were observed.

3. *Decalcification by nitric acid, C. P.*—Two per cent. aqueous solution, changed daily; time required, eighteen days, to allow a needle to penetrate, then

thoroughly washed and in some cases passed through an alkalin solution; then hardened in alcohol of graded strengths. Notes: "Membrane intact; pulp remained in the central canal. The membrane does not shrink and the cells stain fairly well, but not sharp and clear. Carmin gave better results than logwood. If strong solutions are used material must be closely watched, as the acid seems to act suddenly when decalcification is nearly complete, *i. e.*, the tissues though still hard when examined may in an hour or two be all broken into useless detritus."

4. *Chromic acid, 15 grs., distilled water 7 ozs., nitric acid 30 minims, changed on fourth day to one-half the strength, using fresh fluid daily. Time, eighteen days.* Notes: "The membrane appears to be attacked, partially eaten off; it does not shrink; the cells stain well and the pulp is in excellent condition, showing nerves and ganglia cells in a marked manner."

5. *Palladium chlorid, 0.001 per cent. in water 10 parts; hydrochloric acid 1 part. Changed once. Time, four or five days.* Notes: "Does not affect the membrane; the results of cutting and mounting gave most perfect specimens. Staining was not sharp and clear, though somewhat improved after prolonged soaking in solutions of sodium bicarbonate or lithium carbonate and then staining for thirty-six to forty-eight hours. Care must be exercised with logwood to prevent precipitation and the stains should be renewed during the process. The pulp canal showed merely the framework, but no tissue elements. It demonstrates the longitudinal fibers nicely and stains them brown." Sections can be stained somewhat if placed in 1-300 or 1-600 solution of palladium chlorid for one to three minutes, rinsed in water and then put in a cold saturated solution of picro-carminate of soda for eight to sixty minutes. Mount in dammar. Glycerin gives good results here as a mounting medium for immediate use; but for hard or non-decalcified specimens, it affects the structure later. Equal parts of palladium and platinum chlorid is useful where a thickened membrane is found, as it shows connective tissue well.

6. *Phloroglucin* is a good decalcifier and preserves all elements but red blood cells. The agent itself covers the organic part of the tissue against the action of the mineral acids, which can therefore act on the inorganic structure in a more concentrated solution. It is the most rapid decalcifier I have used for bony structures. I recommend great caution in its use for teeth, which it affects somewhat more slowly. To increase its rapidity of action 35 to 45 per cent. nitric acid C. P. can be added and then wash for two days in running water. Staining is easily accomplished after using phloroglucin. If hydrochloric acid is preferred to nitric it may be added in the proportion of 30 per cent. acid with 0.5 per cent. sodium chlorid.

7. *Arsenic acid, 2 per cent. aqueous solution, changed daily. Time, fifteen days.* "Results were uniformly good; membrane normal, cells stain sharply, pulp shows well, filling the canal completely. Arsenic evidently has some special staining powers, as seen in the nuclei of the leucocytes."

8. *Hydrochloric acid and nitric acid.*—[Hopewell Smith's method.²] Harden three to four weeks in Müller's fluid; alcohol ten to twenty days; wash in water. Seal the apical foramen with collodion. Immerse in a 15 per cent. solution of the following to decalcify: Hydrochloric acid 12 parts, nitric acid 30 parts, aquæ dest. 108 parts. Immerse in 12 c.c. of

a 10 per cent. solution of hydrochloric acid, then after fifteen hours add 1.5 c.c. of nitric acid, and after forty-eight hours add again 1.5 c.c. of nitric acid. After seventy-five to eighty hours wash half an hour in a solution of lithium carbonate, 5 grains to the ounce of water; wash in water, cut in pieces, place in gum mucilage and cut.

9. *Hydrochloric acid and glycerin*, in the proportion of hydrochloric acid 5 parts, glycerin 95 parts; is very slow in action, but softens the teeth and preserves the tissues nicely.

10. *Perenyi's fluid* is a most useful agent and gives good specimens, though the subsequent staining is not sharp.

11. *Trichlorid of gold*, 0.5 per cent. aqueous solution, is very useful to demonstrate the transverse fibers, provided the teeth are fresh. Underwood's method may be used when the teeth are not so perfectly fresh.

Staining agents.—The stains used were logwood, borax carmin, picro-carmin, orange and rubin [S.], Weigert's method; dehydration in clove oil or cedar oil. Alum-carmin and glycerin are both liable to dissolve carbonate of lime, and should not be used to preserve pulp stones, etc.

Preservative and mounting media.—Cut sections are apt to curl up when preserved in alcohol. This may be prevented by adding a small proportion of glycerin or carbolic acid to the alcohol. If preferred, 1 or 2 per cent. of the standard 40 per cent. solution of formalin keeps indefinitely. For mounting, balsam in xylol, chloroform, glycerin and glycerin-jelly, monobromid of naphtha and dammar.

Conclusions.—1. No perfect decalcifier has been found; but arsenic acid, phloroglucin, palladium chlorid, nitric acid and chromic acid give fair results, preferred in the order named.

2. It is difficult to stain perfectly after decalcification, except in case of phloroglucin and chromic acid. If a satisfactory stain could be found to use after palladium, I would prefer the latter as a decalcifier, even though expensive, for a small quantity of the solution accomplishes much.³

CHRONIC RINGWORM OF THE SCALP.

Read on Opening Discussion on "Chronic Ringworm of the Scalp" in the Section on Dermatology and Syphilography, at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY L. DUNCAN BULKLEY, A.M., M.D.

NEW YORK.

Ringworm of the scalp has come to be regarded by those who know most about it as one of the most troublesome diseases of the skin; it is also much more frequent than is commonly supposed.

While the other forms of trichophytic disease occur more or less frequently in adults, its appearance on the scalp belongs especially to childhood. In the writer's private practice there were only 2.5 per cent. of patients thus affected who were over 13 years of age, and about the same proportion in public practice; it may affect those but a few months old.

The damage that the parasite may do in some patients is so slight that the disease is often overlooked and undoubtedly there are many cases which

go for years untreated, endangering those around them, as the writer has repeatedly observed both in public and private practice. Alder Smith, of London,¹ has known an outbreak of ringworm to occur in a school from a child with a single spot no larger than a split pea, and where only a few "stumps" could be found on close examination with a lens. Among 1,349 healthy boys, aged from 8 to 10 years, whom he examined for admission to a charity school in London, and who were supposed to be quite free from ringworm of the head, he found this present in 112 cases, or 8.3 per cent. of the whole.

Many cases which came to him with certificates from reputable physicians that their ringworm was cured, were found on careful study to have abundance of the disease in a chronic disseminated form.

In one public institution in New York City, sheltering between seven and eight hundred children, 367 cases of ringworm of the scalp were found, that is, over half of the inmates were infected before the damage was fully realized and active measures for its arrest were inaugurated.

Tinea tonsurans of the scalp is not always as easy of recognition as might be supposed, and in cases which have lasted for any length of time the diagnosis may be very difficult. The typical case of scalp ringworm, exhibiting one or more partially bald patches, of a more or less leaden color, and with stubbed hairs, may be recognized by everyone. But in cases which have lasted any length of time the affected surfaces may and generally do not present this typical tonsure appearance. After a certain duration, and especially after more or less satisfactory treatment, many of the hairs assert their vigor (although by the microscope they may present some evidence of the parasite) and will grow to a considerable length. The real nature of the disease is thus masked and it is only by the most careful search that the "stump" or broken-off hairs can be detected.

To this persistent and rebellious form of the disease the name of chronic or disseminated ringworm has been given, and it is one of the most troublesome affections which can be presented for treatment.

Few realize how exceedingly persistent ringworm of the scalp may become in certain cases. The disease is commonly looked upon as a trivial matter, and undoubtedly in healthy children many cases may yield quite promptly to relatively simple treatment; even tincture of iodine will cure, or seem to cure, a good number of cases. But on the other hand, quite a number of these patients who are supposed to be cured are afterward found still to present evidence of the parasite, which crops out afresh later and, as already mentioned, may start the disease in a school or family.

The physician should therefore be extremely careful whenever scaly conditions of the scalp are presented in children, to determine with positiveness if the trichophyton is present. When the parasite exists on the scalp or hairs, the greatest care should be exercised to prevent the disease spreading to others. And when the patient has been under treatment for this eruption, still greater care should be exercised, if possible, in deciding as to when the patient is cured and no longer capable of infecting others. Few cases of ringworm of the scalp can be thoroughly cured in a short time, such as a month; more frequently from

³ See Histology of the Teeth, Notes on Preparation, etc.; Histology of the Teeth, International J. of Microscopy and Natural Science, 1889, July and October 1892; 1893, January and October; Histology of the Teeth, Scientific Inquirer, vol. 2, p. 196; Hopewell Smith on Micro Methods in Dental Histology; Underwood: Dental Histology.

¹ Alder Smith: Ringworm Diagnosis and Treatment, 2d edition, London.

three to six months is an average time, while some cases, even in skillful hands, may take years, if the disease has obtained a strong foothold. Alder Smith knew of one patient where the disease had resisted all treatment for nine years, the patient still having disseminated ringworm at 18 years of age. Crocker speaks of a woman of 20 who had had the disease since she was 10 years of age, disseminated all over the head.

Before discharging a case of ringworm as cured, every portion of the scalp should be thoroughly looked over with a hand lens of moderate power and with abundance of sunlight. It is well to have the little patient seated on a stool and, beginning with the back of the head, the whole surface is to be carefully searched. To make any satisfactory examination, the hair should be cut to about an inch in length. Commencing at the occiput the hair is turned upward gently with the blades of the forceps or the finger and allowed slowly to fall into place; this should be systematically done in such a manner that every portion of the head can be minutely inspected. As the pale surface of the scalp comes into view, the short, dark stumps will be readily seen. The same method should be employed in examining new cases, where doubtful, and also with children in schools where it is desired to surely detect the disease.

The subject of the treatment of chronic ringworm is a very large one and can hardly be touched upon in this opening of the discussion. It may be premised, however, that the writer quite agrees with the opinion of others that it will often tax the ingenuity and patience of the physician very greatly; and that time is a very essential element in the cure of the disease. The occasional reports of very rapid and certain cures of ringworm of the scalp are to be taken with a great deal of caution; the experience of all who know much about the disease will, I think, confirm that they relate either, 1, to very early cases in very healthy subjects, which yield readily to any well directed treatment; or 2, to cases where previous treatment had largely removed the disease, and, as is often the case, victory comes to the last attendant; or 3, to cases where there was a faulty observation, either in regard to the diagnosis or as to the completeness of the cure. It is not at all uncommon to meet with patients exhibiting chronic ringworm of the scalp who have been regarded as cured by other practitioners.

It would be out of place to dwell here upon the important studies which have been recently made in regard to the fungus of ringworm of the scalp, excited largely by the bold and original work of Sabouraud, at the Hôpital St. Louis, in Paris; while they are of interest and importance from a scientific point of view, as yet they have yielded little, if anything, in regard to the practical management of the disease. They may, however, often have a practical bearing in the direction of prognosis, if careful microscopic studies are made as should be done in every case; for it is pretty well accepted that those exhibiting *microsporon* fungus are more apt to prove rebellious than those presenting only the *megalosporon*.

In regard to the treatment of chronic ringworm of the scalp the remedies which have been advocated at one time and another are so many and varied that the mere enumeration of them would occupy much more time than should be given in the opening of the discussion; they will no doubt be fully considered in the papers and remarks which will follow.

EXPERIENCE IN THE TREATMENT OF RINGWORM OF THE SCALP IN THE NEW YORK SKIN AND AND CANCER HOSPITAL.

Read in the Section on Dermatology and Syphilography, at the
Forty-seventh Annual Meeting of the American Medical
Association, held at Atlanta, Ga., May 5-8, 1896.

BY HENRY A. PULSFORD, M.D.

SOUTH ORANGE, N. J.

The materials from which this paper has been constructed were drawn from the clinical records of seventy-five cases of ringworm of the scalp treated in the wards of the New York Skin and Cancer Hospital during the ten years ending in the spring of 1892. The purpose of the paper being neither to present a brilliant array of suspiciously favorable statistics, nor to puff any one method of treatment, this series of cases has not been subjected to any process of selection or elimination. And if the facts, when allowed to speak for themselves, tell of failure more often than of success, the lesson they teach us is no less valuable on that account.

Of the seventy-five patients who have furnished the facts for this report all were inmates of the hospital during the whole course of their treatment. They were therefore constantly under the care of the resident physicians, under whose supervision all the details of treatment were carried out. The scalps were subjected to frequent examinations, scales and hairs from the diseased areas being examined microscopically, and all changes in the conditions of these areas noted from week to week. In fact all the circumstances were favorable not only to the cure of the patients, but to the accumulation of important data as to the comparative value of the various methods of treatment employed.

Favorable as these circumstances were, it is nevertheless an exceedingly difficult task both to make accurate notes in the records of the cases and to interpret those notes correctly. For after the first cleansing and epilation, the changes in the diseased areas are so slow and trifling that it is often impossible for several weeks to say whether the disease is increasing or diminishing; and, as always happens under such circumstances, the records of the observations and examinations will invariably be modified and colored by the prejudices of the reporter. If, therefore, the inferences drawn from this mass of evidence are to be of any value or significance, due allowance must be made both for all possible errors of observation and for the personal bias of the observers.

The comparative value of different methods of treatment could probably have been more satisfactorily determined if, in addition to the microscopic examinations, systematic cultures had been made of the hairs and scales taken from the diseased spots. Such cultures if properly made, would give us valuable indications, not only of the parasitical properties of a remedy, but also of its ability to penetrate to the depths of the hair follicle.

It is to be regretted that at the time these hospital records were taken, Sabouraud had not yet published the results of his investigations of the mycology of the ringworm, nor emphasized the striking clinical differences between the two varieties of ringworm of the scalp. Although some of the house physicians possibly noticed the differences between the small-spored fungus external to the hair shaft, and the large

spored "trichophyton," infiltrating the hair-shaft, none of them having made any notes of such observations, it is impossible to arrive at any conclusions either as to the relative frequency of the two types of disease, or as to their relative resistance to the various methods of treatment employed.

The results of treatment in these seventy-five cases can scarcely be called brilliant. Of this number only twenty were discharged cured. This is certainly a very small percentage. But in judging the results of treatment in these diseases, it must be borne in mind that long continued treatment is almost invariably required to accomplish a permanent cure. Unna, it is true, has reported cases of ringworm cured by chrysophanic acid in two or three weeks, but few, if any other, physicians have had as happy results with this or with any other remedies. Wickham,¹ using another method of treatment, cured only from 40 to 60 per cent. of his patients in the course of fifteen months. Pottevin,² after using applications of formic aldehyde for more than three months, reports his cases as still very far from being cured. It is not surprising, therefore, that of these cases, in which the duration of treatment averaged twenty-two weeks, only about 25 per cent. were cured. Indeed, the chief obstacle to the cure of these cases lay in the impatience of the parents or guardians, who in many instances could not be induced to leave their children in the hospital long enough to permit the complete eradication of the disease.

Of the many physicians who report their cures of ringworm of the scalp very few tell us upon what grounds they base their assumptions of cure. The fact that a patient whom you have discharged as cured from a hospital or from your office, does not return to you, is by no means proof positive that his "cure" is permanent. If, in spite of your dictum, the disease returns at the end of a few weeks, the patient naturally discredits your knowledge and skill, and applies elsewhere for advice and treatment. In these cases we should be very skeptical of results, especially of brilliant results—when the reporter neglects to tell us how he determines that the disease is finally eradicated. Wickham¹ advises that no case be reported cured until the following examination has failed to reveal the parasite: The hair having been cut short and the scalp thoroughly washed, the head is left absolutely undisturbed for a week; then the scalp is carefully examined for evidences of disease. If none are found the hair is cut again, the scalp washed, and the head left undisturbed for another week, when the second examination is made. If that also proves negative the head, after hair-cutting and washing, is left untouched for two weeks, at end of which period the final examination should be made. Although all the details of this excellent method of examination were not carried out in the New York Skin and Cancer Hospital, our patients were not discharged as cured until they had passed through a similar ordeal. The essentials of this method—repeated examinations of the scalp at short intervals during which all treatment was stopped—were strictly carried out in all cases.

As has often been stated, the best cure for ringworm of the scalp is puberty. It is therefore important in considering the effects of treatment upon a series of cases of this disease, to bear in mind that it is really a self-limited malady, and not to give to remedies credit for improvement which is really due to the increasing age of the patient. There is no doubt

that in many of the cases here reported the advent of puberty has had more to do with the cures than has the application of drugs. Yet our ringworm patients have as a rule been so young, their average age at the time of treatment being only 7½ years, that the element of puberty can certainly be disregarded in the case of most of their number.

In all of our cases the preparatory treatment has been practically uniform. The hair has been cut close, usually with the clipping machine, and the scalp has been freed from crusts and scales by scrubbing with green soap, preceded when necessary by a preliminary soaking in oil or petrolatum. In some cases, especially when such preparations as collodion or plasters were to be used, the whole scalp was shaved. In all cases the hair was kept conveniently short throughout the course of treatment.

The hair-cutting and cleansing was in most cases followed by the careful epilation of the diseased areas. This was done, in the first place to remove from the scalp as thoroughly as possible all the brittle diseased hairs, and in the second place with the view of isolating infected areas by epilating a fringe of healthy hairs about their margins. The epilation of the diseased hairs themselves I consider an eminently proper procedure and an important detail in the management of these cases. The extraction of the diseased hairs, if properly done, is not at all painful; but if it is done hastily and carelessly, is painful and ineffectual. It needs no argument to convince one who is acquainted with the pathology of the disease, that the removal of as much as possible of the infected hair-shaft is a great desideratum. By careful and patient work with epilating forceps and magnifying glass it is usually possible in a comparatively short time to remove the greater part of every diseased hair.

On the other hand I have always had doubts as to the wisdom of epilating the healthy hairs on the verge of diseased areas. The object of this procedure presumably is the isolation of each center from which the disease may spread; but what assurance is there that such epilation prevents the spreading of the disease? It is well known that both varieties of the fungus are capable of growing in the superficial layers of the epidermis, while only the trichophyton megalosporon actually infiltrates the shafts of the hairs. It is therefore only reasonable to suppose that in either form of ringworm the extraction of the healthy hairs about the diseased areas will not only fail to check the spread of the disease, but, by making the mouths of the follicles more patent to the entrance of the spores, will actually encourage the extension of the growth into the lacerated epidermis of the unprotected hair follicles. If there be any force in such reasoning as this, we should be very careful in epilating to spare all the healthy hairs, trusting to cleanliness and antiseptic applications to hold the disease in check.

However this may be, the greater part of the epilation to which the patients at the Skin and Cancer Hospital have been subjected, was of the indiscriminating sort. It was carried out in such a way as to remove all hairs, both healthy and diseased, from the infected spots and from a liberal zone surrounding them. That the disease actually did spread in several instances in spite of this wholesale epilation, the hospital records clearly assert. That it did not spread in more cases, was doubtless due to the vigorous use of antiseptics. Since these considerations impelled me to give up the practice of "isolating" areas of ring-

worm by epilating healthy hairs, I have never had cause to regret it. The proper antiseptic applications will protect the healthy hair follicles better than the removal of hairs can possibly do so.

The average duration of treatment in all cases was five and a half months. In the twenty cases that were cured the duration of treatment averaged seven and a half months. It is probable that could all the seventy-five cases have been subjected to a course of treatment lasting eight months, which according to Wickham¹ is the shortest time in which a cure can be obtained, a much larger proportion would have been relieved. Yet we are obliged to confess that in the case of six of our little patients a vigorous treatment was carried out for periods varying from thirteen to seventeen months without eradicating the disease. It is difficult to tell just what is the cause of the obstinacy met with in such cases. As our hospital records throw no light upon this question, we are almost forced to the conclusion that some idiosyncrasy on the part of the patients themselves makes their scalps peculiarly suitable to the growth and luxuriance of the fungus.

The general method of treatment in all these cases has been, in addition to repeated cutting of the hair and epilation, the application to the diseased portions of the scalp of substances which, either by their chemic properties or by the manner in which they were applied, might be expected to destroy the parasite. Some of these remedies, such as bichlorid of mercury, iodine and carbolic acid, are supposed to act simply as poisons fatal to the fungus; others, like colodion, the various plasters and the zinc and gelatin paint, owe what efficacy they possess probably to their exclusion of the air; croton oil and other similar irritants cure the disease only by causing a suppurative process in the invaded hair follicle which, destroying the follicle, leaves a minute scar in its place.

The preparations of mercury have all been thoroughly tried upon our patients. The bichlorid in particular has been constantly used in various solutions, mixtures and combinations. The treatment of all the vegetable parasitic diseases of the scalp by the extraction of the diseased hairs and the subsequent application of a strong solution of this substance is by no means new, having been introduced by Bazin forty years ago; and it is questionable if this classic treatment does not give as good results in the first stages of the cure, as any more modern method. Upon our cases the solutions used have varied in strength from .5 to 2 per cent. In all cases improvement followed the application of the remedy, but for some reason the treatment was never continued sufficiently long to work a cure. It apparently made no difference what solvent was used for the mercury salt. Solutions in alcohol and solutions containing ether seemed to possess no greater efficacy than aqueous solutions. A 1 per cent. solution containing ether was used for three months without effecting a cure. A solution of the same strength, but containing in addition 30 per cent. of oil of cade, was used for the same length of time with the same result. A 1 per cent. solution in the compound tincture of benzoin proved no more efficacious than the other solutions.

The chief cause of failure in this and in other methods of treatment seems to be the difficulty of making any remedy penetrate to the depths of the diseased hair follicles. This difficulty has long been realized by all physicians who have had much to do

with ringworm of the scalp, and as a result many methods have been proposed with a view to overcoming it. One of them, suggested by Harrison some years ago, consists in the successive application of an alkaline solution of iodid of potassium and a solution of bichlorid of mercury. The idea seems to be that the iodid solution, being more penetrating than the bichlorid, prepares the way for it and by the power of chemic affinity carries it deeper into the follicles than it could go unaided. The method has been thoroughly tried upon some of our cases with mercurial solutions varying in strength from 2 to 4 per cent. The bichlorid being changed to the biniodid upon the scalp, the treatment is naturally a severe one, producing considerable pustulation. For this reason it is difficult to use it for a long period of time. In two cases, however, it was continued for about five months without effecting a cure.

The use of the galvanic current to favor the penetration of parasiticides was suggested by Ambrosi⁴ in Italy and by Cantell⁵ in this country in 1888. Upon our cases the method has been employed in connection with an aqueous solution of bichlorid. A sheet of lint saturated in a 1 to 1,500 solution was placed upon the scalp and pressed in contact with the diseased area by the positive pole of the battery. The other pole was placed upon an indifferent spot and the current allowed to flow for fifteen or twenty minutes twice daily. Unfortunately, the records give no information whatever as to the strength of the current. This treatment was tried upon three cases for two months, but with no greater improvement than would have resulted had the same solution been thoroughly rubbed into the scalp.

Still another method of promoting the penetration of bichlorid was suggested by Dr. A. C. Lewis, one of the resident physicians of the hospital, who first used it early in 1890. In the *New York Medical Journal* for Oct. 10, 1891, Dr. C. G. Kerley reports brilliant results from the use of the same prescription, an emulsion made by adding a saturated alcoholic solution of bichlorid to kerosene oil. The emulsions used upon our cases have varied in strength from .5 to 4 per cent. The capillarity or these petroleum oils is well known, and the microscope shows that in all probability they penetrate deeply into the hair follicles; but it is a question if the oil can carry with it the fine particles of bichlorid which it holds in suspension. This emulsion has been used in the hospital upon sixteen cases, with improvement in all cases; upon which the treatment was continued longer than a week or two. Although the average duration of treatment in the cases Dr. Kerley reported as cured was six and a half weeks, we have treated several patients for periods varying from six to ten weeks without effecting a single cure.

The oleate of mercury, one of the most popular remedies for ringworm, has been used upon about fifty of these cases. It has been used diluted with various oils, ointment bases and solvents, the strength of which varied from 2.5 to 20 per cent. One case which had already undergone a long course of treatment with other remedies was cured after ten days' use of a 10 per cent. solution of this substance. Two other cases were cured after three and four weeks' treatment with equal parts of the 10 per cent. oleate and lanolin. Two more cases yielded after six and nine weeks' use of a strong ethereal solution of the oleate. In several instances, however, similar appli-

cations, although causing undoubted improvement, failed to eradicate the disease and were given up after two or three months' trial.

Closely resembling the oleate of mercury in its penetrating qualities is the ointment of the nitrate of mercury. This vigorous agent has been used diluted with simple ointment bases and as the most active ingredient of several prescriptions upon eight cases. It is probably as effective a remedy as the oleate; but as it is too irritating for long-continued use, it is practically of far less value. None of our cases were cured while applications of any preparation or combination of this substance were being used. The long-continued use of this and similar irritating remedies fails to accomplish a cure for this reason; the effect of the remedy upon the epidermis is to transform its superficial layers into a thin, horny pellicle, which acting like a varnish upon the surface of the scalp, in itself forms an efficient obstacle to the penetration of subsequent applications. It is only after this pellicle is carefully peeled off that any parasiticide can be expected to reach the hair follicles.

A mixture of equal parts of iodine ointment and mercurial ointment diluted and undiluted has been used upon nine cases with varying results. One of these cases was cured after five weeks' treatment with the full-strength mixture, but two similar cases after being treated with the same prescription for six months still showed signs of active disease. In another scalp under the same treatment for ten weeks the disease actually spread.

Ointments containing white precipitate and the red oxid of mercury have been used upon many of these cases. All that can be said in their favor is that they cause some improvement at first and later hold the disease in check, and prevent extension to healthy hair follicles. The following prescription has been used in several cases for long periods of time, and although it can scarcely be expected to eradicate the disease, it is an excellent application to use when we wish simply to guard against contagion and auto-infection.

R Unguenti hydrargyri oxidi rubri ʒ iii 12
 Unguenti sulphuris ʒ v 20
 Unguenti zinci oxidi. ʒ i 32

Misce et fiat unguentum. Sig.: Apply once or twice daily.

Except in such prescriptions as the above, sulphur has not been very thoroughly tried in the hospital, the results in the few cases upon which it was used not having been sufficiently encouraging to warrant further trials. The same thing is true of sulphurous acid, the sulphites and hyposulphites. Our experience with these substances has been too meagre to enable us to form an estimate of their value. With ichthyol, however, the case is very different. This remedy has been used in many combinations, the one which we have used most frequently being a mixture of equal parts of ichthyol, oil of cade, and either cotton-seed oil or crude petroleum. Most of the patients upon whom this has been tried have been decidedly benefited, but only one of them was cured while using it. In one case, however, it was applied for ten weeks without improvement, and in another the disease spread while it was being used.

Iodine has been used chiefly in the treatment of ringworm of the body, and for occasional application to freshly diseased spots upon the scalp. In cases where the tincture or the solution has been applied as a systematic method of treatment, there has gen-

erally been decided improvement. It is so irritating, however, that even the weaker solutions can not be used for more than a few weeks. In one case the result was exceptional, for after three weeks' treatment with a 4 per cent. solution in crude petroleum the disease was found to be extending.

Carbolic acid has been used upon these cases rather to prevent contagion and the spread of the disease than as an active curative agent. In five cases, however, upon which a 1 or 2 per cent. ointment was employed for this purpose, there was a decided extension of the disease. It is therefore evident that the weaker carbolized ointments are absolutely useless. Where stronger ointments have been applied with the object of eradicating the trouble, they have brought about a moderate amount of improvement. Pure carbolic acid, systematically applied to the diseased spots in six cases, improved the condition in only two of them. It is evidently too irritating a remedy to penetrate deeply.

Naphthalin in 20 per cent. ointment has given encouraging results, two cases having been cured after five and five and a half weeks' treatment. As these were the only cases in which this remedy was used it certainly seems worthy of a further trial. A similar substance, hydronaphthol, has been tried in ointment and plaster upon several cases, with varying results. In one case in which the scalp having been shaved, the diseased areas were covered with the plaster, there was a manifest spread of the disease.

Oil of cade offers no especial advantages as a therapeutic agent in this disease. The best that can be said of it is that it holds the disease in check, and, if its use be long enough continued, that it produces moderate improvement.

Veratria has been used in ointments containing from eight to thirty grains to the ounce. Two cures have resulted, one after five and the other after seven weeks' treatment. It would be fallacious, however, to form a high estimate of the value of this drug from these two cases, for they had previously been subjected to long continued vigorous treatment, and in another case a strong ointment used for nine weeks failed to prevent the extension of the disease. It is a question if it is safe to use such a powerful alkaloidal poison as this in the treatment of this disease.

Salicylic acid in solutions and in ointments has been used upward of fifty times with varying results. An ointment containing 12.5 per cent. of this remedy and 30 per cent. of sulphur cured a patient in three months, but other similar applications have been used in vain for periods varying from six weeks to eight months.

Chrysophanic acid, the use of which in the treatment of this disease was suggested by Unna, has been thoroughly tried upon about twenty of our patients. In some of these there was no improvement whatever, and in most of them the improvement was not sufficient to induce us to continue the trial longer than a few weeks. One case, in which the prescription first suggested by Unna was applied, was cured in nine weeks. From the observations made upon these cases, it seems quite evident that chrysophanic acid does not reach far into the follicles, and is powerless against the fungus which grows there. Hairs removed from scalps which have been subject to this treatment, are seen under the microscope to be compact, free from spores and deeply stained only in the extra-follicular portions, while the intra-follicular portions are succu-

lent, unstained and filled with a vigorous growth of fungus.

Fuchsin, another powerful staining agent which has been tried upon these cases, may be dismissed with a few words. One case was cured which under treatment with a 1 per cent. aqueous solution, but as it had previously been subjected to a prolonged and vigorous treatment with oleate of mercury, it is not improbable that the disease was actually eradicated before the fuchsin was tried. That the remedy is useless in these cases, seems to be demonstrated by the fact that there is absolutely no staining either of spore or of mycelium, however vigorous and protracted the treatment may have been.

Croton oil has been used only upon four or five of these cases. The remedy was in all cases applied frequently to the diseased spots until it produced a localized dermatitis with more or less follicular suppuration. In all cases this treatment was followed by some improvement, but is very severe and likely to cause extensive atrophy of the hair follicles. Probably the true value of this remedy is in the last stages of treatment, when it is introduced into isolated follicles on the point of an electrolysis needle in order to destroy the last lurking places of the disease.

From the foregoing analysis we may conclude that of all the remedies used upon these seventy-five cases, the preparations of mercury have proved the most efficient. Of the others, iodine, naphthalin, salicylic acid and chrysophanic acid seem worthy of further trial, while croton oil, properly used, is as valuable as electrolysis in eradicating the last traces of the disease. The results obtained at the New York Skin and Cancer Hospital in the treatment of ringworm of the scalp, finally, give full corroboration to the recent dictum of Wickham: "No matter what methods are employed, the duration of treatment necessary to the thorough cure of ringworm of the scalp can not practically be reduced to less than eight months."¹

DISCUSSION.

Dr. WOLFF of Atlanta considered that in connection with the care of patients in institutions suffering from ringworm of the scalp that isolation was very difficult to obtain; and then there were the factors of the playground, of towels and of the wash bowls. As far as treatment was concerned he had tried almost everything. The plan which he had learned in Unna's clinic in Hamburg he had perhaps found to be the best, and this was that the head was to be shorn, then washed with soap and then the following ointment to be applied with considerable friction twice a day, and used for several weeks:

R Chrysarobin. 5 parts
 Acid Salicylic. 2 parts
 Ichthyol 5 parts
 Vaseline 88 parts

Then if much irritation resulted, a milder salve such as

R Zinci oxidi 6 parts
 Sulph. precip. 4 parts
 Lard. 20 parts

This was used until the irritation was reduced. Caps were to be worn by the patients all the time, except when being treated. Dr. Wolff remarked that he had never seen such rapid cures as in Unna's clinic, where this plan was adopted.

Dr. M. B. HUTCHINS of Atlanta confirmed Dr. Bulkley's

observation since he had been his assistant at the New York Skin and Cancer Hospital. He had tried, where there was only single patches of ringworm of the scalp, a mixture of corrosive sublimate, 1 to 4 grs., with kerosene oil, one ounce, until a thick scaly condition was produced, when the application was changed to an ointment which contained the following:

R Ichthyol. 20 grs. 120
 Acid salicylic. 20 grs. 120
 Zinci oxid. 3 i 3200

until the scales were removed. He had seen cases get well in three months under this treatment.

Dr. SWARTZ of Providence, R. I., had seen about six cases in institutions, and he thought that mercurial ointments were too astringent, hardened the tissues and did not kill the spores. One thing had not so far been mentioned, and that was the special penetrating power of formol, which did not thicken the tissues and ought to be tried. Since the parasite spread only by contact it seemed astonishing that was not easily able to destroy the spores.

Dr. A. RAVOGLI of Cincinnati, who had had considerable experience with ringworm of the scalp in children's homes containing from 600 to 900 inmates, had met with only nine cases of ringworm of the scalp last year and three cases this year. As soon as the disease was discovered the patient was sent at once to the Cincinnati Hospital. For treatment he had used all the remedies which had been recommended, but was not satisfied with any one of them, and he had again returned to the older methods. The course which he therefore adopted was as follows: The hair was cut close, then the scalp was washed with green soap and water, after which the diseased areas were rubbed with Hebra's modification of Wilkinson's ointment. This treatment was carried out twice a day until desquamation began, when a rest was allowed. The same treatment was then renewed. In two or three months the child was cured and returned to the institution, and up to the present no case had been returned.

Dr. A. W. BRAYTON of Indianapolis recommended the use of an old depilatory, called Boettger's paste, which he said was an excellent remedy for removing hairs. The treatment of a case of ringworm of the scalp would then be as follows: The hair to be cut close to the scalp; the Boettger's paste (prepared by passing sulphuretted hydrogen into thin milk of lime till the mass assumes a bluish-gray color) to be applied to the thickness of a line and scraped off after a minute or two with a blunt knife, when the hair would easily come away; then the scalp is rubbed with the parasiticide.

Dr. T. C. GILCHRIST of Baltimore referred to the prevalence of ringworm of the scalp in colored children in public schools. The appearance presented was often not that of typical ringworm, but rather of a profuse grayish scabiness of various portions of the scalp. On account of the method of living of the negro population, it was almost impossible to treat these cases thoroughly. Since the hair is so short and curly in many colored children, Dr. Brayton's suggestion of using Boettger's paste as a depilatory would be a valuable one in these cases. Yet with all the disadvantages, the ringworm in colored children appeared to be more easily cured in a few months with somewhat simple treatment than the white children. The treatment recommended was the following: The scalp was washed twice a day with the tincture of green soap and water, and an ointment consisting of hydrarg. ammon. 1 dram, and lanolin 1 oz., was well rubbed in twice a day. In a fair number of the cases tinea kerion developed, showing that the spores had penetrated much deeper, as was shown by microscopic sections. Dr. Gilchrist also remarked that this disease was a very prevalent one in Baltimore, and particular care was taken that a child should be thoroughly cured before it was allowed to go to school.

Dr. BULKLEY of New York remarked that the clippers could

be used just as well as the depilatory and the instrument could be boiled for half an hour after it had been used on each child. He had seen shaving spread the disease, and so he had abandoned it. When ordering the tincture of soap he had added corrosive sublimate, two to four grains to the ounce, if there was no irritation of the scalp. He thought that Dr. Brayton's suggestion of using Boettger's paste was still a good one, since the parasiticide applied afterward would have a deeper penetrating power. The suggestion also of using formaldehyde was a good one, and he intended trying it. In the chronic cases he recommended internal treatment with tonics and also rigid dietary, because unless the soil was altered the case of ringworm was never cured until puberty. He recommended that all children who had any scaly condition of the scalp should be examined for ringworm, *i. e.*, by examining the scales microscopically before entering institutions. He mentioned that the microsporon was the cause of the chronic form, whereas the *microsporon* was the cause of the acute.

Dr. C. W. ALLEN of New York said he had cured one case of ringworm in one week. It was an acute case and the ring was partly on the forehead and partly on the scalp. Infant's ringworm was easily cured and was not to be confounded with chronic ringworm of the scalp.

Dr. W. T. ALLEN of Davenport, Iowa, remarked that in an institution containing 500 inmates there was an outbreak of ringworm of the scalp. There were 40 cases at first, which increased later to 80. At the end of the first year only 6 to 8 cases were left, but during the second year there were again 80 children affected. Eight of the original patients had the disease even after three years. None of the cases had been isolated until this last autumn (1895). In the first outbreak 1.5 per cent. of corrosive sublimate with red biniodid of mercury was used as a wash every day. Later much stronger applications were used, even up to 30 grains of corrosive sublimate to one ounce of water. In some cases the effects were serious, and one child, 5 years old, died during the treatment, but in others it was not so severe. The ages of the patients varied from 2 to 16 years of age. There were yet 46 cases under observation. New children entering the institution were attacked with the disease in about six weeks. Boys were more attacked than girls.

MASSAGE.

BY JOHN KERCHER, M.D.

CHICAGO.

Having had a number of years of personal experience in the application of massage; having seen massage applied by so-called professors of massage; also having read all available literature on the subject, I was amazed at the diversity of opinion and often utter lack of knowledge of the subject, as to what constitutes scientific massage. On the other hand there are a few books in the English language that treat the subject in an able and scientific manner. I was therefore prompted to write this article in order that the general practitioner may become better acquainted with the indications, contraindications, physiologic action, etc., of massage. I have for this reason taken up the subject in a scientific manner, hoping that the use of massage be thereby elevated and placed in the hands of physicians, where it belongs.

DEFINITION OF MASSAGE.

Dunghlison, 1860—Massage; *massement*; *massing*—all have the same meaning—shampooing.

¹ The definition as given in Dunghlison's, 1860, is wrong, as will be seen by a comparison of its manipulations:

TABLE OF MANIPULATIONS OF MESSAGE.	{	Effeurlage, with subdivisions meaning	Stroking.
		Frictions, " "	Semicircular, circular and to and fro motions.
		Pettrissage, " "	Kneading and pinching.
		Tspotement, " "	Tapping or percussing.

Webster's Unabridged Dictionary, 1890—*Mass*; *masse*; *massa*—and meaning dough, mortar, etc. These words seem to belong to the root of the Greek word *μασσω*—meaning to beat, or pound, or knead. The same word is also found in the Arabic language—*mass*—where its meaning is to press softly.

Quoting Tom Cecil, who in 1888 published a book, and who claims to have been masseur to several London hospitals, he took the following definition from the "Medicales Sciences," Paris:

"It is that action of pressing with the hands the muscular parts of the human body; to exercise traction on the juncture of bones and muscles in order to give them their flexibility or pliability."

According to Dr. Metzger of Amsterdam, massage is a scientific treatment, *i. e.*, based upon the anatomy and physiology of the human body; its manipulations are certain, that is, given or fixed; it is an art that can not be self-acquired; all manipulations are passive, *i. e.*, applied to the patient without his assistance or resistance; the manipulations are arranged so as to act systematically upon the different tissues of the human body.

Gould's Medical Dictionary, 1891, gives the following: Massage (Fr. from *μασσω*—the Greek, to knead). A method of effecting changes in the local and general nutrition, action, etc., of the body, by rubbing, kneading, etc., the superficial parts of the body by the hand or an instrument. Effeurlage, a stroking movement made in a centripetal direction. M. Frictions, superficial rubbing. Petrissage, a portion of a muscle or tissue is picked up, subjected to firm pressure and rolled from below upward. Tapotement, percussion by the hand or an instrument devised for the purpose.

Hare's System of Practical Therapeutics, Vol. 1, devotes 100 pages to Swedish movements and massage. On page 261 is the following definition: "Massage may be defined to be the communication of motion to the tissues of the body from an external source for therapeutic purposes." This at once distinguishes it from movements in which, as already said, the motion takes place through the joints and is extended to the entire extremities, or the trunk. And it also separates it from general exercise, which implies in addition volition, and therefore the communication of motion from an internal source.

It is not egotism which prompts me in adding another to the already too numerous definitions. The following definition defines massage in fewer words than any of the foregoing: Massage is a process of passive, systematic manipulations upon the soft parts of the body, generally without water. I say generally without water, because if these various manipulations be applied to a person while bathing it is still massage. A female operator is a "masseuse," a male operator is a "masseur," while the patient is massaged (pronounced massayed).

The ancient history of massage condensed.—Rubbing, friction and pressing of the soft tissues for certain painful and diseased conditions, undoubtedly existed in the customs of all nations, civilized, semi-

Is generally given without soap and water. Object—To cause a tissue change, to act as a sedative or stimulant or alterative, according to application.

TABLE OF MANIPULATIONS OF SHAMPOO.	{	Effeurlage, a Stroking.
		Frictions, { Semicircular, circular or to and fro motions.
		Slapping, with the flat hand or "hollow" palm.

Is always given with soap and water, with a brush, loofahs, soft rag or glove, etc.; most always preceded by a "sweat" in the hot room. Object—General cleanliness.

civilized and uncivilized, from time immemorable. Sometimes these had connections with religious rites. How these manipulations originated we do not know, except we may assume that in certain affections the people instinctively pressed, rubbed or otherwise manipulated the parts. Any person who has perhaps never heard of massage, rubbings, frictions, etc., may accidentally receive a blow on some part of the body, and immediately the hand is carried to the point and either pressed or rubbed and the pain will be relieved. This same instinct is present in animals. A dog as soon as he is injured will lick the part. In examining the ancient history of Greece, Rome, Arabia, Egypt, China, we find many references made to friction, unctions, rubbing, squeezing, etc., as the following. Herodotus, one of the masters of Hippocrates, in the fifth century B. C., first proposed gymnastics for the cure of disease and the preservation of health. From Herodotus we are informed that after having poured a greasy mixture upon the body, each part

guished Roman physician, who flourished about the commencement of the Christian era, spoke wisely and well of rubbing, in saying that it should sometimes be applied to the whole body, as when an invalid requires his system to be replenished. Hadrian, 76-138 A. D., the able and wise emperor, seeing a veteran soldier rubbing himself against the marble at the public bath house, asked him why he did so. The veteran answered: "I have no slave to rub me," whereupon the emperor gave him two masseur slaves and sufficient to maintain them.

Pliny the celebrated advocate, in one of his letters to the Emperor 103 A.D. says, that his life having been in danger from a severe illness he availed himself of a mode of treatment, which it is presumed was much in vogue at that time. He procured the services of a medical practitioner who cured many of his patients by the process of rubbing and anointing, and so much benefit did he derive from the treatment that he asked the emperor to grant the physician, "who was a Jew,"

should be rubbed. The writings of Plato abound with references, direct and indirect, to friction. Hippocrates, 460 to 380 B. C., says the physician must be experienced in many things, but assuredly also in rubbing. It was Hippocrates, "the Father of Medicine," who used the word *anatripsis*, the Greek equivalent for the process of massaging, although he did not understand the reason of it, as it was not till 500 years after that Galen pointed out that the arteries were not filled with air, as their names seem to imply.

Asclepiades, 128 to 56 B. C., founded a school, practiced at Rome and was very popular with the Romans on account of his simple and agreeable remedies. He relied mainly on diet, bathing, exercise and friction. Cicero, 106-43 B. C., considered that he owed as much of his health to his anointer as he did to his physician. Plutarch, 100-44 B. C., tells us Julius Caesar was pinched all over daily, as means to a cure of a general neuralgia. Celsus, the distin-

the freedom of the city and the privileges of Roman citizenship. Galen, 130-200 A.D. the most learned physician and accomplished man of his age, whose authority in medical matters was regarded in Europe as almost supreme for a thousand years, recommended friction in a great number of diseases. At Pergamus, his native city, he was appointed physician to the school of gladiators these were rubbed before and after their exercises and combats. Before, in order to increase the elasticity and strength of their limbs and after, in order to stroke away the ecchymoses, relieve the pain of the bruises and to rest and refresh them from their fatigue.

Strabo states that the Indians contemporary with Alexander, 326, B.C., esteemed friction highly. They polish their bodies with ebony staves and in other ways manipulate the body. Paracelsus, 1492-1541, in his "Liber de Vita Longa" extols highly the effects of friction on the human body, as indispensable to health

Ambroise Paré, 1517-1590, A.D., who was employed by a family as barber-surgeon and to say the family prayers, but who became the most renowned surgeon of the sixteenth century; the inventor and originator of ligation of arteries, which is the foundation of modern surgery, speaks of friction in dislocations, and recommends passive movements of the joints. Mercurialis, 1530-1606, A.D., an eminent Italian physician who graduated at Padua, published in 1573 a treatise entitled "De Arte Gymnastica" in which he commends the benefits to be derived from active, passive and combined movements.

Alpines, 1553-1617 A.D., a celebrated botanist, occupying the chair of botany at Padua in 1593, in his "Medicina Ægyptia" says that frictions are so much in use among the Egyptians, that no one retires from the bath, without being rubbed; for this purpose the person is extended horizontally, then malaxed, manipulated, or kneaded and pressed, in various manners upon the different parts of the body, with the hands of the operator. Guyon, 1615 A.D., in the "Mirror de La Beauté" says, exercise and friction are advised and it is considered necessary to have the body rubbed gently by some person who has soft hands. Hoffman, 1660-1742, A.D., physician to the king of Prussia, whom we are not likely to forget, so long as the anodyne, which bears his name, continues to be used, in his "Dissertations Physico-Medical" 1708, says that exercise is the best medicine for the body. The illustrious Sydenham, 1624-1689,² abandoned the routine system of practice then prevalent, and based his own upon the theory, that there is in nature, a recuperative power which ought to be aided, not opposed. An example of this is found in his saying that, if anyone knew of the virtues of friction and exercise, and would keep this knowledge secret, they might easily make a fortune. This is fully exemplified at the present day, for in every city of the United States, and indeed, of the whole civilized world, there may be found individuals claiming mysterious and magical powers of curing disease, setting bones and relieving pain by the immediate application of their hands. Some of these boldly assert that their art, or want of art, is a gift from Heaven, due to some unknown power, which they call magnetism, while others designate it by some peculiar word ending with bathing or cure. And it is astonishing how much credit they receive for their supposed genius by many of the most learned people. Should a lone fisherman forsake his boat, a blacksmith his anvil, or a shoemaker his shop and proclaim that he has made a wonderful discovery, that he is charged with magnetism and can cure all diseases, be he ever so ignorant and uncouth, he is likely to have, in a remarkably short time, a large clientele of educated gentlemen and refined ladies. It is not meant to imply that the previous occupation of these people is at all to their discredit, but, were they capable of giving a rational explanation of their methods, the halo of mystery would be removed and their prestige and patronage would suffer a sudden decline.

John Grosvenor, Esq., about a century ago, was professor of surgery, for many years, at Oxford. He practiced surgery only, but in the latter period of practice rendered himself justly celebrated throughout the kingdom, by the application of friction to diseased joints. He had first used it with success in a malady of his own, a morbid affliction of the knees, and by degrees its efficacy was so renowned that he

was visited by patients of the highest rank and respectability from the most distant parts. Mr. Grosvenor further says, in a book entitled "A full Account of the System of Friction," inflammation does not by any means contraindicate the use of massage in such cases, for in the words of Berghmann and Helleday, "Massage will simultaneously further and increase resorption, accelerate the circulation, relieve pain, and reduce elevated temperature."³

MODERN ORIGIN OF MASSAGE.

By this I mean the scientific application of massage, according to a regular system. The system in use today and practiced by all the foremost massage operators, such as Metzger, Prof. Schüller, Douglas Graham, Weir Mitchell, etc., consists of four principal manipulations: Effleurage, friction, petrissage and tapotement. Prof. Robert Bartholow says "massage" is of Arabian origin, because there is a word in the Arabian language *mass*, which signifies to knead. He undoubtedly means the word, "massage" for the system of manipulations is of French origin, although some of the manipulations belonging to the system, were in use centuries ago, by other nations. All authorities on massage, today, agree that the word massage, is French, but originates undoubtedly from the Greek word, *μασσω*, meaning to beat, pound, or knead. Dr. Douglas Graham in the history of massage, *Med. Record*, N. Y. 1879, Vol. xvi, pp. 147-171, says: "To express these various maneuvers collectively, nearly all physicians, who take any interest in the matter, foreign as well as American, seem satisfied with the French word massage from the Greek *masso*, I knead or handle. Therefore the French should receive more credit than any other nation, for our present knowledge of massage, for they first made a scientific investigation of it and formed the various manipulations into a regular system."

In "Tracts on Massage No. III," translated from the German of Reibmayr, with notes by Benjamin Lee, 1887, is found the following: The history of massage, as demonstrated by Weiss (Bella Weiss Ueber Massage, etc., *Wiener Klinick*, 1889, Heft 11-12 and Ritterfeld (Ritterfeld, Confeld, Massage, Wiesbaden 1881), is very ancient. Allusions to it are found in the Chinese literature of a period, three thousand years before our era. Older still than the writings are their traditions, with reference to the subject. The civilized nations of antiquity employed it both as a therapeutic and as a hygienic measure among the Greeks and Romans.

During the middle ages, it vanished completely from the medical schools, receiving only an occasional recognition in connection with midwifery. It thus came into the hands of the laity, and this unfortunately, is sufficient ground, in the minds of many physicians, for glancing askance upon an agent of great value. The first nation to rediscover this therapeutic treasure and rescue it from oblivion was the French, "Fissot 1780" "Weibone" 1795, and Bonnet, 1845, have laid us under obligations in promoting its revival. But the writings of these men scarcely attracted a passing notice, even in their own country. To Dr. Metzger, of Amsterdam and his pupils Berghmann and Helleday, is due the credit of having reduced massage to a system founded upon the basis of numerous experiments and of earning for it the rep-

³ For further reference to this matter see "report on treatment of sprains by massage, by Douglas Graham, M.D., in the N. Y. Med. Record. No. 353, 1877.

² Douglas Graham, "History of Massage."

utation of being a truly reliable agent. His system possesses the great advantage of being as simple as it is clear, and should therefore, be accepted by all adherents of this method of practice.

It is true that massage has received so little attention from the medical profession that Prof. Th. Billroth of Vienna in 1875, and Dr. Wagner of Friedberg in 1876, stated that there were many physicians in Germany who had never heard of massage, and that it was then an every-day question as to what it meant, and some even supposing that Dr. Metzger of Amsterdam was the originator of it. In *Wiener Med. Wochenschrift*, No. 45, 1875, and *Berliner Klinische Wochenschrift*, No. 68, 12, 1876, after making some very commendatory remarks on massage, Professor Billroth concludes: And yet for sixty years prior to this, the word massage had found a place in the medical literature of France, and valuable articles had from time to time appeared on the subject. Dr. Weir Mitchell ("Graham Pract. Treat. on Massage, 1884") says: It is many years since I first saw massage used by a charlatan in a case of progressive paralysis. The temporary results he obtained were so remarkable that I soon began to learn what I could of its employment.

The modern application of massage.—This being of more interest to us and our patients, I will point out how massage is, or should be, applied; and in order to apply massage properly, it is necessary to know the indications and contraindications, the physiologic action upon the tissues, as the skin, muscular, nervous and circulatory systems, the special organs, the changes induced in pathologic or changed tissue, difference of action between active and passive exercises, also general hints and rules to be observed in giving massage, etc. There are certain movements of certain parts, which might be either active or passive, called Swedish movements or physical culture. These are often confounded or classified with massage, therefore I wish to call special attention to the fact that massage and Swedish movements should not be confounded, as they are distinct. Massage means treating the soft parts, muscles, organs, etc., only, while by Swedish movements is meant the movements of the joints, as flexion, extension, adduction, abduction, pronation, supination, traction, etc. Some operators practice massage and others practice movements exclusively. I have always used both for general treatment, spending five-sixths of the time on massage, but change according to indications and object of treatment. The Swede, Peter Link, 1776-1839, was the first to establish a scientific system of the various kinds of movements, and it is therefore called Swedish movements. There is as much or even more variation in the mode of giving these movements as there is in massage. Swedish movements may be given by machinery, as in the Zandersche Institute in Stockholm; there are also institutes in New York and in Battle Creek. The motive power here is generally steam. Various kinds of instruments may be used and the Swedish movements may be active as in gymnastics and Delsarte, or passive, as by machine or operator, or half active and half passive, that is, the patient may offer resistance while the operator makes the movements, or the operator offer resistance to movements made by the patient. Dr. Metzger of Wiesbaden divides massage into four principle manipulations.

MANIPULATIONS.

I. *Effleurage* (stroking).—A. With palm of one hand, used

on small surfaces. B. With palms of both hands, used on large surfaces (is most generally used). C. With thumb or thumbs, on tendons or between muscles or small surfaces. D. With tips of fingers, on tendons or between muscles or small surfaces. Light stroking has a soothing influence on the system; heavy stroking has a stimulating influence on the superficial structures, increasing the arterial, venous and lymphatic circulation.

II. *Frictions* (firm circular, semicircular or to and fro motions).—A. With one hand, used on small surfaces. B. With both hands, used on large surfaces. C. With thumb or thumbs, used on small surfaces, as the face, below the eyes, hand around joints. D. With tips of fingers, used on small surfaces, as the face below the eyes, hand around joints. This manipulation reaches deeper than the former, to the subcutaneous connective tissue and fat overlying the muscles, its aim being to transform pathologically changed parts into a condition that will permit them to be incorporated into the healthy tissues by absorption by the veins and lymphatics.

III. *Pétrissage* (kneading or pinching).—A. With two thumbs, used to get the effect upon a certain small localized area. B. With thumb and fingers (see pinching). C. With two hands, used on large surfaces. (N. B. By pinching is meant the squeezing of the muscles between the fingers and the fleshy part of the palm.) The aim of this manipulation is to reach the separate muscles or groups of muscles, to reach as deep as possible, to cause circulatory, nutritive and alterative changes in the soft tissues within reach, muscles, tendons, organs, etc.

IV. *Tapotement* (tapping or percussing).—A. Clapping, used with palms of both hands. B. Hacking, used with ulnar border of hands. C. Pinctating or titillation, used with tips of fingers with a shoving motion. D. Beating, used with clenched hand, with the ulnar edge or with the knuckles. These manipulations are mainly used on muscular parts, as the back, back of legs, gluteal region, and well developed subjects in general.

I give these four principal manipulations, with subdivisions, because they are recognized and used by all the authorities of the day. Anyone attempting to give massage without a knowledge of these principles is unscientific and empirical. The reason why the four principal manipulations are applied in this order is, 1, it is well known that the circulation at the surface is not so active as that of the interior of the body, therefore in massage, effleurage is applied first in order to warm the surface, to stimulate the blood and lymph changes, to remove the old epithelial scales, that the pores and sebaceous glands may be freed from matter which causes obstruction. The frictions which are next applied reach a little deeper. The pétrissage goes below the skin and fat overlying the muscles and reaches the muscular structures and deep-lying organs. Tapotement imparts its stimulus to the deepest structures. Another reason why we should adhere to this table is, that we should have a system and it is, in my opinion, the best, this being the system, or the table of manipulations, recognized by all authorities on massage. But there are would-be authorities who have tables of their own. One author divides the manipulations of massage into: I, frictions; II, pressures; III percussions; and IV, movements. The first three he divides into moist and dry, the moist he calls unctions; they are used to apply a medicinal principle, as oils, liniments, ointments, balsams, pomades, etc. He says, in his book on massage, that unction does not, properly speaking, belong to massage. He also uses fancy names for some unimportant variations of the principal manipulations, such as attouchments, frolement, agacements, chatouillement, titillations, taxis, malaxation, froissement, foulage, etc. As regards his fourth division, movements, I think they should have been left out altogether, as movements and massage should not be classified together, as each is distinct, and the one may be used where the other is contraindicated.

The physiologic action of massage.—One of the first essentials is to make a diagnosis, and a diagnosis comprises a knowledge of the functional or pathologic changes that have taken place in the tissue. Before a remedy is selected to counteract this process, be this remedy a drug, diet, bath, or mechanical, therapeutic or hygienic measure, it is absolutely necessary that the consultant, before he gives his advice, should possess a definite knowledge as regards the action of the remedy prescribed by him. Unless he possesses this knowledge, he will employ these measures in an unscientific way, not knowing what the results of his treatment will be. If you know the action of the remedy or measure you can recommend it where indicated, and warn against its use where contraindicated.

(To be continued.)

SELECTIONS.

Displacements of the Uterus.—Dr. Howard Kelly in a recent article in *American Journal of Medical Sciences*, December, 1896, states that backward displacements constitute one of the most important gynecologic questions of the day, for two reasons; first because of the frequency, and second, because the treatment is in an evolutionary stage. After a summary of the causes, symptoms and discarded older methods, he says: "The most efficient plans of modern treatment, where treatment is required, are purely surgical, attacking the displacement either through the vagina or abdomen, or through both avenues at once. The correct method of dealing with any given case of retrodisplacement will fall under one of the following heads: 1, cases in which no treatment is required; 2, the use of a pessary; 3, manual reposition and massage; 4, operation upon the vaginal outlet; 5, operation on uterus at the vaginal vault; 6, shortening the round ligaments; 7, a suspensory abdominal operation or ventrofixation; 8, an operation upon the vaginal outlet and a suspensory operation combined."

No treatment is advised where the flexion is the discovery of accidental examination, or where the patient's distress is purely mental. On the use of the pessary he contends that its use in retroversions and retroflexions rarely effects a cure, in spite of the numerous statements to the contrary, that it is often useful in relieving local symptoms of the displacement, as a rule not by correcting the displacement but by checking the tendency to still greater displacement. The only pessaries he finds use for are the Hodge and frequently the Mundé with a thick posterior bar. The large pessaries, horse-pessaries, are to be absolutely rejected, as also all soft-rubber pessaries. Processes for treatment under the headings of "Manual reposition and massage" and "the vaginal operation for retroflexion" are then followed by an interesting account of his method in treatment of ventrofixation or suspension of the uterus, which he has applied on two hundred cases in the Johns Hopkins Hospital between October, 1889, and October, 1896. In no case has there been a death in any way connected with the operation, and no case of hernia or interference with the functions of the bladder has been reported. After carefully preparing the selected patient the operation is performed as follows: "An incision 3 to 4 cm. long is made just above the symphysis pubis, in cases in which the abdominal walls are thin or of medium thickness. . . . The peritoneum is opened the full length of the skin-incision, and caught at once on both sides with forceps and drawn outward. One or two fingers are now introduced through the incision and the fundus of the uterus caught and raised into anteflexion. I invariably use as a suture material for suspending the uterus, a medium-sized silk about a half millimeter in diameter. . . . One side of the incision is lifted, exposing the peritoneal sur-

face of the anterior abdominal wall. The movable peritoneum and subperitoneal tissues are then transfixed 1 or 2 cm. away from the lower angle of the incision. The tissue taken in is about 1 cm. in width and 2 or 3 mm. in depth; the same suture is passed through the posterior face of the uterus 1 or 2 cm. back of the fundus, and finally brought out through the peritoneum and subperitoneal tissue on opposite of abdominal wall at a point corresponding to that of entrance. When the suture is tied it brings the uterus up snugly against the anterior abdominal wall in anteflexion. Another suspensory suture is passed like the first, but about 1 cm. higher up on the abdominal wall and half a cm. below it on the posterior surface of the uterus to hold the uterus in permanent ante-position. This is tied and the abdominal wound closed by sewing up the peritoneum with a catgut suture, then drawing the fascia together with silver wire mattress-sutures, finally closing the superficial fat and skin also with catgut sutures."

Treatment of backward displacements by an operation upon the vaginal outlet and a suspensory operation combined is given. In his recapitulation of the subject he says: "My conclusion in the whole matter would be that operative measures are only to be resorted to for the relief of retroflexion in those cases in which there is good reason to believe that the displacement seriously interferes with the patient's health and comfort. Then if the case is one calling for operation in a woman who has borne children, first look well to the vaginal outlet, and restore it if it is broken down. The Alexander operation, as performed by Edebohls will yield excellent results; my personal preference is to deal directly with the retroflexed body of the uterus by a suspensory operation."

Fresh Air Cure for Consumptive Children.—A most interesting charity has been carried on in France for several years known as the "Fresh Air Cure for Consumptive Children." Two hospitals for this purpose are located one at Ormisson and the other at Villiers-sur-Marne. The medical men interested in this work consider it the most promising method yet employed in trying to reduce the rate of mortality from consumption in France, which was becoming fearfully prevalent, the death rate reaching in some cities (Paris, Havre and Rouen) almost 80 per cent.

We quote from a recent report of the work by Dr. Blache; he says: Medicine forms no part of the treatment, except the occasional use of cod liver oil, in the cold season. The work of cure is left, therefore, entirely to fresh air and to the hygienic living of the patients. With the exception of a very few cases where persistent fever keeps them in bed during the first part of their stay at the hospital, all the patients are obliged to follow the regular system of living. They rise early, bathe well, are dressed all in linen garments loosely fitted. Twice a week unless otherwise ordered by the physician, each patient is bathed and vigorously rubbed by an attendant. After the toilet, the patients eat a light breakfast; this is insisted upon for each child, for suitable and regular meals have proved most necessary in aiding the treatment. After breakfast, the children are sent into the garden, the park, or covered playground, where they enjoy games and exercises varying with the seasons. The most serious cases are kept indoors, lying in reclining chairs, well wrapped in warm coverings, and breathing the fresh air admitted to the room. Except for the two principal meals of the day, the entire time is passed in the open air, and the rooms are also ventilated with the greatest possible amount of fresh air. This out-of-door program has been strictly followed since 1890, in all seasons of the year without any difficulty. As to the amount of nourishment taken by the little patients, it is of course rather difficult to give an exact reckoning, but the following table is as nearly correct as is possible.

For the two principal meals of the day:

Soups	
Bread	150-200 grams
Meat	125-150 grams
Vegetables and fruits.	4-7 deciliters
Wines.	¼ liter

The early breakfast consists of porridge, coffee or chocolate, and the lunch of bread and milk. Considering the youth of the patients and the lack of appetite characteristic of consumption, this is a relatively high average.

Results.—Each year the condition of the patients is set forth in a report to the medical committee of the institution. For five years, or since its beginning, these reports have without the least variation shown the most satisfactory results, surpassing even the hopes entertained by its founders.

The yearly average of cases treated.	109
Number of cures	47.71 per cent.
Number improved.	40.29 per cent.
Number unchanged.	8.79 per cent.
Number of chronic or cachectic	4.59 per cent.
Number of deaths.	3.44 per cent.

We have sought to give some explanation for these figures, which we must confess are surprising. The results have been uniform and much more favorable than we had the right to hope for. It is evident that the results arise from special conditions. All the patients admitted are proved to be afflicted with the disease, but we are careful to prevent as much as possible the admittance of patients in whom the disease is far advanced or has become chronic. On the other hand, the majority of cases treated at our hospitals are brought there in the worst conditions, from surroundings most wretched and unhealthful and with hereditary tendencies to disease; and it is exactly this miserable condition in which we find the children that permits them to derive the more benefit from the rational treatment of fresh air, good food and general hygiene, under which we place them. And this system of obligatory outdoor exercise, regular habits, cleanliness and rules of hygiene is the cause of the satisfactory results already shown. Moreover, the consumptive children readily accustom themselves to this life, and then neither the cold of winter nor the heat of summer seems to affect them.

In closing his report, Dr. Blache adds: "We fear that we may be considered too optimistic, but we are anxious to prove as soon as possible the certainty that consumption is eminently a curable disease and curable in infancy. We will say a disease more easily cured than many others, since its cure requires, in a word, only a persevering, regular and systematic application of a special, well understood hygiene."—Translated from the *Journal d'Hygiène* by M. R. B.

PRACTICAL NOTES.

Cathode Rays in the Diagnosis of Pleurisy.—Burchard states that the cathode ray may be destined to render as great services to internal medicine as to surgery. He has already found it a most valuable aid in diagnosing the effusion in pleurisy, as it enables the entire contents of the thorax to be seen in their correct proportions at a glance.—*Semaine Méd.*, December 9.

Experimental Appendicitis.—All attempts to produce appendicitis by introducing a foreign substance into the appendix of rabbits have hitherto failed, as the foreign substances, shot, etc., were all tolerated perfectly, and expelled in the course of time. But with a piece of laminaria introduced which closed the opening, appendicitis followed in every case.—*Bulletin Méd.*, November 11.

Arsenic Combined with Thyroid Medication.—The *Nord Médical* of December 1, describes a case of goitre treated with the thyroid medication, which produced such disturbances in the circulation and neuralgic pains, that it was about to be abandoned, when arsenic was combined with it tentatively. At once all the accidents passed away and the thyroid medication was continued and even increased without their return, except when the arsenic was suspended. As soon as it was resumed they passed away again. The patient was entirely cured of all her symptoms in one month.

Pre-existing Lesions in Fatal Cases of Diphtheria.—It was announced at the last Russian Medical Congress that in 150 necropsies of children who had died of diphtheria, tuberculous lesions were found in 39, and the same number of cases of nephritis. The two forms of lesions only coincided in 11. In 33 cases the nephritis had evidently been chronic. It was therefore stated that in the speaker's experience, 40 per cent. of the children who succumbed to diphtheria were already affected with some severe chronic disease.—*Presse Méd.* November 21.

Massarini's Improved Solution for the Hypodermic Treatment of Surgical Tuberculosis.—Neutral sterilized glycerin 40 grams, metallic iodine 1 gram, potassium iodide 5 grams, guaiacol 20 grams. For subcutaneous injections. The presence of guaiacol prevents pain in the injections and also the formation of abscesses. It is used in the same way as Durante's solution, which otherwise it resembles, but with a more powerful therapeutic effect.—*Semaine Méd.*, November 18.

Ear Suppositories.—Radlauer of Berlin makes suppositories for the ear of cocain, menthol, resorcin, cocoa butter and olive oil, which also contain a cotton wad to prevent the escape of the fluids as they dissolve. They are recommended highly by Lasser, as they are effectual and save the introduction of the various medicines separately. The patients can insert them themselves, if necessary to save time and trouble in clinics, etc. They are designed to heal inflammations, to soften accumulations of wax, to prepare the ear for operations, etc., and are made in two sizes, for children and adults.—*Therap. Woch.*, December 13.

Significance of Hernia in the Etiology of Gastro-intestinal Disorder.—Schutz impresses upon all the necessity of thorough and careful palpation of the entire abdomen in the case of obscure gastro-intestinal disturbances, and especially of all the typical hernial sites. In this way often the real cause of the trouble will be found, unsuspected hitherto, and proper treatment ensures recovery. At the same time he warns that it will not do to ascribe everything to a hernia, and thus overlook possibly the cause elsewhere.—*St. Petersburg Med. Woch.*, September 26.

Biernacki's Ulnar Symptom in Mental Disease.—Hess urges all to coöperate in determining the importance of this sign in mental disease and paralysis. So far 417 tabetics and paralytics have been tested for it and 66.9 per cent. found to be without sensation or reaction when the ulnar nerve is pressed at the "crazy bone" point. Three hundred and fifty-four paralytics showed similar analgesia in 70 per cent. According to the sex, 73.7 per cent. of the men were analgetic and 43.7 per cent. of the women. Further investigation of the subject may be of great value in time, as if this sign proves what is expected, it will render material service in diagnosing doubtful cases.—*Deutsche Med. Woch.*, December 17.

Double Pneumonia with Hypothermia and Thrush Treated with Cold Baths.—The patient was an insane, elderly woman. The temperature fell to 36.8 degrees C., with such marked adynamia that a fatal termination seemed imminent. Mouth and gums were covered with thrush. Three baths in twenty-four hours, at 25 and 22 degrees C., were administered in the hope of stimulating the vital energies, lasting ten minutes each, nine baths in all. The improvement was perceptible the first day, and all the grave symptoms disappeared during the third day, when the pneumonia was in complete defervescence. The baths were discontinued as soon as the adynamia had passed away. The thrush was treated locally with boric solutions as usual.—Dr. Voisin in *Province Méd.* December 5.

Phosphuria in Diagnosis.—Investigation of the phosphates is indispensable in some diagnoses, which would be very difficult without the knowledge thus obtained. The diagnosis of hysteria for instance, is settled when after the attack, the proportions of the phosphates are inverted and the weight of the

phosphoric acid is normal or slightly diminished. On the other hand epilepsy causes an increase of the phosphates and also of the phosphoric acid. In the same way ascertaining the conditions of the phosphates enables the differential diagnosis between tuberculosis and incipient chlorosis to be established. In cases of phosphuria the surgeon should always reserve his prognosis even in the case of wounds and fractures and as well when intervention is being considered.—*Nord Medical*, December 1.

Hiccough Cured by Traction of the Tongue.—Professor Lepine of Lyons stated that he had arrested and cured a case of hiccough of four days' standing by drawing the tongue out and keeping it outside of the mouth for a few minutes. He does not know whether the procedure is of any practical utility in such cases, but theoretically it is of interest. It may be asked if rhythmic tractions of the tongue excite the respiratory center, as they do in restoring respiration in cases of asphyxia, how can they inhibit this center, as in the case observed? This apparent contradiction is explained by some experiments made by Professor Lepine in 1876, showing that the result of excitation depends, in the greatest part, on the state of the nervous apparatus concerned; so that, while excitation of the nerves at the base of the tongue will excite the respiratory center when this is paralyzed, similar excitation will depress it if it is in a state of exaggerated excitability.—*Universal Medical Journal*.

Spontaneous and Artificial Evacuation of the Stomach.—The phendoscope is rendering many services to science, as expected (described in the *JOURNAL*, page 490, Vol. XXVI). The latest is a contribution to our knowledge of the evacuation of the stomach. J. C. Roux has found with it that the food taken into the stomach remains at the same level during the entire period of digestion, viz., from three and a half to four hours. The limits of the stomach remain the same during this time, except the lesser curvature and the pyloric region, which gradually tend toward the right. At the end of three and a half to four hours after the meal, the evacuation of the food matters occurs "brusquely and all at once." He also has established the fact that this sudden evacuation of the contents of the stomach can be produced artificially at any moment during the period of digestion by administering to the subject a small quantity of a concentrated solution of peptone. This fact is interesting as it shows that the duration of the period of gastric digestion can be regulated at will.—*Bulletin Médical*, December 2.

Successful Treatment of Saturnine Encephalopathy by Lumbar Puncture.—Quincke's lumbar puncture has been principally used for diagnostic purposes, but Seegelken reports a grave case of lead poisoning completely cured by it in the *Munch. Med. Woch.* No. 47. About 60 c.cm of the spinal fluid was withdrawn, at first clear and then becoming turbid. It was alkaline, with a density of 1008, and showed in the microscope some leucocytes and endothelial cells. The part of the fluid that was limpid is supposed to have been derived from the medullary region, still unaffected by the disease, while the remainder came from the cerebral region, altered by the effects of the intoxication. The patient was kept under observation for weeks and showed no return of the coma, clonic spasms, etc., nor of any of the symptoms.—*Bulletin Méd.* December 2.

Helminthiasis.—Cima states that 46 per cent. of seventy-three children in his care for diverse diseases were found infested with helminths, twenty-eight had the trichocephalus; twenty-two ascarides; four the tenia nana; three the oxyuris, and one the tenia medio-canellata. Several were affected with nervous troubles, such as chorea, which were cured with exclusive treatment with vermifuges. The four children with the tenia nana presented a strange combination of symptoms; pains, a peculiar gait, ataxic and choreic, with paresis of the left

limb. These symptoms all passed away with redoubled vermifuge treatment. They may have been due to excitation of the gastric plexus. Careful search was made for Charcot's crystals, which Leichtenstern considers a pathognomonic sign of helminthiasis, but they were found only seven times in all the ten microscopic preparations made of the feces in each case. They were found only in mucous dejecta streaked with blood, which leads him to consider them analogous to the crystals found in other mucous secretions, nasal, bronchial and spermiatic.—*Bulletin Méd.*, December 16.

Ihle's Method of Suturing the Abdominal Walls.—Ihle has been using the following method since October, 1894, with perfect success even in the most obese cases: A curved needle with a strong thread is passed through the abdominal wall a few centimeters to one side of the wound, through the skin and subcutaneous fat, and brought out through the wound between the layers of fat and muscular tissue. The needle is then inserted in the other corresponding side of the wound, between similar layers of fat and muscular tissue, and curving downward is passed through the muscular layers into the abdominal cavity, thus inclosing the peritoneum at the edge of the wound. When it appears in the abdominal cavity it is carried to the opposite side and the same process is repeated inversely, passing it through first the peritoneum and then the muscular layers, to emerge at the edge of the wound between the layers of fat and muscle. It is then passed across to the opposite side and passed in the same way into the tissues between the fat and muscular layers, emerging outside through the subcutaneous fat and skin. Before the threads are tied they are pulled tight laterally, to make the coaptation of the low-lying muscles and fascia complete.—*Cbl. f. Chir.*, December 5.

Necessity of Operating for Incontinence of Urine in Commencing Prolapsus.—Very few consider it necessary to operate for incontinence of urine in these cases, as the larger operation soon required is supposed to include this. But Boursier stated in the November *Archives Clin. de Bordeaux*, that this is erroneous, and that the incontinence frequently persists after anterior or posterior colporrhaphy. He treats it at once with a combination of Duret's process (incurvation of the axis of the urethra, elevation of the meatus and lengthening the posterior wall), and Gersuny's torsion of the urethra. He and Pousson have been successful with this, while in other cases treated merely with the colporrhaphy and colpoperineorrhaphy the incontinence continued. He first inserts a bougie into the urethra, and circumscribes the meatus by a circular incision .5 cm. from the orifice. The canal is then dissected about 1.5 cm., after which the tissues of the vestibule are incised vertically to the base of the clitoris. The bougie is then withdrawn and the dissected portion of the canal is twisted one-half of its circumference on its axis, and drawn upward and forward, when it is fastened with a series of stitches in the upper angle of the vertical incision. The rest of the wound is then closed with a few catgut stitches.

Strangulation of Twisted Intestine after Extirpation of Carcinoma Ceci.—An instructive case is described at length in the *Cbl. f. Chir.* of December 5, in which a fortnight after resection of the cecum and ascending colon (Helferich), the patient returned with acute ileus, fecal vomiting, pains, etc. A second operation showed that the small intestine that had been implanted in the colon had slipped through the space left by the previous operation between the free edge of the mesentery and the stump of the colon, and had become twisted on its axis, closing the lumen completely, with adherences to adjoining loops, requiring a two hour operation to make things right again and impressing upon Helferich the necessity of suturing these parts together henceforth, so that no space will be left. It is a difficult thing to do, and in some cases can only be accomplished by suturing a piece of the omentum into the space if

the resection has been very extensive. In another case since, he was able to close the entire mesenteric slit by a direct suture, and in addition he fastened the side surface of the mesenterium of the part of the small intestine leading away from the colon, to the retro-peritoneal surface of the wound in such a way that this portion of the small intestine took the place of the extirpated colon. Small tampon on the intestinal suture, drainage toward the rear.

Catarrh and Whooping Cough Treated by Formalin.—Following upon the use of formalin in tuberculosis of the larynx by Dr. Solis-Cohen and others, the remedy has been recommended in cases of influenza and catarrh. Dr. Starenbagen was probably the first to employ inhalation of formalin vapor for the latter trouble; he cured himself of bronchial catarrh. Then Dr. Gregner experimented with both inhalations and solutions, as gargles or lotions, and found that some slight irritant action attended the use of inhalations from dilute solutions. This irritation was soon overcome, while gargling could be done with a one-half per cent. (or even 1 per cent.) solution without discomfort. The London *Therapist*, December 15, adds a reference to improvements that are being made in the administration of formalin and paraform in cases of respiratory affections, as follows: The most recent contribution to the therapeutic employment of formalin in the treatment of catarrh and other allied diseases of the respiratory tract, was made by Dr. J. Lardner Green, at a meeting of the Southern Branch of the British Medical Association, held in Salisbury on November 25. This paper it is hoped will shortly be published *in extenso*. The author gave an account of the favorable result he had obtained from the use of formalin vapors, and suggested its employment not only in catarrh but also in cases of pneumonia, bronchitis, etc. With a view to the more extended employment of formalin vapors in this direction by medical men, it is necessary that a convenient and portable means of generating the vapors should be available. Just at the right moment, therefore, it has been discovered that the solid inert form of formic aldehyde known as paraform, may be volatilised and polymerised at a low temperature, giving off active formalin vapors by the employment of suitable apparatus, by means of which a current of air and water vapor is directed over the surface of the paraform. The *Therapist* further alludes to the experience of Dr. Hinman in an outbreak of whooping cough that occurred in an orphanage. The patients were all confined in one ward with closed doors and windows, in which a 1 per cent. formalin solution was freely sprayed twice a day, and also during the night. The immediate result of this treatment was an abatement of the paroxysms of coughing both in virulence and frequency, whilst there was a gradual but marked improvement, and all dangerous symptoms disappeared comparatively quickly.

Urticaria of the Respiratory Passages.—The *British Medical Journal* quotes Delbrel as having treated and collated numerous cases of this affection, and states that from his research and experience, he has come to the conclusion that there are two types of urticaria affecting the respiratory organs: 1, in certain cases the cutaneous eruption appears first, and is followed by respiratory trouble; 2, in others the respiratory symptoms first appear, to be followed later by the eruption, and it is in this latter that the greatest difficulties of diagnosis and the greatest danger to the patient may arise. In many instances the urticarial affection so closely resembles other respiratory disorders that in the absence of any cutaneous condition diagnosis may be almost impossible, and it may even happen that the only manifestation of the disease is that affecting the respiratory mucous membranes. Some cases simply resemble an attack of asthma; others manifest themselves by suffocative attacks with irritating, hacking cough, closely simulating edema of the glottis, for which they may be mistaken. In

such cases a laryngoscopic examination may be of great use, though, unfortunately, it may fail, even in skilled hands, as it seems to cause increase in the symptoms. In the instances where it has been carried out, red, raised erythematous patches have been found in the posterior pharynx, and though it may be impossible to obtain a view of the eruption in the larynx or trachea, the existence of such patches in their neighborhood may be used. In the cases where the respiratory affection is severe the symptoms may be the most alarming. There is no regularity as to the time of their appearance after the ingestion of some article of diet, etc. The author states that severe cases not infrequently end fatally; others may last for periods varying from a few hours to several days, and the appearance of urticaria seems to be a favorable sign. He suggests that in acute cases with severe pulmonary symptoms and no cutaneous eruption brisk friction should be applied to the skin in order to induce its appearance.

Radical Treatment of Congenitally Malformed Anus.—Gangolphe in *Revue de Chirurgie* for April counsels the employment of peritoneal incision and enterorrhaphy in cases of preternatural anus. There are, he points out, two methods of dealing with this condition: In one the surgeon works from without inward in the immediate neighborhood of the opening and, after gradual dissection, exposes the two extremities of the divided intestine, and draws these outward; in the other the peritoneal cavity is opened by an incision made through the abdominal wall at some distance from the false anus. The author holds that the latter method possesses many advantages. It is rapid, and the surgeon, without dread of wounding any important organ, cuts directly into the abdominal cavity. It is sure, as the finger introduced into the abdomen can explore the structures in the immediate neighborhood of the false anus, and can guide the scissors or other cutting instruments by which the perforated portion of intestine is set free. It permits free exposure and complete isolation of the structures submitted to operation. The risks of infection are diminished, and the manipulations of the surgeon facilitated by this free exposure of the perforated or divided portion of intestine. It is applicable to every case of false anus, and is likely to prove successful when the former method has failed. The author concludes with a description of his operative method, which with variations in detail to meet special circumstances, he has practiced with complete success in three instances. The first stage consists in making about the false anus an oval incision extending through sound skin and other layers of the abdominal wall as far as the peritoneum. This membrane is now incised at the upper wall so as to permit the introduction of the finger into the peritoneal cavity for the purpose of exploration. The extent of the adhesions of the intestine to the abdominal wall having been determined, the oval portion of abdominal wall formed by the first incision is set quite free, and the divided portion of the intestinal canal is freely exposed. The subsequent stage of the operation will depend on the size of the false anus and the extent of the intestinal adhesions. If the opening be small and involve only a portion of the circumference of the gut, it may be closed by lateral suture after excision of surrounding callous tissue. If there be much loss of intestinal structure, and a spur has formed at the seat of the false anus, the author would set free both ends of the intestine, and then bring them together either by circular suture or by Murphy's button. The latter method, he states, is indicated in any case in which the patient can not tolerate a long operation, and when the surgeon is inexperienced in the application of intestinal sutures, or is operating under unfavorable conditions. In cases of extensive adhesions it would be necessary, after apposition by suture or button at the ends of the intestine, to separate the loops of intestine from one another and from the abdominal wall by very careful dissection, and after closure of the external wound to drain the seat of operation.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the Association living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, JANUARY 9, 1897.

IDENTIFICATION OF CRIMINALS.

Under a title which may be rendered into English as "General Instructions for a system of Identification," Sr. JUAN VUCETICH, Chief of the Statistical and Anthropometric Identification Office of the Police of the Province of Buenos Aires, has published the second edition of a work on identification by scars and marks. The first edition was published in 1895. In its preface the author related the case of a criminal who was sentenced to confinement for ten years, but who escaped and was subsequently captured and tried for some fresh crime. The evidence was insufficient to convict and the man was discharged. An effort was made to detain him as an escaped convict, but the evidence on record failed to establish identity. Sr. VUCETICH believes that had his system been in use at the time this criminal could not have escaped identification. Its use, he considers, will be of immense advantage in detecting old offenders and particularly in the apprehension of deserters from the army and navy. His proposition was submitted to the Minister of the government and was by him approved and adopted as the official instructions for the use of the police of the province, to go into effect Jan. 1, 1896.

Sr. VUCETICH modestly states that his work is simply the application of the conclusions reached by BROCA, LOMBROSO, BERTILLON and others. The study of the works of these authors suggested the idea of identification by scars and marks and furnished him with most of his materials. But like all those who

apply book knowledge in the elaboration of methods for practical work, his methods are too recondite. He has built up a system which requires careful study and an excellent memory to make use of the proper official terms to be used in a given case. The height of the individual appears to be the only measurement taken; but 145 illustrations are given showing the various points to be noted in connection with the contour of the face, the eyebrows, eyes, nose, mouth and ears. The surface of the body is divided into considerably more than a hundred regions and a long list of abbreviations and signs for indicating the character, size and location of marks and scars is given, with the result of building up an intricate system out of that which should have been kept as simple as possible. Directions are given for taking photographs and also for recording the digital impressions of each individual.

While disclaiming any title to originality in the system advocated and now officially adopted, its author takes credit on behalf of the Province of Buenos Aires for having been the first to apply a system which without being anthropometric has all the accuracy and precision of this system; but even this claim does not hold good in the light of a fuller knowledge of what has been accomplished elsewhere. A system of identification by scars and marks has been in use in the United States Army since 1889. The effort in our army has been to preserve the simplicity of the system and to avoid all tendency to elaboration of details. Instead of a tedious description in words requiring thought to ensure an accurate record and more thought to enable the reader of the record to realize the locality, size and general appearance of the scar or mark, the record of the United States Army may be made and read with precision by one who is ignorant of the name of the region on which the scar is situated. This is effected by placing a representation of the mark to be described on the appropriate part of an outline figure of the person. No results have yet been announced in Buenos Aires because no identification can be made until the files of the identification bureau contain a number of cards or descriptions, and time is required to effect this. Since the system was established by the Surgeon General's office of the United States Army, 785 identifications have been made and there are now on file the cards of over 13,000 men of undesirable character, each of whom can be identified should he present himself for enlistment before a recruiting officer or should a call from other quarters be made for his identification.

THE CHEAPENING OF THE PROFESSION.

A recently published work on "The Mystery of Sleep," among other statements wise or otherwise, says that if the investigation of the mystery of sleep

were taken up with the same incentives and by the same class of minds as those now engaged in the study of electricity, it would be as clearly understood as is that agent at the present time. Of course this involves the assumption, based on very insufficient appreciation of the facts that we have at present a better knowledge of the nature and phenomena of electricity than we have of those of sleep, but the feature of the utterance that chiefly calls for notice is the implied assumption that a superior grade of intellect is engaged in the field of physical than of physiologic research, in short, the too common notion that the medical profession does not contain the highest type of intellect as compared with scientific workers in other special lines. When this notion is given expression it is often enough, it is true, associated, as occurs in this instance, with evidence of gross ignorance on the part of the utterer; but this does not altogether relieve the sting of the fact that it exists. There is no need of attempting to refute the error to medical men or to scientific workers generally; they know well enough already that the medical profession throughout the world has its full share of the greatest minds as it has always had, the only point to be considered here with any profit is why should the contrary idea exist to any extent whatever among the average intellects of the general public. We all like to be estimated at a full or at least a fair valuation; our philosophy does not usually reach the point of making us absolutely indifferent to public opinion even when we know it to be misled.

The real trouble seems to be in this matter that the medical profession is judged by its minimal average, while physicists and other scientists are only recognized above a certain high standard. The average practical electrician is not an especially accomplished man and is hardly recognized as a scientific worker; but the public regards one like EDISON or TESLA, who may be really only an unusually ingenious and successful practical mechanic, as an especially brilliant corypheus in the world's scientific advance. On the other hand, all doctors are too often counted alike, from the painstaking physiologic investigator down to the advertising peddler of patent pills, and this even by the literary magnates of our Eastern centers of culture. To paraphrase Mr. BIGELOW's dictum properly one would say that if the mysteries of sleep were studied by especially active minded practical mechanical geniuses and business men, with the facility of adapting whatever facts scientific research can give to economic uses, and with the intent to appropriate by patent all useful results for personal profit, they would become as much revealed as he supposes those of electricity to be. It can be safely assumed that the author did not allude to the purely scientific investigators who study the physical agencies for science's sake alone, or he would not have shown the lack of

knowledge as to the work of the physiologists who have traced the phenomena back to the vital processes and have given us far more rational theories of sleep than we can be said to possess in regard to the intimate nature of electricity. As to the practical points involved, they have been solved more or less fully long since by mankind in general, and Mr. BIGELOW's book finds no additional data of value to enlighten us.

The fact that such misapprehension can be shown by an eminent literary man in a work touching on a semi-medical theme, is enough to suggest to our profession the fact of the need of a better education of the public in this respect. It was not always the case that the medical profession was valued below any of the others; in the early history of this country doctors seem to have been rated among the best. The JOURNAL has already editorially called attention to the fact that in the first Continental Congress physicians were represented even out of proportion to their numbers in the general population. At the present time there are nearly a hundred thousand physicians in our country and over twenty thousand medical students, and the public estimation of the profession appears to have, in a measure, grown in an inverse ratio to its increase in numbers. We have cheapened ourselves by making ourselves too common, and the over-use of what seems to be regarded as the only legitimate mode of advertising, viz., connection with some sort of institution for making more physicians, is daily increasing the evil. A year or two ago there were counted fourteen medical colleges in one great center, today the number is said to be nineteen; perhaps next year it will be twenty or more. The advance sheets of the report of the United States Bureau of Education for 1894 and 1895 call attention to the fact, that while it took sixty years (between 1765 and 1826) to establish the first twelve medical schools in this country, half this number were started in one year, 1893, and if the estimated increase in Chicago is correct, this ratio is very rapidly increasing.

The medical profession is said to have led all the other so-called learned professions last year in the number of suicides of its members, a not very enviable distinction, but one that it may continue to hold if its members continue to increase with a correspondingly cheapened popular estimation. The reforms that are under way do not go far enough, or perhaps we should say that they are too slow in their action to materially mend matters. A four years' course and State examinations are excellent, but they must be made universal, and even when that is accomplished it will be years before we can realize fairly their benefits. In the meantime, at all events, it would seem worth while to call a halt in the present undue multiplication of medical colleges of every kind, if there is any way that this can be accomplished.

THE METOPIC SUTURE.

At birth the frontal bone consists of two halves, separated by the interfrontal or metopic suture. Toward the end of the first or the beginning of the second year, this suture begins to close from below upward. In cases of premature closure before birth, the suture closes both from above and below toward the middle, and a marked cranial deformity ensues, known as trigonocephaly. As the name indicates, the skull is of a triangular shape, with the apex in front, so that the forehead runs out into a very sharp point.

In the lower animals the frontal bone remains in two halves during life, but in the primates a single bone is the rule. Persistence of the frontal suture is known as metopism, and is found in various degrees. It may be, 1, entirely open; 2, open at both ends; 3, closed only at the lower end; 4, closed only at the upper end. Its frequency varies in different races, as shown by ANOUTCHINE'S statistics:

White race	11,459;	crania 8.2 per cent.
Mongolian	621;	" 5.1 "
American	1,191;	" 2.1 "
Malay	892;	" 1.9 "
Negro	959;	" 1.2 "

What is the cause of metopism? Has the process of synostosis never commenced, or has its course been arrested? As ANOUTCHINE'S figures show a marked preponderance of this condition in the higher races, many authors have considered that its presence is due to an increased size of the frontal lobes and a relative increase in the intellectual faculties. Thus PAPILLAULT ("La Suture Metopique," Paris, 1896), from comparison of a large series of crania of various races, sexes and ages, concludes that metopism is due to the influence of the brain, and is therefore an evidence of superior cerebral activity. "Metopism," says BROCA, "corresponds to a notable enlargement of the anterior cerebral fossa, coming on during childhood, either from the rapid development of the frontal lobes, or from slight hydrocephalus, traces of which can be found in other parts of the cranium." TOPINARD thinks hydrocephalus is the most probable cause. He adds, "No matter what is the mechanism producing it, is metopism a step toward perfection or a reversion, a condition foreshadowing the future, or a pathologic state? We have shown that cerebral hypertrophy leads to mania as well as to genius, and that the difference may be without a difference. Is not a double frontal bone a corollary, does it not indicate the effort of the encephalon to make a place for itself in the cranium, and being found more frequently in the higher races are they not paying too great tribute to the pathologic states resulting from it?"

TOPINARD examined the crania of 361 insane persons and found the proportion of persistent metopic sutures very large (17.7 per cent.); SIMON (*Virchow's Archiv*, 1873, p. 576) found only 9.4 per cent. in 809 crania.

Attention may be here directed to the practical significance of this anomaly, viz., that in wounds of the median line exposing the skull, the possible occurrence of this metopic suture should be borne in mind, otherwise it may be mistaken for a fracture.

LORD KINNEAR.

The JOURNAL suggested in its editorial column (Oct. 24, 1896, p. 920), that as the season was approaching for the annual distribution of peerages in Great Britain, it would be a fitting time to recognize the learned profession of medicine by promoting one of its members to the peerage.

We are therefore pleased to chronicle the fact that Sir JOSEPH LISTER was created Lord KINNEAR December 31.

This material recognition can not be otherwise than gratifying to the medical profession throughout the world, for whatever we may think of rank or title, we must admit that the world sits in judgment, and that its decrees favor rank and station, as a means of distinction. Republics are alone ungrateful, and since the foundation of the world, have paid little reward to their citizens who have rendered services to the state or distinguished themselves as discoverers in any branch of science. True, France has still the "Legion of Honor," but that was transmitted from the first Empire, and can not be cited as disproving the rule. Ingratitude is the basest of all personal attributes, and a government should no more lay itself liable to this charge than an individual, and the educated citizen of the world, who looks upon the age he lives in without regard to political divisions, is naturally pleased that radicalism in the French Republic not only left the Legion of Honor untouched, but added a few medical life senators. The various orders of other countries, such as the Iron Cross of Prussia, the Victoria Cross, and the like, have been appreciated by all good men as above riches or political position, as a public certificate of honor natural to the man, of which the decoration is only the symbol.

The services to the profession and to mankind which have made the name of JOSEPH LISTER famous in the annals of his profession, and the recognition by his government a suitable one, may be briefly mentioned as follows: He was born in 1828 and at the age of 19 received the degree of B.A. at London University. In 1852 he received the M.B. degree from University College, London, with the scholarship and gold medal. In the same year he became Fellow of the Royal College of Surgeons, and at Edinburgh during the year following, his first original investigation was entitled "Observations on the contractile tissue of the iris." Among his other contributions to medical science are "Observations on the minute structure of involuntary muscle fiber," "On the early stages of inflammation," "Spontaneous gangrene from arteritis and

causes of coagulation of the blood in diseases of the blood vessels," "Preliminary account of an inquiry into the functions of the visceral nerves, with special reference to the so-called inhibitory system," "Observations on ligature of arteries on the antiseptic system," "Remarks on a case of compound dislocation of the ankle with other injuries, illustrating the antiseptic system of treatment," "On some cases illustrating the results of excision of the wrist for caries, treatment of deformity from contracted cicatrix, and antiseptic dressing under circumstances of difficulty, including amputation at the hip joint," "A further contribution to the natural history of bacteria and the germ theory of fermentative changes," "On the relations of microorganisms to disease," etc.

For several years he was lecturer on surgery in the Edinburgh Extra-academical School, and afterward elected Professor of Surgery in Glasgow University and surgeon to the Glasgow Royal Infirmary. Here it was that his investigations led him to formulate the principles of antiseptic surgery, which revolutionized this branch of medical science. He attended the International Medical Congress at Philadelphia in 1876.

Professor LISTER was awarded a medal by the Royal Society of London in 1880. He was created a baronet in December, 1883, and has received degrees from the Universities of Cambridge, Edinburgh and Glasgow.

THE PRESS AND QUACK ADVERTISEMENTS.

At the recent discussion of this question by the Chicago Physicians' Club the lay press entered what was practically a plea of confession and avoidance. In lieu of denunciations of medical abhorrence for mossgrown mendacity (which the "false and fraudulent advertising" of the quack has entailed for centuries), so common in the editorials of the newspapers, the newspaper representatives admitted abuses of the advertising columns, pleaded impossibility of censorship and denied the authority of the Code of the AMERICAN MEDICAL ASSOCIATION. One representative said that the policy of a newspaper must be dictated by the counting room. This, the other representative (who, when editor of a great Chicago newspaper, purged his advertising columns of massage shops and clairvoyants) refused to consider true. Even were this claim true, it must on the most ordinary business principles, as the medical representatives pointed out, exclude quack advertisements since, as was long ago shown by the *National Advertiser*:

Exceedingly large advertisers tend to discourage the smaller ones and hence, while a certain amount of revenue can be obtained from any colossal advertiser, the diminution of receipts will be noticeable from the many minor advertisers who become overshadowed by the gigantic one. Many of the leading papers in the leading cities are publishing colossal advertisements of certain "advertising doctors." The aggregate amount expended by these "doctors" is very great and while it is probable that there may be enough weak, sickly and

gullible men and women in America who will be induced, in their weakened condition, to pay a stipend each month to these charlatans, it can only be a question of time when both they and their methods must cease. Meanwhile the papers that are receiving large revenues from them are keeping out many good and legitimate advertisers whose aggregate revenues would probably exceed that of the sporadic "doctors." It would seem that shrewd publishers should be able to see these truths, see what the tendency must be, and see the inevitable outcome. Especially should publishers be able to see this in the fact that these so-called physicians pose as philanthropists. In their announcements they say they "make no secret of the fact that they aim to be in every sense the people's physicians and that they are more anxious for the approval and respect of the public than for the financial returns of their work. The practice of medicine was not a necessity to them. They were men of independent means before they placed a line in the columns of these newspapers and they had no need to look to the returns of their work for either livelihood or profit." Such disinterested, such high minded philanthropy has not been known to the world since the days of HOWARD and it is to be hoped that publishers may understand and profit by the lesson it conveys.

The press is now dominated by display advertisers who, having driven small advertisers from the field, pool their issues and dictate advertising rates. The quacks have not yet formed a "trust," but the indications are that the big quack will eat up the little one, thus rendering advertising impossible, except to incorporate quacks who can induce banks to loan on their stock. Even this is fraught with danger to quack and bank alike, as witness the fate of a Nebraska rupture-cure company. The head of this induced an Omaha national bank to invest in his stock and give itself as financial and medical reference. Through the credit of the bank, enormous advertisements were inserted in leading newspapers. The bank was forced to suspend lately. The "Napoleon of finance" who headed the rupture-cure company has just been sentenced in the Omaha federal court for fraud and misrepresentation. The advertising bills are still unpaid. Ordinary business sagacity would therefore dictate exclusion of mendacious quack advertisements from newspapers.

A REVEREND ALIENIST.

The daily press informs us that a certain clergyman by the name of BOYD, residing in St. Louis takes issue with the well-known alienist, Dr. CHARLES H. HUGHES of that city as follows:

Upon what authority is it charged that JOSEPH B. McCULLAGH committed suicide! Upon the authority of only one man, Dr. C. H. HUGHES, a neurologist, a man whose business it is to prove all men insane, to prove that we are insane. Shall we accept such testimony as this? Most assuredly not. I am surprised that this man should stand up as a public prosecutor and try to prove a crime against so well-known and so great and intellectual man as our friend. It is surprising to me that a man of the character of this neurologist would have the audacity to accept the position of public prosecutor, such as he has done, and I trust and believe that no one who has heard these facts will ever believe that Mr. McCULLAGH's death was due to suicide. To my mind it was just as surely an accident as any accident that ever occurred.

The great editor is dead. He is unable to make any defense, and it ill becomes us under such circumstances to charge upon him what is considered almost a crime.

According to Mr. BOYD insanity is a crime, and Dr. HUGHES a "prosecutor."

The truth is that Mr. McCULLAGH had for some months been very ill with insomnia and nervous prostration, and if we mistake not, under the care of Dr. HUGHES. We do not know whether our colleague at any time pronounced his patient insane, but at this distance it would seem appropriate to believe the opinion of the attending physician rather than that of a gentleman who seems to have exercised his constitutional right of free speech, with less regard for accuracy than for the ears in his immediate vicinity.

CORRESPONDENCE.

Medical Practice in Cuba.

PHILADELPHIA, Dec. 30, 1896.

To the Editor:—It may interest your readers to know how much a graduate of our medical schools has to pay in Cuba for the right to practice medicine.

A graduate of the University of Pennsylvania was practicing in a town of about 1,000 inhabitants, and in a municipal district of about 14,000.

To begin with, he had to pay \$494 for a license to practice. This was given after an examination in all the branches of the medical curriculum of the University of Havana. After such examination he had the option to take the degree from that University, but this would have cost him \$1,500. The license must be renewed every six years, without an examination, but with a renewal of the payment.

Beside this, the Doctor paid \$10.60 quarterly in professional taxes to the state, and \$2.50 half yearly to the city. He had further to provide himself with personal papers—a sort of ticket of leave system—which in the case of a practicing physician, cost \$10.60 annually.

Our country Doctor had to pay therefore the sum of \$140.45 annually. An examination of the Spanish Cuban budget will show how this money was expended. Our Doctor paid:

To general obligations, charges of the debt, etc . . .	\$ 66.95.
“ public worship and justice	4.65.
“ army and navy	41.15.
“ treasury department	3.74.
“ interior department	20.91.
“ public improvements, including education . . .	3.05.

Total \$140.45.

It will be seen that our friend was paying 77 per cent. of his taxes toward securing two inestimable blessings: an army and navy for his own subjugation, and the payment of a debt contracted by Spain for the subjugation of the same worthy Doctor and his fellow natives.

JOHN GUITÉRAS, M.D.

Locum Tenens.

DECEMBER 26, 1896.

To the Editor:—Please answer the following question: Dr. A. was engaged to attend Mrs. Blank in confinement. When labor came on the husband telephoned for the Doctor, but received a reply from the residence that he was absent from town for the night. The husband then called Dr. B., who responded and delivered the woman. The next morning Dr. A. called on Dr. B. and told him that Mrs. Blank had been confined during his absence. Which physician should properly look after the case during the puerperium? The two physicians are the best of friends and enjoy the easiest professional intercourse.

Respectfully, M.D.

Answer: Dr. A. should attend the case. Dr. B. was simply *locum tenens*.

PUBLIC HEALTH.

Anti-depopulation Congress.—The subjects discussed at this congress, held in Paris in December, were: To increase the nuptialty and natality, protection of maternity, protection of infants and children of all ages and of adults, and means to secure the adoption of the resolutions of the congress.—*Progress Médical*, December 5.

Prevalence of Syphilis in Russia.—A congress for the study of prophylactic measures against syphilis will meet in Russia before long, and preliminary investigations are now being conducted on a large scale. According to the *Annales de Derm. et de Syph.*, this disease is assuming such proportions in that country that in certain regions the number of syphilitics is no longer counted, merely the non-syphilitics.

Cremation or Removal of Garbage by Railroad.—The committee appointed by the Paris Académie de Médecine to investigate this question, report in favor of the removal and distribution of the garbage of Paris by railroad, stating in conclusion that the 1,000,000 cubic meters of refuse spread on poor land would produce nearly 100,000 tons of cereals and meat, milk and wool from 40,000 to 50,000 head of animals. To incinerate this 1,000,000 tons would cost 3,500,000 francs, aside from all questions of hygiene. This conclusion is the result of eleven years' study of the subject.—*Bull.*, November 3.

Alcoholism and Crime.—The statistics of the Belgian prison at Louvain show once again the importance of alcohol as a factor in crime. Out of 2,826 criminals received there during 1874 to 1895, drunkenness at the time of the crime was proved in 12.4 per cent. of the total cases; in 40.7 per cent. of those under life sentence, and in 43.1 per cent. of those condemned to death. Habitual drunkenness was proved in 44.7 of the total number received; in 54.6 per cent. of those under life sentence, and in 60 per cent. of those condemned to death. The importance of alcohol as a factor in criminality thus increases with the gravity of the crime; not so much transient drunkenness as habitual alcoholism. The tabulated statistics are given in the *Journal de Méd. de Paris* of December 6.

Sanitary Regulations of Hungary.—The *Deutsche Med. Woch.* December 17, states that the sanitary regulations of Hungary are only surpassed by those of England, and in some particulars, are superior to the English. Medical care and assistance is assured to all by their systems of community doctors, and fines are enforced for neglect to summon a physician when a child under seven is ill, and also for administering opiates, etc., to children without a physician's prescription. It is one of the duties of the Minister of the Interior to send an expert to localities where the death rate is higher than usual, even when there is no epidemic, to ascertain and remedy the causes. All manufacturing establishments are compelled to keep appliances and dressings for wounds and to arrest hemorrhage constantly in readiness. Pensions are bestowed upon the widows and orphans of physicians, surgeons and nurses who die in the performance of their duty. Syphilitics are received into military hospitals, if there are none others convenient. The regulations in regard to epidemics, midwives, charlatanism, and sanitary homes for the poor are especially stringent. With it all, however, the death rate was 32.5 per thousand in 1890, and 29.4 in 1895. In Prussia the same years it was 24.5 and 21.8.

Immunizing Against Diphtheria.—The frequency of diphtheria contagion among the numbers of children received at the great Berlin hospital, the Charité, for other diseases, induced those in charge to experiment with the diphtheria immunizing antitoxin on a large scale. The results are published in the *Jahrbuch der Kind.* No. 1, in which it is announced that every child received into the hospital since the beginning of 1896, has received a preventive dose of 200 to 250 immunizing units, and

only one case of diphtheria has occurred among them during that time, and this case was the one child exempted from the immunizing on account of severe articular rheumatism. Previous to these attempts, one-half of the children who died in the measles ward, succumbed to croup. Since they have been immunized in this way, the mortality has been reduced one-half, and no cases of consecutive croup have appeared among the 99 cases received. Löhr states his conviction that the croup after measles is nothing but a secondary diphtheria, as he has always found diphtheria bacilli in the fibrinous patches. Similar favorable results were obtained in the scarlet fever pavilion. In spite of the fact that the 460 children received into the hospital were often in the gravest condition from other diseases, no threatening after-consequences were observed in any case. Exanthema appeared in 4.34 per cent. of the cases, but never anything more serious, even in the most advanced stages of other diseases. The *Deutsche Med. Woch.*, December 17, regards Löhr's communication as a distinct advance in this line, and urges all to read and ponder his report, which is sure to overcome the prejudices still held by many against this life-saving measure.

The Stamping-out of Typhoid at Wheeling, W. Va.—Confirmation of the good news that had reached us through other channels of the improved conditions at Wheeling, is well set forth in an article by Dr. C. F. Ulrich, in the *Dietetic Gazette*, December. The writer accords to the late Dr. J. E. Reeves an important part in the fight for a purer water supply that was begun about twenty years ago, when typhoid fever had a prevalence almost epidemic in gravity. In his first year's practice, the writer had in the same month, twenty-two cases of fever within two blocks' radius of his office. And now behold the difference; he has not had a case for two years and over! There was a time when he and his fellow physicians had more cases of fever than of all the other serious diseases "put together." From 1873 to 1893 there was an average annual mortality by typhoid of 47. In 1894, just after the opening of an improved water supply, the typhoid deaths were 16; in 1895, 10; and in nine months of 1896, 16. The first public result of the agitation by Dr. Reeves and others was the establishment of a crematory for the destruction of garbage and night-soil. Next, the water plant was moved to a point higher up the Ohio River, a mile above the point of discharge of the Wheeling sewers. This change was effected and the new pumps set in motion in January, 1894. This improvement is not to be regarded as an ideal reform, since there are many cities and towns on the river above Wheeling that pour fourth their sewage into that stream. Dr. Ulrich continues as follows: "But there is a sort of purification taking place in the water as it flows down; the sediment being deposited in the bottom and sides of the stream, carrying with it a large proportion of the malignant bacteria that are entangled with the solid material of the water; whereas the water that flows past the upper end of the city as far as Eighth Street, receiving the outpourings of the sewers and surface-drainage of the First Ward, could not possibly be thus purified. This territory has in it the old hospital, and this, until a few years ago, was the only hospital the city possessed. Within five or six years past another public hospital and three private institutions of that character have been established in the city, so located, that even before the removal of the pumping-station, their waste material would not have been within reach of the intake of the pumps. Now we can make a comparison between the state of things then and now. Then we had the garbage dumped into the streets and alleys, the privy-vaults overflowing, or their contents taken out and emptied into the river; all the filth from the dwellings, stables and out-houses of one-eighth of the city, including the Wheeling Hospital, which then did all the work of the city, washed into the river and immediately pumped into the reservoir, whence it was distributed to all the dwellings as a pleasant beverage. Now, we have

the garbage and the human excreta destroyed by fire, the intake of the water-works located a mile above the upper end of the city, fifteen miles below the next town on our side of the river, and nine miles below the nearest village on the other side. Then, nobody paid any attention to the sanitary condition of the water, fearlessly drinking it as it issued from the hydrant. Now, many of our families possess filters in their dwellings; others use artificial ice, manufactured from distilled water, melting it as required for use. Again, others, who can not afford these luxuries, boil a sufficient quantity of water every morning to last for the day."

Composition of two Deposits in Water Pipes.—In the *Analyst*, July, Dr. Voelcker, before the Society of Public Analysts of London, reported, first, a case showing how the action of a soft water on galvanized iron pipe may give rise to serious results. We had lately occasion to examine a deposit which had formed in a pipe connected with the hot water apparatus of a private house in the country. The pipe in question was completely blocked up with a white deposit, and the owner of the house was very disappointed to find that the water which we had previously reported to be a very soft and pure one, and suitable for general domestic use had, after a comparatively short time, given rise to a deposit in the hot water pipes. The owner was under the impression that the deposit was due to lime. Upon analysing the material we found that it contained no lime, but consisted almost entirely of a basic carbonate of zinc, together with oxid of zinc. On inquiry we found that the water was lifted by a ram to the height of 300 feet, along about half a mile of galvanized iron pipes. These appear to have been very rapidly attacked by the water, the zinc being dissolved and deposited in the pipes at those points where the water was very hot, and also in the boiler and hot water cylinder. Dr. Voelcker said that upon first inspecting the pipe in question, he naturally thought that the deposit was of the ordinary nature, viz., carbonate of lime. His brother (Mr. E. W. Voelcker), however, noticed that it was particularly soft; this led to a further examination of the deposit, when it was found that there was no lime at all in it, but that it consisted mainly of carbonate of zinc. On referring back to the analysis of the water, which had been made some time previously, it was found that the water was distinctly soft, it containing only about six grains of total solids per gallon. The portions of the pipes upon which the deposit had mostly formed were those nearest the boiler. The deposit contained something like 64 per cent. of basic carbonate, and some excess of oxid of zinc, which might have been due to change in the basic carbonate consequent on the heating. The chlorine amounted to about one grain per gallon. As regarded the composition of the carbonate, there certainly was a large quantity of oxid of zinc present in the deposit, but ordinary carbonate of zinc would, without doubt, have been decomposed by the high temperature and pressure to which the deposit had in all probability been subjected. The water was slightly acid. It was taken from a Welsh mountain stream, and contained very little organic matter. The oxygen absorbed was a mere trifle, and the water was not colored like a peaty water would be. The second instance shows the action upon iron of a very hard water containing a good deal of sulphate of lime and organic matter. The well water in question contained over 40 grains per gallon of total solids. It was noticed that on the pump-rods in the well a black scale was formed, and in the stand-pipe there was a considerable amount of deposit. The analysis of the scale and of the deposit revealed the presence of a notable quantity of free sulphur. In the deposit in the stand-pipe the free sulphur amounted to over five per cent. This probably is to be accounted for by the action of the organic matter on the sulphates in the water, sulphureted hydrogen being produced and then absorbed by the hydrated oxid of iron formed by the rusting of the iron pipes, while the subsequent oxidation resulted in the liberation of sulphur, the action being the same as takes place when the oxid from gas-purifiers is exposed to the air.

NECROLOGY.

William H. Pancoast, M.D.

The distinguished surgeon and physician, William H. Pancoast, died at his residence in Philadelphia, January 5, after an illness of a few days. He was a son of Dr. Joseph Pancoast, professor of anatomy in Jefferson Medical College, and was born in Philadelphia, October, 1835. He completed his collegiate education at Haverford College, Philadelphia, and was graduated with the degree of B.A. at the age of 18, subsequently receiving the degree of M.A. from the same institution. He pursued his medical studies at Jefferson Medical College and was graduated from this institution in 1856. Two and a half years following were spent in Europe, visiting the great hospitals of London, Edinburgh, Paris, Vienna, Berlin, etc., and in the pursuit of his profession and in the study of special courses. While in Paris he was a special student of Civiale, the distinguished French surgeon. He returned to Philadelphia where he commenced a general practice, but devoting himself chiefly to surgery, also to private teaching and anatomy. He was a member of the Academy of Natural Sciences of Philadelphia; fellow of the College of Physicians of Philadelphia; member of the Philadelphia County Medical Society, of which he was president in 1869; permanent member of the Pennsylvania State Medical Society, of which he was vice-president in 1870; of the AMERICAN MEDICAL ASSOCIATION, etc. His contributions to medical literature consist of articles written for various medical journals. He published a report of the surgical anatomy of the band which united the Siamese twins. He was elected visiting surgeon to the Charity Hospital, Philadelphia, in 1859—a position which he held for ten years, and during which he established a large surgical clinic. Upon his resigning that position he was elected consulting physician and placed upon the board of trustees. In 1862 he was appointed demonstrator of anatomy of the Jefferson Medical College and held that position for twelve years; was appointed lecturer on surgical anatomy in the summer school. In 1866 he was elected one of the visiting surgeons to the Philadelphia Hospital. During the absence of Professor Joseph Pancoast in Europe in 1867 and 1868 he was appointed adjunct professor of anatomy and in that season lecturing as demonstrator of anatomy, teaching operative surgery, holding surgical clinics at the Philadelphia Hospital and at the Jefferson Medical College. In 1873 and 1874 he served a second time as adjunct professor of anatomy in the Jefferson Medical College, aiding his father; and in the spring of 1874, on the resignation of his father, he was elected professor of general descriptive and surgical anatomy of that institution. During the War of the Rebellion he was appointed surgeon-in-chief and second officer in charge of the Sixth and Master Streets Military Hospital, Philadelphia; and for volunteering surgical services in the field upon three occasions during the war he was elected a member of the Loyal Legion. He was one of the founders in 1887 and professor of anatomy and clinical surgery in the Medico-Chirurgical College of Philadelphia. He was president of the Section on Anatomy of the Ninth International Medical Congress. His home was the center of hospitality and no medical gathering was quite complete without the presence of Professor Pancoast. Socially he was one of the most genial of mankind, and he will be greatly missed by the members of the AMERICAN MEDICAL ASSOCIATION, a majority of whom had the pleasure of his personal acquaintance.

Charles Frick, M.D.

BALTIMORE, Jan. 2, 1897.

To the Editor:—I send a slight tribute to the memory of Prof. Charles Frick, to whom a memorial room and library were dedicated here on the 10th ult. Professor Frick held the chair of materia medica in the University of Maryland and

died March 25, 1860, from diphtheria contracted in an attempt to save the life of a poor negro girl by tracheotomy. His patient recovered by the loss of his own life after tracheotomy performed by Professor Milbenberger. Professor Frick was unquestionably the ablest and most original physician whom Baltimore has ever given to the medical profession. Prof. S. D. Gross gave an excellent memoir of him in his "Lives of Eminent American Physicians." Yours respectfully,

EUGENE F. CORDELL, M.D.

CHARLES FRICK, M.D.

Though time oft mantle of oblivion throws
O'er lives that in brightest lustre seem'd to close,
It has not yet effaced the memories thick
That cling about the honor'd name of Frick.
Him nature form'd in gentlest, manliest mold,
Unselfish, patient, modest, yet large-soul'd,
And amply gifted with those powers rare
That mark the man of genius everywhere.
Him nature taught her secrets to explore,
To penetrate disease's inmost core,
And in the crimson current's heated tide
To trace the paths where fevers lurk and hide,
To carve and clear away by methods new,
To analyse, to measure, gauge, and view
With sharpest glass, cast, pigment, granule test,
And over cell and fiber hold inquest;
Reaction to determine and to sift
The ashes of life's wear and tear for golden drift;
Naught to take on faith but all things to try
In the crucible of his own alchemy;
Authority duly to respect but thrust
From musty shelves the antiquated dust;
To grasp the essence of a thing forsooth,
And let in grateful light upon the truth.
Such was the man—his work; faithful in all
And brave, 'till came the fatal duty's call
And—ere into full noon the morn of life
Yet had ripen'd—cut short his noble strife.
Like some young lusty oak whose head doth cleave
The sky, far o'er the grove, where zephyrs heave
A purer breath, and the great king of day
Emits his brightest, first and latest ray;
When storms arise and darkness rules the air—
Save for the forked lightning's angry glare—
His ample bosom rends the bolt—although
Safe are his humble comrades far below.
These glorious lives, they are our heritage,
Friend, hero, benefactor, martyr, sage;
And though to them the world is so unjust,
Nor craves for them their due—memorial bust,
Nor gilds their mem'ries with immortal fame,
Such as he who for his country dies may claim,
No nobler deeds the page of history bears,
Nor lives the man who nobler does and dares.
No matter though there be danger and death,
No matter though it call for one's last breath,
May those be always found dispos'd and quick,
To do, and if need be, to die like Charles Frick!

C. E. SEGER, M.D., of New Hackensack, Dutchess County, N. Y., one of the best known physicians of the Hudson Valley, died at his home in that village December 10, after an illness of two weeks of typhoid fever. He was 54 years old. He was an alumnus of the Albany Medical College, of the class of 1863. He was health officer of the town in which he lived.

JAMES B. GILBERT, M.D., of New York city died December 9. He was born in Gilbertsville, N. Y., in 1852; was graduated from Phillips Academy, Andover, Mass., in the class of 1870, and from the medical department of the University of the City of New York in 1873. After two years in the General Hospital in Vienna he returned to that city to practice general medicine.

THEODORE GEORGE WORMLEY, M.D., of Philadelphia, died January 3, aged 70 years. His death was due to gastritis. He was born in Cumberland County, Pennsylvania. He attended Dickinson College and in 1849 graduated from the Philadelphia College of Medicine. In 1850 he went to Columbus, Ohio, and two years later he was appointed professor of chemistry and the natural sciences in Capital University, Columbus, which

position he held until 1865. While in Columbus in 1854 he was made professor of chemistry and toxicology in Starling Medical College. This he held until 1877, when he was elected to the same professorship in the University of Pennsylvania, which he occupied until his death. For eight years Professor Wormley was State gas commissioner of Ohio, and was State chemist of the Ohio geological survey from 1869 to 1874. Professor Wormley was a member of numerous scientific bodies and was a frequent contributor to scientific journals.

FRANK OBERHOLT, M.D., of Harlan, Iowa, December 9.—L. A. Lagle, M.D., of Tuscola, Ill., December 9.—J. S. Serrin, M.D., of Indianapolis, December 13, aged 65.—J. D. Pollock, M.D., of Aurora, Ill., December 14, aged 86.—S. W. Jones, M.D., of Leavenworth, Kas., December 16.—Gustavus B. Taylor, M.D., of Owensboro, Ky., December 1.—John S. Blankenship, M.D., of Rushville, Ill., December 2.—W. H. Hayman, M.D., of Chicago, December 2. He graduated from Rush Medical College in 1886.—John C. Hall, M.D., of Medical Lake, Wis., November 29, aged 75.—Walter H. Leighton, M.D., of Togus, Me., November 30.—W. M. Cochran, M.D., of Butler, Ohio, November 30, aged 33.—J. M. Rainey, M.D., of Nashville, Tenn., December 10.—K. A. Bushnell, M.D., of Little Falls, N. Y., December 24, aged 40.—Charles G. Anderson, M.D., of Belmont, N. Y., November 26, aged 62.—William Wallace, M.D., of Brooklyn, N. Y., December 23, aged 61. He was born in Ireland and was graduated from the Royal College of Surgeons in 1856 and the Royal College of Physicians in 1860. He was acting assistant surgeon in the royal navy during the Russian War and was on the staff of the Royal Infirmary and Maternity. He came to this country in 1864 and began the practice of medicine in Brooklyn.

BOOK NOTICES.

An Autumn Singer. By GEORGE M. GOULD, A.M., M.D. Philadelphia: J. B. Lippincott Company, 1897.

Those who know Dr. Gould only as a lexicographer, a leader writer, a metaphysician, or sociologist, will have a surprise in store for them when they view him as a poet.

In his prose writings we seldom see his sympathetic side. He writes prose to correct some abuse. There are so many abuses to correct, and so few with the courage to correct them!

Think of a grave physician skilled in comparative anatomy, writing like this:

"A bit of sunshine, warmed by spring,
A heart of song, a fluff of feather,
A wing put there, and here a wing,
A breath blown in—all kissed together
With sweet low croon of half-heard words,
This was the way Love made his birds!"

This is rather romantic embryology, but sentiment rarely runs smoothly with science, and the verse is sweet nevertheless.

Here speaks the philosopher:

THE SOUL'S MASQUE.

The soul is like the man in visored steel
Whose face by strange mysterious decree
He dare reveal to none, none live and see.
The body is the masque whose folds conceal,
More absolute than iron's locked anneal,
Soul-prisoner hid within, whate'er the plea,
Self's secret deep is kept more utterly
Than were it doom of death should we reveal.

And hence our piteous, awful loneliness!
Alone we live and die, and can not tell
The truth although the secret kill; unshown
Soul's face to dearest friend! More merciless,
Fate makes us mysteries to ourselves—in cell
Of flesh unknown of all, by self unknown!

Here speaks the lover to the "soft insistent breeze."

ABSENCE.

"Go, go, and kiss her hair,
Winds that run and woo;
Kiss her eyes, wonder-fair,
Say her lover's true.

O, homing wind, o'er all the far way glide,
And tell her who waits at the window side
The curtain fluttering—beg her open free
The blinds, her arms, her heart, to us, to me.

Blow, blow and stronger blow,
Wind from out the south;
Kiss her eyes, and below—
Tenderly—her mouth."

One of the prettiest things in the book is the following:

JUNE.

"As soft as silence is the moon;
The leaves of every tree are stilled;
The trees are full of love and swoon
To joyous sleep, with dreams fulfilled,
While high and faint the half-heard croon
And lullaby of day, distilled
To monotone of ending tune,
Drops softly down to dream unthrilled
Of aught except the bliss and boon
Of Heaven that broods, and God who willed
That earth beloved should be of June."

In the brief space of a book notice we can do no more than reprint the foregoing extracts as samples of the goodly contents of Dr. Gould's newest book, and to compliment the author on the production of a work which abounds in the true spirit of poesy, which with tender sympathetic touch reveals nature itself. Whatever may be the conclusion of the literary critic concerning the versification, none can doubt the sincerity, the wisdom, and the virility of the sentiment underlying the verses. We hope that Dr. Gould will not rest here, but continue to sing as taught by the Muse, who according to Homer "loves the harmonious race" of poets, notwithstanding the advice of Horace, that a new poet should keep his manuscript in his portfolio nine years before publishing.

Eating and Drinking. The alkalinity of the blood, the test of food and drink in health and disease. By ALBERT HARRIS Hox, M.D. Cl. 8vo, pp. 303. Price \$1.50. Chicago: A. C. McClurg and Company.

This book is a well written monograph on dietetics from a rather narrow standpoint, but an entirely sound one. It contains an introduction and six chapters as follows:

I. Air, water and food, and the relation of vegetable to animal life. II. How food is digested. III. The effect of different kinds of food on the blood. IV. The food of primordial man. The classification of fruits, and the proper and improper use of them. V. Drinks, harmless and harmful. VI. Food and its effects on the alkalinity of the blood. The work is intended more for physicians than for the general public.

The author follows Haig closely in his belief in the universality of the uric acid diseases and the necessity for the administration of alkalies. He opposes the use of fruit in all such conditions and goes to the verge of radicalism against what he calls artificial fruits.

Nevertheless, the book is highly instructive, and well worthy a place in the medical library. The author shows a thorough familiarity with his subject.

The Diseases of the Male Urethra. By R. W. STEWART, M.D., M.R.C.S. Pp. 221. Illustrated. New York: William Wood and Company. 1896.

This little book is one of the "Medical Practitioner's Library" series, and bound uniformly with the other volumes of the series.

"With the advent of improved instruments for intra-urethral inspection, together with the general advancement in our knowledge of bacteriologic and pathologic subjects, a new era in urethral pathology has been ushered in and many radical advances have been made not only in the pathology but also in the treatment of urethral diseases." The author is conservative in the main and his advice is sound. We entirely agree with him in regard to the letting alone of strictures of large caliber.

The chapter on epididymitis is defective in diagnosis; the author assumes apparently that all cases of epididymitis are due to invasion of the gonococcus. He nowhere mentions that very many cases of tubercular epididymitis exist and that in every case of tubercular testicle the first signs have been seen in the epididymis, and that such cases being frequently accompanied with discharge through the urethra, are too often mistaken for gleet. The book is an excellent one and we cheerfully commend it.

ASSOCIATION NEWS.

Section on Physiology and Dietetics.—It is the earnest desire on the part of the managing officers of this Section that its work at the coming meeting in Philadelphia shall be attended, with success.

The field in which subjects for contributions may be chosen will, on a little reflection, be seen to be large and varied.

It is therefore hoped that the members of the AMERICAN MEDICAL ASSOCIATION who are expecting to attend this semi-centennial meeting will be free to make contributions to this Section, and that they will send at an early date the titles of their papers to my address or to that of Dr. E. Cutter, the Secretary, Equitable Building, New York City.

AUGUSTUS P. CLARKE, M.D., Chairman.

825 Massachusetts Avenue, Cambridge, Mass.

SOCIETY NEWS.

The Congress of Internal Medicine to be held at Berlin next June, will discuss chronic articular rheumatism, address by Bäumler; epilepsy, Unverricht, and morbus Basedowii, Eulenberg.

The Pan-American Congress.—Between four and five hundred members attended the congress and enjoyed the hospitality of the City of Mexico and its beautiful scenery while participating in the great scientific meeting, which draws the ties between the great nations of the two Americas closer together. The wonderful energy and progress of Mexico in the last decade in scientific matters was duly acknowledged, and her enlightened government congratulated. An international committee of public health suggested by Dr. Trader was voted and organized *ex profeso*, its principal duty at present to draw up an international sanitary code. In the Section on Medicine, after the address on serotherapy by Dr. Lavista, various papers were read on malaria and its treatment. The physicians of the City of Mexico declared that no cases were known there except those contracted elsewhere. Dr. Bedford Brown's address is given in full in the JOURNAL, Vol. xxvii, p. 1319. Dr. Terrés (Mexico) observed that those unaccustomed to such tasks found it difficult to distinguish the Laveran plasmodium in the blood, and that it was sufficient for all practical purposes to note the coffee-colored pigment and the granulations, either free or inclosed in spherical bodies. He added that the quinin should be administered as soon as the diagnosis is established, as he considers it an error to wait to give it previous to the recurrence. He has never observed glycosuria consecutive to malarial attacks. Dr. Bibb stated that the semilunar forms of Laveran's parasite were characteristic of pernicious malaria, but Dr. Terrés denied this, having found them frequently in the course of his 500 examinations of the blood of malarial subjects, and never corresponding to malignant types. Physicians of Mexico and Cuba denied the existence of latent forms of paludism, as the characteristic elements are missing in the blood in what are known as the latent forms. Coronado (Havana) urged the establishment of an American pyretology, which is entirely distinct from the European pyretology. Tuberculosis was also studied from various points of view, Dr. Crook (New York) recommended creosote as very successful in his experience. He gives 25 to 60 drops in twenty-four hours, combined with cod liver oil, and the germs disappear from the sputa as the treatment progresses. Altamirano (Mexico) considers intestinal tuberculosis a contraindication to the use of creosote, and as it is painful administered hypodermically he substitutes guaiacol for it. Terrés always administers the creosote by the rectum, combined with cod liver oil and the yolks of eggs. Its beneficial action is most evident in this way. Dr. Holmes (Denver) described his method of early diagnosis of tuberculosis before any of the typical symptoms appear, by microscopic examination of the leucocytes, which show the characteristic disorganization of the tissues in this disease by their altered shape and certain special micro-chemic spots. The fact was mentioned that tuberculosis in the Mexican mesa was essentially a long,

chronic disease, extending over fifteen to thirty years and never acute. The especial benignity of pulmonary affections in San Diego, Guanajuato, was the subject of an address by Dr. Cano. Yellow fever was also discussed by experts, and the value of investigation of the toxicity of the urine for the prognosis established. Dr. Pepper addressed the congress on the subject of the cathode ray in thoracic aneurysm, and presented the fine set of photographs he exhibited to the N. School of Medicine. He dwelt upon the great advantage to be derived from the cathode photographs in the cases of aneurysm, especially when all symptoms point to an aneurysm, and still the photograph shows the organ intact. Dr. Llambias of the Argentine Republic describes the anatomic causes of ruptures of the aorta, which he ascribes to previous alteration in the arterial walls, and not to traumatism. Dr. Debayle of Nicaragua described his method of saturating the tissues with antiseptics by immersing the part or the whole body in a continuous bath, which has given him very satisfactory results, in gangrene especially. The amount of antiseptics employed must be less than the toxic dose, and the state of the patient carefully watched, especially the renal excretions, which must be examined for traces of the antiseptic fluid. The congress was also requested to enlighten an individual presented by Dr. Ortiz of Morelos in regard to his or her sex, a peculiar case of pseudo-hermaphroditism, who left the hall a man. The section adjourned after papers had been read by Dr. Kellogg on the treatment of chronic diseases by diet and exercise, by Dr. Curtin of Philadelphia on the importance of heredity in the etiology of Graves' disease, by Dr. Debayle of Nicaragua on tricuspid insufficiency of reflex gastro-intestinal origin, mentioning the diagnostic importance of the accentuation of the second sound and of the right "galloping sound," and by others. The congress will convene next at Caracas.—*Rivista Quincenal*, December 1.

MISCELLANY.

The First Hydrotherapeutists, and the most extreme and successful in enforcing their views upon mankind, were Mohammed and Moses, who even incorporated hydrotherapy in their religions, states the December *Janus*.

The Parthenon at Athens, which has been in danger of falling into total ruin for some years owing to the action of the recent earthquakes, is now being repaired by a commission acting under the authority of the Greek government.

Serotherapy of Smallpox.—O *Brazil Medico* states that the President of the Republic has summoned Dr. Caldas to Rio Janeiro to investigate the results of his application of the serotherapeutic processes to smallpox, with which he claims to have been very successful.

Congenital Anonychia.—Jacob of Berlin describes a case of three children in one family, all otherwise healthy and well developed, and of robust parentage, who have no traces of nails on either fingers or toes, except on one finger in one girl.—*Deutsche Med. Woch.*, December 10.

Dry or Mummy Preparations.—Bruns recently exhibited a valuable set of limbs, especially adapted for educational purposes, which he had prepared by soaking them in undiluted alcohol for a quarter of a year, and then merely hanging them up in the air to dry for another three months. By renewing the alcohol frequently the length of time they are soaked can be shortened.

Experimental Study of Thoracic Surgery.—Quenu and Longuet have secured interesting results by compelling animals to breathe with their heads in a balloon filled with compressed air at a high pressure and then opening a flap in their thorax. The lung bulged out, pink and convex, still breathing regularly. It was easy to palpate the entire organ by slipping the hand inside the opening. The respiration remained normal, without asphyxia or syncope, and the lung seemed to effect its own hemostasis in the hernia when it was incised.—*Bulletin Médical*, December 5.

Paradoxical Action of Lavage of the Blood.—Carrion and Hallion have been studying the diuresis produced by injections of

NaCl, 6 to 9 grams per 1000. They assert that numerous tests before, during and after the injections have proved that when the urinary secretion is most abundant the elimination of urinary substances, aside from the NaCl, diminishes to a very small proportion. The chlorid of sodium seems to take the place of the other elements.—*Bulletin Médical*, December 5.

Male versus Female Clerks.—According to English statistics, the number of days lost in their work by the government employes on account of slight indispositions, was 154 by the women to 100 by the men. In France the proportion is even larger, being 174 by the women to 100 by the men.

A Vast Pill Business.—We note an item among other interesting bits of news transmitted by the news gatherers of the daily press, that the business of a certain patent-pill nostrum in New York city, was sold to an English syndicate for \$2,000,000! The former manager of this pill factory, we are informed, is to be retained for five years by the new company at an annual salary of \$50,000! "*O dura Messorum ilia.*"

A Surgeon on the War Path.—Lepelletier had occasion recently to address the graduates of the military school at St. Cyr, France, and called upon them "to arise in their might and as surgeons of the honor of France, perform *rhinoplasty* upon the territory of their fatherland, and restore the flap of living flesh so brutally severed by the conquering Germans!"

Tuberculosis of the Inferior Maxillary Bone.—In all the cases treated in Czerny's clinic during the last twelve years there have only been eight undoubted cases of tuberculous affections of the lower jaw. As medical treatment proved ineffective, he advises prompt resection as soon as the diagnosis is certain, in young persons, and in elderly patients, cleaning out the cavity, followed by resection if necessary later.—*Centralbl. f. Chir.*, December 12.

Permanently Slow Pulse.—Brissaud describes at length in the *Presse Méd.* of November 21, a peculiar case of facial paralysis with genital and prostatic lesions of probable tuberculous etiology, which establishes once more the exclusively bulbar origin of a morbid permanently slow pulse. He mentions the fact that Napoleon had only 42 pulsations to the minute, but this was normal and does not come under the head of bradysphyxia, as the morbid condition is called.

Blatta Orientalis in Medicine.—At a certain London hospital a patient was given some extract of malt with instruction to take a teaspoonful twice a day, commencing on the following morning, and to report himself at the end of a fortnight. At the expiration of this time he returned and said to the physician, "Please, sir, am I to go on taking them insects you gave me?" "Insects," said the physician, "what insects?" "Why, them cockroaches, sir. I've taken one night and morning in a teaspoonful of the sticky stuff." Inquiry elicited that the cockroaches had not been dispensed, but had got into the jar during the first night of its stay in the patient's house.

Calliano's Method of Artificial Respiration.—Calliano has simplified the familiar Sylvester method of artificial respiration, which requires two persons to accomplish and is liable to produce injuries in the hands of the unskillful, by tying the hands of the asphyxiated person together behind his head with a handkerchief. This expands the chest and produces the inspiration of the Sylvester method. All that is necessary now is to expel the air by compressing rhythmically the thorax with the two hands, eighteen to twenty times a minute, and thus alternate expiration with the mechanically produced inspiration.—*Gazzetta d. Osp. e d. Clin.*, No. 98.

The Thomson Case.—A Miss Thomson died recently in the private office of Dr. Boisleux of Paris, in the course of an operation, and her lover, Mr. Mansuy, committed suicide when the news reached him. The authorities refused to issue a burial

permit and examination of some letters raised the suspicion of a criminal abortion. Dr. Boisleux and the physician who accompanied Miss Thomson to his office and assisted at the operation, were arrested and are now in prison, while a committee of experts, including Professor Brouardel, the dean of the Faculté, are investigating the case. The first lesson to be drawn from it in the meanwhile, according to the *Journal de Paris*, is never to perform any important gynecologic operations in one's private office.

No Inquest Authorized.—The supreme court of Georgia declares, in the case of Meads, Coroner, v. Dougherty County, July 13, 1896, that there is no law in that State which either requires or authorizes a coroner to hold an inquest over "a lot of bones, bleached by time," constituting parts of a human skeleton casually found upon the bank of a creek, it being obviously impossible to ascertain who the deceased was, how long since death ensued, or in what manner it was caused. Such bones do not constitute "a dead body" within the meaning of the act of Dec. 18, 1893, relating to coroners' inquests. And the interment of such bones in a "soap box, without expense to any one," the court further holds, does not entitle a coroner to the fee of \$15 prescribed in section 3701 of the Code "for furnishing coffin and burial expenses."

Quack Sentenced.—An alleged "homeopathic" practitioner has been carrying on an immense business in Germany, dispensing drugs by mail all over Europe, claiming to cure coughs, stomach and liver troubles, etc., with a host of employes who prepared the medicines in the rear rooms of his fine pharmacy, which he kept open as a blind. He has been condemned to four years and a half in prison, with a large fine and the suspension of his civil rights for five years. His advertising bills amounted to over 160,000 marks annually. Another celebrity of the kind is still prospering, the "Miracle Doctor" Ast, as we notice that he has just purchased an estate, for 225,000 marks, which confers several knightly privileges upon its owner in the local legislature.—*Deutsche Med. Woch.*, December 12.

Dyspepsia in the Etiology of Chlorosis.—The frequency of dyspeptic disturbances in chlorosis is familiar to all, but Mongour states that they are the actual cause, and that appropriate treatment, milk diet, daily lavages of the stomach, etc., without the specific iron medication will cure the chlorosis with no further treatment. If the patients resume their old habits of life and diet, the chlorosis may reappear, but appropriate stomach treatment will conquer it again, while the "usual martial treatment of chlorosis entails the complete destruction of the glandular apparatus of the stomach and an irremediable chronic lesion." His arguments as set forth in the November *Archives Clin. de Bordeaux*, with numerous observations, are certainly worthy of consideration.

Must Show Amount Expended.—In the personal injury case of Fry v. Hillan, where \$350 was claimed for drugs and medical attendance, there was no proof as to the amount so expended, only testimony of the plaintiff that he had employed doctors for a long time. Under these circumstances, the court of civic appeals of Texas holds, October 14, 1896, that it was error to instruct the jury that they might find for the amount expended for medical attention and drugs, as the jury might conclude from it that they were authorized to allow what they saw proper without any testimony as to the amount, whereas that is not true.

Annual Distribution of Prizes at the Paris Academie de Medecine.—Beside the Saint Paul prize of 25,000 francs divided between Roux and Behring, over \$11,000 were distributed among the successful competitors, most of them French professors, internes and students. Many of the prizes were divided among two or more, and large numbers received honorable mention for their contributions. We notice among these the names of S. A.

Knopf of New York, Claus of Antwerp, Ehlers of Copenhagen, Lambros of Athens, Stricht of Ghent and Arthus of Freiburg. Other foreigners honored were Brun of Beyrouth, several physicians in the colonies, M. and Mad. Christiani, M.D., of Geneva; Theremin of St. Petersburg, Duvigneau of Cochinchina, Matignon of Pekin and Felix of Brussels. The largest undivided prize was awarded to Gilles de la Tourette, 3,000 francs.

A Contribution to the Question of Cheap Living.—An article in the *Deutsche Med. Woch.* of December 3 describes the methods of preparing the family meal which have prevailed for three generations in certain Thuringian towns to the satisfaction of all. Each family has one or more earthen crocks and these are filled with materials for the family dinner and taken to the baker, who places them in his oven after he has baked his bread for the day. The heat is sufficient to cook the meat, potatoes, vegetables, etc., in the crock slowly and evenly, so that when the family call for the crock on their way home from church or work, they have an appetizing and wholesome hot dinner ready for them at the trifling expense of 3 pfennigs, the baker's charge. As every family does the same, there is nothing derogatory in the practice. An English friend informs us that the same practice is current in Cumberland to a certain extent and that she has a most vivid remembrance of the delicious odors that proceeded from the crocks the millhands were carrying home on their return from work as she passed them on her way from school.

Bravery of Military Surgeons in Cuba.—From the *Revista des Sanidad Militar* of Nov. 15, 1896, we learn that on August 21 last a board of army medical officers was convened in Havana, Cuba, to consider the various acts of heroism officially reported as having been performed during the present war in Cuba, by army medical officers, and to determine to whom should be adjudged a purse which had been offered by a retired medical officer, D. Eduardo Pérez de la Fanosa, now residing in Madrid, Spain, to the medical officer who had most distinguished himself in the line of duty on the field of battle. In offering the purse the donor stated that while it was perhaps of small intrinsic value it represented his affectionate regard for the corps to which he had for so long belonged. The secretary of the board read reports from all parts of the island which showed there was no lack of praiseworthy acts to the credit of the army medical department. Many of these reports related to deeds of which members of the board had personal knowledge. After due consideration the board reached the unanimous opinion that the deeds which should be singled out for this special mark of commendation were those performed July 5, 1896, by Dr. Jerónimo Durán y Cottés. On that day the battalion of Antequera, 600 strong, Lieutenant Colonel Escudero commanding, encountered at Hato-Jicarica, Matanzas, a force of 3,000 insurgents under various leaders, among whom were Lacret and Clotilde Garcia. In the fight Dr. Durán, the medical officer of the battalion, was struck by a Mauser bullet while dismounting to attend a wounded man. The ball penetrated the center of the popliteal space and traversing the joint made its exit on the left side of the patella. The bleeding was so free that it was feared the popliteal artery was injured; but notwithstanding this, Dr. Durán proceeded with his work after applying his handkerchief as an extemporized tourniquet to restrain hemorrhage. He had the wounded brought to the place where he had been disabled and attended to them. Sixteen men were brought in. Among them were a soldier wounded in the abdomen, with protrusion of the intestine requiring reduction and suture of the abdominal wall; a case of hernia of the testicle requiring closure of the scrotum; a wound of the gluteal region from which the bullet had to be extracted, and a fracture of both bones of the leg, which was reduced and immobilized by splints of Mauser bayonets. After the fight

the Doctor started for Havana, but was unable to complete his railroad journey. He went into hospital at Matanzas, where he remained under treatment twenty days. The board appointed September 15 as the day on which the formal and public presentation to Dr. Durán would be made.

Louisville.

YEARLY HEALTH REPORT.—Health Officer White has just submitted his report for the year 1896, and it contains some interesting facts. The mortality report is as follows: Estimated population 211,100; total number of deaths, 3,206; white, 2,347; colored, 859. Annual death rate per 1,000 inhabitants, 15.1; average death rate, white (population 173,600) 13.5; colored (population 37,500) 22.9. Consumption caused 389 deaths, typhoid fever 96, pneumonia 251. There were 353 cases of diphtheria placarded with 72 deaths during the year, showing a mortality of slightly over 20 per cent.; 340 cases of scarlet fever were placarded with a mortality of 4.1; 1,383 vaults were cleaned during the year, 776 diseased cattle killed; 5,580 diseased cattle condemned and sent from the city; 2,457 cases were vaccinated. There were 304 more deaths during 1895 than during the past year. The number of deaths from typhoid fever alone is a fairly good method of estimating the health of the city. During 1895 there were 195 deaths from this cause, or 77 per 100,000 of the population, during 1896 there were 96 deaths from typhoid fever, or 45 per 100,000, a reduction of 37 per 100,000. This decrease in typhoid fever is attributed by the Health officer to the much improved sanitary condition of the city, which has been made possible by the numerous sanitary regulations which have originated in the health office and which the officer in charge has been enabled to enforce. Among these may be mentioned better sewer connections, which has been one of the chief objects of the department during the year; inspection of the milk; placarding the buildings in which there are infectious or contagious diseases, though typhoid fever is not included in the list of diseases to be placarded at present; enforcement of a sanitary nuisance ordinance; the flushing and thorough cleaning of the Water Company's reservoirs, the first time in eleven or more years; a vigilant supervision of the city well-water, frequent tests being made by careful analyses.

Dr. CHARLES GROVES was thrown from a buggy and in the fall, sustained a compound Pott's fracture of the right ankle, which may result in the loss of his foot, though there are hopes that this will not prove necessary.

CITY SUE.—A suit was brought recently against the city by the Nazareth Literary and Benevolent Association, for \$250, claimed to be due for services rendered by four sisters of charity at the Eruptive Hospital. These sisters were removed by the general council soon after its election and salaried nurses employed when necessary. Shortly after this the above organization brought suit for the sum named, and in the common pleas division of the court were adjudged the amount asked for. Soon after the city attorney entered a motion for a new trial, the existence of a contract being denied by him.

SPRING AND SUMMER SCHOOLS.—The Kentucky School of Medicine and the Hospital College of Medicine began their annual sessions on the first of January, both with large classes. The faculty of the former school instead of the regular lectures on New Year's day gave a reception to the students and their friends during the afternoon, which was largely attended. The Gray Street Infirmary, connected with the Hospital College has been completed in time for the opening of the session and will add very much to the teaching facilities of the school. Students entering the colleges this year must attend four courses of lectures before they can graduate.

PHYSICIANS' LICENSE.—When the bills for licensing physicians were presented some time ago (\$10 a year when the income is less than \$2,000; \$20 when between \$2,000 and \$5,000; \$40 when between \$5,000 and \$10,000 and \$100 when over

\$10,000), Dr. J. M. Mathews, President of the State Board of Health, on behalf of the physicians of the city, brought suit against the city and the Sinking Fund Commissioners, to prevent the collection of these licenses, on the ground that it was unconstitutional. Judge Toney on the 2d inst. in joint session handed down an opinion covering twenty-five pages of type-written matter, in which he decides in favor of the plaintiff and overrules the demurrer entered by the defendant at the time the suit was brought. The tax was originally imposed by the council on physicians, surgeons, architects, veterinary surgeons, chiropractors and civil engineers. The judge said in part as follows: "The first question that presents itself is: What is the real legal character of this tax? Certainly it is not a police regulation. If it was a police regulation the ordinance would be manifestly void, upon familiar principles of law. It is strictly a revenue ordinance, wholly disassociated from any purpose of police regulation. It is a tax not upon property, nor upon income, but upon the calling or profession of medicine or surgery. It is competent undoubtedly for the legislature, if it sees fit, to tax his income, which is a wholly different thing from the privilege which as a citizen he enjoys of trying to earn an income in his particular calling. Still the question under consideration admits the power of the State to restrict or prohibit the natural right of the citizen to follow his calling, business or occupation as a physician, unless and except upon payment of a privilege tax first be made. The right to earn a living or an income is not a grant from the State, nor from the city, but it is a natural and inalienable right, inherent in every man. It is not transferable nor subject to seizure, nor vendible under execution. In other words, it is not property, in any just or legal sense of the word. It antedates the formation of society or government, and is therefore a natural, absolute right. But the State has power, undoubtedly, for the purpose of revenue, to lay a restriction on this natural right and to prohibit the citizen from enjoying it until and except he pay, as a condition precedent, a license or privilege tax so to do. And the State has also the right and power to delegate to city, municipality, this branch of sovereignty, in fact raise revenue for the purpose of defraying the expenses of the municipal government. The character, extent, and scope of the delegated power of taxation distinctively and exclusively depends upon the language of the statute delegating such power. It is plain from the sections 3 and 40 of the ordinance that the license fee or privilege tax in dispute is not a tax on the income of the plaintiff; that is, a tax on the amount of money which he had earned in his profession the previous year, or which he may or may not earn in the year which the license is required to be taken out. He may decline to further practice his profession, in which event the city makes no demand whatever for what he had earned the year previous, and he would have to pay nothing for having practised his profession and having earned an income from it the year before. This may properly be termed a privilege tax on the privilege of earning a living by his particular profession." As to the proposition of the ordinance to grade the tax, the Judge says: "The palpable injustice and inequality of the classification is strikingly apparent in the first and fourth of said classes. One whose yearly business amounts to less than \$2,000 shall pay a yearly license of \$10. Is it equal or just that the physician or surgeon just commencing, and who perhaps the first year of his practice does not make \$100, shall pay the same license as one who has practised several years, whose business amounts to \$1,900? Is it equal or just that one whose yearly business amounts to \$10,000 shall pay the same amount as license as one whose yearly business amounts to \$50,000? Yet such is the justice, uniformity and equality of the personal classification of physician and surgeon sought to be established in section 3. If there is to be a personal classification, with a corresponding scale of license tax upon the right of physicians and surgeons to earn a livelihood in their profession, such classification and scale or graduation of license or privilege tax should be intrinsically uniform and just. Thus viewed, section 3 of the ordinance is not only unreasonable, but unequal and unjust, arbitrary and irrational."

Hospitals.

THE INFANTS' HOSPITAL on Randall's Island, N. Y., is to be investigated by the grand jury. During the last three years the annual death rate has averaged about 43 per cent.—Owing to a disagreement with the board of trustees of the New York Medical College and Hospital for Women, the staff and nurses

of this institution have resigned.—The New York Polyclinic Hospital was damaged by fire December 25. The patients were moved without loss of life. Loss about \$50,000.

THE PUBLIC SERVICES.

Army Changes. Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from Dec. 26 to 31, 1896.

Major William C. Shannon, Surgeon (Ft. Custer, Mont.), leave of absence granted on surgeon's certificate of disability is extended three months on surgeon's certificate of disability.
 Capt. William L. Kneidler, Asst. Surgeon (San Diego Bks., Cal.), leave of absence granted for seven days is extended twenty-three days.
 Major William R. Hall, Surgeon, relieved from duty at Whipple Bks., Ariz., and ordered to Washington, D. C., for duty.
 First Lieut. Irving W. Rand, Asst. Surgeon, relieved from duty at Ft. Clark, Texas, and ordered to Ft. Huachuca, Ariz., for duty.
 First Lieut. Alexander S. Porter, Asst. Surgeon, relieved from duty at Ft. Huachuca, and ordered to Whipple Bks., Ariz.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for two weeks ending Jan. 2, 1897.

P. A. Surgeon R. M. Kennedy, ordered to the naval hospital, Norfolk, D. C. 28.
 Surgeon Charles T. Hibbett, ordered to the Norfolk navy yard, Dec. 22.
 Surgeon N. McP. Ferebee, detached from the Norfolk navy yard and ordered to hold himself in readiness for sea.
 Surgeon R. Whiting, detached from the "St. Mary's" and ordered before the retiring board at Washington Dec. 28, then placed on waiting orders.
 P. A. Surgeon R. P. Crandall, detached from the naval hospital, New York, and ordered to the "St. Mary's."
 Asst. Surgeon L. Morris, ordered to the "Essex."
 P. A. Surgeon A. R. Wentworth, detached from naval hospital, Portsmouth, N. H. on relief, and ordered to the "Marblehead."
 Surgeon E. H. Green, detached from the "Marblehead" on reporting of relief and ordered to naval dispensary at Washington, D. C.
 P. A. Surgeon H. B. Flitts, ordered to naval hospital, Portsmouth, N. H.
 Surgeon A. C. H. Russell, detached from the naval medical examining board, New York, on relief, and hold himself in readiness for the "Lancaster."
 Surgeon J. M. Edgar, detached from the "Saratoga" and ordered to the "Vermont."
 Surgeon H. Wells, detached from the "Vermont" on relief and ordered as member of naval examining board, New York.
 P. A. Surgeon W. C. Braisted, detached from the "Columbia" and ordered to the naval hospital, Newport, R. I.

Change of Address.

Duncan, W. E., from Aberdeen, S. D., to 603 W. 63d St., Chicago, Ill.
 Fortler, J. J., from Chicago, Ill., to West Superior, Wis.
 Lockwood, W. D., from Eureka, S. D., to Rock Port, Mo.
 McDaniel, E. D., from Milton, Fla., to Mobile, Ala.
 Meany, W. B., from 2602 Locust St. to 3907 W. Belle Place, St. Louis, Mo.
 Monette, G. N., from 1620 Calliope St. to 1124 St. Charles St., New Orleans, La.
 Oneal, Oren, from Wabash, Ind., to 291 Ontario St., Chicago, Ill.
 Palne, H. M., from West Newton, Mass., to 69 N. Fo. syth St., Atlanta, Ga.
 Whitman, C. H., from Mt. Pleasant Hotel to 529 S. Broadway, Los Angeles, Cal.

ORIGINAL ARTICLES.

THE OPERATIVE TREATMENT OF PTERYGIUM.

Read before Mississippi Valley Medical Association, September 18, 1896,
at St. Paul, Minn.

BY EDUARD BOECKMANN, M.D.

ST. PAUL, MINN.

It is a pleasure to me to have the opportunity of directing the attention of the Mississippi Valley Medical Association to an operative procedure for pterygium which I have employed for nearly fifteen years with eminent satisfaction and of which I gave a preliminary description in the *Medicinsk Revue*, September, 1885, published in Bergen, Norway. My original operation has in the course of time undergone some modifications, and as I can not, for the time being, conceive of any further improvement, I thought it might be of interest to present it to the medical public at large, and I have chosen this opportunity for the following reasons:

Pterygium is of frequent occurrence in the Mississippi Valley.

The members of the Association are undoubtedly, from personal experience, familiar with this characteristic affliction and many of you without doubt have treated it surgically in the capacity of oculists, surgeons, or general practitioners.

In a goodly number of cases you have obtained good results not only immediate, but also permanent.

The majority of you have, I suppose, employed excision, which is commonly recommended, but which *per se* is unjustifiable, and not infrequently followed by relapse.

Other operative procedures have not yet proven their ability to effect a cure in all cases.

Finally, pterygium is so easy of access, the operation for it so devoid of danger both to life and eye, and its clinical nature so evident, that we must make the reasonable demand that it should be satisfactorily performed with permanent good results by every one in possession of surgical and antiseptic qualifications and in every case.

The etiology and pathogenesis of pterygium are unfortunately not yet satisfactorily settled; it is still a somewhat mysterious calamity. In the days of humoral pathology, pterygium was the local evidence of a constitutional malady which should be treated before and after operation with iodids and sarsaparilla. Nowadays we believe just as much in this as that pterygium is due to strain of the interni, and that it should be treated with glasses. It is a trifle annoying that pterygium preëminently occurs in people who do not strain their interni, and that it occasionally occurs over the interni, which hardly can be over-exerted. A wound of the limbus can not by itself produce pterygium, or we would see pterygia daily in scrofulous ophthalmias; experimentally, pterygium

can not be produced by such wounds; we can safely eliminate this theory which, I grant you, sounds very plausible. Episcleritis has also been advanced as a cause. I acknowledge that episcleritis is or has been present in every case of pterygium, but an episcleritis, which is a disease of quite frequent occurrence, does never (as is notorious) *per se* give rise to true pterygium, so that under all circumstances there must be something peculiar to that episcleritis, which by some is accepted as the cause, and as there is also much which speaks in favor of such an interpretation, it is thus not improbable that the microorganisms, found by some observers in several cases of pterygium, play their part in its causation.

The circumstance that pterygium by preference occurs in people who are especially exposed to wind and dust; furthermore, that a good many positively date the beginning of their trouble to such an exposure; and finally, that I have actually a few times found in my operations on pterygium a minute foreign body in the episcleral tissue near the head, has created the firm conviction that the cause must be an infected episcleritis, in all probability due to a foreign body and that the peculiar mode of growth of the pterygium over the cornea results from the endeavor of the diseased tissue to rid itself of the offending particle. Such a traumatic infected episcleritis, limited to that part of the eyeball exposed, when the lids are open, is a common affection among the farmers of the west; but only when this episcleritis invades the cornea, dragging the superadjacent conjunctiva with it, do we call the disease a pterygium; there are, however, more such episcleritides than pterygia. As long as this episcleritis is active, the process is progressive in all directions, most conspicuously toward the center of the cornea, where the supposed foreign body presumably makes its escape.

As is well known, pterygium is divided into two general classes: crassum or sarcomatosum, and tenue or membranosum; this simply means that in the first group the disease is active or progressive, and in the second passive or stationary.

It may perhaps seem superfluous that I have dwelt so long upon the episcleritis, which I believe to be the cause of pterygium, since even a successful treatment of this condition can not effect anything toward the cure of pterygium itself, which is the affection we are consulted for, while we rarely are asked to treat the underlying condition, which gives the patient little annoyance, if any at all. Nevertheless, we must take cognizance of this casual factor, because, first, there may be question in some cases of a prophylactic operation, and second, in our operation on the pterygium proper we should also eradicate the episcleritis.

Pterygium is only a clinical term. Scrutinized from a pathologic standpoint it offers unmistakable evidence that it is a dislocation of a certain part of

the conjunctiva toward and upon the cornea, because: First, the pterygium is histologically identical with the conjunctiva; second, it is continuous with it; third, we can observe how the semilunar fold in nasal pterygia is drawn forward and later obliterated; and fourth, we also notice how the caruncle is dragged forward from its original position to assume the shape of a horizontal oval.

The dislocated part of the conjunctiva is usually the seat of a moderate conjunctivitis in the progressive form; in the stationary form the conjunctiva is normal except at the point of attachment to the cornea where there is a limited hyperplasia.

To sum up: Pterygium is a dislocation of a certain part of the conjunctiva over the cornea, dependent upon a localized episcleritis, in all probability due to an infected foreign body, which has penetrated the subconjunctival tissue and which is expelled at the apex of the pterygium, whereupon the latter becomes stationary.

While the preceding considerations ought to furnish valuable indications for the treatment of this affection surgically, a short synoptic review of leading symptoms is necessary to determine *when* such procedures are desirable.

The principal symptoms of pterygium are deformity, limited mobility with double vision, epiphora, irregular astigmatism, and amblyopia.

Deformity, whether great or little, is a plausible indication for operation for cosmetic reasons. Limited mobility justifies operation as soon as it produces double vision. Annoying epiphora, a natural result of the displacement of the parts concerned in the physiologic absorption of the tears, is likewise indicative of operation. Double vision and epiphora belong, however, to advanced stages of the disease, where more important indications present themselves for consideration. Amblyopia, due to irregular astigmatism, may occur in pterygia which have not encroached on the pupillary area; it is caused by traction on the cornea and is relieved by operative interference. Amblyopia caused by invasion of the pupillary field is by all means the most important symptom of advanced pterygium; surgery at this late stage of the disease will certainly accomplish much good, but it is not to be compared with the results afforded by operation undertaken before this invasion has occurred, and it is a very difficult matter to distinguish between a stationary and a progressive pterygium.

There are therefore in my opinion weighty reasons, cosmetic as well as prophylactic, to advise early operations, which in addition are easier to perform and give more ideal results than those undertaken in later stages.

I am thus totally at variance with the majority of authors who advise operation only when the pupillary field is invaded.

Unfortunately pterygium occurs preëminently in a class of people and usually at an age, when they do not particularly care about a little disfigurement, limited mobility, epiphora, and irregular astigmatism, in many cases also little about the amblyopia; at any rate in my experience, it is a noticeable fact that the minority of cases submit to operation, which is to be regretted, as I maintain that pterygium is absolutely under our surgical control.

The treatment of pterygium can, according to the preceding, only be an operative one. A dislocation of the conjunctiva must be treated upon the same surgi-

cal principles, which obtain in any dislocation, by *reposition* and *fixation*. I protest against operative procedures which aim at excision of the pterygium, as such mutilation is as unjustifiable here as in dislocations in any other parts of the body, and its only excuse is that it ordinarily is followed by good results.

Before I pass to the description of my operation of reposition and fixation for the cure of pterygium, a few remarks on the antiseptic technique will be in order, so that septic complications of annoying, even if not dangerous character, may be avoided, and a rapid and uneventful recovery ensue. For the operator, it is sufficient that he disinfects his hands. I confine myself in this respect to scrubbing thoroughly in a warm 1 per cent. lysol solution; then I wash the patient's face with the same sort of solution. The instruments, gauzes and bandages and the bottle containing the cocain solution, have been sterilized in Boeckmann's small sterilizer for combined sterilization. The field of operation is flushed with the cocain solution (my favorite formula being cocain mur. 3 per cent. dissolved in a saturated solution of boracic acid and sulphate of quinin); to quiet the other eye, a few drops are instilled into it. The speculum is introduced and I proceed to the

Reposition.

Reposition: The head of the pterygium is grasped with a good forceps and it is carefully dissected from its corneal attachment either by scissors, knife or evulsion. It must be dissected to its full extent and even a little beyond; after this the dislocated conjunctiva is unfolded by putting it on the stretch, which is simply effected by placing the blades of the scissors underneath it and lifting it up away from the globe. After this the conjunctiva will retract somewhat from the corneal periphery and assume its anatomical position as nearly as possible.

Fixation: In order to effect this properly we must recognize as a fact, that a *sine qua non* for the establishment of pterygium is the existence of the subconjunctival connective tissue. This is indeed the medium which makes it possible for the conjunctiva to slide over the cornea; if it did not exist, if in other words the conjunctiva around the cornea was intimately connected with the sclera, a pterygium would be an impossibility. If we remove the subconjunctival tissue to an extent that the edge of the replaced conjunctiva is freed therefrom and brought into direct contact with the sclera itself, a solid adhesion between the two will result and a successful fixation established.

With one forceps therefore, the conjunctiva is lifted up near its junction with the corneal margin (above or below) and with another forceps the subconjunctival tissue is dragged forward, and, steadily pushing the conjunctiva back, a good sized band of connective tissue is removed with the scissors along the whole extent of the conjunctival edge. If there is active episcleritis we do well to remove all inflamed tissue as good practice for the cure of the episcleritis itself and as an additional safeguard against a possibility of relapse.

After the excision of the subconjunctiva, the conjunctival edge will retract further backward, whereupon the whole wound, scleral and corneal, is thoroughly scarified and scraped for inflammatory remnants with a cataract knife. The hyperplastic conjunctival edge is trimmed off. To secure the conjunctiva in position, until adhesion is firm, and to prevent it from sliding over the cornea again by the movements of the eye, I fasten the edge to the internus (externus) muscle at its insertion with a single fine catgut suture and the act of fixation is complete.

We have now a triangular wound outside of the cornea, the free edge of the cut conjunctiva in direct contact with the denuded sclera, and a fresh corneal wound extending to Bowman's membrane. Cicatri-

Fixation.

zation will follow rapidly from all sides and by virtue of this cicatrix a recurrence of the dislocation will be prevented for all time.

The after-treatment is extremely simple. The eye is occluded with folded sterilized gauze; the bandage is changed daily and a 2 per cent. solution of nitrate of silver applied to the conjunctiva for a week; the bandage is then removed and the patient discharged.

Only one eye is operated on at a time as bandaging of both means discomfort.

I take the liberty to recommend this operation to the profession as being in my mind and according to my experience a rational, a justifiable and, when properly performed, an always reliable method.

Lowry Arcade.

AMBULATORY TREATMENT OF FRACTURES OF THE FEMUR; NEW MATERIAL FOR SPLINTS AND ORTHOPEDIC APPARATUS.

BY ALEX. C. WIENER, M.D.
CHICAGO, ILL.

Although I am perfectly well aware of the obstacles which still beset the ambulatory treatment of fractures of the lower extremities, I nevertheless claim that it is not necessary to confine the patient to bed for more than a week, even with fracture above the middle of the femur. On admission, the whole extremity should be carefully disinfected with soap, water and alcohol, and the hair removed. Then strips of cotton lining are pasted on the skin with Heusner's fluid adhesive plaster, and included in the dressing in such a manner as to leave the ankles free and to allow a small square board to be fastened at least three inches below the sole. To this board weights for extension are fastened. In the morning when the ambulatory apparatus is put on again, the weights are taken off and the strips are reversed and fastened with pins. In this way is secured a permanent extension with weights varying from ten to fourteen pounds according to the strength of the muscles. If, while

the leg is being dressed, it is carefully stretched, the patient experiences very little pain or inconvenience.

A glue dressing should be carefully applied and, beginning from the toes, should include the whole extremity up to the inguinal region. Rollers of soft muslin or, better, of light flannel, should be used, and also the best white glue. The glue should be boiled and then cooled sufficiently not to scald the patient. The rollers, which are about two inches wide, should be moistened on the end with glue and pasted on the skin in such a way as to prevent creases. Should it become necessary to fold the bandage, it must be cut and repasted. It is of the utmost importance that the toes, the foot, the leg and the space of 10 or 12 inches above the fracture, be provided with this tightly fitting compression bandage, as it would be impossible to endure a perpendicular position of the injured limb without it. Care should be taken that those parts at the joint of the foot which are especially subjected to pressure—the heel, Achilles tendon and the instep—are protected from pressure by a thin layer of absorbent cotton, and that the bandages are not pasted in this place, as motion will cause the glue to crumble and the skin will be irritated. I wish to particularly emphasize that in applying the bandage too much care can not be exercised in placing the foot in a perpendicular position to the leg, in order, by shortening the Achilles tendon, to prevent an equinus position, as this would be difficult to correct later on. On taking off the first bandage it may frequently be observed that the foot is already in a pes equinus position, which will later prevent the patient from using the extremity, even if the fracture is well healed, and a tedious and painful course of treatment will be necessary to overcome what might have been avoided in the first place by the observance of a few simple rules.

A firm "contentif" (compression) bandage in which the patient can walk may be obtained by including strips of thin fiber or pasteboard at the seat of the fracture. This will make a dressing not thicker than the blade of a knife, very light and yet firmer than the plaster dressing. If after a few days the bandage becomes too loose, a strip must be cut out and the defect remedied by pasting on new strips. Glue as an adhesive material produces compression like collodion, but, at the same time, does not interfere with the sudoriferous glands of the skin and forms a safe protection against the invasion of pus microbes and saprophytes. As soon as the glue touches the skin the patient will experience a sensation of coolness and relaxation. With this bandage, which within twenty-four hours becomes thoroughly dry, forming a solid capsule, the patient is enabled to walk about on crutches, since the leg can be suspended in a perpendicular position without pain.

The three following cases of fracture of the femur in the service of Drs. Lee, Halsted and Moorhead, were treated at the Cook County Hospital:

Case 1.—I saw the patient about nine days after the accident, when he was placed in an extension apparatus with twelve-pound weights. He was furnished with a tightly fitting glue dressing and the same was strengthened on the femur with thin pieces of pasteboard. After the extension apparatus was put on he walked from the table with the aid of two canes. He never experienced any inconvenience or edema. On one occasion I found him playing ball on the hospital grounds. At the end of six weeks the apparatus was taken off. The leg was shortened less than one-fourth inch. The muscles of the femur, particularly the quadriceps, which is most liable to atrophy, had the same strength as on the other side. At no time did edema or other disturbance of the circulation occur.

Case 2.—Patient was run over by a heavy cart shortly before his admission to the hospital, the wheels passing over the right femur. He entered the hospital May 6, 1896, and was put in an extension splint for six weeks. The first day he was up walking on crutches he fell again and fractured the femur again at a point just below the callus. The first fracture was located in the upper third of the femur, ten inches above the upper edge of the patella. The second fracture was eight inches above the patella. Eight days after the second accident the patient was furnished with a glue dressing, and two days later with an ambulatory apparatus. (I prefer to have the glue dressing thoroughly dried first; this takes about twenty-four hours.) One inch of shortening had resulted from the first fracture, the knee joint being almost immovable; the quadriceps muscle had atrophied to such an extent as to cause a difference of one and one-half inches in the circumference of the thigh. Four weeks later the extension apparatus and glue dressing were removed. Callus at site of first fracture was quite large, while that at the site of second fracture was scarcely perceptible. The quadriceps muscle was much more developed, the difference in circumference having been reduced to three-fourths inch. The knee joint could be bent to half a right angle. The astragalo-tibial joint was freely movable. No disturbance in circulation was noticeable at any time. A decubitus about the size of a half dollar located on the posterior surface of the thigh, which had resulted from the dressing of the first fracture, was healed up. There were no signs of pressure from the apparatus, which was worn over four weeks. There was a slight elasticity in the bone at seat of fracture. The patient was provided with a flannel bandage and sent home.

In this case we have right at hand a comparison of the old method of treatment and the new method. Under the former method the patient was compelled to lie in bed for six weeks and then, being unable to stand, had to use crutches. The muscles of the whole leg were atrophied, the knee stiff and the astragalo-tibial joint almost immovable. There was an extensive and luxurious callus and one inch of shortening. During the ambulatory treatment of the second fracture we not only took care of the fracture itself, but succeeded also in mitigating the bad effects of the first fracture.

1. The muscles of the leg, especially the quadriceps muscle, had gained considerably in strength, the difference being only one-half inch in the circumference. 2. The knee joint was immobilized to 45 degrees and the ankle joint absolutely free in mobility. 3. The original shortening of one inch was reduced one-fourth inch. It is remarkable that the formation of callus is very small under the ambulatory treatment compared with the callus formation under the stationary method of treatment. During the course of the stationary treatment the patient had lost in flesh and looked pale. When he left the hospital he was in the best of health and spirits, having enjoyed an outdoor life during the hot season. The measurements in this case were also taken by Dr. Jackson, interne of the hospital, so as to avoid any mistakes.

Case 3.—Strong laborer; oblique fracture of the left femur seven inches above the upper edge of the patella; considerable extravasation of blood; difference in circumference three inches; overriding of the fractured ends; shortening two inches. Admitted October 23; provided with a glue dressing October 26, combined with extension. As a shoe with a high sole for the healthy side could not be procured at once, it was necessary to postpone putting on the apparatus until the evening of November 2. He then walked through the ward with the aid of two canes, and the next day being election day, he was driven in a buggy three miles to his district to cast his vote. He returned to the hospital next morning in good condition, having been driven over rough roads and walked through a considerable crowd. Having gained confidence in the treatment he asked for his discharge from the hospital, which was granted. He is now going about at home still provided with the apparatus.

The construction of the apparatus has already been described in detail in the *Railroad Surgeon* of Feb-

ruary, 1896, and the *Chicago Medical Recorder*, February, 1896. The fractured shaft rests immobilized in the apparatus, the weight of the body being transferred to the tuber ischii, which is astride the uppermost steel bar. The apparatus is about two inches longer than the extremity, so as to allow the extension of the extremity. The same apparatus may be used in any joint disease in which the indications are rest of the joints, extension, and at the same time outdoor exercise.

The only objections to the general use of the apparatus are, 1, the expense; 2, the adapting of the steel bars. In experimenting to overcome these disadvantages I have succeeded in finding a material which, in my opinion, is ideal for use in general practice as well as in surgery. It is fiber. It is used in three thicknesses. The thinnest one takes the place of pasteboard in glue dressings and molds itself closely to the outlines of the extremity. I have experimented with the two next sizes for quite a while, and find that when soaked in hot water for different lengths of time it readily adapts itself to the outlines of the extremity. When soaked in hot water for about ten minutes it can easily be adapted to the outlines of the arms or legs. In order to mold it right to the skin around the joint so as to secure a capsule for the same, it is necessary to soak it for twenty-four hours. When dried, fiber takes the place of wooden, hard rubber or papier maché splints. In a half-soaked condition it replaces pasteboard, felt and pliable wood. When thoroughly softened it replaces leather for making capsules and immobilizing splints for diseased joints. When dried again it retains the form of the part of the body to which it was applied, and the different parts can be connected with steel bars by means of copper nails. The way to proceed is, to cut out a pattern of simple parchment paper and then cut out the same in the fiber sheet. Then this fiber pattern should be soaked in water, placed around the extremity and held there with tightly fitting rollers until dried. It is then taken off and connected with steel bars. I consider fiber the most universal material yet devised, and recommend it for extensive use by the general practitioner, as well as for railroad and army purposes, as it takes up but little room and is inexpensive. It can be kept clean. Stains may be removed with water and soap. When applied directly to the skin it does not irritate, as its surface is absolutely smooth. Greasy matter may be easily washed off with alcohol or ether. I now use it extensively in ambulatory apparatuses for joint diseases in clinical work, in correcting malpositions of joints, combined with rubber bands and permanent extension. The fiber capsules are adapted during the hour of the clinic and brought to the instrument maker.

The surgeon does not have to depend on a special instrument maker, as any skilled locksmith is able to connect the fiber casts with longitudinal steel bars according to given measurements. For this reason, the introduction of fiber in surgery is likely to result in a more general use of the extension splint.

911 Venetian Building.

A LARGE FIBROUS NASAL POLYPUS.

BY F. A. LONG, M.D.

MADISON, NEB.

Fibrous polypus of the nose is much more formidable than the soft or mucous variety, but is fortunately

rarely met with. The tumors may attain enormous size and give rise to frightful deformity. It may occur at any period of life, arising from the periosteum or the bone proper, usually from the posterior nasal or the cavities accessory thereto, but with a special predilection for the roof of the posterior nares. Its growth is far more rapid than that of the mucous variety; the filling of the nasal and post-nasal spaces does not stop its growth, and the continued and ever-increasing pressure forces the bones of the nose apart (as is apparent to any observer by the appearance of frog-face), causes absorption and caries of the bony walls and ulceration of soft tissues, giving rise to an acrid discharge and also to frequent hemorrhages. Repeated severe hemorrhages may sap the patient's vitality. The constant direct absorption and swallowing of purulent discharges may gradually end life by septicemia. Sarcomatous degeneration is liable to take place, ending in a horrible death.

The appearance of the fibrous variety is so different from the soft that a mistaken diagnosis is impossible. It lacks translucency, has the color of surrounding tissues, perhaps a little deeper red, is firm and resistant to the touch.

EXPLANATION OF CUT.

a, Anterior surface presenting at left nostril; t, portion showing convolutions of inferior and middle turbinates; s, sulcus dividing polypus into nasal and naso-pharyngeal lobes; n p, naso-pharyngeal lobe; p, pedicle; length along left side of mass from a to n p, $2\frac{3}{4}$ inches, height at t $1\frac{1}{4}$ inches. The cut is nearly natural size.

With these preliminary remarks I wish to record the following:

A young German-American farmer presented himself complaining of total nasal obstruction. He had the general appearance of good health, but "frog-face" was at once apparent. Complained of some headache, of lack of ambition and of eyes watering constantly, mostly on left side. He frequently felt nausea, worse when reclining. The trouble came on insidiously and he thinks it may have been a year in its development. On inspection a solid mass completely occluding the anterior nares, presented itself at the left nostril. The septum was deflected decidedly to the right side; the soft palate was bulging downward. Digital exploration of the naso-pharynx revealed the entire space anteriorly occupied by a solid mass, its attachment uncertain.

The mass was removed with a polypus forceps through the anterior nares, the deflection of the nasal bony walls caused by the pressure of the mass

and the very slender pedicle (see cut), having made removal by this method and through this way comparatively easy. Macroscopically it is a soft, fleshy mass $2\frac{3}{4}$ inches long by $1\frac{1}{4}$ high in the middle portion (t) showing here beautifully the impression of the turbinated bodies on the tumor; width across the base, which corresponds to the floor of the nasal fossa, $\frac{5}{8}$ inch. Just back of the attachment of the pedicle is a deep sulcus (s) caused by its impingement on the nasal septum posteriorly, and which divides the polypus into two lobes, the nasal and naso-pharyngeal. The naso-pharyngeal lobe (n p) is $1\frac{1}{2}$ inch wide and $\frac{7}{8}$ inch high turned toward the right side, and by its shape, size and position occluded the right nasal fossa behind. The pedicle is very slender, $\frac{3}{8}$ inch long, very much constricted at the polypous end, showing conclusively that the polypus originated in one of the accessory sinuses, probably the sphenoidal. From the sulcus forward the growth is an almost perfect cast of the left nasal cavity.

This case is believed to be sufficiently unique to deserve a place in the literature of nasal polypi.

THE PHYSIOLOGIC ACTION OF THE THYROID GLAND.

BY HUBERT RICHARDSON, M.D.

BALTIMORE, MD.

The very different results obtained by the administration of the thyroid gland, or its extracts, and the reports of its success in so many forms of disease, require some further explanation, and I here give the results of a few observations made during the past six months on its possible physiologic action among the insane.

In the paper read by Dr. C. G. Hill on the subject of thyroid feeding, an analysis of the urine made by Dr. Whitney is given, which shows that though the excretion of chlorids, phosphates, sulphates and to a lesser extent urea are slightly increased, the total solids are decreased, pointing to the non-elimination or non-formation of the more toxic products of metabolism, with the possible exception of the ethereal sulphates. Dr. Haig showed by experimentation on himself that thyroid feeding produced a retention or possibly a reduced production of uric acid. Dr. Perry, in his paper on the blood in thyroid feeding, has pointed out that the blood coagulates more quickly, that very slight leucocytosis, or none at all, takes place, but that there is an increase in the number of lymphocytes. A general desquamation seems to take place in the mucous membranes, as well as in the skin, pointing to an increased activity of cell production. Horbaczewski has shown that uric acid is formed from the destruction of polynuclear cells and that those drugs which produce a leucocytosis also cause increased elimination of uric acid, with a few exceptions, as antipyrin, which he suggests produce the leucocytes by the arrest of destruction consequently diminishing the excretion of uric acid.

In my own analyses I have found that the first result of thyroid feeding was to reduce the elimination of uric acid, though after a week or ten days it became normal, or slightly excessive, as the patient improved, presumably by increasing the production of the lymphocytes and also those of the mucous membranes and decreasing at first the destruction of the polynuclear cells. I have observed that when the

thyroid is given to patients whose urine showed excess of toxins, viz., uric acid, ethereal sulphates and pigment, it either produced little or no effect, or caused fever and debility without improvement. The best results have been obtained with patients who had been for some time in the institution and whose elimination had been attended to. I would infer from the above that the physiologic action of thyroid is, 1, increased production of lymphocytes and increased cell production generally, especially in the mucous membranes; 2, an arrest of the destruction of the polynuclear cells.

The above hypothesis would help to account for its success in some reported cases of albuminaria.

THE PALLIATIVE TREATMENT OF CANCER OF THE CERVIX UTERI AND BLADDER IN WOMEN.

Read at the Thirteenth Annual Meeting of the New York State Medical Association, Oct. 14, 1896.

BY NATHAN G. BOZEMAN, M.D.

GYNECOLOGIST TO ST. FRANCIS HOSPITAL, J. C., ST. MARY'S HOSPITAL, HOBOKEN, AND BAYONNE CITY HOSPITAL, NEW YORK.

I shall confine my remarks to the treatment of carcinoma of the cervix uteri and the bladder in the stage of the disease when any operative measure may be of doubtful expedience, or in cases where operations have been undertaken and the disease still progresses, the condition of the patients being most distressing from hemorrhage, sepsis, incontinence of urine and all the evils resulting therefrom. My interest has been aroused in this class of patients, and no doubt you feel the same, because of their hopeless condition and the difficulty of caring for them in our public hospitals. Certainly, treatment will be directed to alleviating their suffering and rendering their surroundings as wholesome as possible.

Women afflicted with inoperable epithelioma of the cervix uteri, when they are not undergoing any treatment, complain most frequently of hemorrhage and a foul-smelling, bloody discharge from the vagina. The vaginal examination reveals a hard unyielding band of sclerous tissue in front of the cervix extending nearly around the vagina and constricting it; beyond this is the diseased cervix, which is either destroyed, leaving a deep cavity with necrotic walls, or there may be a cauliflower growth on the cervix. Usually digital examination causes excessive hemorrhage, which is controlled by placing the patient in the supported knee-elbow position, exposing the cervix by introducing a perineal elevator guided by the finger and gently brushing over the bleeding surface with a solution of persulphate of iron, or if necessary, touching it with the Paquelin cautery, then packing or columning the vagina with dry cotton. Great caution must always be observed not to injure the ulcerated surface with the end of the speculum. This accident I have found causes more bleeding than the digital examination. To guard against this I also use the knee-elbow position.

In some cases the first indication is to overcome the partial stricture of the vagina which I have referred to, in order to gain free access to the disease and to allow the uninterrupted escape of the discharges. This is accomplished by means of hard rubber intravaginal dilators of suitable sizes to admit of easy introduction. They are worn for several hours a day and are removed for douching. This gradual

dilatation is continued until the contraction has yielded. The treatment sometimes is painful and has to be alternated with columning the vagina. The column of antiseptic gauze and dry cotton I employ in all cases after first dusting on aristol or some other antiseptic powder, for a twofold reason: pressure and absorption of the secretions. When it is properly introduced it may be worn forty-eight hours, then removed for thorough vaginal douching during the next twenty-four hours. It produces pressure on the diseased surface and against the constricting band in the vaginal wall. The secretions are retained in it for a considerable time and it prevents bleeding; consequently the surface of the ulcer is maintained in a fairly clean state. I treat my patients about three times a week and I find that they are kept quite free of pain and are not annoyed by the discharges. The disease has a natural tendency to extend, but in none of my cases has a perforation occurred into the rectum.

Bozeman's Air and Water Irrigator.

I have had several where the bladder became involved and here is when I believe most of the pain from the disease begins. The first manifestation of the extension to the bladder is a severe form of cystitis with excessive vesical tenesmus and frequent urination, but when the perforation of the vesico-vaginal septum takes place and the urine finds a free outlet, all these painful symptoms subside; a vesico-vaginal fistula is then established and the bladder has physiologic rest.

Some of us are familiar with the pitiable and loathesome condition of urinary fistula cases in former times, when the sloughing of the vaginal and bladder walls was due to prolonged pressure of the head in the parturient state, and we all know of the successes of my father in his untiring efforts to close these openings and restore such patients to health, so that now by following his teachings we are enabled to close all forms of vesico-vaginal fistulae. Those caused by carcinomatous ulceration, however, should

never be closed. We must content ourselves with other means of treatment.

In three cases which I have had under observation I have used continuous irrigation of the vagina and bladder, alternating with Dr. Nathan Bozeman's vesical drainage support, which is worn in the vagina and collects the urine and conducts it into a soft rubber receptacle which is attached at the knee.

Now as to the continuous irrigation. When this process is kept up for any length of time we must of course economize the fluid which we use, so I have had constructed an irrigator¹ which does this by mixing air with the solution and the two, while coursing through a perforated tube in the vagina when the patient is in a recumbent or sitting posture, produces a current which carries off with it all secretions and particles of debris. The reservoir, a glass bottle, stands upon a table near the bed and is connected with the perforated tube in the vagina. The bottle has a constant outflow, that is, as the fluid escapes from it by the opening at the bottom, air passes down the long glass tube and takes its place. The pressure is thus maintained constant and it is represented by the weight of the column of fluid extending from the lower end of the perpendicular glass tube to the circular opening at the bottom of the vessel. The stop-cock does not regulate the velocity of the efflux but shuts off or turns on the flow. A certain proportion of the fluid, as it escapes from the bottle, collects in a small reservoir, where it is also maintained at a constant level. In the bottom of it is a round opening, the area of which is such that with a column of liquid two inches high one-half an ounce escapes per minute. This is made to produce suction. The excess collects in an intermittent syphon and is discharged by it. The suction pump and the intermittent syphon being connected with the perforated tube in the vagina alternating columns of air and fluid pass quickly through it, carrying off with them the urine as it is secreted. Three hours is about the longest time that a bottle holding one gallon will irrigate and drain. I have now under observation a patient who has been using the irrigator with very great comfort to herself for nearly a year. In her case I am also making applications once a week of hydrogen peroxid. The upper portion of the vagina, the cervix and the bladder are destroyed, but still she can be drained and is comparatively easy. In summing up I would recommend:

1. Keep the seat of the disease in an aseptic condition.
2. Prevent or counteract any narrowing of the vagina in front of the disease.
3. When the bladder becomes involved use effective irrigation and drainage to carry off the urine as soon as it is secreted.

THE THERAPY OF CALCIUM SULPHID IN INFLAMMATORY DISEASES OF THE AIR PASSAGES.

W. BAYARD SHIELDS, M.D.

ST. FRANCIS, ARK.

My attention was first attracted to the therapeutical uses of calcium sulphid in inflammatory diseases of the air passages by an article which appeared in the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*,

¹"An Air and Water Irrigator and Drain for Prolonged Douching in Deep Cavities." *New York Medical Journal* for May 27, 1893.

April, 1892, written by Edward F. Wells of Chicago. Dr. Wells has been using this drug in tuberculosis for a number of years and claimed to have had good results in selected cases. He had antedated Burgeon's treatment of rectal injections of sulphuretted hydrogen gas by several years. It seems that his attention had first been called to this treatment by noticing that his tubercular patients who frequented sulphur springs improved more rapidly and uniformly than those going elsewhere. There seems to be no doubt in my mind that to a certain extent that this drug has a beneficial but not curative effect in tuberculosis, as my experience leads me to know that I have seen cases in which it ameliorated the symptoms, resulting in a number of cases in an improvement in general condition and a gradual reduction of fever conducing to the general comfort and well being of the patient. In several there seemed to be a cure, but I am satisfied after a more extensive use of the drug that I was mistaken in my diagnosis, especially as there was no microscopic examination of the sputa made, although they had other signs of tubercular disease. These apparent cures were probably cases of purulent bronchitis, a disease not uncommon in very miasmatic districts and frequently accompanying remittent and intermittent malarial fever. In these fevers with the lung complication I invariably give a calcium sulphid and quinin combined with excellent results. In abscess of the lungs it seems to have a beneficial effect, liquifying the contents of abscess more rapidly and hastening its discharge.

Within the past two years I have treated not less than fifty cases of pneumonia with an extremely small per cent. of deaths, giving quinin four grains, calcium sulphid one grain every two hours for four doses and then every three hours in connection with 1-75th of a grain of nitroglycerin, the latter in place of alcohol. Pneumonia is a disease of a serious nature in the section in which I am located on account of the complications of anemia following malarial disorders, and my death rate was much larger under the old treatment including the free use of alcohol than it has been under my present mode of treating this disease. The calcium salts seem to inhibit the pneumonic inflammation to a great extent, in which way I do not know, but imagine on account of it being an anti-uric acid remedy of no feeble power, and that the uric acid diathesis is a predisposing cause which favors the activity of the pneumococcus in the production of this disease. Nitroglycerin, a remedy which has been advocated a number of years in pneumonia, has in my hands filled my utmost expectations in relieving the lungs by dilating the arterioles of the system and hence relieving the venous congestion. It also more than takes the place of alcohol as a stimulant as it has no bad effect on the digestion, and flushes the kidneys, thus assisting to relieve the body of effete material.

It is more especially in the inflammatory diseases of the throat, tonsillitis and quinsy, that I have most remarkable and gratifying results by the use of calcium sulphid. I had not seen the use of this drug advocated in these affections, but going upon the well-known fact that its use modified the furuncular inflammation, frequently preventing the formation of abscess, I was lead to the conclusion that it might in the same way inhibit the tonsillar inflammation. I commenced with small doses, one-fourth of a grain every three hours, but not getting good results, increased to one grain doses every hour until four doses were

taken, then every two hours for six doses, then every three hours apart until all inflammatory symptoms would disappear. These are seemingly large doses but I have observed no bad effects of weakness in any case. In the past four years I have treated not less than one hundred and fifty cases of quinsy and tonsillitis according to this plan and have recollections of only four cases in which it failed to relieve promptly and effect a perfect cure in from two to six days. The relief is so sure and prompt in my hands that I am inclined to think that perhaps local conditions in this miasmatic climate favor the production of those cases of tonsillitis which are more amenable to this treatment than it would be in other sections.

Many of these cases had been treated by other drugs such as guaiacum, the salicylates, quinin, opium and salol during former attacks, but I found that the calcium sulphid relieved and effected a cure more rapidly than the other treatment. Recently I have seen it advocated in tonsillitis but think the reason why more uniform success has not been obtained in its use is in not giving it in large enough doses. If the heart acts feebly in any case, or there are organic lesions I use heart stimulants such as small doses of digitalis and nitroglycerin combined, for fear that the calcium sulphid should have a depressing effect in these cases. In no case have I used local applications of gargles, simply confining myself to the use of the single drug and in a few cases giving an opiate. I also would keep the bowels open with salines and allow a restricted diet. I do not see the necessity of using the new drugs advocated in this disease when we have an old one which relieves more certainly and promptly than any other.

CATCHING COLD—ITS CAUSE AND PREVENTION.

Read by invitation before the St. Louis Academy of Medical and Surgical Sciences, Nov. 28, 1896.

BY FAYETTE C. EWING, M.D.

Late Senior Clinical Assistant Central (London) Throat, Nose and Ear Hospital, and at the London Throat Hospital; Fellow of the British Rhinological, Laryngological and Otological Association; Laryngologist to Missouri Baptist Sanitarium; Aurist, M. E. Home, etc. Member of the St. Louis Medical Society and of the American Medical Association.

I think I may assert without fear of contradiction, that there is no commoner morbid condition to which the human family is subject, than that designated "a cold." People speak of having "caught cold," by which they do not mean that they considered the condition so desirable that they troubled themselves to lay hold on it, but rather, the opposite, whereby the pathologic process inaugurated itself in their systems in spite of their desire and attempt to escape it. Again, almost invariably, the adjective "bad" is prefixed to "cold," so that by common consent we have only "bad colds." All this serves to emphasize a point I wish to make, viz., the absolute fear in which that congestion of various organs resultant from meteorologic conditions is held by the laity. This is not surprising, when we consider that fully three-fourths of the diseases of the respiratory passages, constituting such an important class, originate in colds; and added to these are many, of other organs, that are indirectly due to the same cause. When we realize the importance of the subject, it seems strange that there should be no unity of opinion among physicians as to the precise manner in which it is acquired. Numerous

theories have been advanced, yet none seem sufficiently substantiated to be accepted by the profession at large. Of those that have been held worthy of note, I may call attention to the following: Rosenthal declared that a lowered temperature, acting upon the peripheral vessels excites contraction shutting off the blood current and causing congestion and inflammation of internal organs. This assertion is not above reproach, for, very often parts that are not internal are affected: The Schneiderian membrane lining the nasal tract, is more frequently attacked by inflammation than any other portion of the anatomy, and it is not internal, since it is always exposed to the atmosphere.

Seitz affirms that the morbid state we are discussing, is occasioned by the removal of heat from some part of the body resulting in a functional derangement of the heat centers, with attendant pathologic changes in some organ possibly distantly removed from the part exposed. The fact that some time elapses between the exposure and the condition may be accepted as favorable to this theory.

Woakes believes in a vaso-motor disturbance using the term "modification of nutrition," arguing for a uniformity of type. He declares that there is a normal animal mechanism represented by the sympathetic chain of ganglia through its afferent and efferent branches.

Bosworth more forcible and comprehensive than the others, accepts Seitz's theory in part, but attributes the effect to those nutritive changes that are ever progressing, and whose proper functioning is dependent upon the temperature being maintained at 98.6. He affirms that, "In the ordinary phenomena of taking cold, we have still the results of a low temperature acting on the heat-producing processes, but in an indirect manner. The direct action of the cold is, as a rule, upon the surface of the body, but the resultant morbid condition is upon some organ remote from the exposed part. In both cases, however, the cause and the effect are the same, and the connection between the exposure and the resultant inflammatory condition is the disturbance of those nutritive changes in the tissue which result in the production of animal heat." The nutritive processes in every part of the body are controlled by a central nervous system from which there is a general distribution of force. The "nutritive changes" having been arrested, or interfered with, in a certain portion of the body, the central system contributing the same amount of force, naturally there results increased nutritive activity elsewhere, constituting inflammation. The fact that the nasal membrane, in this climate, is generally affected with more or less chronic inflammation, makes it the point of least resistance and accounts for it being most commonly attacked. Bosworth illustrates this by citing the example of a chandelier whose jets represent the nutritive processes and the supplying stem the central nervous system. Should all the jets be lighted at one time, the result is even light, but when we turn off all except one, this one flares up unevenly with extra force.

PREVENTION OF COLD—NATURE'S PART.

That catarrhal diathesis which predisposes to colds, may be hereditary, or acquired. Its avoidance or prevention when once established, can be accomplished only by a gradual hardening of the system, which must be educated to the making of an amount of heat

to compensate for that which is lost under circumstances of extra radiation. The conditions of life on this sphere, render exposure inevitable—we can not dodge it. Rich and poor, high and low, one time or another, will feel the breath of this *bête noire* of our existence, who gives no quarter, and shows no mercy. Only by fashioning ourselves to withstand its assaults, can we hope to win in the “rough and tumble” battle, with this “catch as catch can” wrestler. Nature, our universal mother, seeming cruel, is often kind. She is the great equalizer, ever ready to give here, for what she takes there. She will deal fairly with us if we trust her, but we must not ignore her rules. Today, with irrevocable hand, she presses into place one chord of that divine instrument we call the larynx, and tomorrow, with compensating kindness, she sweeps the other across the median line, that it may vibrate in touch with its fellow, and, where there was silence, there is song. Should indifferent chance stop an ear, she makes its mate responsive to higher keys, and lower tones, that the harmonies of life’s little time may be not lost. She shapes the body to the shortened limb, that grace may move without a halt. Pomona-like, with hands full-fruited, she would give what is asked, but is zealous of our faith and thrusts nothing upon us. She would forestall the finger of time, and with its line of wrinkle trace a smile; she it is, who lifts the weary heart that tears may be delayed. Nature is constantly striving to adapt herself to our necessities, but she may need time in which to weave for us a garment not made with hands. When heat is demanded, she endeavors to make it, but when her services have been spurned on so many occasions as to constitute a lengthened period, she can not be expected to supply in emergency. On this principle, she deserts the man who wraps his throat to scare away the roaring elements with a red rag. She is jealous of the rag, and the latter’s services having been invoked in preference to her, she declines to interfere when it happens to be left at home. The hardening process should begin with infancy. Should the timid and captious knit their brows at this wholesome doctrine, I would add that we do not consider feather-headed mothers, nor that lighter genus, hysteric fathers, who are ever ready to trace a cold in their children to some supposed indiscretion of their more sensible wives. Intelligent discrimination is always required in the interpretation of hygienic rules. Idiosyncrasies are inevitable, and since no two constitutions are exactly alike, only directions that are generally applicable can be laid down. Each parent must discern any condition that would render the rule applicable to her child, or only in a modified form. A person may become strong, or delicate, through habit. Habit is a knife that cuts both ways—he who wields it, may turn it for, or against, himself. Nature gave us hair as a protection to the scalp, and but for habit, one would contract cold not more readily from lack of covering on the head, than from exposure of the face. Children, from infancy, should be accustomed to bare heads. That foolish woman, so solicitous lest the cold penetrates her baby’s skull, might still her fears, if she would pause long enough to recall her girlhood days, when habit enabled her to dance all night in a draughty ballroom, with, mayhaps, nothing more substantial to shield her neck and chest from the flirting zephyrs, than a coat of paint. The *fin de siècle* mother lolling in her cushioned carriage, with hands encased in fur, and rubber bottles at her feet, need but drive through

“Hell’s half-acre” of the modern city, to note the contrast in health between the ragged urchins with snow numbed feet, and her puny pale-faced boy she left at home because it was “too cold to take him out.” Truly, nature “tempers the wind to the shorn lamb.” The free air grows the rose, and the sunlight gives it tinting, whether on rocky soil, or velvet cheek. Coddling and care can not save us from the demon we dread. A large proportion of the human family earn their livelihood in the open air, with the attendant exposure. In such climate as that of Western Oregon and Washington, where rain is steadily falling for half the year, people go about their business oblivious to it, so far as a consideration of the effect upon health is concerned. Daily contact soon inures them to it, and the diseases resultant from exposure are not materially multiplied. What necessity does for the poor, compelled to toil in rain or shine, and for the inhabitants of the Puget Sound district, we, who are more favored in environment, may do for ourselves by applying the universal law, which teaches that the more we house ourselves, the less vigorous become our constitutions in direct ratio as we pamper an organ, its susceptibility increases.

Admitting the stability of our argument, we may pass to an enumeration of some of the special factors in the production of colds. The evils arising from over-wrapping have been lightly touched upon, but in discussing the very important matter of

CLOTHING

it would be well to be specific. If we admit that the theory of catching cold is based upon an interference with nutrition in some portion of the body, we can not deny the necessity for warm and comfortable covering that will insure equable protection for the heat forces in every organ. Opposed to this, are the commonly used chest protectors that every druggist exhibits in his window as a preventive of lung and bronchial disease. Acting in a similar manner to the flannel throat-band, or woolen muffler, they contribute to the delicacy of the parts they cover, and bring about the troubles they are supposed to prevent. Fur caps and boas are equally an abomination, and according to Bosworth, the deaths in New York City, resulting from the use of seal skin sacques, exceed those from smallpox. A lady proud of her five-hundred dollar furs, calls upon a friend and sits in a furnace-heated house in a temperature of 80 degrees F. for several hours, because she would not think of removing so enviable and becoming a garment. She becomes overheated, goes home in a zero atmosphere, is suddenly chilled and finds herself in bed the next day. This is not an exaggerated illustration of the evil effects of concentration of clothing. We are constantly being called upon to treat lesser ills, yet the thoughtless victims would scorn to acknowledge the cause. No clothing compares to wool as a preventive of heat radiation, because none is so light, porous, and elastic. It is also absorbent, but does not absorb into the fiber. Cotton, linen and silk, are heavier, less elastic, much less porous and far better conductors of heat. The perspiratory glands assist us in the elimination of effete matter, and in using wool next the skin we have a material that takes up the perspiration and prevents a constant soaking in our excreta. One should wear wool the year round, and now that so many weights are manufactured and of such soft texture, the garment may be adapted to the season. The better plan

would be to confine oneself to the medium weight and have outer clothing suitable to the season. A person should wear just enough clothing to keep him from discomfort, no more, no less. Having observed in my practice, the undesirable results from over-dressing, and being convinced of the invariableness of the law I am trying to impress upon my readers, I am tempted to say that given an intelligent subject, if the exposure is to be for a short time only, when the thickness becomes a question for decision, dress in the light rather than the heavy garment, and trust the heat centers to supply the possible deficiency. Physicians, whose vocation calls them out at all hours, realize how frequently they miss their estimate of the weather, and find themselves too thinly clad, yet they may experience no ill effects, because of the movement which increases the supply of animal heat. A man may subject himself to such condition as to cause a tremendously increased radiation of heat from his body, as for instance when in swimming, and catch no cold, for the same reason. The motion stimulates the heat-making machinery, and compensation is maintained, yet if a bath be too prolonged, the processes tire, are unequal to the strain, and the bather becomes chilled or cramped. As a rule, Americans load themselves with heavy clothing and have their feet—whose large amount of surface exposure makes them excessive radiators of heat—covered with thin stockings and paper-soled shoes. If we would only learn from observation of our more robust English cousins, one source of catarrh would be removed. Rubbers are useful enough in heavy rains, but we should not make ourselves dependent upon them because of wet streets, but guard against such dangers by wearing thick soled shoes and woolen stockings. The feet are so much in contact with cold pavements and dampness that they are least adapted to scant covering.

THE AIR WE BREATHE

contains anywhere from 60 to 80 per cent. relative humidity and along the seaboard it may range as high as 90 per cent. This moisture is necessary to the preservation, in a healthy condition, of the mucous membrane lining the air passages. In mountainous climates where the relative humidity is very low, the muciparous glands of the Schneiderian membrane become exhausted in their extra endeavor to supply the deficient moisture necessary to the dry air passing into the lungs. Watery vapor prevents dessication, and if the air we breathe did not contain moisture, both animal and vegetable life would be impossible. Fishes die when removed from the water, though the air contains much more oxygen than the water, and all organisms would perish if deprived of atmospheric moisture. Dew and rain have been called the scavengers of the atmosphere. According to present scientific knowledge, certain atmospheric particles are considered accidental, and of these dust occupies an important place. Of the various kinds of dust, some are very deleterious to animal life, though most of them are harmless. Yet, if we eliminated the aqueous vapor, suffocation would result. Therefore we have a ready explanation of the unhealthful effects of

FURNACE HEAT,

which dries the air we breathe, giving the muciparous glands additional work, tending finally to their exhaustion, weakening the system in part and whole,

and making a constitution incapable of enduring sudden and prolonged exposure. Children should be kept out in wind and sent out in weather. Every hour passed in the open air tends that much toward developing a constitution that will last to three score and ten. This, of course, applies to children with normal or open respiratory passages. No child with obstructed nose can escape the cold-catching habit. The function of the nasal passages, which are sufficiently supplied with blood vessels to elevate its temperature several degrees, is to cleanse and warm the air destined for the lungs, as well as arrest the multitudinous microbes with which it is laden. Whether on ice or snow, the shifting sunbeam is never cold; no parent need fear the specter that would seize the racing, rollicking, well-wrapped sprite that glows with its own heat. This brings us to the consideration of

THE DAILY BATH.

The Americans are not a bathing people; certainly not in the same sense as the Englishman, who has been known to take his tub traveling with him, that he might not forego what is a delight to him as well as a necessity. We build our palaces and construct marble pools that a Roman might envy, and hang our bath rooms with paintings as suggestive as the Venus Anadyomene, worthy Apelles' fabled touch, yet we forbear to take the plunge. When we do perform our ablutions it is for cleanliness alone. Remembering that cutaneous transpiration has much to do with the proper regulation of animal heat, and is largely dependent upon the functional health of the skin, we should be sufficiently impressed with the necessity of the bath as a matter of hygiene. Indeed, bathing for cleanliness is of secondary importance. Nothing conduces more toward strengthening the system and making it proof against colds, or breaking off the habit when once established, than the daily bath, which is best taken on arising. The water should be cold, direct from the hydrant, and in winter the temperature of the room at least 60 degrees F. The sponge, shower or plunge (selected according to the constitution of the bather) should be accomplished within a minute. It is well to begin with the sponge, which can be taken by all except the most delicate. The sponging can be taken as readily by wringing a towel sufficiently to prevent dripping, and sawing it rapidly over the body. A quick drying follows, and this, succeeded by a vigorous rubbing with a coarse linen crash, until the body is in a warm glow. The test is the after-feeling of well-being and warmth. Should these directions be carefully complied with and this reaction absent, there are some special reason why the bath is contraindicated. The wrapping of a towel, wet with cold water, around the neck preliminary to the general dip, tends to stimulate the throat's resistance to sudden draught and cold.

FOOD

exerts an undoubted influence in producing that vigor and strength of constitution that is required to withstand varying atmospheric conditions. In supplying the table the season should always be considered. We know that fatty and albuminous foods contribute more heat than vegetables and fruits; and for this reason such a diet is indicated for cold weather and should be curtailed with advancing summer. The Esquimau, influenced partly by the law of environment and partly by that instinct which guides an animal in selecting what

is best for its needs, subsists entirely upon fats and oils. The South Sea Islander, with as little design, turns to succulent vegetables and fruits. The exigencies of life, thus supplied by nature in opposite zones are combined in our varying climate, and we should be guided into an intelligent application of what is best suited to our requirement. The system is capable of oxydizing just so much food, and when we overcharge it with heavy eating in spring, giving it more fuel than is necessary to keep the furnace heated to 98.6 degrees, the body's temperature, we find it overtaxed and the blood charged with effete matter, constituting spring fever. Thus we may appreciate the wisdom of the Catholic church in establishing its period of abstinence in the early spring.

PUERPERAL ECLAMPSIA, WITH REPORT OF A CASE AND TREATMENT.

BY NORMAN W. BELLROSE, M.D.

EATON, COLO.

I doubt very much if there is a disease of pregnancy in regard to which there is a greater diversity of opinion as to its etiology and pathology than puerperal eclampsia. Do we know its cause? Yes, I think we do.

Braun tells us that the kidneys are responsible, and is an advocate of the nephritic origin. Playfair, on the other hand, does not consider the albuminuric theory as clearly proven. Lever, in 1843, pointed out the connection between albuminuria and eclampsia, and that the two conditions occupied the relative position of cause and effect.

Further investigations, however, lead one to believe that the kidneys are not wholly responsible. In twenty-eight cases of eclampsia reported by Schauta, three were found to have normal kidneys. Ahlfeld found in seventeen cases two in which the kidneys were normal.

Vinay, after making thorough microscopic examination, states that in a large number of cases the disease can hardly be attributed to renal lesion. Rivere, Auvard and others declare eclampsia to be a form of auto-intoxication. I believe that the theory of toxemia, not one but several different poisons, is generally upheld. I am a firm believer in the toxemia theory of Rivere and Auvard; but, nevertheless, I can not but believe that the kidneys play an important part in the toxemia of eclampsia.

Bouchard has said that man is constantly menaced by poisoning. He labors each instant for his own destruction, making incessant attempts at suicide; nevertheless this intoxication is not realized, for the organism has multiple resources to escape it.

It is not necessary for me to tell you that in pregnancy the composition of the blood is profoundly altered, and that the quantity is somewhat increased. Why is this? Because the quantity of blood before pregnancy is inadequate to meet the condition of pregnancy. We know the pregnant woman has to provide nutriment to breathe, to maintain blood circulation, to secrete and excrete for two individuals, herself and her fetus. All this means that extensive changes in the general system must occur. In order to carry on this extra work properly, certain viscera of the circulatory apparatus become somewhat modified in size and in function. I might mention the heart, the hypertrophy of which is a wise provision of nature to meet the increasing demands of the blood

supply in the advancing months of pregnancy. Other organs are likewise increased in size, namely, the liver, spleen and kidneys. The lungs and skin also become more active. Why is this change? My answer is, nature has an increased amount of work to do, and such being the case, she endeavors to increase the working capacity of her organs accordingly. It is my belief that in eclamptic cases the kidneys (possibly the liver, lungs and skin) fail to accommodate themselves to the extra work that the pregnant state requires of them. You are aware that the kidneys excrete largely from the solid constituents of the blood, and that many of the inorganic salts of the urine are elaborated in the kidneys. Toxic substances in the blood, whether generated within the body or derived from without, are in a great measure eliminated by the urinary organs. In pregnancy the need of this elimination is necessarily greatly increased or should be. If the kidneys fail to do this extra amount of work, accumulation is produced and intoxication results. At first this is hardly noticeable; but as pregnancy advances and the amount of toxic matter to be eliminated is increased in the blood, the greater is the effect of the poisons on the great nerve centers, and as a result, other symptoms develop that are characteristic of eclampsia.

Some writers state that eclampsia is the result of albuminuria, which is caused by intra-abdominal pressure, thereby interfering with the renal circulation. If this be true, why is it that a non-pregnant woman can have her abdomen as greatly distended by an ovarian tumor as from plural pregnancy at term, and yet not suffer from either? Statistics tell us that one in three hundred women who bear children suffer from eclampsia, and that about twenty-five per cent. of them die. I can say that I have had two cases out of a record of two hundred and fifty pregnancies. I take pleasure in making report of one of them. I can say, however, that both of my cases made a good recovery.

Mrs. A., primipara, 23 years of age, pregnant about 265 days. She enjoyed fairly good health up to within about fifteen days of full term, having had only light attacks of headache from time to time, with some stomach symptoms. On April 16, 1893, she first noticed that her feet were somewhat swollen. On April 18, about 3 P.M., she was taken with a severe headache, which grew gradually worse until about 8 P.M. At this time it was almost impossible to endure. Not suspecting anything serious, both she and her husband thought it would "wear off" after getting some sleep. She failed in doing so, and at 10 P.M. the pain in the head was no better. I was called about 11 P.M.; arrived fifteen minutes later. I found my patient in a very restless condition; the pulse was tense and about ninety-five to one hundred beats per minute; some nausea and vomiting. The quantity of urine voided during the preceding twenty-four hours was thought to have been about two and one-half pints. About one-half hour after my arrival she had a severe convulsion (epileptic in character), which lasted about five minutes. It was followed by more or less stupor. She would answer all questions rationally but slowly. I at once gave a five grain powder of phenacetin combined with one-eighth grain of morphia sulphate, which relieved the head and nervous symptoms for a short time. Her family physician, Dr. J. Hawes, of Greeley, Colorado, was then sent for; he being out of town, Dr. Wallace was

called. He arrived about 2:30 A.M. on the 19th. There was no question about diagnosis. Fluid extract of *veratrum viride* was given hypodermically, every two hours, beginning with two-drop doses, and was gradually increased one drop at a time until ten drops were given. Dr. Wallace remained until 3:30 A.M., and at Mr. A's request I took charge of the case. At 4 A.M. she had a second convulsion which was of longer duration and more severe in character. The face became more congested. She then went into a profound coma, and did not recover consciousness until about 10 P.M. After the second attack I immediately began giving hydrate of chloral and potassium bromid, of each thirty grains, in four ounces of warm water, per rectum, and repeated every three hours. The convulsions continued in spite of treatment, and by 11:45 A.M. April 19 she had had seventeen. Eight o'clock next morning I decided that the best thing to do was to empty the uterus, and the sooner the better for the safety of the mother and the child. Dr. Wallace was again sent for; he not having arrived at 10 o'clock, I proceeded to prepare the patient and myself for the operation, which was conducted under strictly antiseptic conditions. Squibb's chloroform was administered, more for the purpose of controlling the convulsions than pain, as the patient seemed to be insensible to pain. A soft rubber catheter was then passed into the bladder and about a pint of dark colored urine was obtained which contained about one-fourth in volume of albumin. Dr. Wallace had not arrived at 10:30, so I decided to operate at once with what assistance the nurse could render. The manipulations necessary in dilating the os excited uterine contraction and by the time I had sufficiently dilated it to admit the hand, the child's head had descended and version was impossible. Forceps were applied, and at 11:45 I succeeded in delivering a nine-pound boy. Life was extinct, however. I labored with it for some time, but without success. The placenta was removed by Credé's method with very little difficulty. Post-partum hemorrhage was very slight.

The *veratrum viride* was then continued in nine-drop doses hypodermically every two hours, as was also the hydrate of chloral and potassium bromid every three hours. Rectal enemas of peptonized milk were given every four hours. I also used dry cupping and sinapisms over the kidneys. As soon as the patient could swallow, a thirty-grain powder of compound jalap powder was given in a little water to open up the bowels, and a saline laxative given daily to keep up a free action. After consciousness was restored the hydrate of chloral and potassium bromid were discontinued, and potassium acetate with infusion of digitalis was given instead to keep up a free action of the kidneys. The usual diet and tonics were then given. Up to 6:30 P.M. April 19, she had had twenty-seven convulsions, making seventeen before the operation and ten thereafter. The albumin disappeared from the urine in about ten days. Diplopia was complained of from the fourth to the seventh day. My patient sat up in bed on the tenth day, and on the fourteenth day was dressed. She made a good recovery.

Wilson, Hammond and others, tell us that the eclampsia of pregnancy is caused by the presence of an excess of urea in the blood. How can this be, when Bouchard tells us that to kill a man, it would require the quantity of urea which he makes in sixteen days? Clinical observation is therefore here

in accordance with experimentation in denying to urea the power of producing the intoxication called uremic.

It seems to me that if the nephritic origin of eclampsia is correct as many writers claim, the kidneys would not have cleared up as quickly in this case. I do not think that the nephritic symptoms were in proportion to the gravity of the eclamptic manifestations. In closing I wish to state that I think it is a mistake not to induce premature delivery when the child is viable in eclamptic cases that do not respond to treatment after a fair trial. I firmly believe that in Mrs. A's case the child's life might have been saved if delivered after the third or fourth convulsion.

Since reading the above paper before the Colorado State Medical Society I have again attended Mrs. A. in confinement. The following is a brief history of the case: April 22, 1896, Mr. A. informed me that his wife was again pregnant, and thought "she was about five months along." He was greatly alarmed about her condition, fearing that she would again suffer as in her former pregnancy. I consoled him with the assurance that if the bowels and kidneys were kept active, that I did not think there was much danger of her suffering as before. I requested him to bring me a four oz., bottle full of her urine about every two weeks for examination. The first sample was examined on May 22. The examination revealed the following condition: Sp. gr. 1020, reaction faintly acid, albumin none, average amount voided in twenty-four hours at this time was about fifty ozs. Bowels acting from one to three times a day. She had at times a sense of fullness in the head, but it was never severe. Appetite good, obtaining from six to eight hours sleep in every twenty-four. Her condition remained pretty much as above stated, until about July 1, at which time she had some swelling of her feet, but it never interfered with her wearing her shoes. She also had some headache at times. Appetite was still good. Sleeping quite well; bowels and kidneys still active, some days passing as much as sixty ozs., of urine in the twenty-four hours. July 15 urine slightly turbid, sp. gr. 1015, reaction acid, amount forty-five ozs. She had slight diarrhea, and some nervous symptoms. Drank a great deal of water, so special attention was given to diet. Mr. A. did not bring any more urine for examination. It was not convenient for him as he lived 7 miles in the country; further he did not think it necessary as his wife was "getting on so well." On August 31 I was called to attend her in confinement. She was about four hours in labor, some adhesion of placental membrane, otherwise the labor was normal in every respect. Child, female, weight, eight and one-half pounds, well nourished and active. One-half hour before delivery, urine was voided, later examined and found free from albumin. Pulse, five minutes before birth of child's head, 98, full, soft and regular; ten minutes after completion of labor, 88, character the same. On my return visit (3rd day) she told me that she felt strong enough to sit up, but was instructed not to do so before the ninth day, at the earliest. She is now enjoying the best of health.

The above case demonstrates very clearly to me the fact that a woman once having suffered from an attack of puerperal eclampsia, and who recovers without any permanent injury to the kidneys, will not necessarily suffer from a second attack, if she again becomes pregnant. I do believe, however, that when the kidneys are permanently injured (whether the injury be great

or little) that she would be predisposed to trouble of this kind and that the danger of a second attack would be great. I have been unable to find anything in the text-books that I possess (and they are some of the best) bearing upon this subject. About one year after Mrs. A.'s first illness her husband consulted me, wishing to know what the chances were for his wife to again suffer from convulsions, if she should again become pregnant. I told him that the chances were *very* great, and that a second attack might prove fatal, but it seems that I was mistaken.

The above case is convincing to me that puerperal eclampsia is not caused primarily by a diseased condition of the kidneys, but as before stated, I believe the poisons, or toxic substances, whatever they may be, accumulate in the bloody, and if not eliminated through the natural channels, will produce inflammation of the kidneys, hence the origin of albuminuria. In some cases the great nerve center first becomes affected, causing the convulsion, the kidneys being only secondarily impaired; but if the toxins are eliminated through the natural channels the kidneys and nerve centers remain unimpaired. I believe it is the duty of every physician engaged to attend a case of confinement, two or three months in advance of the expected time (as they sometimes are), should in every case of swelling of the feet, especially if accompanied with some headache and stomach symptoms, give special attention to the kidneys and bowels, and in bad cases the skin and diet. By so doing, much or all of the "toxins" that accumulate to excess in the blood, could be largely eliminated, thereby preventing a possible attack of puerperal eclampsia.

A RATIONAL TREATMENT OF DIPHTHERIA WITH OR WITHOUT ANTITOXIN.

BY EMERSON M. SUTTON, M.D.

PEORIA, ILL.

Recognizing the doubts of all treatments, I submit four cases taken from my case book which were true diphtheria occurring in an epidemic, and which show a positive result:

Case 1.—July 18, 1891. Patient, a female, aged 15. Two brothers had just died of diphtheria when she contracted sore throat and fever with constitutional symptoms. The membrane formed over the posterior fauces, extended anteriorly and to the sides of the throat. Treatment, spray 2 per cent. cocain sol. very carefully and small amount, followed by second spray of Condy's fluid. Ordered to be repeated each hour till all soreness was relieved. Internal treatment, zinc sulpho carb. 1 gr. each hour. Quinia and iron tonic every three hours. Food every fourth hour, taken after spraying. Result, second day membrane disappearing from anterior pillars and only patches left on sides. No fever. Good appetite. Third day, no patches remaining, inflammation subsiding. Fourth day, throat not the least sore. Fifth day, discharged recovered.

Case 2.—July 11, first symptoms developed in boy aged 6. Membrane formed on sides and back of throat. Constitutional symptoms profound on the 13th, when first seen. Treatment: Cocain spray three times a day (at each visit). Permang. potash sol. spray each hour; gargle of solution every fifteen minutes or one-half hour. Internally iron and quinin. Pepsin cordial after food, which was always following cocain spray. July 14, throat not so sore; membrane disintegrating; general condition good. July 15, membrane only in patches. July 18, discharged well.

Case 3.—October 28. Boy aged 8 sent home from school with fever and sore throat, treated by family physician for tonsillitis. October 29, no better under sprays, antipyretics, etc. October 30 and 31, patches coalesced, forming membrane, constitutional symptoms became alarming. Treatment inaugurated for diphtheria October 31, spray 2 per cent. cocain sol. followed by Condy's fluid. Spray every two hours. Internally, milk every three or four hours; 5 drops each, digitalis and nux-

vomica tinctures in spirits of mildererus at same intervals as food. November 1, constitutional symptoms less profound, membrane disintegrating. Additional treatment, 1 gr. mild chlorid followed in six hours by magnesia. November 2, much better. Nov. 3 and 4, membrane disappeared, sleep undisturbed after 8 o'clock evening spray. November 5, eats, feels well. Tonic given of quinia and ferrum. November 6, discharged well.

Case 4.—B. N. aged 11, December 3 contracted diphtheria from association. Constitutional symptoms severe, great prostration, membrane extensive, extending to anterior nares. Treatment: Carbolic acid gr. 1, cocain 2 per cent. sol. ζ ii, use spray cautiously every two hours, gargle every fifteen minutes with Condy's fluid. Internally, tonic, calisaya. December 4, soreness disappeared, membrane disintegrating, less inflammation. December 5, patches only remaining. December 6, patches disappeared. December 7, discharged well.

Not going farther into the pathology than to state that either preceding membrane formation an intense hyperemia may exist and form a local affection at first, the disease becoming constitutional as well at a later period, or the constitutional may precede the local symptoms, but at the point of infection passive hyperemia first takes place and exudate follows. A treatment that will relieve this hyperemia will prevent the exudate and subsequent systemic poisoning. Such a remedy is a 1 or 2 per cent. cocain solution acting on the capillaries, used in the form of spray. I first tried this in 1891, after noticing the continuance and even increase of the primary congestion following the use of the usual spray, especially observed after hydrogen peroxid, and I found that the immediate relief from the soreness was so manifest that it required no coaxing to gain consent for repeated treatments. The patient could take nourishment at once following the spray, which is itself a great desideratum, and recovery has taken place rapidly in every case, more of which I have to report. A word as to spraying. In some cases it was necessary, at first, to have the patient inhale the spray, as the deeper parts of the throat were affected, and in none of the cases were untoward effects observed.

328 Woolner Building.

TUBERCULIN IN OBSCURE MANIFESTATIONS OF TUBERCULOSIS.

BY W. H. WEAVER, M.D.

CHICAGO, ILL.

If the earliest symptoms and signs of consumption were as easily definable and as pathognomonic of the disease as those manifested in the later stages, it might be easily diagnosed in its incipiency. But, unfortunately, this has not been the fact. In a great many cases the onset is sudden or occurs during the progress of a severe cold or bronchial catarrh, or following in the wake of some other acute disease. Frequently, however, it is ushered in by symptoms which point to no particular form of disease, and it is this class of cases that is the most puzzling until we find pronounced symptoms pointing to lung infection. There are often certain symptoms of a general constitutional impairment, insufficient in themselves to render a diagnosis possible, but which do point to a definite disease if properly studied. There are many cases occurring in active practice in which a positive method of diagnosis would be of the greatest advantage. It is often easy to find out what a disease is not, but to tell what it is, is quite another matter.

The patient calls upon his medical adviser frequently, with the consciousness that there is some-

thing wrong. He is told that he has a little malaria or biliousness, and probably the diagnosis is changed frequently at the appearance of new symptoms. Restrictions of diet and some other measures directed toward the improvement of digestion improves his condition for a while. These measures soon fail and the case has advanced another step. There is now a thicker coating on the tongue, a general feeling of malaise with loss of appetite and possibly diarrhea, intestinal indigestion or constipation. There is anemia, insomnia, rheumatic pains or intercostal neuralgia, and possibly the heart's action is accelerated, fatigue toward evening with elevated temperature, chilly sensations and symptoms due to combined poisoning from the ptomaines of intestinal fermentation and tubercle bacilli, which resembles malarial toxemia. The blood may be surcharged, or at least infected with tubercle bacilli and their products, long before any local inflammatory action is discoverable in the lung tissue, a sort of prolonged incubative period. Now to make a positive diagnosis of this condition would be to gain much time. There is but one recognized test which may be applied and that is tuberculin.¹ If there is reaction after a test dose of this agent the case is one of tuberculosis, and if afterward treated on that line rapid recovery is certain. I have recently had under my care four cases which illustrate this use of tuberculin.

Case 1.—W. G., age 23, had typhoid fever one and a half years ago, from which he made a good recovery. During the past six months he had been steadily declining, continuously complaining of some new symptoms as soon as he had recovered from an old one; diarrhea, headache, loss of appetite, pain in the back, now and then a severe cold. In February he had afternoon fever, temperature 101 degrees F., pulse rapid, losing weight and constant fatigue, examination of lungs entirely negative. A small test dose of tuberculin was given and was followed in about ten hours by a characteristic reaction. About six weeks of treatment restored him to his former good health, which has continued to the present time.

Case 2.—Mr. W. H., age 38, for more than a year has been very susceptible to colds, followed by rheumatic pains in the back, indigestion, rapid pulse, increasing weakness, constant afternoon fever. During the fall of 1895 a severe cold was followed by a descending bronchitis, but no lung infiltration was discoverable, and no bacilli could be found in the sputum. However, a test dose of tuberculin was given and followed by a considerable reaction. Treatment consisted in the use of tuberculin and other measures indicated by his condition and removed every symptom of the previous trouble.

Case 3.—Mr. F. S., age 23, for several years has been subject to a mild form of asthma, seldom coughing but always wheezing and suffering from partial dyspnea. He came to me complaining of weakness, insomnia and indigestion; pulse 95, temperature 99.5 degrees F. Examination of the lungs showed sibilant râles heard over both lungs, no moist râles or other signs of localized infection were found.

This patient was found to be very sensitive to the action of tuberculin, but under its influence recovered from all the symptoms complained of as well as recovering his weight and lost strength.

Case 4.—Mr. F. M., age 22, came to me complaining of a protracted cold, pain in the chest and at times in the throat, cough and expectoration of mucus, loss of strength and weight. Examination of the chest and sputum both negative. Tuberculin gave the reaction and today the patient has entirely recovered from his symptoms.

In a recent article by Dr. Taylor of Minneapolis on "Tuberculin in Pulmonary Consumption" it is shown that 84 per cent. of first stage cases were greatly improved by his use of tuberculin. And as the cases are more advanced the percentage of improvement or recovery grows less. It is also true that a great many cases in the later stages may and do recover reasonably good health.

Now, if we can get the cases in the incubative or first stages a very much larger percentage ought to recover. There is no other method by which this test can be made. Inoculation of rabbits or guinea pigs with blood taken from the patient would hardly be reliable, because the particular specimen of blood obtained might contain no bacilli, and other sources of error would enter into the case, which would involve uncertainties. Tuberculin is used in detecting bovine tuberculosis and has probably never failed as a crucial test. It is undoubtedly just as reliable in the human subject.

Of course where there is expectoration containing bacilli no other test is needed than the microscope. If there is no sputum or no bacilli to be found, the test will be decisive.

It might be objected that as consumption is such a very fatal disease, unless there is some positive cure to be promised the fact of an early and positive diagnosis would be a source of great worry to the patient and sorrow to his friends which would only hasten the rapid progress of the disease. This objection is born of ignorance of both the disease and its treatment and should have no weight with one who has in his mind the welfare of his patient. That consumption is curable, especially in the stage under consideration—the first stage—should be firmly impressed on his mind so that he may not leave any stone unturned which will aid in his recovery. Next to the disease itself this general conviction that the disease "can not be cured" is the greatest obstacle the physician has to encounter in his efforts to enlist the energies of the patient. That physicians as well as others have encouraged a patient to "sin away his day of grace" by calling his disease bronchitis, malaria or something else, can not be denied. Ambition to do something in the right direction should have been instilled into him early, before he became too weak to help himself. By far the greater majority of patients seen by lung specialists are already far advanced in the second and third stages of the disease, and then we are requested not to let the patient know that he has consumption. Who is responsible for this immense loss of time and life?

Professor Jaccoud says in his work on phthisis that "pulmonary phthisis is curable in all its stages and in its two forms—the ordinary and the pneumonic." Tyndale says "consumption is curable." It has been the belief of the great physicians of Europe that consumption is curable—Celsus and Galen, Willis, Laennec, Rokitansky, Schuller and Koch. In this country Lindsay, C. T. Williams, Professor Flint in Pepper's System of Medicine, and Professor Loomis (in Practical Medicine) says that chronic pulmonary phthisis is not necessarily a fatal disease. And it is well known by every physician that cases in all stages recover every day. Now if it is curable in all stages it is certainly most easily curable in the first stage.

Let the profession educate the laity in this direction so that it may be regarded as a curable disease, and this great and general dread of the disease will gradually give way to the desire to know the truth, and a determination to coöperate in the efforts put forth to eradicate the disease. An early diagnosis and successful treatment will be demanded, and it will be counted criminal carelessness or a great misfortune for a patient to advance beyond the first stage of the disorder.

¹ Recently it has been proposed by Dr. Alfred Worcester of Waltham, Mass., as a test for human tuberculosis.

PYORRHEA ALVEOLARIS.

PAPER NO. 3.¹

Read in the Section on Dental and Oral Surgery at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY E. S. TALBOT, M.D., D.D.S.

CHICAGO, ILL.

This disease is evinced by simple inflammation of gums around the teeth, followed by chronic inflammation with or without suppuration, with or without calcic deposits, a gradual destruction of the peridental membrane, with recession and absorption of the alveolar process and gums, concluding with loosening and exfoliation of the teeth. The physician is more familiar with this disease, as it appears to him as a consequence of scurvy, mercurial or iodid salivation.

Few diseases have received as many names as that under discussion. More time has been spent in apology for and discussion of new names than in original research as to its etiology. The term pyorrhea alveolaris, which has become so popular, and which I have selected for the title of this paper, does not elucidate the exact condition, since many cases which come to the dentist do not suppurate.

Riggs's disease seems a more appropriate title, since to it is affixed an exact clinical picture of the various stages, from simple gum inflammation to wasting of the alveolar process and loss of teeth.

Many theories have been advanced as to the cause of this disease. None require discussion at this time, except the uric acid hypothesis advanced by Dr. Reese, of Galveston, Texas, May, 1885, and most forcibly advocated by Professor C. N. Peirce. This theory owes its prominence more to the eminent position of Professor Peirce than to the intrinsic value of the experiments upon which the theory is based.²

"I have had three specimens of this tooth deposit examined chemically by Prof. Ernest Congdon of the Drexel Institute, whose experimental skill is a sufficient guarantee for the accuracy of the results obtained. Specimen No. 1 contained, as shown by microscopic analysis, a number of fine needle crystals of calcium urate, a few crystals of free uric acid, and crystals of calcium phosphate. Destructive distillation analysis yielded a strong ammonia reaction. The murexid test for uric acid and its compound was faint, though the characteristic color showed in several places. Specimen No. 2 presented the same crystals on microscopic investigation. The murexid test was strong, producing a number of purplish red spots. Specimen No. 3 yielded similar results. In addition to these analyses by Professor Congdon, some six or eight specimens were examined by Prof. A. P. Brubaker, in my presence, the results obtained corresponding to those of Professor Congdon. In three of these, an abundance of urate of soda crystals were observed. It must be remembered that, as the quantity embraced in each specimen was small in amount, large results could scarcely be obtained or expected."

The publication of Peirce's researches led to investigations of the question, which demonstrated to me that patients may suffer with uric acid diathesis without pyorrhea or even chronic gum inflammation. Moreover, most people over 40 years of age are afflicted to a greater or less extent, while comparatively few have either lithemia or gout.

Certainly no physician would claim that resultant loose teeth were consequent upon scurvy or mercurial poisoning, uric acid much less. From the comparatively doubtful results obtained in so few cases, the claim seems far from warranted that pyorrhea is caused by uric acid or gouty diathesis. Since I prepared my second paper,³ I have continued my examination with the view of obtaining the percentage of cases which actually show uric acid. These examinations were conducted personally by Dr. Jerome H. Salisbury, of the Northwestern University Woman's Medical School. The teeth procured from institutions which make a specialty of extracting were all selected by the writer. All contained the dark calcic deposit above the pus line.

Dr. Salisbury reports thereon as follows:

"I have examined a second series of 300 teeth by the murexid test and microscopically with following results: By the murexid test, six out of the three hundred gave a distinct reaction; eighteen showed crystals under the microscope. The murexid test was performed as follows: The deposit was selected as carefully as possible, removed from the tooth, and placed in a small porcelain crucible. A drop of pure nitric acid was added, and the mixture evaporated on the water bath. When dry the evaporation was repeated with another drop of nitric acid, and the crucible allowed to cool. When cool, the color produced by the nitric acid was observed, and then a glass rod, wet with ammonia water, was brought near the deposit, and any color produced was noted. If no color was observed, the ammonia was allowed to flow over the residue. A yellow color was produced in many cases by the nitric acid, which was deepened by the addition of ammonia. The microscopic examination was made by scraping off the deposit and evaporating it with a drop of hydrochloric acid. The residue was moistened with water, and the insoluble material placed on a slide and covered with a cover-glass. It was examined with a No. 7 objective. We may assert that uric acid occurs in a certain but very small proportion of cases of calcic deposit on the teeth."

Dr. J. A. Wesener, after an examination of several teeth from patients over 48 years of age, under treatment for uric acid, reports that the murexid test was negative and uric acid crystals were absent. Since there is some doubt whether the crystals are free uric acid or calcium phosphate crystals (resembling each other), and since but 6 out of 300 responded to the murexid test, it would seem justifiable to accept as a fair average 12 as responding to both tests. This would give 4 per cent., of cases of which uric acid was present. This corresponds closely with the results previously reported in my second paper upon this subject, when 5 per cent., was found. It will be remembered that the 215 cases were examined independently by two chemists of known ability.

While one-fifth of the 518 cases examined had decided lithemic or gouty symptoms, but 3½ to 4 per cent. gave positive results by the chemic and microscopic examination. These results seem sufficient to demonstrate conclusively that pyorrhea was not due to uric acid, and that uric acid when found is merely an expression of uric-acid diathesis. As so many colors are observed in the porcelain crucible, these examinations should be made by expert chemists.

Ten years ago⁴ I published some observations on pyorrhea, which it was hoped some one proficient in

¹ Paper No. 1, Dental Cosmos, 1886, p. 689; paper No. 2, *ibid.*, 1896, p. 310.

² International Dental Journal, January, 1894.

³ April Cosmos, and International Dental Journal.

microscopy would take up and pursue the investigations to the end, but these seem not to have attracted attention. Among the points then made was that pyorrhea was on the increase, that a large majority of patients suffered more or less from it, and that modern dentistry had most to do with the cause; that it was of local origin.

I still hold these opinions, since clinical experience in the different asylums of this country and Europe, as well as close observation of my office patients has

a destruction of an inflammatory character, of chronic progress, proceeding from the neck to the end of the root, and leading without fail to the loss of the tooth. This special feature, its mode of origin, and the precise seat of the lesions, seem to justify the name alveolo-dental periostitis. But notwithstanding its primary origin in the periosteum and its complications with the gum and bony alveolar wall, the study of the successive morbid phenomena does not allow us to admit, as various authors have claimed,

Figure 1.

Figure 2.

given me a broad range to study the etiology of this disease.

Dr. E. Magitot, in 1867, published the most complete paper upon this subject, describing the disease in its progress to the end, but says that the gum being in all cases attacked subsequently only, is not the real seat of the lesion. The disease with which we are occupied, he says, "seems essentially characterized from an anatomic point of view by a slow and progressive destruction of the periosteal membrane,"

that these parts are originally the seat of the disease. Dr. Peirce takes the same view.

I hold just the opposite; that the gum is the first tissue attacked, and these parts are originally the seat of the disease.⁵

Clinical observation shows that in the incipient stages of pyorrhea active and chronic gum inflammation and calcic deposit may attack one, two, three or even four teeth at once. General invasion of all the teeth *never occurs* at the same time, which would

⁴ Dental Cosmos, 1886, vol. xxv, p. 689.

⁵ See original paper.

be the case if it were of constitutional origin. The calcium salts being in solution in the blood, are deposited. Only local conditions favor such deposits, which militates strongly against the uric-acid theory. As Ziegler⁶ remarks, "the cause of calcification is for the most part to be found in local changes of the tissues, since the deposits of lime-salts usually occur in localities in which the tissue has already died or is in process of degeneration and necrobiosis. It looks as if dying tissue which has undergone more or less modification possesses a kind of attraction for the lime-salts in solution in the body, and enters into intimate combination with them. Among the degenerating or dead tissues which are particularly prone to undergo calcification, we may mention in particular connective tissue which has undergone hyaline degeneration, such connective tissue being quite often encountered in the walls of the blood vessels, in the endocardium, in an enlarged and degenerated thyroid, or in the thickenings of the pleura or pericardium. It is common also in degenerative areas in the walls of blood vessels, or in tumors, or in any other portion of the body in which hyaline and fatty degeneration are in progress, in degenerating cartilage, in dead cell bodies, as for example in dead ganglion cells or kidney epithelium (especially in corrosive sublimate, aloin, or bismuth poisoning), or in circumscribed cheesy areas of considerable size."

When a tooth associated with pyorrhea has been extracted, clinical observation shows that the margin of the peridental membrane has changed its locality. Instead of being in its normal position at the neck of the tooth, it has receded in a more or less irregular line toward the apex of the root. The extent of this recession depends upon the duration and power of resistance of the disease.

The membrane, instead of being thin and of a pink color, is quite thick and of a deep red. The inflamed membrane may extend through the entire length of the root, or in circumscribed localities. The space upon the root made vacant by the destruction and loss of the peridental membrane may be made clear and smooth, or it may possess calcic deposits. These deposits may consist of a uniform ring extending around the entire tooth, or circumscribed masses of deposits may be located at different points about the root. As the membrane recedes, the deposits follow after it upon the roots.

Between the border of the calcic deposits and the peridental membrane, is a space, one or two lines in width, where the roots of the tooth are perfectly smooth. This is the pus-line of clear, smooth tooth-structure, and is nearly always situated between the calcic deposits of the peridental membrane, showing that the calcic deposits are not always found in the membrane, as Dr. Peirce claims. The space upon the root of the tooth between the peridental membrane and the neck of the tooth, including the calcic deposits, is bathed in pus. This disease, which first makes its appearance as an inflammation of the gums, is due to irritation from constitutional and local causes.

Constitutional causes are tartar, mercurial salivation, potash iodid and other drugs, syphilis, loss of vitality, locomotor ataxia, parietic dementia, and the menstrual nisis. In neurotic and degenerate classes, as a whole, pyorrhea exists to a greater extent than in the more healthy classes. In any and all of these dis-

eases in which systemic disturbances produce trophic changes, this disease is present.

LOCAL CAUSES.

As has already been shown, modern dentistry is producing more pyorrhea than any other one cause. Some cases result from infection, from microorganisms, application of the rubber-dam, clamps, wedging the teeth, correcting irregularities, sharp edges of decayed or filled teeth, protruded fillings, spaces between teeth, crown and bridge work, overstimulation in the use of a tooth-pick, artificial teeth, more particularly ill-fitting plates, injuries, tartar, accumulation and decomposition of food and collections around the necks of teeth, tobacco and everything of a foreign nature, as observed in the mouths of idiots, imbeciles, epileptics and all individuals who do not take care of the teeth. The result of irritation from constitutional and local causes is inflammation. The constitutional factors merely produce inflammation of the gum-margins and trophic changes.

Light is thrown upon this subject by a careful study of the anatomy and physiology of the parts involved. We have the roots of a tooth on the one hand, and the bony structure of the alveolar process on the other, and between the two resisting walls we have the peridental membrane, composed of fibrous elastic connective tissue, which gives nourishment to both the tooth and the alveolar process. The alveolar process is a transient, bony structure simply for the purpose of holding the teeth in place after they have been erupted. The gum or mucous membrane which covers the alveolar process, and which is united with the mucous membrane throughout the mouth, connects with the peridental membrane at the margin of the process. That the lymphatic system is richly developed in young people at this locality is demonstrated by the fact that when the temporary and permanent teeth are lost, the alveolar process absorbs. No structure of the body is similarly situated as the peridental membrane. The structure of the tooth not changing its former size, sends very little nourishment into the cementum.

The peridental membrane obtains its blood-supply from the arteries at the apex of each root, just before they enter the foramen, and through the alveolar process but the largest amount passes through the gingival border of the gum.

According to Black⁷ (and I have since verified this statement), "these capillaries run longitudinally from either end of the root toward the center, giving off branches which enter the alveolar process, but not the cementum, because of the peculiar locality of the membrane." May not the anatomic position and a physiologic action on this membrane have something to do with the disease?

The changes which take place in structure are excellently described by Richard Thoma.⁸ "The occurrence of atheromatous degeneration is not limited to epithelial structures, however. It is also found in connective tissue. The pathological new formations of connective tissue, which so frequently develop in the intima of the large arteries, are especially liable to atheromatous degeneration. In the description of the simple hyaline degenerations, it was mentioned that many general disturbances of nutrition lead to a weakening of the middle coat of the vessel. The vessel wall is stretched by the blood pressure,

⁷ American System of Dentistry.

⁸ General Pathology, and Pathological Anatomy, p. 398, 1896.

the lumen of the vessel dilates, and connective tissue thickening of the intima takes place, so that the lumen of the vessel becomes again adapted to the blood-strain. Not infrequently this stretching of the middle coat of the vessel becomes very excessive at some parts of the circumference of the vessel, and accordingly the new formation of connective tissue is very considerable. The newly formed connective tissue has now to support the great part of the tension of the walls. For this, however, it is not quite competent. The increasing dilatation of the lumen of the vessel

sel, or sometimes extend to the media. Atheromatous degeneration, like simple hyaline degeneration, is associated with increase in volume and swelling of the degenerating parts, so that the atheromatous foci project somewhat into the lumen of the blood-channel."

Substitute the peridental membrane for the middle coat of the aorta, and this describes the changes which take place in this locality to a more marked degree, owing to the location of the membrane between the bony walls, and contain more connective tissue.

Figure 3.

Figure 4.

continues to stretch the wall, until at last the nutrition of the newly formed connective tissue is impaired, some portions of it die, and undergo simple hyaline degeneration. In the hyaline portions a finely granular disintegration, with softening and liquefaction, develops under certain circumstances. This softening is atheromatous degeneration. These areas of softening occur, as a rule, in the deeper, oldest connective tissue layers of the intima, nearer the media. They may, however, break into the lumen of the ves-

The gums are rarely found in a healthy condition. They may become inflamed from either constitutional or local causes mentioned above. If the cause is removed early and antiseptic and astringent washes used, together with the stimulating effect of the tooth-brush, the gums will return to a healthy condition. The peridental membrane is never invaded by pus-germs so long as it is in a perfectly normal state. If, on the other hand, inflammation of the gums, due to either constitutional or local causes, persists, it will

extend to the capillaries of the peridental membrane, causing inflammation and stasis of blood in that direction. The peridental membrane has not lost all of its source of nourishment, although the greater part is cut off; its vitality is thus impaired.

When inflammation of the peridental membrane takes place, a proliferation of small round cells produces a new connective tissue. This tissue causes inflammation and thickening of the peridental membrane, which is subject to necrosis, first, from its position between the two bony walls, causing pressure, and second from deficient blood-supply.

Atheromatous patches composed of granular débris, and granular débris and fatty detritus, in which are deposited lime-salts liberated from the tissue-cells and from the blood or lymph, are then formed. These patches soon become infected with pus-germs, or infection of the tissue in the primary stage of the inflammation may take place.

These pus germs, according to Miller, are found in nearly every mouth, but more especially around the necks of teeth. Infection means degeneration and liquefaction, not only of the immediate tissue, but also of the more healthy peridental membrane, but in a less marked degree.

Pus infection producing pockets are formed first by circumscribed inflammation at a particular point of the gum or peridental membrane at the neck of the tooth. The inflammatory process extends into the peridental membrane along a blood vessel or lymph-stream. This may extend part of the entire length of the root of the tooth, the tissue degeneration taking place in precisely the same manner as before, only in a circumscribed way. In phthisical patients and those with low vitality, and patients who have been ill for any length of time, a low form of inflammation of the gums, extending to the peridental membrane, with pus infection, takes place and, degeneration of tissue ensues with or without granular patches and calcic deposits.

The granular débris or calcic deposits in all cases are a secondary consideration in this breaking down of tissue, the inflammatory exudate and pus formation being primary.

Sometimes the degeneration of tissue will extend the entire length of the root. The atheromatous patch of degeneration is always located in that part of tissue farthest from the blood-supply or at the point of least vitality, hence the reason of the breaking down of membrane and deposit upon the root of the tooth.

Believing that the disease is due to local atheromatous degeneration, I have continued my investigations with the aid of Dr. Vida Latham, of the Northwestern University Woman's Medical School. Loose teeth, the result of pyorrhea, were extracted and placed in 50 per cent. alcohol, and given to her for preparation for the microscope. The illustrations here presented are some of many she has prepared, and are magnified 480 diameters. These illustrations, other than the first which is normal, are pathologic conditions of the peridental membrane in different stages of inflammation and degeneration.

Fig. 2. Longitudinal section of cervical portion of the mucous and peridental membrane in connection with a central incisor. Man, 54 years of age. *aa*, epithelium; *b*, coarse fibrous tissue of the gum connecting the mucous and peridental membrane, the lymph-stream passing through from one tissue to the other;

the tissues are in a state of chronic inflammation; *c*, deeper connective tissue.

Fig. 3. Cross-section of peridental membrane of the anterior buccal root of a right superior first permanent molar. Man, 59 years of age. The dark lines show round cell inflammation extending along the lymph-channel; the lighter lines less inflamed, membrane center; *a*, blood vessel.

Fig. 4. Cross-section of peridental membrane of left superior lateral incisor. Woman, 32 years of age. This tooth became loose on account of pressure from plate. The white spaces show the fibers of the connective tissue. The dark spaces are round cells of inflammation extending into the lymph-streams, showing how pus-pockets are produced.

Fig. 5. Cross-section of peridental membrane of left inferior central incisor of a lady 29 years of age, who has been under my care for fourteen years. By treatment I was able to preserve the tooth that length of time, but finally had to remove it. The disease first started by accumulation of tartar between the two incisors. She was in the habit of biting her thread with this tooth. I could not prevent her from occasionally doing so until it became loose.

The black center shows active inflammation extending along the mesial surface, with cross-section of two blood vessels, with violent small-cell inflammation, having for its starting point the perivascular lymph space.

Fig. 6. Cross-section of central incisor with the peridental membrane. *a*, dentine; *b*, cementum; *c*, cementoblast; *d*, peridental membrane highly inflamed; *e* and *f*, blood vessels cut longitudinally.

The following four illustrations show different stages of inflammation and degeneration of the peridental membrane of a right superior first molar. A lady, 40 years of age. She has had pyorrhea for the last twenty years and is now losing teeth very rapidly.

Fig. 7. Cross-section of palatal root near apex, showing connective tissue with active inflammation.

Fig. 8. Cross-section farther down showing further stage of inflammation of peridental membrane, with all sizes and kinds of connective-tissue cells.

Fig. 9. Cross-section still further down on same root, showing further stage of inflammation.

Fig. 10. Cross-section lower down and of lower magnifying power; shows degeneration and liquefaction of tissue. *aa*, two pus-pockets with violent inflammation around them; *bbb*, violent inflammatory areas about to break down; *c*, blood-vessel.

The following cases are here given to show that uric acid and the gouty diathesis are not the cause of pyorrhea.

A woman, 58 years old, has been a patient for sixteen years and has all the symptoms of gouty diathesis. The enlarged joints of her fingers and toes indicate this, together with neuralgic and rheumatic pains in limbs and body. All these years she has come to my office as often as once in every three months, and frequently as often as twice a week to have her mouth kept in order. I removed two loose teeth when she first came to me in 1880, and the remainder are firm in the jaw today. I have been able to keep them in a fairly good condition ever since. I have had the greatest trouble with the inferior and the palatine surface of the superior incisors. I have kept the gums in a fairly healthy condition without calcic deposits, and have neglected the buccal surfaces of the molars. The patient has done the same. This

was her weak point, therefore I encouraged it. The result is that where the gums are kept healthy there is no deposit, and where they had become diseased the deposit was excessive. When the deposits were removed they were examined chemically without uric acid results. This case has already been reported in second paper.

B, man 49 years old, came to me eleven years ago with a very bad case of pyorrhea. The right inferior first molar was loose, and I informed him that I could

C, woman, 22 years old, had her anterior superior teeth regulated owing to a protrusion. This required four months' time. After they had been restored to their proper position they were anchored to the first bicuspids. She was dismissed and after a year had passed I removed the retaining band, and found chronic inflammation of the gum along the palatine surfaces of the incisors and cuspids, with thick calcic deposits when she did not reach them with her tooth brush.

Figure 5.

Figure 6.

do nothing with his mouth as long as it remained. He reluctantly had it removed, and in less than two months I had his mouth in a healthy condition. For six months I watched it to see that he followed my instructions, which he did faithfully. He had very powerful muscles, and soon after the time mentioned he neglected to get the brush back by the right upper second and third molars. In a short time inflammation of the gum commenced and deposits took place, while the remainder of the mouth was in a comparatively healthy condition.

D, girl, 14 years old, had the upper dental arch expanded, and the anterior teeth rotated and carried back into place. This required two years time. After the appliances were removed calcic deposits were found in connection with all the teeth banded on the upper jaw, while no deposits were observed on the lower. It will be observed that had the gum been kept in a healthy condition no deposit would have occurred.

The glandular structure in the peridental membrane decreases with age. Black says, "in young subjects

glands are found in great profusion lying along the fibers close to the cementum. Their number is so great that I have counted from 100 to 200 of them cut across in the cross-section of the root and alveolus of an incisor tooth of ordinary size." They seem to diminish in numbers as age advances, though this point has not been studied sufficiently. I have examined 120 healthy and diseased peridental membranes, and have succeeded in finding only a few glands. This, no doubt, is due to the fact that all patients examined were over 30 years of age. There can be no

margin. In such cases, whether due to constitutional or local causes, acute inflammation occurs which, if not cured, becomes chronic, and extends to the peridental membrane, and the small round cells of inflammation follow the blood and lymph streams, which may affect the membrane as a whole or only in circumscribed masses. When this is the case pus infection takes place and total destruction of the peridental membrane results, or pockets are found. In anemic cases the vitality of the membrane is greatly impaired, and inflammation and atheromatous degeneration occurs.

Figure 7.

Figure 8.

question but that the number of glands in the peridental membrane greatly diminishes in numbers as life advances. There are, however, a set of glands located at the gingival margin of the gum, which remain so long as the tissues are in a healthy state. When, however, chronic inflammation takes place, these, to a certain extent, are destroyed. The glands invariably become involved in scurvy, mercurial and iodine salivation, and in many cases of syphilis and other constitutional conditions which affect the gum-

I can not understand why Dr. Peirce and his disciples advocate the uric acid and gouty theory when the only evidence in even the 3 or 4 per cent. of cases, the only link in harmony with the two conditions, is the name calcic deposits.

The clinical features of the beginning and progress of the two diseases are wholly unlike; we never see in pyorrhea deposits taking place and accumulating in large quantities within the peridental membrane not exposed to the air. In gouty deposits in the joints,

we never find the primary deposits starting from the external surfaces intermingled with pus. The advocates of the uric-acid theory are quite content to prescribe for their patients suffering with pyorrhea, a glass of hot water three or four times a day, in which a tablet of from 3 to 5 grains of lithia has been dissolved. What effect does that have upon the 95 per cent. of patients who do not have uric acid? What dentist will know when he has one of the 5 per cent. cases to treat, since they all resemble one another. Why use the lithia? It is wholly unnecessary. Chemists

same manner. But for the sake of argument let us use lithia water for one of the cases in which we have found uric acid and also crystals by the murexid test. The deposits are located upon the root of the tooth from one-fourth to one-half the extent, with inflammation of the peridental membrane (which is always present) and generally pus. Do the advocates of this theory believe that by removing the calcium salts in the blood it will have any effect upon those lymph and blood streams, which have become invaded by cells of inflammation and infection, far beyond the

Figure 9.

Figure 10.

will tell us to flood the system of gouty patients with good, pure water, which will carry away all the insoluble substances in the blood.

There are physicians in this country with international reputation who are treating and curing patients of typhoid fever, pneumonia, syphilis, constipation, smallpox, acute Bright's disease, cystitis, and other allied diseases by the simple use of water alone. The blood of a gouty patient can be cleansed by flooding the system with distilled water in precisely the

pus line as illustrated in Figs. 3, 4 and 5? It would seem to me to be folly to think of such results.

In this enlightened age random treatment will not do; we must ascertain the cause, and relief is easy when taken in time. Dr. Riggs and hundreds of other dentists are treating the disease locally with perfect success in those cases where the disease is not too far advanced. Admitting that the first symptoms of pyorrhea are simple inflammation of the gums, recognized by their bleeding, after removing all foreign

substances, the use of a medium stiff brush and an astringent mouth-wash stimulates the gums, continue this treatment until they are hard and do not bleed, and keep them so. The longer we wait, and the longer the disease progresses from one stage to another, the more difficult the treatment and the less assurance of success. If chronic inflammation of the gum has extended to the peridental membrane and pus-infection has ensued, scarify or mutilate the gums in removing the deposits so as to remove as much blood as possible, afterward saturate the gum with the officinal tincture of iodine. This treatment should be continued two or three times per week until the gums are hard and tight about the teeth. Care should be taken to remove all foreign matter and accumulation. In cases where calcic deposits have taken place, we must not forget that inflammation of the membrane and pus-infection has preceded it. The deposit being the result, we must therefore be careful not to injure the membrane in removing it. We must not carry the instrument toward the apex of the root, thus wounding the membrane, but very gently carry the instrument beyond the deposits, and draw it away from the raw edge of the membrane. By removing the deposit we must not consider that we have removed the cause. There is beyond this deposit and even beyond the parts of degeneration and liquefaction of the membrane a diseased connective tissue which can not be reached by local treatment, and in such cases we must disinfect the parts with germicides and antiseptics. Constitutional treatment in the form of tonics is here indicated to restore the membrane to a healthy condition. In most cases it is useless to expect to cure a peridental membrane after the tooth has become loose in the socket, and should be extracted. The inflammatory cells have penetrated the lymph and blood-streams throughout the entire length of the root, hence the difficulty in reaching them. The margin of the alveolar process should not be cut away except to reach the edges of the peridental membrane with the drugs. The main points to consider in such cases are to disinfect the space between the root and alveolar process, including the edges of the peridental membrane, and contract the gum tightly about the necks of the teeth to prevent the accumulation of foreign matter and pus-infection. I have used the officinal preparation of tincture of iodine with success. I know nothing better. Pyorrhea due to trophic changes, as observed in locomotor ataxia, parietic dementia, spinal injuries, and all defects in neurotics, must be treated constitutionally as the case may require.

MEDICAL MUNICH AND BERLIN.

NOTES FROM MY SKETCH BOOK.

BY L. HARRISON METTLER, A.M., M.D.

CHICAGO, ILL.

Roll together the ancient cities of Athens and Constantinople; sprinkle them with a few mediæval palaces and renaissance churches; populate them with an art-loving, beer-drinking, easy-going race of Bavarians, and you have modern Munich. And the strangest part of it is that all this curious and quaint antiquity has had its growth within the last fifty years. For extravagant extremes, for sudden changes of hot and cold weather, for much art, good and bad, for startling effects in color, for genuine industry and much dilettantism, for abundance of strong beer and for not

much else beside, the city of the Little Monk remains unique among European capitals. It is decidedly a modern hybrid, a creation of a monarch's imagination, an attempt to out-Florence Florence and to set the rest of the world agog with open-faced astonishment at its kaleidoscopic splendor and sumptuous gorgeousness. Above all things it lacks originality, and yet its counterpart is nowhere to be found. It is a copy of everything ancient and modern, and while individually the reproductions are exquisite, regarded en masse, they form a queer conglomeration that is at least interesting, if not beautiful. In Munich the eastern idea and the western are inextricably jumbled together. The color, frivolity, airiness, fantasy and flimsicality of the orient are thrust, without the remotest thought of harmony, upon the stateliness, grandeur, dignity and repose of the occident. Is this to be wondered at when it is remembered that a certain King Ludwig, with certain innumerable millions of good thalers, gathered all this architectural frenzy about him in the short space of a half century! Babylon, Rome, Paris, Madrid, Moscow, London and Edinburgh needed years and centuries to acquire their peculiar characteristics, their grace and beauty, their wealth and dignity. One city is as unlike the other as the rose is unlike the lily; but Munich, gay Munich, like Jonah's gourd, sprang up in a night. It hadn't time to develop. It borrowed from all its neighbors and from every age in history. It is a pretty child, bedecked in the flaring bonnet and ridiculous court-train of its grandmother. It is wayward and winsome, laughably attractive, and so we tourists always love our München.

So great is the reputation of Munich in the world of art, that one wonders how students from other lands ever thought of going there to study medicine, or anything else beside art. And yet the city is richly endowed with all kinds of scientific, literary and benevolent institutions. The arrangement and government of these are usually in advance of those of other places. The university is one of the most noted in the German Empire. It is housed in a chaste, stately edifice, forming with the Georgianum and the Erziehungsinstitut a large closed square, through which passes the famous Ludwigstrasse, one of the most artistic streets in the world. The foundation of the university took place in 1472, at Ingolstadt. In 1800 it was removed to Landshut. The two schools of Landshut and Munich were amalgamated in 1826, and in the same year established in the latter city under the name of the Ludwig-Maximilian University. The government and methods of instruction are the same as those of the other German universities. In addition, however, to the usual four faculties, there is a fifth one for political economy. They comprise a staff of about 121 professors and instructors. The medical department has become famous under the care of such men as Liebig, Ludwig, Voit, Pettenkofer, Ziemssen, Kupffer, Grashey, Ranke, Amann, Oestel, Bezold and others. Liebig occupied the chair of chemistry from 1852. In 1859 the jubilee of the school was celebrated with royal pomp and in 1891 it had upon its rolls no less than 3,622 matriculates.

As Munich itself is of such recent development, so are its asylums and hospitals quite modern, both in regard to the structure of their buildings and in regard to their management. Even the prison is a model of its kind. The principal institutions for the care of

the sick are the General Hospital, the St. Elizabeth Hospital, the Maternity, the St. Joseph Hospital and the Insane Asylum. These with a few minor retreats furnish about 1,371 beds, or about 5.04 beds to every 1,000 of the population. The General Hospital, on the right bank of the Isar in the outskirts of the city, is a magnificent specimen of architecture, surrounded by large and well cultivated grounds. It contains about 237 beds and its wards are models of their kind. The Insane Asylum, I found still farther beyond the limits of the city, on the opposite side of the river from the General Hospital. In no one particular has Munich shown its progressiveness more than in its treatment of the feeble-minded. The non-restraint and humane methods were in vogue here long before they were adopted in most of the other asylums. In fact, neither jacket nor stool was ever generally used here for the control of maniacs, and the popularity of the treatment is evidenced in the fact that the asylums were always crowded, though the authorities had from time to time enlarged them and increased their facilities. Though originally built for 280 patients, the main asylum now has room for nearly 700 beds. The present building is a commodious and artistic structure, having been opened in 1859 and extensively reconstructed and enlarged some fifteen years later. Munich is an excellent field for the study of medicine, and in some departments, as for instance obstetrics, it can claim to be second to none. Its distractions are many, however, and it is so overshadowed by its own great reputation as an art center and by the medical renown of its neighbor, Vienna, that comparatively few students from abroad are found walking the wards of its hospitals. With this brief passing notice of the capital of Bavaria, I will hasten on to sketch medical Berlin and its university.

BERLIN.

Voltaire used to insist that Berlin was a grand city, and one better laid out than Paris; but Voltaire was a mercurial individual and an adept at shifting in accordance with the direction of the wind. When Frederick was gracious and took his lessons condescendingly and the French atheist in turn listened to the King's poetry and flute tooting, pleasant indeed was it to bask in the royal smiles. Sans Souci was a veritable paradise and Berlin the finest city under the sun. But when recriminations took the place of mutual compliments, when royal mandates began to fly around, when angry edicts appeared instead of bad poems, when rivals arose and captured the monarch's ear, in fact, when Frederick presumed to be the master in place of the caustic Frenchman, things took on a different hue; San Souci was not such a delightful place and Berlin was only a miserable Dutch hamlet somewhere on the banks of the Spree.

Berlin impressed me as a very modern city and its people as tremendously in earnest. It has a few artistic features about it in the way of ornamentation, but its essence is solidity, somberness and invincible power itself. If Munich suggests a child bedecked in the gaudy raiments of an ancestor, Berlin makes one think of a mighty giant clad in the small clothes of a child. The art is there and the architecture is manifest, but the former is overlooked in the presence of so much somber militarism, and the latter fails to attract because of the rigidity of its style and the dullness of its uniform coloration. From Munich to Berlin is like going from Vanity Fair into a fortified

castle. It contains a population of over a million and a half in addition to a large military garrison. It is subject to extreme heat in summer and intense cold in winter, largely on account of its situation in the midst of a broad sandy plain. As an evidence of the general flatness of the city and surrounding country, it is curious to note that the famous Friedrichstrasse, more than two miles in length, has not a single descent of a foot from end to end. Most of the buildings are constructed of brick and plastered with stucco. This quickly fades in color and gives the city a worn, heavy, unattractive appearance. The newer tenements are being made taller, which of course darkens the narrow streets. On account of the rapid growth and development of the population, rent and real estate values have increased enormously, and so produced a gloomy side to the picture of life in the German capital. It is almost a fact that as the tenements advance skyward so *pari passu* do the poorer inhabitants descend into the earth. It is calculated that more than one-tenth of the population live in underground cellars, which of course is not conducive to good health and pure morals. Though the city has nearly 100 churches not more than 2 per cent. of its people attend them. The cost of living in Berlin is greater than in many other university towns of Germany, a fact which has had its influence upon the growth of the Berlin University.

As everybody knows the system of university education in Germany is peculiar and differs more widely from that of America than probably from that of any other country. The German university is a government institution, under the control of the crown and supported by the state. The emperor is the nominal head and it is with the approval of his representatives that the appointments are made in the faculties. This insures a uniformity of government and method throughout the various faculties. There are about twenty-one universities scattered throughout the empire and though they vary in popularity one is actually no better than another. Students are not required to pass their whole course before taking their degrees at one university, but may go from year to year to this or that school until the required amount of study has been completed. In this way a poor pupil may go to Rostock in preference to Berlin because living expenses are less in the former place; or another of ample means may attend a certain eminent professor's lectures at Heidelberg one year and another professor's at Göttingen the following year. Oftentimes universities in the smaller towns are preferred by distinguished men when called to a chair in one of the faculties because of the lessened cost of living and the more favorable opportunity for quiet study and research. The four faculties of theology, law, medicine and philosophy constitute a university. There are three sets of instructors, the *ordinary* or regular professors, the *extraordinary* or assistant professors, and the *privat-docenten*. The ordinary professors are usually men who have distinguished themselves by unusual scholarship or some special line of research and who are given full liberty to lecture upon their chosen theme in whatever way they desire. The extraordinary professors are men who have distinguished themselves as *privat-docenten* and are also given considerable license but are expected to follow more or less the teachings of the professors whom they assist. The *Privat-docenten* belong peculiarly to the German system and are not represented in any way by the instructors in either the English or American universities.

They are usually men who have shown special talent or done some original work during their student days. They are intimately associated with the university but look for their remuneration entirely to their fees from the students. They are allowed to teach whatever they like and in any way that they desire. Sometimes it will happen that a privat-docent of considerable eminence will teach conflicting views in the very same department of the professor with whom he is associated. Of course this is liable to lead and has more than once led to bad feeling, but as the professors are usually selected from the ranks of the privat-docents, a wholesome rivalry is thus maintained greatly to the credit of the school and the benefit of the pupils. The communal life of the German university resembles in some respects that of the middle ages. The university is a kind of community separate and apart from the rest of the world. Its life from studentship to professorship, is looked upon as a career in which a man who adopts it expects to pass his entire existence. Its teaching staff is always selected

technical schools and the polytechnicums. A *Zweck* is implied in the German idea of a university as an object of study. The object is *Wissenschaft*. Two conditions or *Bedingungen* are also involved, namely, *Lehrfreiheit* and *Lernfreiheit*. *Wissenschaft* means knowledge in the highest sense, it is the search of the truth irrespective of its utilitarian value. By *Lehrfreiheit* is understood the absolute freedom of the professor or privat-docent to teach whatever he chooses in whatever way he prefers. *Lernfreiheit* is the freedom of the student from *Schulzwang* or compulsory drill by recitation. In a word, the *theory* rather than the *practice* of knowledge is the ideal of a German university and in the attainment of that ideal both teacher and student are granted the largest liberty. Of the four departments medicine is the only one in which anything like a practical knowledge, a knowledge capable of being put into actual practice in every-day life, is imparted. The exception is, however, more apparent than real, for medicine is largely a theoretical science and the art of medicine is obviously

UNIVERSITY OF BERLIN.

from its own students and we never hear of a German professor who was at one time a tradesman, a clerk or a village schoolmaster. A university career is a profession to be decided upon in early life, to be prepared for in youth and to be persistently and consistently followed ever after. When a student leaves his university and passes out into the every-day life of the practical world, or into Philistia as he calls it, he rarely if ever, returns to his alma mater except as a pilgrim returns to his early home to taste once more the joys of his merry boyhood days. It is this isolation as it were of the university from the outside practical world that makes the student life in Germany so unique and keeps alive in the memory of its pupils their tender fondness for their alma mater.

It is often said that the Germans are great theorizers. This is shown largely in their system of university education. The fundamental idea of the German university is the study of the *theory* of knowledge, the teaching of men how to think. Practical science and practical information must be acquired at the

dependent upon the practitioner's powers of observation as much as upon the mere application of a number of memorized facts.

The chief medical schools in Germany associated with universities are those of Berlin, Leipzig, Heidelberg, Göttingen, Greifswald, Erlangen, Bonn, Jena, Rostock and Tübingen. While the size and importance of the towns in which they are situated vary, the teaching is the same in all. Sometimes one or more professors of special eminence, as Virchow in Berlin, Erb in Heidelberg, Thiersch in Leipzig, will cause the school with which they are associated to enjoy unusual popularity. Sometimes the student will wander from one university to another before taking his degree, so as to avail himself of the instruction of the various eminent men. In all of the German medical schools very great attention is given to the laboratories of anatomy, physiology, chemistry and pathology. For clinical teaching all of them have hospitals officially connected with the universities of which they are a part. Certificates from these

special hospitals only are accepted as qualification for the degree. Before matriculating in any one of these schools, the student must present evidence of having passed the *Abiturienten-examen*. This is a severe preliminary test and requires considerable knowledge of Latin, Greek, English and French, and an elementary knowledge of the sciences in general. Two years after beginning his medical studies, the first examination—the *Testamen Philosophicum*—is undergone. This examination is upon the subjects of chemistry, physics, botany and zoölogy. At the end of five years the student comes up for the *Examen Rigorosum*, after which he receives his degree of M.D. Before he can practice, however, he must pass the state examination. The last is purely a practical examination and like all the others is conducted by the professors of the universities. The medical curriculum of the five years includes the usual medical subjects and is comprised in lectures and hospital clinics. In the hospitals a large class usually accompanies the professor, and a discussion of the cases is held after the manner of a consultation. The fees are charged for each separate course of lectures, so that a student may take a few courses at one university one year, and other courses at other universities other years. Every university accepts the credentials of every other university, for they are all government institutions under one head and the teaching is the same in all. The professors of the medical schools are all well paid by the government and are expected to give a large part of their time to the work of the school.

It was but a few years ago that Leipzig held the honor of being the greatest of the German universities. Today, however, that of Berlin stands second to none. The history of this great school is full of interest and when I first saw it, it seemed to me that I could almost read in the severe, dignified appearance of its exterior the singular conditions under which it had its origin. In 1809, when it was decided to establish the university, Berlin was under the domination of Napoleon and French patrols were marching through the streets of the city. So oppressed was Germany at this time that certain of its universities were closed by the conqueror, and to undertake in that troublous period to assemble a band of independent outspoken scientists in a new university was attended with no little risk. But though conquered by arms for the time, the German spirit and the German love of learning remained indomitable. With the assistance of the Minister, Von Stein, and upon the earnest suggestion of Fichte, who had been expelled for his peculiar ideas from Jena, the university was founded and opened in 1810 and some of the most eminent scholars and scientists of the day were invited to occupy its chairs. Schleiermacher, who had lost his position through Napoleon's suppression of the University of Halle, took charge of the department of theology. Savigny, the famous jurist, lectured upon law; Wolff gave Fichte his most valuable support. Wilhelm von Humboldt brought renown as well as strength in those early days of the school. Above all was the scientific and moral support of Hufeland, physician-in-ordinary to the king, whose position gave him an unusual opportunity to bring to the assistance of the school the approval and favor of the crown. From such a splendid beginning the university grew and flourished in spite of the depressing influence of the French occupation of Berlin. The

fortunes of war changed ere long and victory led the Prussian banners to the gates of Paris. Under the favor of Emperor William and especially of Prince Bismarck, who felt a peculiar regard for the school, it quickly developed a reputation which surpassed that of its rivals. Being young and full of enthusiasm it worked out a career of success for itself. Being independent it invited men of eminence whose views may have been too radical for some of the older institutions, and gave them the widest liberty for the promulgation of their ideas. It could not fail to have become renowned, independent as it was and fondled in the arms, as it were, of the growing capital of a victorious nation. The Emperor was its guardian, the prime minister its friend and a palace its home. The university building was formerly the residence of Prince Henry, brother of Frederick II, and was erected in the years 1754 to 1764. It is a stately edifice, consisting of a central portion with two wings partially surrounding an ample courtyard. Its simple, massive architecture, which, by the way, is illustrative of the general architecture of Berlin, is suggestive of the repose and dignity of learning. Situated at one end of the elegant avenue known as Unter den Linden and in the midst of some of the city's finest public buildings, a student who approaches the university, as I did, for the first time, would be dull, indeed, if his enthusiasm were not kindled and his impatience to enter the halls of learning were not increased. Something like 3,500 students are now in attendance at the university and of these about 350 are taking the medical course. The teaching staff comprises the usual four faculties. There are twelve ordinary professors, seventeen extraordinary and nineteen privat docents. Two of the most noted men of the faculty of late years are Helmholtz and Virchow. I wish I had space to refer more in detail to the lives and characteristics of these eminent scientists. But I can not refrain from indicating the spirit of the university and the splendid independence of science by reminding the reader of Virchow's radical politics, which, though often in conflict with the government, even to the point of provoking a challenge to a duel from Bismarck, nevertheless did not interfere with his position as a professor in the university, the protégé of the throne. The study of the lives of Helmholtz and Virchow is an incentive to struggling ambition. Among the men who have been and are associated with the medical faculty of the Berlin school are Bardeleben, Du Bois Reymond, Gerhardt, Olshausen, Leyden Waldeyer, Bergmann, Schweigger, Jolly, Rose, Koch, Henoch, Munk, Salkowski, Fritsch, Senator, Hirschberg, Ewald, Baginsky, Martin, Fränkel, Remak, von Noorden, Langerhaus, Posner and Westphal. What other university can show a more brilliant galaxy of names?

Now just a word in regard to practical medicine in Berlin. When the old Hospital of the Holy Spirit for Lepers was founded (1208) and St. George's for the same class of patients (1258 to 1278), both of which are now united in the Neubau, Berlin was scarcely more than a couple of Wendish fishing hamlets, whither the courts of Brandenburg had led some German colonists. About this time the city first began to figure in history under the name of *Koeln* and *Berlin*. Some time between 1405 and 1408 the St. Gertrude Hospital and Church were erected in the Spittelmarkt, for twelve patients of noble birth. St. Jacob's Hospital was opened for cases in 1605,

when the city was threatened with the plague. The Jerusalem Hospital (1671) and the Cathedral Hospital (1753) were more in the nature of almshouses and retreats than actual places for the cure of the sick. Today Berlin is abundantly—perhaps over-abundantly—supplied with hospital accommodation. With its population something like a million and a half, it averages 3.85 hospital beds per 1,000. It can boast of eleven large general hospitals, six special hospitals and about twenty-six private hospitals and no less than fifty private maternities, beside an innumerable number of private clinics and dispensaries. And yet it was only a little over a hundred years ago that Formey, surgeon to the King of Prussia, wrote: "It must be acknowledged that in our public institutions for the sick reform is urgently called for, and that in these respects Frenchmen, Englishmen, Swedes and Danes—in a word, most nations—have far surpassed us. Every foreigner who visits our lazarettos, after seeing those of other lands, leaves them full of painful astonishment at their deficiency." Even as late as 1841 to 1850 and 1851 to 1860 the reports upon the government of the Township of Berlin say absolutely nothing about any hospital belonging to the municipality. At that time the capital possessed only state and private institutions. There are now two fine municipal hospitals, both of which are perfect models of their kind. The experience of the American war hospital system and the adoption of the pavilion and barrack plans instead of the ancient ones, have enabled Berlin to claim the finest hospital system in the world. Not far from the famous Brandenburg Gate at the western terminus of the avenue Unter der Linden stands the chief hospital of the city, the Charity. It was erected by Frederick the First in 1710, when a plague was threatening Berlin. It consisted of four pavilions three stories high, and was constructed after the most approved plans of that day. The plague did not reach Berlin and the building was transformed into a workhouse, and later on into a garrison lazaretto. For these purposes it was totally inadequate and so was made into a hospital in 1725, to be used for the benefit of the poor under the care of the municipality. It continued, however, to be a state institution. By a royal decree a surgical training school was established in connection with it and a wing added for the use of civilians. This was in 1727. A horticulture, a dairy and a brewery were operated at this time in connection with the hospital. It was supported by the crown, by the state (not the city) and by private gift. It has steadily grown until now its departments number sixteen, under the supervision of twelve superintendents. Most of the departments serve as clinics for the University lectures. In close connection with the Charity, which contains nearly seventeen hundred and fifty beds, is an excellent Midwives' school for Berlin and Potsdam.

The finest hospital in Berlin, the large and elegant Friedrichshain, was opened in 1874. After the Charity, medical visitors will not fail to see this model institution. It represents the ideas of the leading German surgeons, particularly Esmarch and Esse. It consists of a group of isolated buildings, spread over a large area of ground and having no covered ways or corridors of intercommunication. There are twelve ward pavilions and they all extend north and south. Four of these pavilions are for surgical cases and are made only one story in height. Six pavilions are set apart for medical cases and extend to two

stories in height. The remaining pavilions are for infectious diseases. Between the surgical apartments are the operating room and general offices. In each ward there are about twenty-eight beds and at the end of the ward is the so-called "dayroom," having a commodious covered balcony attached to it. In connection with every ward are lavatories, closets, bath rooms, small operating room, a couple of small separation wards with one bed in each, a duty room and nurses' room. The ward's offices, receiving rooms, general baths, heating apparatuses, etc., are in the basement. Hot water is used for heating purposes and free ventilation is obtained by gratings just behind each pair of beds. Two open fireplaces are also constructed in each ward. The floors are all made of tiling. The capacity of this fine, modern hospital is about seven hundred beds.

The Urban Hospital, completed in 1890, with its 600 beds (75 beds for children) is another admirable institution. It is unfortunate, however, that its closets and lavatories are not separated from the associated wards by means of corridors or some form of ventilating shaft. It is lighted throughout by electricity and its bath room contains in addition to the ordinary baths, a frigidarium, a sudatorium, a tepidarium, a lavarium and a Russian steam bath.

Among the other great hospitals of Berlin, more than a passing notice ought to be given to the Moabit, with its 750 odd beds; the St. Hedwig, founded in 1844, having 470 beds; the Bethany, with its 354 beds; the Lazarus, Augusta, Elizabeth, Jews', and the Elizabeth Children's Hospitals, each with less than 200 beds, but nearly all modern and complete in their appointments. A feature in connection with the Bethany is its broad ample balconies attached to each ward and closed in at the ends with glass screens. Ofttimes patients remain day and night continuously in these balconies, and the ventilation and sunlight thus obtained afford most favorable results. In connection with the Augusta as well as the Victoria Home is a fine training school for nurses, and their clinics are especially used by the teachers of the university.

I presume no city in the world has so many *private* hospitals as Berlin. It would almost seem that every assistant, every privat-docent—in fact everybody who pretends to do something more than attend to a private practice—must have his own hospital. Surgery, ophthalmology, obstetrics and the diseases of women and children are all represented among the private hospitals, clinics and dispensaries. I sympathize with the practitioner of Berlin and since my return from that city I have been less surprised at the penchant shown by some of our German confrères when they come to this country to at once open a corner dispensary or announce a private clinic. Berlin is undoubtedly a great center for medical education, but for general practice I fancy it must be a place for the harrowing of one's soul and the utter depletion of one's pocket-book!

In regard to the insane, Berlin took no systematic care of them until about the 18th century. Then they were first confined to the workhouse in the Waisenbrücke, called the Friedrich's Hospital. They were sheltered along with the orphans and aged paupers. When this became overcrowded, they were again removed to another workhouse near the Dorothea Hospital. Later on, the famous Faber Institution was constructed and occupied. The history of this is full

of interest but space forbids my doing more than merely naming it here. Ultimately it was destroyed by fire in 1798. After this date the Charity Hospital received the insane, and even at the present time it takes charge of some of them until room is found for them at the Dalldorf Asylum. As the hospitals of Berlin are models of their kind, so this famous asylum is notable for its modern construction and perfect equipment. Dalldorf is a suburb lying a short distance to the northwest of the capital. The asylum contains 600 beds for curable cases and 600 more for the incurables and the infirm. Both sets of patients are in the same establishment, but under the control of different superintendents and in different buildings.

Having now brought these sketches to a close, I am almost tempted to say a word or two from personal observation in regard to medical education abroad. In many respects the advantages of a medical training in Europe preponderate over those in America. In some things I am convinced America can teach Europe. But comparisons are odious and usually unnecessary; so in conclusion I will merely say that I hope these brief and imperfect sketches may have been of some use in awakening pleasant reminiscences for those who have visited Europe either as tourist or student, and in pointing out some items, not found in any guidebook, to those of my confrères who are still looking forward to the pleasure and profit of a trip abroad.

SOCIETY PROCEEDINGS.

Chicago Academy of Medicine.

Stated Meeting, November 10, 1896.

CASEY A. WOOD, M.D., in the Chair.

DERMATITIS FOLLOWING THE ROENTGEN RAY.

Dr. E. H. LEE—What I wish to say this evening will have reference more to the significance of skiagraphs in the diagnosis of fractures and the condition of the fracture after treatment, than to dermatitis following the X rays. As far as the latter is concerned, I expected to present this evening a patient suffering from severe dermatitis following prolonged exposure to the X rays, but he is so sick that he was unable to be here. The dermatitis which is produced by the X rays has been frequently observed. I have seen but one or two cases of it. Dr. E. E. King of Toronto, in the *Canadian Practitioner* for November, 1896, reports the case of a patient who was submitted to the X rays for demonstration. The patient submitted himself to exposures for two and three hours a day for several months, and later for six hours for several months. It was not until the second or third month that changes in the derma were noticed, and then a dermatitis was produced similar to that which follows heat. The skin became blistered and the hair bulbs were entirely destroyed and all the nails of the hand were lost.

My case was one of bullet wound of the head which was followed by a cerebral abscess. I saw the patient four days after he was shot; the physician with whom I consulted supposed that the bullet would be imbedded in the bony tissue beneath the skin. The patient had no elevation of temperature, the only indication for the exploration of the wound being a slight inflammatory edema around the small opening which the bullet had produced. In operating I found the bullet had penetrated the cranium, and removed several splinters of bone around the entrance of the bullet. There was no pus present. I, however, inserted a gauze drain. The patient did well for ten days, then suddenly developed chills and fever. His temperature arose to 103 degrees, so that it was plainly evident that infection had taken place. The question arose as to the source of the infection. Did it come from without, or was it from the bullet which had penetrated the brain and was lodged in the opposite side of the head? I removed the gauze drainage and a large quantity of pus escaped, after which the temperature disap-

peared and the patient did nicely for two or three days; on the fourth day he again got a chill with elevation of temperature. I established efficient drainage by removing a large piece of bone and flushing the abscess cavity as much as possible. After two ounces of pus had escaped we had no means of determining the further direction of the abscess. It was after this second operation that he was submitted to the X rays. For over a week he underwent three or four exposures a day, each exposure being from three-quarters of an hour to one hour's duration. The results were not satisfactory. The bullet had entered the right temporal region, the skiagraph showed a large shadow in the posterior occipital region on the left side. On the strength of these skiagraphs I trephined on the other side, but failed to locate the bullet. I exhibit a skiagraph which shows the shape of the head, and here you can see a spot which is supposed to be the bullet. The patient after the second operation did well, and it would have been really unnecessary to have submitted him to the X rays, but it was still my opinion that the bullet was the source of infection, and that recovery would not take place until the foreign body was removed.

The dermatitis developed after the third or fourth exposure, beginning with edema and redness of the skin. After the fifth or sixth exposure the edema was quite marked and the skin red and tender. It was three or four days after the last exposure that dermatitis developed to a marked extent, and then a severe blistering of the skin took place. The eyebrows and eyelashes were destroyed, and the hair over the left side of the face. At the present time the dermatitis is very severe. He has a very large granulating surface over the whole left side of his head, with complete loss of the hair. There is complete destruction of the hair bulbs.

It would be interesting to determine how this dermatitis is produced. No heat is present in the application of the present X rays, but the dermatitis acts very similar to one produced by heat. Then, too, the condition of the patient's eyelids is quite interesting, although the eye itself was not affected. He always had his eye closed during the application of the rays, but at the present time he has an extensive edema of both eyelids of the left side, and a most complete ectropion of both lids. The conjunctiva at this portion (indicating) is a granulating surface. In this case we made every effort to locate the bullet, and it is for this reason that the patient was exposed for such a length of time.

The removal of foreign bodies by means of skiagraphs has opened up a great field of observation in this line. I have in this connection an interesting case, which was that of a policeman who, in pursuing a burglar, shot himself in the heel. The skiagraphs show the bullet imbedded in the upper portion of the os calcis. I located the bullet before removing it by Girdner's bullet probe. By the skiagraph it is seen that the bullet is not located in the joint. This is a point which was of the greatest importance, for the joint was not opened during the operation. It was supposed that we could not remove the bullet without opening the joint, and it would hardly have been avoided had we not had such accurate knowledge of the location.

It is my desire this evening to say a few words on the application of skiagraphs in the treatment of acute fractures. In a recent article which appears in *Medicine* this month, I have reported experiments which consisted in producing Colles' fracture on the cadaver. This fracture we know is a most frequent one and therefore of great importance. It is usually produced by falling on the hand when the arm is in full extension and the hand in dorsal flexion.

In my first experiment the cadaver was laid flat upon a table, the forearm placed at a right angle to the upper arm and vertically to the surface of the table. The hand was now placed in exaggerated dorsal flexion, so that it formed a right angle with the forearm. A large block was placed on the palmar surface of the right hand, and with a heavy piece of wood considerable force was exerted by blows on the block resting on the palmar surface of the hand. The first two blows did not produce the fracture, but the third blow was followed by a snap which could be distinctly heard. Examination revealed a fracture of the radius, apparently about one inch above the joint, giving the typical deformity. The muscular contraction being absent, the deformity was not as pronounced as it would have been in the living subject, and its reduction was very easy. A careful dissection of the elbow joint was now made to determine if a fracture or dislocation had taken place in this region, as the force had been directly transmitted to the elbow joint. No fracture or dislocation was present, the only injury being that of the radius.

In experiment 2, in a similar manner a fracture of the radius of the other arm was produced, this time as a result of the first blow. The section of the elbow again showed that no

fracture or dislocation had been produced in this region. I now amputated both arms at the elbow joint and brought the specimens to Dr. Otto Schmidt, who had the kindness to make skiagraphs of them.

I first placed both arms over the plate, volar surface downward, allowing the deformity (silver-fork position) to remain as pronounced as possible. A comparison of the skiagraphs shows that in both specimens we have:

1. A typical fracture of the radius about one to one and a half inches above the joint.
2. A displacement and overriding at the point of fracture.
3. The ulna is not fractured at any point.
4. There is not a dislocation of the wrist present. A careful inspection of the carpal bones shows that they are in position.

Both arms were then placed over the plate with the dorsal surface downward, a wad of paper being placed above the line of fracture to maintain the deformity. The result is very similar to the former one, showing the fracture of the radius and the displacement of the epiphyseal fragment.

Later the deformities were reduced, and the skiagraphs showed them in perfect position. The line of fracture was with difficulty determined.

In three cases I have produced typical Colles fracture with no other injury associated with it, one and a half inch above the joint, producing a silver-fork deformity and a typical dislocation. The muscular contraction being absent, which would be in the living subject, the deformity was not as well marked as it would have been, and the reduction would have been comparatively easy. Afterward I had a skiagraph of the arm which I amputated, and I showed excellent skiagraphs of typical Colles fracture. The lateral views do not show as well.

The next skiagraph I show you is one of a baby's arm, four days after the injury, in which both ulna and radius were fractured. We can not see the point of fracture, but we notice the parts are in very good position.

The next skiagraph is a fracture of the elbow joint which shows distinctly the line of fracture. The next skiagraph is one of a patella fractured in three places. It is an old fracture. I show you now an old fracture of the femur. You will notice the callous formation and the faulty position of the bone.

I wish now to speak of a case that I am at present treating. It is an old man, 72 years old, who was injured about five weeks ago. After treating him for two weeks I had a skiagraph taken of the leg. At the time of the injury he was anesthetized, but acted poorly under the anesthetic, consequently we only partially succeeded in anesthetizing him. The skiagraph shows a subluxation of the knee with complete laceration of the patellar ligament and a comminuted fracture just above the knee joint, although at the time we could not determine that it was comminuted. It is now five weeks since the fracture occurred. There is no attempt at union whatever. For what reason? The reason is very easily explained by this skiagraph, which was taken two weeks after the accident. It shows that we have here a displacement of the lower portion of the femur down into the muscular tissue, and that we undoubtedly have between the upper portion of the femur and the lower portion either connective tissue or unaltered muscular tissue. I feel that the lower portion of the femur has embedded itself in muscular tissue, and that reduction apparently had taken place, because we had the leg in full extension and apparently in perfect condition; but the skiagraph shows that we have considerable displacement yet.

Here we have another fracture which goes upward, and a third small fracture, showing that we have a severe comminuted fracture in the lower third of the femur. After seeing the condition which is present in this case, at the end of two weeks we would have been justified in operating and wiring the fragments in a younger subject. As it is, this patient is so old and feeble that I have hesitated as yet to resort to operative interference. I have the patient at present walking around in an ambulatory splint.

I think the use of skiagraphs will undoubtedly be of importance in the treatment of fractures. We will be enabled by them to make an accurate diagnosis in the beginning. We will be able to see exactly the nature of the fracture and of the condition present, particularly if there are any associated dislocations or displacements. Furthermore, after we have subjected the fracture to the X rays we are able to see if our reduction is perfect, and later, say after a week or ten days or two weeks, or as often as necessary, we can take further skiagraphs and see that our fracture is retained in perfect position.

Dr. WM. L. BAUM—If the patient of Dr. Lee should die, it would be interesting to have an autopsy made with especial reference to the condition of the skin and of all those nerves which supply this region. I have frequently noticed that firemen who are exposed to a high degree of heat in the boiler

rooms of steamboats, and then afterward exposed to the sun's rays become sunburnt. It is not alone the high degree of heat which is responsible for the dermatitis that we see, but there must be something else in the light rays of various kinds; that is, there must be a chemical condition present to account largely for the dermatitis. The question arises, when a patient has been exposed to the action of the X ray for a long time and there is no pain experienced, what is the action upon the nerve itself? There certainly can not be any effect upon the sensory nerve filaments; it must be entirely a motor disturbance, whatever that may be. The dermatitis is frequently merely a secondary condition to something else preëxisting in the skin. The destruction of the hair follicles I would like to see demonstrated in the skin itself. It would be interesting if a small portion of the skin of Dr. Lee's patient were excised and carefully examined. There is an excellent description of what we know of dermatitis as given by Heitzmann in the *Archives of Dermatology* in 1890 or 1891. There are other forms of dermatitis, which are due to the action of heat and direct burns, and are markedly different, pathologically speaking from those which we find here described.

As far as the application of skiagraphs is concerned and as to patients having immunity from the action of the X rays, it is easily explained on the assumption that some patients have a predisposition to dermatitis, and the long continued use of the rays would naturally result in some alteration of the skin.

Dr. JAMES G. KIERNAN asked Dr. Baum whether he had seen any cases of dermatitis following the use of the electric current, to which Dr. Baum replied he had not. Dr. K. had found one or two isolated cases in the literature away back in 1883 or 1885.

Dr. LUDVIG HEKTOEN—Inasmuch as all explanations concerning dermatitis following the X ray at the present time must be theoretical, it may not be out of place to suggest still another pathogenesis, namely, that the X ray might in some obscure manner so lower the resistance, to use a broad term, of the tissues of the skin that the pathogenic microorganisms constantly present in the skin might be permitted to induce the long continued inflammation characteristic of these cases.

Dr. CASEY A. WOOD—So far as the diagnostic value of the X rays in ocular diagnosis is concerned, the subject may be dismissed in a few words. When the Roentgen rays were first suggested as a means of diagnosis, it was thought by many ophthalmologists that they might be of great use in determining the exact position of foreign bodies within the eye. As far as my recollection goes these experiments were first made in France, and in most instances the patient was suffering from penetrating wound of the globe. But it was found that, inasmuch as the eyeball is surrounded by a bony casing, and thus furnished an obstacle not to be overcome by the penetration of the rays, the experiments proved to be of very little value. Here in the laboratory of Drs. Harnisch and Schmidt, quite a large number of similar experiments were also made, some of them coincidentally with those of the French laboratories. The results were practically the same; the X ray was found to be of little or no value. At my request a paper was written by Dr. Harnisch embodying these experiments and published in the *Annals of Ophthalmology*, in which it was further acknowledged that after a good many trials the X ray was impotent, so far as the localization of foreign bodies within the eye is concerned. In my reading of these experiments I do not recall any case of acute inflammation of the eye, either of the external membrane or of the interior of the eye, set up by the use of the Roentgen ray. I have just asked Dr. Lee as to the sequence of the acute purulent conjunctivitis set up in his case. It followed a general dermatitis of the scalp and ocular region. That being the case, I think the acute conjunctival disease has in all probability resulted from secondary infection of the conjunctiva itself. I should judge it as an infection by continuity from the skin. There is, on the other hand, no essential difference so far as the effect of the rays is concerned, between the conjunctiva and the skin itself. If a dermatitis can be produced by the action of the rays, I see no reason why it might not also induce an inflammation of the conjunctiva directly exposed to them.

I much regret that we can not make use of the Roentgen ray apparatus in cases where a piece of metal or other body has penetrated the eyeball. In those instances where the ocular media are or have become cloudy, we are, at present, at a loss when we try to localize the missile, and yet the fate of the eye largely depends upon the situation of the foreign substance—whether it has lodged within the eye, or has passed directly through the eyeball and has lodged in the orbit behind. I hope, later on, when this apparatus has been further perfected, that we shall be able to make use of the Roentgen ray for purposes of this sort.

(To be continued.)

PRACTICAL NOTES.

Fistulas Cured by Painting with Cocain.—A salivary fistula cured by painting with cocain is reported in the *Bulletin Méd.* of November 25, and the issue of December 2 describes a similar success obtained with it in the case of a fistula of the parotid gland, treated previously with nitrate of silver and chlorid of zinc without effect. The solution of cocain used was 5 to 50 grams each of water and glycerin. The skin alone was painted, over quite a large surface, twice a week. No result was perceptible at first, but by the end of the second week the improvement was evident and the cure progressed to completion.

New Method of Staining Bacteria.—Pick and Jacobsohn describe a new stain which they state is much more effective than those usually employed. The bacteria show deep blue, the cell nuclei light blue, the protoplasm, mucus and necrosed cell elements bright fuchsin color and the body of the epithelial cells a brilliant red. The contrasts are usually marked and the bacteria, especially the gonococcus, show up finely, the intracellular as well as the intranuclear microorganisms. The pus is first spread on the cover glass and dried, then passed three times through a flame. It is then placed eight to ten seconds in a solution of aq. dest. 20, carbol-fuchsin, gtt. 15; conc. alcohol solution of methylene blue, gtt. 8; then rinsed off in water and dried. Canada balsam for cover glass preparations.—*Cbl. f. Chir.*, December 12.

Partial Resection of the Lower Jaw and Natural Prothesis.—Bardenheuer recently extirpated a carcinoma on a 73 year old patient which required the removal of a triangular piece of the inferior maxillary bone at the angle of the body and ramus, leaving a space 3.5 cm. in width below and about 1 cm. on top. To hold the parts of the jaw left in place, he cut out a lengthwise portion of the adjoining body, parallel with and including the lower edge, extending forward of and just below the mental foramen. The muscles, etc., were not detached and by stretching them the cut-out piece was slipped along into the vacant space, where it was fastened with one wire stitch at each end. As the piece slipped along was still growing, the wound rapidly healed and the jaw retained its original shape. The mucous membrane inside the mouth was not disturbed in the operation, which is illustrated and described in full in the *Cbl. f. Chir.* of December 12. No external appliances were required.

Effect of Intravenous Injections on the Renal Excretion.—Various tests with rabbits enable Roger to state that intravenous injections of saline solution following injections of toxins, cause the toxins to be eliminated one hour sooner than in the control animals. Two c. cm. of potassium ferrocyanid were given to a rabbit and the toxin was found in the urine in thirteen minutes, while the same amount given to another rabbit and followed by an intravenous injection, showed its presence in the urine in six minutes. The entire elimination of the toxin was accomplished in three hours and a half in the animals that had received the intravenous injections, while it required four hours and a half in the control animals. Tests with sodium sulpho-indigotate produced similar results; the renal mucosa showed the blue stain for seven hours after the intravenous injections, while it persisted very much longer in the control animals.—*Bulletin Médical*, December 2.

Comparison of Thyroid and Iodin Medication.—A French army surgeon has been studying the comparative effects of thyroid and iodine medication in the treatment of goitre in sixty cases that have come under his observation in the last few years. The average duration of treatment was twenty-one days; seven to forty-five the extremes. He states that he found the thyroid the best treatment in recent cases of acute goitre, simple hyperplasia of the gland. In chronic indurated goitre no bene-

fit is derived from iodine and not much more from the thyroid. He notes the coincidence of rheumatism with the goitre; he found personal or hereditary rheumatic antecedents in nearly every case. The fresh gland was more effective than the tablets, and the accidents from its use not so frequent. In some cases persons having taken only one gram in a tablet showed evidences of intoxication, while others could take twenty grams of the fresh gland without inconvenience. The accidents were weakness, cephalalgia, vertigo and nausea; the severer cases had profuse sweats, with elevation of temperature to 39 and 40 degrees C., palpitations, tendency to syncope, cramps and muscular contractions.—*Bulletin Médical*, December 2.

Treatment of Alopecia Areata.—Dr. Brocq recommends the following prescriptions: Resorcin, 1½ grains (.09); hydrochlorate of quinin, 3 grains (.18); and pure vaselin, 1 ounce (32). This is to be applied to that part of the scalp from which hair is falling, but only a limited area is to be covered at one application. If the hair still falls off, from 15 to 20 minims of tincture of cantharides may be added, or in other cases sulphur may be introduced into the ointment as: Resorcin, 3 grains (.18); hydrochlorate of quinin, 5 grains (.30); precipitated sulphur, 30 grains (1.80); and pure vaselin, 1 ounce (32). If these ointments produce too much irritation of the scalp, after their removal a simple ointment consisting of 20 grains (1.20) of borax to 100 (6) of vaselin may be used. If the loss of hair be associated with seborrheic eczema it is often well to apply a mercurial ointment.—*London Lancet*, August 22.

Melancholia Treated by Subcutaneous Injections of Ether.—Dr. R. J. Shepherd of Pau, France, writes to the *London Lancet* as follows: "Some remarks by Professor Renault of Lyons on the protective action of the subcutaneous injection of ether in uremia led me to try its effects in a case of brain trouble from uric acid. Twice before a similar attack had been accompanied and followed by deep melancholia. I did not, indeed, think of the melancholia in giving the drug (10 minims injected deep into the buttock) but was surprised and pleased to find that it at once disappeared. I gave about six injections in as many weeks and always with the same effect; it did not need to be repeated for the time. I feel sure that the method deserves a systematic trial, and need hardly say that if it should turn out to be a discovery it will prove an enormous benefit to suffering humanity, more especially in commencing stages of melancholia, which so often leads to suicide; while superintendents of insane asylums may hope to increase their percentage of cures. We need not be surprised that such a remedy should produce such a result, seeing that melancholia seems to be, *per se*, purely a functional condition of the nerve cells, coming and going no one knows how and leaving no appreciable trace of its presence. The utter harmlessness of the drug in such doses is largely in its favor."

Inoculation for Cholera.—Some interesting information regarding the effects of inoculation for cholera is to be found, according to the *Pioneer Mail*, in the report on the railway reconnaissance from Assam to Burmah via the Hukong Valley. Mr. Way, the engineer-in-chief, had to engage coolie transport, and 357 Khasias were collected at Margherita. Cholera was raging in the neighborhood at the time, and, in spite of all precautions, the coolies were attacked. Fortunately, Surgeon-Captain Hare was at Dibrugarh, engaged in the special duty of inoculating laborers on the tea gardens, a work which had been begun by Dr. Haffkine some time before. He willingly agreed to deal with the Khasias, and the majority of them submitted to inoculation. The effect was very marked; the deaths among the inoculated were only 2.55 per cent., while among the uninoculated they came to nearly 19 per cent. The disease made such ravages among the latter that the coolies themselves became thoroughly convinced of the efficacy of

inoculation, and finally all agreed to undergo the treatment. From that time onward no fresh cases of cholera occurred. Here, then, we have the strongest evidence of the good done by Dr. Haffkine's treatment, and Dr. Hare's report should be widely studied by the medical profession. The coolies were, it is stated, all living in the same camp and under like conditions, so that the experiment was really a most practical one. We need give only one illustration to prove this. Dr. Hare states that the fifty-two men first dealt with formed a separate group messing together in the same sheds. Of these, thirty were inoculated and sixteen left; of the sixteen uninoculated eleven developed cholera and died; among the thirty-six there was only one case, but this terminated fatally. There seems to be no room for doubt that if all the coolies had been inoculated at the outset the disease would have ceased in a few days.—*British Medical Journal*, December 5.

Permanganate of Potassium as an Antidote to Morphia.—Permanganate of potassium was first recommended by Barker Smith in 1877 as an antidote to morphia, experiments having shown that when taken after a large dose of either morphia or opium it may entirely neutralize the effect of these drugs, and it is also an efficient antidote against any vegetable poisons. Numerous cases have been reported in which morphia poisoning in children had been successfully treated by internal or hypodermic administration of permanganate of potassium. In a recent number of the *Klinische Wochenschrift* Dr. Vucetic has published the case of a child aged 3 years who accidentally had taken about thirty drops of tincture of opium, and showed typical symptoms, viz., somnolence, cyanosis, contracted pupil and slow pulse. A 1 per cent solution of permanganate of potassium was prescribed, and in the first place was injected with a Pravaz syringe into the right hypochondrium, in addition to which the child was given some teaspoonfuls of the solution. After some hours the toxic symptoms disappeared and the child eventually recovered, although it remained anemic and showed some mental impairment. If it be considered that children up to the 5th year of age are extremely susceptible to morphia and opium, that those under four months sometimes show signs of poisoning after from two to four drops of laudanum, and that the legitimate dose of laudanum for children of from 2 to 4 years of age amounts to three and a half drops a day, it is clear that in the above case the recovery was due to the permanganate of potassium. The way in which the permanganate acts has not yet been cleared up, but experiments have shown that in a mixture of solutions of morphia and of permanganate of potassium the characteristic reactions of morphia are not obtainable. Only one case of poisoning with permanganate of potassium has been described; in this case, after a dose of about four ounces death occurred from paralysis of the heart. In these cases Dr. Vucetic proposed morphia as an antidote. In morphia poisoning permanganate of potassium may be administered first hypodermically and then internally.—*London Lancet*, October 31.

Peritoneal Tuberculosis.—Naumann of Helsingborg reports twenty cases of peritoneal tuberculosis in the *Nordiskt Med. Arkiv*, No. 5. All but one were operated, as he considers surgical intervention the most effectual means of cure, and the sole contra-indication is the presence of advanced tuberculous lesions elsewhere. The difficulty is to form a correct diagnosis, and in several cases his only ground for the assumption of the tuberculosis was the exudation in the abdominal cavity. He states that the parietal peritoneum is frequently thickened, as much as 2 cm. in some cases, and that what is known as "nodular peritonitis" is in fact an old cured tuberculous peritonitis. According to Pic the proportion of recoveries with medical treatment is 34 per cent. in children and 18 per cent. in adults. But 70 per cent. recover completely after laparotomy. In two

cases of congenital hernia, Naumann withdrew the effusion through the hernial opening. The laparotomy seems to favor a cure as the traumatism from it draws the blood to the spot, and the bacilli are destroyed by its bactericidal action in such large quantities. This factor in the cure of local tuberculosis has not been emphasized until recently. The afflux of sanguine serum imparts the first impulse toward cure. Then comes the inflammatory reaction with the migration of the white corpuscles and a new formation of tissue, with the absorption of the cells of which the tubercles are composed. In this inflammation the antitoxins generated as also the phagocytosis, are the chief factors in the destruction of the bacilli. He reviews the important experimental researches of Nanotti and Baciocchi and Osler and Jordan's observation of the transformation of the tubercles into lamellar tissue five months after laparotomy, concluding that the results of the latest investigations of the progress and processes of cure after laparotomy, all tend to increase our confidence in this most rational method of treating peritoneal tuberculosis. At the recent Congress at Rome, 253 cases of tuberculous peritonitis operated by the members were reported, with 85.4 per cent. of recoveries. Of the thirty-seven fatal terminations seven occurred at the time of the operation, eight from immediate complications, and the remaining twenty-two only after considerable time had elapsed. Several of the cures have continued three to six years. Margarucci emphasized the necessity of simplifying the operation as much as possible, avoiding extensive irrigation and only draining or tamponing when there are intestinal tumors requiring local treatment. Ruggi diagnoses all cases according as fever is present or absent. In the latter cases surgical intervention is always successful, but when there is fever, the prognosis is less favorable. Seganti has been very successful with the "apneumatic lavage," which he performs with a couple of trocars introduced into the hypochondriac regions.—*Cbl. f. Chir.*, December 5.

Attenuated Test Cultures as a Safeguard Against Pseudo-reactions in Serum Diagnosis of Typhoid Fever by the Dried Blood Process.—Dr. Wyatt Johnston of Montreal has issued a circular, dated January 7, regarding the progress of his work in the new diagnosis of typhoid fever: "In my work in serum diagnosis done jointly with Dr. D. D. MacTaggart, we recently met with a series of peculiar partial reactions in which the dried blood solution from many perfectly healthy persons gave a very decided agglutination. The blood serum from the same persons was found much less liable to give these pseudo-reactions. This made it less easy to exclude other febrile diseases, and as with this test, accuracy in the negative diagnosis is of great practical importance; others who may meet with similar pseudo-reactions will be interested in learning how they may be avoided. These pseudo-reactions were not encountered in our earlier cases when attenuated cultures were used. They began to appear when we employed a short time virulent cultures and disappeared again on resuming the use of attenuated ones. Active, virulent cultures, intensified by daily transplantation and growth at the body temperature were therefore not suitable for the dried blood test. Where only active cultures are employed, we do not think that the dried blood method can be considered to have had a fair trial. The explanation of this difference appears to be that the serum contains relatively less of the substances causing agglutination than solution of the entire blood. Hence solutions of the entire blood react more intensely to the test than solutions of the blood serum alone. This was the reverse of what we had anticipated. It is found that the old laboratory stock cultures kept at room temperature and transplanted at intervals of about one month, give us the best result. Bouillon test cultures grown from this stock for twelve to twenty-four hours at body temperature are found to react decisively with solutions of typhoid blood

or typhoid serum, the reaction being as a rule well marked within fifteen minutes. With non-typhoid blood or serum solutions, the same test cultures give no reaction even after twenty-four or forty-eight hours contact. Intraperitoneal injection of 1 c.c. of such living bouillon culture produces in guinea pigs a marked blood reaction and immunity without much disturbance of health. We find that the best results in cases of dried blood are obtained with cultures where the motion as seen under the microscope is of a rapid gliding character, but free from darting movements. If the movement is sluggish, owing to great attenuation of the culture, a few daily transplantations at body temperature will make it more active. Exact estimation of the degree of dilution has not been found necessary for ordinary diagnostic work when attenuated cultures are used. A very faint tint in the drop examined usually indicates sufficient strength. The solution should not be thick and viscid. All the results which I have reported (*New York Medical Journal*, Oct. 31, 1896, and *British Medical Journal*, Dec. 5, 1896) were obtained with attenuated cultures. A report giving some additional technical details has been prepared and can be sent to any who desire further information."

The Ultimate Results of Removal of the Adnexa.—Prof. Richelot of Paris has performed 300 vaginal hysterectomies and 300 laparotomies for lesions of the adnexa. His interne analyzes these operations in an able article in the *Bulletin Medical* of December 9, and reports the after-results in 257 cases which he was able to follow to date. He finds that absolute cure is the rule; 94 per cent. after vaginal hysterectomy and 64.5 per cent. after laparotomy. The patients have resumed their work or their social life as in the past, and almost all state that their health never was better. The exceptions to this rule are the women of a nervo-arthritis tendency, who complain still of pains and discomforts, and although their general and local health is now perfect, still they are not satisfied. This point Richelot considers an important indication in deciding to operate. Patients with this tendency will never be completely cured in their own opinion, and hysterectomy only adds to their troubles the inconveniences of sterility and the annoyances of the menopause. He styles them the "*noli me tangeres*" of gynecology and advises against operating for comparatively slight lesions, even although the patients may complain of great functional distress from them. (See Jonas' vigorous article in the *JOURNAL*, page 10). Leaving one or both of the ovaries does not seem to modify the congestive and nervous troubles produced by the artificial menopause, but they are favorably influenced by rational hydrotherapy and the ingestion of ovarian tissue (Jayle's ovarin, made by desiccating the ovaries at the temperature of the animal's body, one powder, 125 milligrams, fifteen minutes before eating. To be continued several months). Two singers operated upon assert that their voice has grown lower. Obesity has appeared in some, but this is ascribed to a predisposition, which would have manifested itself sooner or later, probably, and is merely hastened by the artificial menopause. Glycosuria was similarly noted in two cases. Richelot's mortality is 5 per cent. At one time recently, he had an unbroken series of 130 successful cases. He is very careful to protect the peritoneum from irruption of pus, and when it is hazardous to attempt to decorticate the appendages, he merely opens and drains the pockets. Many surgeons pay no attention to the slight oozing of blood that persists sometimes after vaginal hysterectomy, and yet it may lead to post-operative hemorrhage or the formation of a few clots which may favor the infection of the pelvic peritoneum, and thus the continuance of the pains. Richelot never proceeds to the dressing of the wound until the vagina is absolutely dry, and if the oozing persists, no matter how slight it may be, he always seeks the cause and remedies it. He also always accomplishes the hemostasis of the posterior vaginal cut sur-

face, by bringing the edges of the serosa and the mucosa together and holding them with three or four hemostatic forceps. He is very particular about his dressings, which are tampons of absorbent cotton, the size of a nut, impregnated with iodoform and each with a string attached. One is placed at the level of the vaginal incision, without pushing it into the pelvis. Others are placed around the lateral forceps, and in contact with the vaginal walls. The forceps are removed at the end of forty-eight hours, but the tampons are left in place eight days. Injections of boiled water are made with extreme care and gentleness after the eighth or ninth day. If hemorrhage occurs when the forceps are being removed, the patient is placed in the dorso-sacral position and after disinfecting his hands the surgeon removes the tampons and places a couple of valves; finds the bleeding point; applies a pair of forceps to it, and then dresses the wound again as at first. The failures after laparotomy are due in almost every case to the fact that the uterus was left in place after the appendages were removed. Fifty-three have had to undergo a consecutive vaginal hysterectomy for the removal of the uterus, and several of the recent cases will probably require it also. Pains continue and the uterus is often hypertrophied with a large and fungous cervix, or again small and sclerotic, leucorrhœic and painful. Metrorrhagia is frequent, usually irregular, but sometimes accompanying the menses. After laparotomy the external surface of the uterus is often infected and raw, ready to contract adhesions with neighboring organs or the omentum. The remains of the tubes are difficult to disinfect entirely and the ligature of the pedicle is not always successful in obliterating entirely their mucous surface. From this cause inflammatory accidents may supervene, or fistulas may be produced, directly or by inoculation of the ligature of the pedicle. The uterus is liable to be infected or become infected secondarily, causing metritis or perimetritis. The fistulas are one of the great inconveniences after laparotomy. No fistulas were found in any of Richelot's cases that proceeded from the stitches of the sutures, as his septic precautions prevent their occurrence. Deep fistulas are avoided, the article states, if the ovarian pedicle is tied separately at the level of its vessels, and the stump of the tube is profoundly excised into the very wall of the uterus. A small suture of the serosa of the uterus will then isolate the uterine from the abdominal cavity. The danger of evisceration will always render vaginal hysterectomy superior to laparotomy, everything else being equal, as the inconveniences from this are so severe and necessitate a second operation with possibility of relapses. Its sole cause is suppuration, and this does not seem to depend upon the kind of thread nor the method of suturing. Extreme care in asepsis and drainage by a posterior vaginal incision instead of a subpubic, are the only means to prevent it. The troubles after vaginal hysterectomy have only been those connected with the menopause, in most cases. A few women still have leucorrhœa, but it proceeds from the vagina, and in some cases there has been previous gonorrhœal infection. There has been a very slight cystocele in three cases. In some cases the wound remained sensitive for a few months—all nervous cases. Ten cases out of 300 were followed by fistulas that lasted from a few weeks to eighteen months, and healed spontaneously. There were five cases of vesical fistulas. One recovered spontaneously and three were treated surgically. Richelot has injured the ureter once in the course of 600 vaginal hysterectomies. The ultimate results are the same in these cases in which the appendages were left after the removal of the uterus. They have become atrophied, absorbed, "volatilized." No pain, no fistulas, but the same phenomena of the premature menopause. The article concludes by stating that all the ultimate results seem to affirm the superiority of the vaginal route, as the chief troubles are due to the retention of the uterus, and if this is to be removed, the vaginal route is to be preferred, as it is less of a shock to the patient; there is less danger of contaminating the peritoneum; there is no danger of the annoying eviscerations, and above all because it allows the appendages to be left in place if they are adherent, and there would be danger in detaching them. In the cases in which the abdominal route is especially indicated, the operation should include the removal of the uterus.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the Association living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, JANUARY 16, 1897.

THE REVIEWING OF MEDICAL PUBLICATIONS.

The mode of criticism in the medical journals of today is unsatisfactory. In many respects it is unprofessional and unjust to both author and reader. There are not so many meritable medical publications that each can not be thoroughly, but concisely, and intelligently and dispassionately reviewed. A glance at the current review columns shows that this is not the present status of affairs.

Many good books are inadequately noticed and many inferior works are given undue prominence by reasons of personal influence or publisher's advertisement. Much available space is wasted by the reviewers in the exposition of personal knowledge and judgment. MATTHEW ARNOLD says that to be of real service to his readers a critic should be entirely disinterested and should shun eccentricity of taste and violence of speech. There should be no misstatements or misconstruction of the author's object. A compend should not be viewed as a text-book, nor a practice as an encyclopedia. Every author declares the exact object and particular sphere of his book, either on his title-page or in his preface. It is the reviewer's duty to reiterate this, and then to briefly and honestly tell whether and why the volume in question does or does not adequately fulfill its mission. In addition to this a candid personal judgment on the innovations or leading features of the work is always desirable; but this does not mean that severe terms of condemnation are necessary. There should be no phraseology calcu-

lated to ridicule a serious and honest man, thereby injuring the sale of his book and preventing full dissemination of medical thought. It should be remembered that some of the most important medical truths were at first rejected by the most learned critics. It is a flagrant abuse of power and a manifestly unfair procedure to attempt to influence a reader against purchasing a work because it is personally distasteful to the reviewer.

The persistent notice of minor discrepancies and typographical errors is entirely unnecessary. Broad criticism has little regard for detail. This is the business of a proofreader. Authors can be benefited and readers satisfied to a far greater extent in the limited space for review in many other ways. Such criticism is usually prompted by a desire to convey the impression of great personal erudition, or is born of an omnipresent desire to be "smart," and to be maliciously on the alert for errors. Criticism does not imply fault-finding. Some of the most valuable medical works are full of small mistakes. Erudite men are most prone to carelessness.

Fortunately medical books are beyond the reach of the general newspaper critics, who to a great extent unfortunately do not attempt a candid and intelligent review, but aim at entertainment and amusement. Medical books are solely works of instruction and reference, and should be viewed as such. They should never be spoken of jocularly or discussed with levity.

The review columns of a journal should be the *sanctum sanctorum* of editorial purity. Of all departments, that of review should be unsullied by personal animosities. Sad to relate, there have been very recent instances in which the review column has been plainly used to satisfy personal dislikes and to pay off old grudges. This is absolutely so narrow minded and suicidal that a feeling of disgust prevents any thought of sympathy or desire to advise the miserable offender. The serious and conscientious critic is as incapable of willfully misrepresenting the merit of the book of a rival or even an enemy, as he is of doing him personal violence or picking his pocket. To the critic who realizes his trust there is no moral difference in the crimes.

At the present time large publishing houses generally have their own medical journals, and unfortunately there is a mercenary tendency to convert their review columns into masked advertisements for their own publications. Particularly is this true of the so-called distribution numbers. This is both unjust and impolitic. By such a policy intelligent and unbiased criticism will eventually be suppressed and the healthful influence and really beneficial advertisement of general honest review lost. When the reader is compelled to read a criticism which has become mere laudation and advertisement, all the value of the criticism is gone. There can be no compromise in this

matter. Readers can not be deceived for any length of time. To be of any value to either party criticism must be absolutely free and liberal.

A difficulty from the editorial standpoint is the necessity of committing volumes consigned to the large journals for review to other hands. Although editorially responsible for the review columns of his journal, for many obvious reasons the editor can not personally inspect the books sent to him. Generally the volume is presented to the reviewer, and when a severely critical or objectionable review is returned the editor is often compelled to expurgate or publish in full the passages in question without being able to consult a duplicate. This is manifestly unfair to both author and reader, and is an injustice to the honest labor of the reviewer. It would be better for all concerned if the publishers would adopt the French custom of sending two copies of the volumes for review to the larger journals; one copy to be used for critical inspection and one for editorial reference.

SUICIDE AND ITS MEANS.

A recent case of attempted suicide in Chicago which has created a great deal of amusement, was that of a German tailor who, while actually engaged in drowning himself, was forced to cease by a policeman who threatened to shoot him. It has been assumed, though wrongly, that this suicide was a sham one. The fact is however, that suicide is often the result of an obsession (imperative conception) which may seize on any mind when the unity of the will is destroyed by conditions of depression resulting from mental stress, or from any of the ordinary somatic diseases, and may pass into an imperative act or not in proportion as the unity of the will is involved.

The obsession may involve simply the question of suicide, or the question of suicide and its method. In the first case the method will be determined by its ease of accomplishment, or by surrounding circumstances. This choice, as MORSELLI ("Suicide") points out, has often considerable regularity. If, as he remarks, there be a human act which seems in apparent relation with free choice, it is the preference given to an instrument for self-destruction; yet statistics do not leave a doubt that in an aggregate of men in whom the physiologic and moral conditions are constantly equal, the nature and number of means of death are always the same, their choice belonging to the general stability of social phenomena.

GUERRY (the first to demonstrate the regularity of this choice out of a considerable number of cases) justly compared it with the annual distribution of births, marriages and crimes. First, should be taken into consideration the fact that the choice always falls by preference on the same means of destruction, so that, amidst such a variety of disposition, they remain limited to the following, principally: drowning, hang-

ing, fire-arms, wounds, poisoning, falls from a height, and asphyxia. Suicide by other means, such as starvation, crushing, bruising, purposely induced diseases and infection, striking the head, through crucifixion, by falling into the fire, setting fire to one's clothes, splitting the skull with dynamite, swallowing hard or pungent bodies, or boiling water or oil, or great quantities of brandy, are exceptional and scarcely ever registered in statistics. Each country certainly has its particular predilections, but in the aggregate of the people by whom suicide is practiced, the rope appears to be chosen before every other instrument, and immediately after that water, fire-arms follow, then those arms which cut or stab; falling from a height is preferred to charcoal and poison and lastly come all the other means. From this, it may be inferred that, in the choice of the means of death, man is generally guided by two motives, the certainty of the event and the absence or shortness of suffering. When suicide is accomplished by very painful means or at the cost of prolonged agony, in ninety cases out of a hundred it is the act of a mind disordered by fanaticism, by insanity or by morbid excitement. The terrible wholesale suicides of the Oriental population suggested always by exaggeration of the religious feeling, are as WAGNER notices, the opposite to those accomplished with indifference, sometimes with coquetry by the cultured European. It is true that the habits and civilization of a people cause the choice of means to vary by exercising a kind of fatal coercion on the individual, so that, for example, in Russia where carrying arms is subject to severe laws and where the cold climate obliges one living within doors for almost the whole year the suicide hangs himself by preference, while in Italy the hurtful facility for possessing arms, perpetual serenity of the sky, and the high temperature give opportunity for the most frequent suicide by means of the pistol or by drowning. Taking into consideration all the means chosen the constant dependence of man on the nature of his surroundings is seen even in the death which he procures for himself by violence.

In Chicago, a suicide dropping into "poetry," left the following couplet:

"Here's a receipt for a popular suicide,
Take twenty grains of potassium cyanide."

He was a photographer and sought a painless death. German maidens often soak matches in beer and leave the world with a libation to Gambrinus. "Rough on rats" and strychnin are astonishingly popular, considering the painful death produced by them and the ease with which morphin and laudanum can be procured. Suicides by poison and drowning are most frequent among women, since they disfigure least. Revolutionists, miners and quarrymen often use dynamite. A Chicago lunatic convicted of the murder of a policeman at an anarchist meeting blew his face off with a dynamite cartridge and

thereby insured what in a sane man would have been horrible suffering.

Dr. BRAINERD of Los Angeles, California, points out (JOURNAL AMERICAN MEDICAL ASSOCIATION, Vol. xxi) a peculiarity of suicides which explains their seeming immunity for a long time from the impulse. Most of them have an impulse to accomplish it by some special method and are quite likely not to attempt to take their own lives though numerous opportunities may offer unless the one method to which their minds constantly revert presents itself. The man who has an impulse to hang himself is quite unlikely to cut his throat or poison himself, though he may have ample opportunity to do so. He reports the case of a patient who had made numerous attempts to hang or strangle himself, but was as much frightened as anyone at the prospect of being killed by a tornado. This was singularly well illustrated in the case of the German tailor, and still more so in the case of an Italian paranoiac who, with other less painful means of suicide at hand, determined to crucify himself for the sins of the world. He deliberately set about the manufacture of a cross and all the adjuncts necessary for crucifixion. Perceiving it would be difficult to nail himself firmly to the cross, he made a net which he fastened over it, securing it at the bottom of the upper beam, a little below the bracket he had placed for his feet and at the ends of the two arms. The whole apparatus was tied by two ropes, one from the net and the other from the place where the beams intersected each other. The ropes fastened to the bar above the window, were just long enough to permit the cross to lie horizontally on the floor of the room. These preparations finished he put on his crown of thorns, some of which entered his forehead. Stripping himself naked he girded his loins with a white handkerchief. Then he introduced himself into the net and seating himself on the cross drove a nail into his right palm by striking its head on the floor until the point appeared on the other side. He placed his feet on the bracket and with a mallet drove a nail through them both, entering a hole he had previously made to receive it and thus fastening them to the wood. He then tied himself to the cross by a piece of cord around his waist, after which he wounded himself with his shoemaker's knife in the left side, but failed to injure any important organ. He had made several scratches on his breast to determine the place of least resistance. This knife represented the spear of the crucifixion. This was done in his room. In order to show himself to the people he placed the foot of the cross upon the window sill, which was very low, and by pressing his fingers against the floor, he gradually drew himself forward until the foot of the cross overbalancing the head the whole machine tilted out of the window and hung by two ropes fastened to the beam. He then nailed his right hand to the arm of

the cross but could not succeed in fixing the left although the nail by which it was to be fixed was driven through until half of it came out on the other side. After hanging thus an hour he was noticed, detached from the cross and put to bed. He recovered from the wound but remained morose, taciturn and solitary.

The same fact is shown in imitative suicide. Here the imitator follows his predecessor so closely as to adopt identical or very similar means (STRAHAN'S "Suicide and Insanity") of terminating his life. Thus the women of Miletus committed suicide by drowning in large numbers because their husbands and lovers were detained by war. The epidemic was put an end to by carrying the bodies of all suicides naked through the streets. In the seventeenth century an epidemic of suicide by hanging broke out among the women of Lyons, France. There was no known cause for the outbreak. In this case the epidemic was checked by decreeing that the bodies of suicides should be exposed naked in the market place. No suicide had occurred in the Hotel des Invalides for some years, when a man was found one morning hanging from the lintel of a doorway. Within fourteen days thereafter five men suspended themselves from the same beam. The Governor had the passage closed and so soon as the identical method of suicide was rendered impossible the epidemic disappeared as suddenly as it began. Religious suicide in India under the wheels of the car of Juggernaut have been prevented more than once by English soldiers threatening to shoot the fanatics.

THE CRAIG COLONY FOR EPILEPTICS.

The successful results of the efforts of Dr. FREDERICK PETERSON and his associates in the establishment and maintenance of the Craig Colony, New York, should be a stimulus to the development of similar organizations for the rational and economic care and treatment of epileptics in other States. The model settlement at Bielefeld, Germany, has furnished indisputable proof of the benefits of the colony or village system over any hospital or house of refuge for persons afflicted with nervous and mental disorders, and the Craig Colony has further substantiated this fact in this country.

Although only at intervals incapacitated for labor and social intercourse, the epileptic is unfortunately debarred by his malady from the usual avenues of self-sustenance and mental and moral development. Relegated to charity hospitals and almshouses he becomes an easy prey to all degenerative tendencies, and either drifts into insanity or is soon a hopeless invalid and a life-long dependent on the charity of the community at large. On the other hand, taken from the deleterious confinement of an almshouse to the healthful, industrious life in a colony, the epileptic

feels that he is on an equality with his fellows, and no longer a semi-outcast of society. He is bound to his associates by a common affliction, and has a common purpose with them. New hopes and new ambitions arise. From his former apathy he is stimulated to follow his bent in both education and occupation. All the feelings so intimately connected with social dependence disappear. The exercise, the life out of doors, the manual and industrial training, and the mental occupations, bring about the bodily and psychic conditions which conduce to improvement and recovery. Indeed, in the last report on the effect of colony life on the patients at Craig Colony it is stated that nearly every individual of the 145 patients admitted since the informal opening, Feb. 1, 1896, has been markedly improved physically and has gained weight. Their epileptic seizures have diminished in frequency to a noteworthy degree, and in a few instances there has been a complete cessation of attacks for months at a time. One of the most striking changes has been in the expression of the patients. Almost every beneficiary loses his dull, apathetic look, born of idleness and neglect of years, when he enters upon the regular life of the colony, and begins to understand and appreciate the opportunities for occupation, education, treatment and general physical and mental development which it offers. A strong evidence of the appreciation of the colony by the patients is afforded by the fact that, although held here by no legal form of commitment, and having perfect liberty of the premises, they rarely manifest the least desire to leave.

Besides the manifest moral advantages there are the scientific advances that are furthered and fostered by such an institution. Necessarily ordinary treatment must be better under such circumstances. At Craig Colony chemico-physiologic and pathologic laboratories are in the course of construction, and when completed will doubtless open new fields of discovery in the pathology and treatment of psychic and neurotic disorders.

From an economic standpoint the Craig Colony promises to be a success unparalleled among similar charitable organizations. Eliminated from political jurisdiction it bids fair to become self-sustaining. The dietary for patients afflicted with epilepsy is simpler than that needed for other classes of patients, so that almost everything in the way of foodstuffs required by a large population can be produced from the land itself by the labor of the colonists. During the year previous to the opening of the colony, the managers by renting out tracts of land in shares cleared \$7,000 or \$8,000, which is evidence of the productiveness of the land and of what may be expected when each acre is made to yield its treasures to the unremitting care and attention of the colonists: There is already a large flock of sheep, a goodly herd of cows,

and other stock of various kinds under the care of the patients.

But in addition to these features which characterize it to a great degree as an agricultural and stock-raising settlement, numerous other trades and callings will need to be summoned into being with the gradual evolution of a self-supporting and independent colony.

From the date of the opening, Feb. 1, 1896, to Oct. 1, 1896, the colony produced about 50 per cent. of the cost of maintenance. This percentage should increase each year as the agricultural plant is enlarged and the industrial facilities are added to. The importance of encouraging the industrial features of the colony is thus emphasized. It is with this end in view that most of the appropriations asked for from the Legislature of the coming year, aside from those buildings needed to increase capacity, relate to the economic development of the colony.

In this day of extravagant hospital abuse and philanthropic profligacy (in themselves inducive to pauperism and social debauchery) it is delightful to learn of such a deserving and truly charitable organization. Such administrative methods as those of the Craig Colony must be appreciated by the student of social economy as well as the physician. It is hoped that the New York Legislature will have the wisdom and forethought to endow Craig Colony sufficiently to enable Dr. PETERSON and his co-workers to include under their care all the dependent epileptics in the almshouses and hospitals of New York State. After the capacity has thus become enlarged, and the primary object of the colony accomplished, arrangements can be made to receive persons of other communities who are able to pay for the colony life and treatment. Thus the indigent epileptics may be cared for and educated to become useful citizens, and sufferers of this unfortunate affliction of all classes may be ultimately benefited, either directly by actual residence in the colony, or indirectly by the scientific study in the pathology and treatment of epilepsy pursued at the colony.

MEDICAL EDUCATION IN THE UNITED STATES.

The advance sheets of the Annual Report of the Commissioner of Education are always noteworthy. In those now at hand (for the Report of 1894-95), there are to be found some interesting remarks and deductions as regards medical education and requirements for practice in the United States. These latter are graphically represented by different degrees of shading in a map, which gives, as it were, a bird's eye view of the present situation. As last year, there is only one State, New Hampshire, that has absolutely no medical law, but in several of the others the restrictions and conditions have been made more rigid, so that on the whole the safeguards against quackery are increased. The District of Columbia is the latest of

the political divisions of our country to adopt a stringent medical practice act, which was approved only last June, and as it is under the direct control of Congress the enactment is in its way a National one, though the territory in which it is enforced is small. In nine States and Territories, however, there are no medical boards, and the medical practice laws can hardly be said to have much effect.

On the whole the outlook is more promising each year as regards the regulation of medical practice in the interest of the public and the profession. The movement is fairly under way and it will not be many years, in all probability, before efficient medical practice acts will exist in all or nearly all the political divisions of our Union. The question will then arise as to the unification of the standards so as to do away with certain inconveniences that must follow from the existence of so many separate laws varying more or less from each other. This however is a matter that need not trouble us at the present time; the living question, and it is that in more than one sense to the individual practitioner, is that of raising the local or State standard of professional qualifications.

When we turn to the Commissioner's report to see what is being done in other ways to bring this about we find some further encouraging facts. In the Eastern medical centers the increase of medical students is not in proportion to the increase in the total number of students, and while it has increased in Chicago, it would probably be shown, were the figures published, that it is there caused by the multiplication of minor schools whose existence is due to the raising of the requirements of the larger and well established ones. This is clearly enough an evil, serious at the present time, but, it is to be hoped only a temporary one. As State examinations, as a requirement, become more universal the conditions that permit these mushroom growths to exist will be done away with and students will find it necessary to go where the means and appliances for a thorough medical education can be found. This statement applies still more to the many small medical colleges in minor towns, where clinical advantages can hardly be said to exist to any extent. The time may soon come when any medical school outside of the great cities will be a rare exception.

Another significant sign of the times, shown in the report, is the increasing cost of medical education. It appears that the richest and best endowed schools charge the highest fees, and the tendency seems to be to increase rather than to diminish the cost of medical education. This might not appear, at first sight, an unmixed benefit, but considering the crowded state of the profession it can hardly be seriously objected to if it is in any way efficient in preventing the excessive production of doctors. It is to be presumed, moreover, that the quality of the medical education given corresponds with the price it costs, and that being

true, no one ought to complain. There are, and probably always will be, some State-endowed colleges where the fees are moderate, and scholarships and other endowments for poor but meritorious students will also increase in time.

One of the most hopeful features of the report is the evidence it gives, that endowed medical professorships and colleges are beginning to make their appearance. As yet it is only a beginning and a small one, but it will increase, and the time when a medical professorship will necessarily mean something more than the possession of a certain amount of stock in a speculative enterprise or a device for "legitimate" medical advertising, may be said to be in sight. When it comes, and it is to be hoped it may come quickly, the status of a physician will be higher socially and financially, and one might perhaps even say morally, than it is, sometimes at least, at the present day.

CORRESPONDENCE.

Ether and Chloroform.

BOSTON, MASS., Jan. 6, 1897.

To the Editor:—Considerable has been written on the comparative use and danger of ether and chloroform. Only a few weeks ago I saw an article in which was the statement that a number of deaths by chloroform had occurred in women in confinement. Not many months ago I also saw it stated that no such case is on record. Now, which of these writers is correct? Has chloroform killed any woman under such circumstances? I, for one, have no remembrance of seeing such an instance reported. If both ether and chloroform cause death in such cases we must then select accordingly. There are several points, however, we may properly consider as between the two.

1. Help: An etherized patient, unless thoroughly under its influence, must be regarded as drunk or crazy, requiring considerable assistance to control and take care of her. It is not so with chloroform. The patient rather likes it and will call for it when not given to full anesthesia, and is able to think and talk and help the physician, quite different from ether. So that the assistance of the nurse and one other woman is all the help really required. I put the chloroform on the handkerchief and keep watch on the patient. The whole apparatus required is a lady's pocket-handkerchief, folded as it comes to me, and a small phial having a small neck for the chloroform. Then by placing the kerchief firmly over the mouth of the phial, the bottle is inverted so that only a few drops escape on to the kerchief. This bottle I keep within my reach and handle myself, using my left hand and removing and inserting the cork with my teeth. Thus any woman can hold the chloroform to the patient, returning the kerchief to me for renewal of the chloroform just preceding the next pain and keeping the more or less exhausted kerchief to the nose in the intervals of the pains. Thus more or less of the anesthetic can be used as the exigency requires to keep the pains bearable. If more chloroform has to be given during the last few pains that does not seriously affect the child. And even in instrumental cases, it is rare to need any extra skilled help; for by the time this is reached the woman giving the chloroform has become quite competent to follow the directions of the physician and take full charge of giving the anesthetic herself.

2. In heart cases chloroform has the advantage over ether.

3. Chloroform is not so dangerous to the child, since the

mother takes less of it to make her confinement comfortable, so that the child is rarely but slightly anesthetized as compared with ether, and speedily, in most cases, responds to changed circumstances and begins to breathe. Even in the heavier cases of anesthesia of instrumental cases, the time being short, there is usually little difficulty in bringing about respiration in the child, if the chloroform is laid aside and the cord is not cut. I remember but one child over which I worked many minutes before respiration was established. This mother was a particularly nervous woman and required considerable anesthesia and it was continued a much longer time than usual. When I hear of a stillbirth, the child being alive before, I always inquire if the mother did not take ether at the confinement, and this is generally answered in the affirmative.

4. Ether, by its greater stimulation of the circulation, I believe, is much more liable than chloroform to be followed by hemorrhage.

Without trying to exhaust the subject, I think these four points are greatly on the side of chloroform. And then if it is true that it is safer for the mother it becomes almost imperative that the accoucheur should give it, and give it instead of ether in confinement cases; for, if judiciously administered it is a most glorious blessing to this feature of suffering humanity. To be sure, etherization is a home invention, and the writer entered Harvard only a few years after its first application, and has witnessed the continuous prejudice in its favor ever since. Yet, from my own judgment and experience, I am strongly in favor of chloroform instead of ether in confinement cases, and from its easy application I believe no woman should be left to suffer much without it, and certainly we can not hesitate to use it when we would be slow to begin with ether.

E. CHENERY, M.D.

NEW INSTRUMENTS.

NEW AND COMPACT CASE FOR A COMPLETE SET OF OPHTHALMIC INSTRUMENTS WITH STERILIZING TRAY.

BY S. D. RISLEY, M.D.

Attending Surgeon Wills Eye Hospital Philadelphia; Professor Diseases of the Eye in the Philadelphia Polyclinic and College for graduates in medicine.

Much annoyance is frequently experienced in transporting either a broad and unwieldy instrument case which will not fit into any convenient sized bag, or by the necessity of carrying about numerous smaller boxes containing instruments. I have avoided this for a long time by a number of smaller boxes containing a complete set of instruments for any of the more usual operations.

One of these contained a cataract set, another the instruments required for iridectomy, while a third contained a complete set for tenotomy, advancement, etc. Miscellaneous instruments were mingled in a fourth.

This plan requires an unnecessary multiplication of many instruments, *e.g.*, specula, lid elevators, forceps, scissors, etc., needed in almost all operations upon the eye. Then too it is not always possible to anticipate every requirement, so that in operating away from the office, it became necessary to carry a large bag, containing numerous instruments, boxes, a sterilizing tray, dressings, etc. To avoid these several inconveniences and annoyances, I have had constructed by Wall & Ochs, a small sterilizing apparatus, and a series of small trays, into which all the necessary instruments for any ophthalmic operation are carefully fitted with ample room for a considerable additional supply of knives, keratomes, etc. Each of the trays is readily withdrawn and replaced like the drawers of a desk, or bureau. The instruments are held firmly in place in each tray, by a readily adjusted binder. The entire case is so compact, that it will fit in a small-sized hand bag, and still leave

room for necessary dressings. With it the surgeon goes to his patient, confident that he has at hand every possible instrumental requirement.

The accompanying cut illustrates the general appearance of the case when open. The drawers or trays are represented as partially open. When pressed home and the front closed, and clasped under the flat leather handle at the top, the outside dimensions of the case are, $4\frac{1}{2}$ inches wide, $6\frac{1}{2}$ inches long and 6 inches high. The case may be purchased of the manufacturers, with or without these instruments, or orders for any portion of them will be received.

The following is a list of the instruments which have been carefully selected for filling the trays:

Speculum: Knapp's aseptic; lid elevator.

Forceps: Fixation, broad serrated grip; Stevens' fixation; tenotomy, fine rat tooth; iris; Knapp's capsule; Prince's advancement; cilia; Snyder's needle forceps; Knapp's roller forceps for trachoma.

Scissors: Spring, McClure's very small for operations in the anterior chamber, iridectomy, etc.; Knapp's iris; Stevens' tenotomy; angular; enucleation, curved on the flat; straight, one probe point.

Knives: 3 cataract, hollow ground; 1 Weber's canaliculus, probe point; 1 Beer's; 1 bistoury; 1 scalpel, small; 3 angular keratomes; 2 capsule knives, Risley's, secondary cataract, dissection, etc.; 1 paracentesis; 1 cystotome and spoon.

Miscellaneous: aluminum spatula; needles, assorted in case; Desmarre's clamps; set of Bowman's probe silver Nos. 1 to 8; Risley's special lachrymal syringe, 2 canulas; Risley's canaliculus dilator; 2 fine silver lachrymal probes; 2 strabismus hooks; Stevens' strabismus hooks; Stevens' divulsor; Stevens' advancement hook; iris hooks, sharp and blunt; Knapp's silver spatula and probe; tortoise-shell spatula; tortoise-shell spoon; fine grooved director; foreign body spud; double hook; wire cataract loop.

These instruments have all been selected with special care, and are so constructed as to meet the writer's views of desirability in form and size.

Attention is called especially to the cataract knives, which are hollow-ground, the radius of curvature being 32 mm. Particular attention has been given to securing a suitably shaped point. A serious practical defect in many of the Graefe knives, as found in the market is the finely drawn long point. While this favors the easy puncturing of the cornea at the commencement of the incision, it often embarrasses the surgeon in making the counter puncture. Since the fine, almost needle point can not be readily followed in its course across the anterior chamber and at the corneal limbus, the counter puncture is almost certainly made further back than is intended. The large Annel's syringe I have found extremely cumbersome and unnecessarily large. The one included in the case is smaller,

has a circular flange at the upper part of the barrel, and a thumb ring for the control of the piston, so that the syringe can be filled and emptied readily with one hand. Another special feature is the small sterilizing tray with lamp constructed after the Andrew's model. This can be omitted if so desired, and an additional tray for larger miscellaneous instruments substituted.

This case has now been in use for almost two years, and has proved a great convenience. The instrument trays are constructed of white mahogany, and are very light though strong and durable. The outer box of the sterilizing tray is of nickel plated copper, while the inner tray and instrument rack are of aluminium. The knives have metal handles, and all the instruments are so constructed as to secure as far as possible ready sterilization. Special instruments have in each case been procured from the manufacturers selected by the surgeon who devised them. The others have been manufactured by J. H. Gemrig & Son, of Philadelphia, to whom and to Messrs. Wall & Ochs, opticians of Philadelphia, I am indebted for many courtesies in meeting my many demands in order to secure the instruments in exactly the form desired, and a neat, compact and convenient case for their suitable care.

PUBLIC HEALTH.

New York State Board of Health.—At the January meeting of this board there was some discussion over a novel question referred to the board in the matter of compelling the discharge of a popular principal in one of the public schools of Cazenovia on account of his being a consumptive and likely to inoculate the scholars with the disease. The local board of health was ordered to make a thorough investigation as to whether the health of the children was endangered, and to report to the State board.

The New York City Board of Health.—The following is a New Year's sentiment supplied to the *Herald* by the stock-broker president, C. G. Wilson, of that board. But, as usual, medical men have done all the important work. It may be taken as another argument why a medical man should be eligible to that presidency. If he actually believes what he says below, there are a host of his fellow citizens who can not follow him:

"The closing year has seen the lowest death rate New York has ever had. The year has been remarkable for a decrease in contagious diseases. We hope to attain the same degree of efficiency under Greater New York as in the New York of the year 1896. Every year has seen some little improvement; the coming year will see more. *In this department politics have never had a place*, and will not have in Greater New York. With the increase in population and territory there will be an expansion of organization. It is just as easy for the Health Department to care for three millions of people as for one and a half millions. Our methods will be the same in the future as in the year just ended." Whatever else is false in the above, it is certainly true that the last quarter of the year has had a very low rate of mortality. Twice during the quarter the rate fell below 15.2 per mille, and the average rate for the quarter should not exceed 16.75, which is a phenomenal showing for that section.

Death Rate by Sexes in New York.—In 1894 the tables of the Bureau of Vital Statistics recorded among men 56.91 per cent. of deaths from pneumonia, as against 43.09 per cent. among women, and in the following year 57.57 per cent. of men and 42.43 per cent. among women. Another year shows 2,759 deaths among males from pneumonia and 2,230 deaths among females. A similar proportion also exists in the deaths from consumption. During the past year there were 1,750 deaths from nervous diseases among men and but 1,460 deaths among women. Another popular notion which these statistics discredit is that

women are more likely to become insane than men. Last year there were some 162 deaths from insanity among men and only 90 deaths among women. There is also a similar proportion in the case of deaths from suicide, which may be classed as the result of acute nervous disorders. There were 190 deaths from suicide among men last year, and but 49 deaths among women. Among the stronger, sturdier sex there were 1,023 deaths from heart failure last year, as against 955 among women. Women are also freer from diseases of contagion than men, although they are exposed to such dangers in about an equal degree with men. In the case of typhoid fever, for example, there were last year 201 deaths males, and 51 deaths females, and about the same proportion occurs in similar diseases. The contrast in the death rate among men and women is especially noticeable in the diseases which are for the most part self-inflicted by over-eating and drinking. The popular notion that most women suffer from eating too much candy and all the jokes based upon this theory, are quite without foundation. There is, for example, little or no gout among New York women. The vital statistics do not record this, because gout is seldom fatal. The very rare cases which have occurred for several years have been in almost every instance inherited from fathers. The immense contrast in the suffering from over-indulgence in alcohol between men and women is familiar to all. The statistics show that during 1895, 276 deaths occurred in New York from alcoholism, of which 219 were men and 57 women. Indigestion with all its accompanying ills is also much less common among women. There is also a very marked difference in the number of deaths from apoplexy, which may be classed as a result of this form of over-indulgence.

Disposal of Excreta in Rural Communities—The Dry Earth System.—In the *Dietetic and Hygienic Gazette*, December, Dr. Bashmore points out that no danger to health exists in rural sections that can for a moment compare with that which inheres in the dirty privy-excavation and the foul cesspool. These nuisances contaminate the ground-water, which is about the only drinking-water that is available. For the reason that the changes that take place in the ground water are out of sight, the conjectures of our sanitarians may at times be overdrawn while the rural dweller may ignore the perils that await himself and family simply because they are not visible. The earth-closet for excreta and the deep driving of wells are points of vast importance, but it is safe to say that in the country not one person in a hundred knows what the words mean. If we could get village dwellers to understand the sanitary value of this method of excreta disposal, it would be a great step in progress. Some of the State Boards of Health are working in the right direction and issue circulars containing instructions for the making of earth-closets. The material to be used in the receptacle may be either ashes or dry earth. In summer dry earth can be taken directly from a garden bed and for use in winter may be stored in barrels. Ashes are perhaps better if the closet is in the house, for the ashes are lighter and more absorbent. Experience has shown that an ash closet if properly used, is absolutely inodorous; hard coal ashes are the right kind to use and should be sifted through a fine sieve; there is no better way than this to dispose of the winter's ashes. The disposal of the contents of the closet is perhaps the stumbling block to many. This material, whether ashes or earth has been used, may be placed on a corner of the garden bed and covered with a little earth or it may be buried a few inches under the soil; or lastly, it may be kept in a dry place, covered with earth and carted away at some suitable time by the farmer for use as fertilizer; of course the agent of disposal in all cases is the nitrifying bacteria. To be sure, if too much ash is used, nitrification is delayed, but with the mixture of a little earth the results are all that one could desire. Another way of using the earth closet, especially for schools or large dwellings, is to have the privy constructed with what Prof. Coore calls a dry catch,

which is a large, dry and cemented vault underneath. The seat is very much like the hopper of an ordinary water-closet with a movable pan at the lower end to prevent draught. The excreta fall to the vault beneath and every evening they should be covered with dry earth through an opening on the outside. Every week or so the contents are taken away for fertilizer. This is the ideal method for disposal in country schools but it will likely be many years before country school boards adopt it. It seems to me, that small incorporated towns might be able to do something on the line of the dry earth privy, by having a scavenger clean all privies every week; individuals can not be depended to take care of earth privies, at least just at the present state of progress.

Advance in Teaching Methods in Hygiene.—The *Montreal Medical Journal*, November, points out some of the improvements about to be made at the McGill University, saying:

The scope of hygiene is enormous; almost equal with that of medicine itself. Even as ordinarily taught there are three highly important subdivisions of the subject, namely, 1, preventive medicine; 2, environmental hygiene as we may term it, namely, hygiene of the surroundings of the individuals, *i. e.*, ventilation, water supply and disposal of sewage, and 3, hygiene of food, pure food and its adulterations and departures from standard. To treat properly the first of these, the hygienist should be a fully equipped bacteriologist and pathologist; to deal authoritatively with the second, he should be a professional engineer and sanitarian; to enter into details of the third, it is imperative that he be an organic chemist of the first order. When we knew relatively little and the subject was in its infancy, it was possible for one man to deal comfortably with all these subjects; but this is no longer possible, and the teaching of hygiene in every university has, in consequence, suffered. In Great Britain the difficulty is often disposed of by making the professorship or lectureship in hygiene one of the stepping stones to professorships in other subjects, and as a consequence the teaching is poor and perfunctory. In Germany, the professors in hygiene are now almost entirely trained bacteriologists, and but a few of the disciples of Pettenkofer have attempted, with partial success, to cover the whole ground. In America, again, it would seem, judging from the department of hygiene in University of Pennsylvania, that following the German system, the bacteriologic aspect of the subject is being regarded as the most important. For more than two years the medical faculty of the McGill University has been debating as to how, under the circumstances, to make the best use of Sir Donald A. Smith's endowment of \$50,000 toward the establishment of a department for hygiene, and as Dr. Craik points out in his introductory address in this number, the solution reached is, that it is impossible to appoint one man to teach the whole subject. Dr. Craik himself is appointed head of the department, but the teaching in the three main branches is given over to those members of other departments who are presumably most competent to deal authoritatively with each special branch of this subject. In this way it is hoped that the subject will be treated in a manner commensurate with its importance in the medical curriculum.

American Pharmaceutical Association.—The following subjects have been referred by the American Pharmaceutical Association to the AMERICAN MEDICAL ASSOCIATION, to be considered at the next meeting of the latter in Philadelphia, hoping that some action may be taken expressing the sense of physicians in convention assembled in relation to the important points requiring coöperation between the physicians and pharmacists of the United States for decision.

That these points may be taken up for joint debate, the following mentioned gentlemen, representing the National organization of pharmacists, State associations and educational institutions, have been appointed by the President of the American Pharmaceutical Association as a delegation to attend the meeting of the National association of physicians. This delegation will report back to the American Pharmaceutical Association when it meets in convention at its next annual convocation at Lake Minnetonka, Minn., August 23 to September 6, 1897:

A. E. Ebert, Chicago, Ill.; John U. Lloyd, Cincinnati, Ohio; H. H. Rusby, M.D., New York, N. Y.; E. L. Patch, Boston, Mass.; Joseph P. Remington, Philadelphia, Pa.; A. B. Prescott, Ann Arbor, Mich.; H. M. Whelpley, M.D., St. Louis, Mo.; S. P. Sattler, Philadelphia, Pa.; Lucius E. Sayre, Lawrence, Kan.; Chas. Caspari, Jr., Baltimore, Md.; Wm. S. Thompson, Washington, D. C.; D. M. R. Culbreth, M.D., Baltimore, Md.; Henry Trimble, Philadelphia, Pa.; C. Lewis Diehl, Louisville, Ky.; Wm. M. Searby, San Francisco, Cal.; H. R. Slack, M.D., La Grange, Ga.; J. N. Hurty, Indianapolis, Ind.; L. F. Chalin, New Orleans, La.; T. D. Reed, M.D., Montreal, Canada; C. S. N. Hallberg, Chicago, Ill.; Jas. H. Beal, Scio, Ohio; Louis C. Hopp, Cleveland, Ohio; Joseph Jacobs, Atlanta, Ga.; A. R. L. Dohme, Baltimore, Md.; O. Oldberg, Chicago, Ill.; C. R. J. Kellam, M.D., Heron Lake, Minn.; R. W. Williams, Three Rivers, Canada; R. G. Eccles, M.D., Brooklyn, N. Y.; Chas. Rice, New York, N. Y.; Virgil Coblentz, New York, N. Y.; W. C. Alpers, New York, N. Y.; Edw. Kremers, Madison, Wis.

The subjects referred are as follows:

1. Liquor Selling in the Drug Stores. This was the subject of a paper read before the American Pharmaceutical Association at its last annual meeting, held in Montreal in August, 1896, by Mr. H. M. Whitney, of Massachusetts. It is to be hoped the paper will receive that attention that its merits and the importance of the subject demands, and that physicians may come to the next meeting of the AMERICAN MEDICAL ASSOCIATION prepared to discuss the points that have been raised, both pro and con.

2. The following Sections from the Report of the Committee on Revision of the United States Pharmacopoeia of the AMER-

ICAN MEDICAL ASSOCIATION: 15. Dismiss spiritus frumenti and spiritus vini gallici from the United States Pharmacopœia. 16. Dismiss vinum album and vinum rubrum, and all medicated wines, from the United States Pharmacopœia. 17. Dismiss all tinctures having a fluid extract of the same drug official, and all fluid extracts having a tincture of same drug official, and substitutes for such tinctures and fluid extracts, 50 per cent. tinctures under a distinctive title. 22. Return to potassium sulphate as a diluent in making Dover's powder, in place of sugar of milk, used since 1880.

In addition to the above points referred by the American Pharmaceutical Association, the Special Committee on National Legislation of the American Pharmaceutical Association will bring up for joint debate the question: Would it be advisable to advocate legislation in each State making it obligatory for the manufacturers of medicine, whether advertised to the laity, or to the medical profession, or put up in packages for sale to the public, or for physicians dispensing, to publish the exact working formulas and methods of manufacturing all such medicines, in some well-known periodical, or other publication of ready reference, or in some bulletin devised for the purpose, or, when practicable, on the labels of such medicines, so that all may be able to ascertain their exact composition? The object of this proposition is to protect the public from imposition by designing persons who make it a business to delude the public by promising cures for serious diseases by the administration of remedies that have been long ago tested for such affections and proved valueless, or offering alleged new remedies for similar purposes which may or may not be valuable, but whose true merits it is impossible to understand without a careful study of the claims made for them, which is impossible under the present system of secrecy, or semi-secrecy, with which they are enveloped by those who manufacture and market them.

F. E. STEWART, M.D.

Chairman of the Delegation, and Chairman of the Special Committee on National Legislation of the American Pharmaceutical Association.

SOCIETY NEWS.

The Twelfth International Medical Congress.

EXECUTIVE COMMITTEE AND COMMITTEES OF SECTIONS.

Executive Committee.—President, Prof. J. Th. Klein, Moscow; Vice-President, Prof. A. J. Kojewnikow, Moscow; Treasurer, Prof. N. Th. Filatow, Moscow; Secretary-general, Prof. W. K. Roth, Moscow; Secretaries, Profs. P. J. Diakonow, J. J. Neyding, W. A. Tikhomirow, Moscow; Members, Profs. S. S. Korsakow, J. F. Ognow, B. D. Cherwinsky, Moscow.

SECTION 1.—ANTHROPOLOGY, NORMAL ANATOMY AND HISTOLOGY.

1. *Anthropology.*—President, Prof. D. N. Anoutchine, Moscow. Members of Committee, Profs. N. M. Maliew, Tomsk; A. J. Tarcnetsky, St. Petersburg; A. A. Tikhomirow, Moscow. Secretaries, A. A. Ivanovsky, curator of museum of anthropology, University of Moscow; S. A. Weissenberg, M.D., Elizabethgrad; N. W. Guiltchenko, M.D., St. Petersburg; A. D. Elkind, M.D., Varsovie.

2. *Normal Anatomy.*—President, Prof. D. N. Zernow, Moscow. Members of Committee, Profs. M. A. Tikhomirow, Kiev; A. M. Fortunatow, Kazan; M. D. Tchaoussow, Varsovie.

3. *Normal Histology.*—President, Prof. J. F. Ognow, Moscow. Members of Committee, Prof. K. A. Arnstein, Kazan; Prof. J. M. Doghiel, Kazan; Prof. T. N. Zavarykine, St. Petersburg; Prof. A. A. Korotnew, Kiev; Prof. N. K. Koulchitsky, Kharkow; Prof. M. D. Lawdowsky, St. Petersburg; Prof. S. M. Loukianow, St. Petersburg; Prof. P. J. Mitrophanow, Kharkow; Prof. F. B. Oviannikow, St. Petersburg; Prof. A. E. Smirnow, Tomsk; N. K. Tchermak, preparator attached to the chair of histology in the academy of Military Medicine, St. Petersburg; Prof. P. Schifferdecker, Bonn. Secretary, M. M. Gardner, asst. prosector, University of Moscow.

SECTION 2.—PHYSIOLOGY AND PHYSIOLOGIC CHEMISTRY.

Presidents, Prof. J. M. Setchenow, Moscow; Prof. A. D. Boulyguinsky, Moscow; Prof. L. Z. Morokhovetz, Moscow.

Members of Committee, Prof. J. M. Doghiel, Kazan; J. A. Kabloukow, agrégé, Moscow; Prof. N. A. Mislavsky, Kazan; S. A. Salazkine, M.D., Kiev. Secretaries, P. G. Statkevitch, M.D., Moscow; W. S. Goulévitch, preparator attached to the chair of physiologic chemistry, University of Moscow; P. A. Samoilow, agrégé, Moscow.

SECTION 3.—GENERAL PATHOLOGY AND PATHOLOGIC ANATOMY.

Presidents, Prof. A. B. Vogt, Moscow; Prof. M. N. Nikiforow, Moscow. Members of Committee, Prof. K. G. Blumberg, Kazan; Prof. W. L. Brodowsky, Varsovie; N. N. William, M. D., Moscow; A. W. Grigoriew, agrégé, St. Petersburg; G. N. Dourdoufi, prosector, Moscow; D. P. Kischensky, prosector, Moscow; W. C. Lindemann, M.D., Moscow; Prof. S. M. Loukianow, St. Petersburg; Prof. N. M. Lubimow, Kazan; A. G. Mamourowsky, agrégé, Moscow; Prof. N. W. Petrow, St. Petersburg; Prof. W. W. Podwyssotsky, Kiev; J. O. Siawtsillo, M.D., Moscow; A. J. Taliantsew, agrégé, Moscow; Prof. N. G. Ouchinsky, Varsovie. Secretary, G. N. Dourdoufi, Moscow.

SECTION 4, A.—GENERAL THERAPEUTICS.

Presidents, Prof. M. P. Tchérinow, Moscow; Prof. N. A. Mitropolsky, Moscow. Members of Committee, Prof. S. S. Botkins, St. Petersburg; G. N. Gabritchevsky, agrégé, director of institute of bacteriology, Moscow; J. O. Goldendach, physician-in-chief of the hospital of the Emperor Alexander III; Prof. K. K. Degio, Iouriev; Prof. M. K. Zienets, Varsovie; Prof. A. Ch. Kouznetsov, Kharkow; Prof. S. W. Lévaschew, Kazan; Prof. J. N. Obolensky, Kharkow; Prof. W. N. Sirotnine, St. Petersburg; S. A. Smirnow, M.D., Moscow; Prof. A. J. Stcherbakow, Varsovie. Secretaries, N. S. Kischkine, agrégé to the children's clinic, University of Moscow; P. S. Oussow, M.D., Moscow.

SECTION 4, B.—PHARMACOLOGY.

President, Prof. V. S. Bogoslovsky, Moscow. Members of Committee, Prof. R. W. Kobert, Iouriev; Prof. S. D. Kosturine, St. Petersburg; G. G. Storjew, M.D., Moscow; S. J. Tchirvinsky, agrégé, Moscow. Secretaries, E. O. Grœulich, assistant at the Pharmacological Institute, University of Moscow; J. J. Kalning, preparator at the Pharmacological Institute, University of Moscow; D. M. Stcherbatchew, preparator at the Pharmacological Institute, University of Moscow.

SECTION 4, C.—PHARMACOGNOSY AND PHARMACY.

President, Prof. W. A. Tikhomirow, Moscow. Members of Committee, N. A. Alexandrow, agrégé, veterinary school, Iouriev; E. A. Althausen, M.Ph., editor "Le Pharmacien," Moscow; H. A. Antouchévitch, M.Ph., editor "Le Pharmacien," Moscow; Prof. D. L. Dawidow, Varsovie; J. P. Joltzinsky, M.Ph., preparator attached to the chair of agricultural chemistry, Moscow; K. J. Kresling, M.Ph., editor "Journal of Russian Pharmacy," preparator in the institute of Experimental Medicine; N. J. Krommer, agrégé, Iouriev; Prof. M. W. Nentsky, St. Petersburg; Prof. A. B. Poehl, St. Petersburg; Prof. S. A. Pribytek, St. Petersburg; Prof. M. P. Serguiew, Kazan; Prof. J. K. Trapp, St. Petersburg; W. K. Ferrein, M.Ph., President Society of Pharmacists, Moscow; A. W. Ferrein, M.Ph., Moscow; Prof. R. W. Kobert, Iouriev; A. D. Tchirikow, Kharkow; E. S. Schatsky, agrégé, Kazan. Secretaries, E. A. Keyser, provisor, preparator attached to the chair of pharmacy and pharmacognosy, University of Moscow; A. G. Klinge, provisor, director of Leforto Pharmacy, Moscow.

SECTION 5.—INTERNAL DISEASES.

Presidents, Prof. A. A. Ostrooumow, Moscow; Prof. K. M. Pavlinow, Moscow; Prof. B. D. Schervinsky, Moscow. Members of Committee, Prof. K. K. Degio, Iouriev; Prof. S. W. Lévaschew, Kazan; Prof. J. N. Obolensky, Kharkow; Prof. W. P. Obratzow, Kiev; Prof. L. W. Popow, St. Petersburg; Prof. W. N. Sirotnine, St. Petersburg; Prof. B. B. Tschirkow, Kiev. Secretaries, A. P. Langowoy, agrégé, Moscow; E. W. Gauties-Dufayet, assistant to the therapeutic clinic, University of Moscow; A. A. Ansérow, assistant in the therapeutic clinic, University of Moscow.

SECTION 6.—DISEASES OF CHILDREN.

Presidents, Prof. N. T. Filatow, Moscow; Prof. N. S. Korsakow, Moscow. Members of Committee, Prof. A. A. Anoufriew, Varsovie; Prof. Prince P. M. Argoutinsky-Dolgoroukoff, Kazan; Prof. N. J. Bystrow, St. Petersburg; Prof. M. D. Ponomarew, Kharkow; K. A. Raukhfuss, physician-in-chief of the Prince of Oldenburg Hospital for Children, St. Petersburg; W. M. Rojansky, agrégé, Kazan; Prof. N. A. Tolmatshew, Kazan; Prof. J. B. Troitsky, Kiev; Prof. B. E. Tchernow, Kiev. Secretaries, Drs. W. J. Gold, N. N. Neypert, A. A. Strachounsky, Moscow.

SECTION 7.—NERVOUS AND MENTAL DISEASES.

Presidents, Profs. A. J. Kojewnikow, S. S. Korsakow, W. K.

Roth, Moscou. Members of Committee, Prof. J. A. Amfimow, Kharkow; Prof. B. M. Bekhtérew, St. Petersburg; Prof. L. O. Darkchevitch, Kazan; Prof. P. J. Kovalevsky, rector Varsovie University; J. P. Merjéevsky, academician, St. Petersburg; Prof. O. O. Motchoutkovsky, St. Petersburg; Prof. J. G. Orchansky, Kharkow; Prof. M. N. Popow, Tomsk; Prof. N. M. Popow, Kazan; Prof. Runeberg, Helsingfors; Prof. J. A. Sikorsky, Kiew; Prof. Soelan, Helsingfors; Prof. W. F. Tchige, Iouriew; Prof. A. E. Stcherbak, Varsovie. Secretaries, L. S. Minor, agrégé, Moscou; W. P. Serbsky, agrégé, chief of the clinic of mental diseases, Moscou.

SECTION 8.—DERMATOLOGY AND VENEREAL DISEASES.

Director, Prof. A. J. Pospélow, Moscou; Members of Committee, Prof. A. J. Brouew, Kharkow; K. M. Watraschewsky, physician-in-chief St. Lazare Hospital, Varsovie; Prof. A. G. Gay, Kazan; G. M. Herzenstein, agrégé, St. Petersburg; P. J. Gratziansky, agrégé, St. Petersburg; S. O. Givout, assistant to physician-in-chief Golitzine Hospital, Moscou; J. A. Maew, agrégé, physician-in-chief Kalinkins Hospital, St. Petersburg; S. E. Molodenkow, physician-in-chief Miasnitskaia Hospital, Moscou; Prof. E. S. Obratzow, Tomsk; O. W. Petersen, professor in the medical clinic of the institute of the Grand-duchesse Hélène Pavlovna, St. Petersburg; Prof. G. Smirnow, Helsingfors; S. A. Smirnow, formerly director of Caucasus mineral waters; Prof. M. J. Stoukovenkow, Kiew; Prof. W. M. Tarnovsky, St. Petersburg; T. K. Trapeznikow, agrégé, St. Petersburg; Prof. E. G. Tautvetter, Varsovie. Secretaries, Mme. E. R. Wyschinkaia, physician to the city ambulance for women, Moscou; A. P. Zabolotsky, interne St. Catharine Hospital, Moscou; A. N. Zabolotsky, interne Miasnitskaia Hospital, Moscou; W. P. Krasnoglazow, principal interne Miasnitskaia Hospital, Moscou; S. F. Kracht, assistant in the dermatologic clinic University of Moscou; G. A. Kuzel, interne in the dermatologic clinic University of Moscou; A. K. Likhatchew, interne in the dermatologic clinic University of Moscou; J. M. Malychew, interne Miasnitskaia Hospital, Moscou; L. N. Mourzine, interne Miasnitskaia Hospital Moscou; N. W. Nicouline, interne dermatologic clinic, University of Moscou; J. A. Orlov, interne dermatologic clinic, University of Moscou; J. J. Priklonsky, interne, Miasnitskaia Hospital, Moscou; W. G. Pouzenkine, ex-assistant dermatologic clinic, University of Moscou; A. J. Rosenkwist, interne Miasnitskaia Hospital, Moscou; W. M. Sérébriakow, physician to the city ambulance for women, Moscou; N. S. Spéransky, interne, Miasnitskaia Hospital, Moscou; A. D. Stépanow, interne Kalinkins Hospital, St. Petersburg; N. W. Tvéritinow, interne St. Catharine Hospital, Moscou; A. P. Oustinow, physician to the city ambulance for women, Moscou; N. P. Fiviesky, interne, Miasnitskaia Hospital, Moscou; A. A. Vogeler, M.D.; A. N. Tchernogoubow, interne Miasnitskaia Hospital, Moscou; M. D. Fokine, formerly assistant in dermatologic clinic, Kiew University.

SECTION 9.—SURGERY.

Presidents, Profs. A. A. Bobrow, L. L. Levchine, T. J. Sinitzsyne, Moscou. Members of Committee, Prof. F. K. Bornhaupt, Kiew; Prof. M. A. Wassiliw, Varsovie; Prof. N. A. Wéllaminow, St. Petersburg; Prof. W. F. Grube, Kharkow; Prof. P. J. Diakonow, Moscou; Prof. P. J. Morozow, Kiew; Prof. J. N. Novatski, Moscou; Prof. L. W. Orlov, Kharkow; Prof. E. B. Pawlow, St. Petersburg; Prof. W. A. Razoumowsky, Kazan; Prof. W. A. Ratimow, St. Petersburg; T. A. Rein, prosector, Moscou; Prof. E. G. Salistchew, Tomsk; Prof. N. B. Sklifossovsky, director of the clinical institute for physicians founded by the Grand Duchess Hélène Pavlovna, St. Petersburg; Prof. J. K. Spijarni, Moscou; Prof. M. S. Soubbotine, St. Petersburg; Prof. A. S. Tauber, Varsovie. Secretaries, T. A. Rein, prosector, Moscou; S. T. Dérujinsky, M.D., Moscou.

SECTION 9, A.—DISEASES OF THE TEETH.

President, T. A. Rein, prosector, Moscou. Members of Committee, same as for Section on Surgery.

SECTION 10.—MILITARY MEDICINE.

President, Prof. L. L. Levchine, Moscou. Members of Committee, A. J. Bieliaew, M.D., associate inspector-in-chief of military medical service, St. Petersburg; L. A. Zaoustinsky, inspector of the military service, district of Moscou; W. S. Koudrine, inspector-in-chief of the medical service of the navy, St. Petersburg; B. B. Pachoutine, chief of the military medical academy, St. Petersburg; J. T. Raptchewsky, agrégé, St. Petersburg; A. A. Remmert, inspector-in-chief medical military service, St. Petersburg. Secretary, S. E. Beresowsky, agrégé, assistant, surgical clinic, Moscou University.

SECTION 11.—DISEASES OF THE EYE.

Presidents, Profs. A. A. Krukow, T. O. Evetsky, Moscou.

Members of Committee, Prof. E. W. Adamuck, Kazan; Prof. P. N. Barabaschew, Kharkow; Prof. L. C. Belliarminow, St. Petersburg; W. T. Wagner, M.D., Odessa; Prof. W. von Wahlfors, Helsingfors; Prof. L. L. Hirschmann, Kharkow; Prof. G. A. Donberg, St. Petersburg; S. N. Lojetchnikow, M.D., Moscou; Count J. Ch. Magavly, physician-in-chief Ophthalmologic hospital, St. Petersburg; Prof. E. P. Raehlmann, Iouriew; Prof. A. W. Khodine, Kiew. Secretary, S. S. Golovine, agrégé, assistant in ophthalmologic clinic, University of Moscou.

SECTION 11, A.—DISEASES OF THE EAR.

President, S. T. von Stein, agrégé, Moscou. Members of Committee, W. R. Beyer, M.D., Moscou; Th. Heiman, M.D., Varsovie; M. S. Jirmounsky, M.D., Moscou; E. N. Malutine, M.D., Moscou; W. N. Okounew, M.D., St. Petersburg; S. S. Préobrajensky, agrégé, Moscou; Fr. Voss, M.D., Riga; A. Chr. von Schwanebach, M.D., St. Petersburg. Secretary, K. J. Kaspariantz, M.D., Moscou.

SECTION 12, B.—DISEASES OF THE LARYNX AND NOSE.

President, E. M. Stépanow, agrégé, Moscou. Members of Committee, G. N. Boëw, M.D., Moscou; A. T. Biélaew, M.D., Moscou; B. W. Werkhovsky, agrégé, Moscou; N. M. Wolkovitch, agrégé, Kiew; A. E. Gaudring, M.D., Moscou; T. Ed. Hering, M.D., Varsovie; Prof. M. M. Lomikovsky, Kharkow; Prof. W. N. Nikitine, St. Petersburg; K. A. Raukhfuss, physician-in-chief infants' hospital of Prince of Oldenburg, St. Petersburg; Prof. N. P. Simanowsky, St. Petersburg; A. J. Sokolowsky, M.D., Varsovie; M. A. Fronchtein, M.D., Moscou; N. J. Skott, M.D., Moscou; A. W. Jakobson, M.D., St. Petersburg. Secretary, A. T. Biélaew, M.D., Moscou.

SECTION 13.—OBSTETRICS AND GYNECOLOGY.

Presidents, Profs. Makéyew and Snéguirew, Moscou. Members of Committee, Prof. A. P. Goubarew, Iouriew; Prof. A. J. Krassovsky, director obstetric hospital, St. Petersburg; Prof. J. P. Lazarévitch, St. Petersburg; Prof. A. J. Lébédew, St. Petersburg; J. M. Lwow, agrégé, Kazan; Prof. D. O. Ott, director obstetric institute, St. Petersburg; Prof. G. E. Rein, Kiew; B. B. Soutouguine, inspector medical service, St. Petersburg; Prof. J. T. Tolotchinow, Kharkow; Prof. N. N. Fénoménow, Kazan; Prof. P. A. Yassinsky, Kharkow; Prof. N. B. Yastrébow, Varsovie. Secretaries, W. F. Bobrow, agrégé, assistant in the gynecologic clinic, University of Moscou; N. J. Pobiédinsky, agrégé, assistant in the gynecologic clinic, University of Moscou; G. T. Matvéiew, assistant in the obstetric clinic, University of Moscou; J. J. Eichtmeyer, M.D., Moscou; G. D. Hume, Moscou.

SECTION 14.—HYGIENE, ETC.

Not yet published.

SECTION 15.—LEGAL MEDICINE.

President, Prof. J. J. Neyding, Moscou. Members of Committee, E. F. Belline, agrégé, Kharkow; A. J. Bogoslovsky, member of medical directory, Moscou; P. J. Zarine, member medical directory, Moscou; Prof. N. P. Iwanowsky, St. Petersburg; J. A. Krasnowsky, member of medical directory, Moscou; Prof. V. A. Légonine, Moscou; P. A. Minakow, prosector, University of Moscou; Prof. N. A. Obolonsky, Kiew; B. M. Ostrogglazow, chief of medical directory, Moscou; Prof. T. A. Patenko, Kharkow; J. J. Souslow, member of medical directory, Moscou. Secretaries, P. A. Minakow, prosector, University of Moscou; A. J. Zaborowsky, assistant prosector, University of Moscou.

Medico-Legal Society.—At the election held on Wednesday, Dec. 16, in New York City, the following officers were elected:

President, Hon. Jacob F. Miller, New York City; First Vice-President, Geo. L. Porter, Conn.; Second Vice-President, Albert Bach, Esq., N. Y. Vice-Presidents for the States, Territories and Provinces: Alabama, Judge Thos. W. Coleman, Montgomery. Alaska, Clarence Thwing, Sitka. Arizona, George Goodfellow, M.D., Tucson. Arkansas, H. C. Dunavant, M.D., Osceola. Austria, Prof. R. Krafft-Ebing, Vienna. Belgium, Dr. Jules Morel, Ghent. Brazil, Prof. Nina Rodrigues, M.D., Bahia. California, A. E. Osborne, M.D., Glen Ellen. Colorado, Prof. J. T. Eskridge, Denver. Connecticut, Judge A. M. Talmadge, Bridgeport. China, Harold Browett, Esq., Shanghai. Cuba, Dr. Venancio Zorilla, Havana. Dakota, N., O. W. Archibald, M.D., Jamestown. Dakota, S., John M. Harcourt, Steele. Delaware, Judge Ignatius C. Grubb, Wilmington. Denmark, Prof. Godeken, Copenhagen. District of Columbia, W. W. Godding, M.D., Washington. Dominion of Canada, Hon. A. G. Blair, Ottawa. England, William L. Orange, M.D., London. Ecuador, Senor J. M. P. Cammano, Washington. D. C. Florida, Dewitt Webb, M.D., St. Augustine. France, Victor Parent, M.D., Toulouse. Georgia, Richard J. Nunn, M.D.,

Savannah, Germany, Dr. H. Laehr, Berlin. Gautemala, Senor Rafael Montufar. Holland, Dr. P. A. H. Sweets, Vucht. Hungary, Staatsanwalt Em. V. Havas, Buda Pesth. Illinois, J. E. Owens, M.D., Chicago. Indiana, W. B. Fletcher, M.D., Indianapolis. Indian Territory, I. H. Bailey, M.D., Dexter. Iowa, Jennie M. Cowen, M.D., Davenport. Ireland, Conolly, Norman, M.D., Dublin. Italy, Enrico Ferri, M.D., Rome. Japan, Dr. J. Hashimoto, Tokio. Kansas, Judge Albert H. Horton, Topeka. Kentucky, Dr. D. W. Yandell, Louisville. Louisiana, I. J. Scott, M.D., Shreveport. Maine, Judge L. A. Emery, Ellsworth. Manitoba, D. Young, M.D., Selkirk. Maryland, Wm. Lee Howard, M.D., Baltimore. Massachusetts, Theo. H. Tyndale, Boston. Michigan, Prof. Victor C. Vaughan, Ann Arbor. Minnesota, T. Gold Frost, Esq., Minneapolis. Missouri, W. B. Outten, M.D., St. Louis. Mississippi, Dr. C. A. Rice, Greenville. Montana, Judge Wm. H. Francis, Missoula. Nebraska, Hon. John M. Thurston, Omaha. Nevada, S. M. Bishop, M.D., Reno. New Brunswick, Judge A. L. Palmer, St. John. Newfoundland, Dr. K. D. McKenzie, St. Johns. New Hampshire, Gran. P. Conn, M.D., Concord. New Jersey, Judge C. G. Garrison, Camden. New Mexico, Gov. Bradford L. Princes, Santa Fe. New South Wales, George A. Tucker, M.D. New York, Mrs. M. Louise Thomas, New York City. New Zealand, Prof. Frank G. Ogston, Dunedin. North Carolina, E. C. Smith, Esq., Raleigh. Norway, Dr. Harold Smedal, Christiania. Nova Scotia, Hon. Wm. S. Fielding, Ottawa. Ohio, R. Harvey Reed, M.D., Columbus. Oklahoma Territory, A. H. Simonton, M.D., Oklahoma City. Ontario, Daniel Clark, M.D., Toronto. Oregon, Ex-Chief Justice, Hon. Wm. P. Lord, Salem. Pennsylvania, J. B. Murdock, Pittsburg. Peru, Senor F. C. C. Zegarro, Washington, D. C. Portugal, Bettincourt Rodriguez, M.D., Lisbon. Quebec, Wyatt Johnson, M.D., Montreal. Rhode Island, Henry R. Turner, M.D., Newport. Russia, Prof. Dr. Mierzejewski, St. Petersburg. Saxony, Judge de Alinge, Oberkotzton Hof. Scotland, W. W. Ireland, Preston Pans, Edinburgh. Servia, Hon. Paul Savitch, Belgrade. Sicily, Prof. Dr. Fernando Puglia, Messina. Silesia, H. Kornfeld, M.D., Grotkau. South Carolina, J. W. Babcock, M.D., Columbus. Spain, Sig. A. M. Alv. Taladriz, M.D., Valladolid. Sweden, Prof. Dr. A. Winroth, Lund. Switzerland, Prof. Dr. L. Wille, Basle. Tennessee, Michael Campbell, M.D., Nashville. Texas, Dr. D. R. Wallace, Terrell. Utah, Frederick Clift, M.D., St. George. Vermont, Prof. A. P. Grinnell, Burlington. Virginia, William F. Drewry, Petersburg. Washington, J. W. Waughoo, M.D., Ft. Stellacom. West Virginia, F. M. Hood, M.D., Weston. Wisconsin, Dr. U. O. B. Wingate, Milwaukee. Secretary, Clark Bell, Esq., New York. Corresponding Secretary, Moritz Ellinger, Esq., New York. Assistant Secretary, Caroline J. Taylor, Connecticut. Pathologist, Paul Gibier, M.D., New York. Treasurer, Hon. Rastus S. Ransom, New York. Chemist, Geo. B. Miller, M.D., Philadelphia. Pa. Curator, F. R. Downs, M.D., Bridgeport, Conn. Toxicologist, Prof. W. B. McVey, Boston. Librarian, Margherita Arlina Hamm. Assistant Librarian, Judge Lewis J. Conlon, New York. Bacteriologist, G. Bettini di Moise, M.D., New York. Microscopist, Prof. Moses C. White, M.D., Connecticut. Trustees: Legal, for three years Ida Trafford Bell, to fill vacancy Jas. L. Bennett, Esq.; Medical, J. C. Maguire, M.D., New York. Counsellors, for three years, Rosalie Loew, Judge A. M. Tallmadge, Connecticut. Permanent Commission: Legal, Clark Bell, Esq., New York; Medical, Geo. L. Porter, M.D., Connecticut.

The Northern Tri-State Medical Association will meet in Fort Wayne, Ind., Jan. 19, 1897. The following papers will be read: Report of surgical cases, by Dr. W. D. Hamilton, Columbus, Ohio; The chromoscope, a new instrument useful as a ready test of color perception, by Dr. L. E. Maire, Detroit, Mich.; Some of the diseases of the lachrymal apparatus, by Dr. A. E. Bulson, Jackson, Mich.; Ocular manifestations of syphilis, by Dr. Kent. K. Wheelock, Fort Wayne, Ind.; Diagnosis of syphilis, by Dr. Carl Proegler, Fort Wayne, Ind.; Ectopic gestation with retained fetus, by Dr. L. H. Dunning, Indianapolis, Ind.; Errors of refraction as an etiologic factor in the production of blepharitis marginalis, by Dr. A. E. Bulson, Jr., Fort Wayne, Ind.; Posterior deviations of the uterus, by Dr. J. H. Carstens, Detroit, Mich.; Some thoughts on the treatment of incipient phthisis, by Dr. Budd Van Sweringen, Fort Wayne, Ind.; A year's acquaintance with appendicitis, by Dr. H. O. Walker, Detroit, Mich.; The radical cure of hernia, an improved method, by Dr. Hal. C. Wyman, Detroit, Mich.; The doctor as a witness, by Dr. D. C. Chapman, Toledo, Ohio; Surgical

treatment of senile gangrene, by Dr. E. B. Harrison, Napoleon, Ohio; Some suggestions on the treatment of the heart, by Dr. W. E. Dickey, Tiffin, Ohio; Bacteriology of the vaginal secretions, by Dr. C. U. Smith, Toledo, Ohio. Papers will be read by Drs. W. H. Myers, Fort Wayne, Ind.; D. W. Fenton, Reading, Mich.; Hausencamp, Toledo, Ohio, and Curran Pope, Louisville, Ky.

NECROLOGY.

JOHN C. HALL, M.D., of Medical Lake, Wash., died Nov. 29, aged 76 years. Dr. Hall was a native of Vermont. He graduated from the medical department of Harvard University and afterward located at Monroe, Wis. At the commencement of the civil war he entered the army as assistant surgeon of the Sixth Wisconsin Infantry, and at the close of the war was chief surgeon of Gen. Bragg's famous "Iron Brigade." He then returned to Wisconsin and engaged in general practice. He served one term in the Wisconsin State Senate and also served for many years as a member of the Board of United States Pension Examiners. In 1891 Dr. Hall and his family moved to Medical Lake, Wash., where he lived a retired life. At the time of his death he was president of the Board of United States Pension Examiners at Spokane, Wash.

WILLIAM NEWMAN, M.D., of Brooklyn, died Dec. 31, 1896, aged 76 years. He was a native of England, came to this country about 1846 and one year later received an honorary M.D. from the State Medical Society of New York. He practiced in New York city during the greater part of his professional life, going to Brooklyn, about 1890. He was a member of the New York County Medical Society. The cause of his illness was valvular lesion of the heart.

Prof. EMIL DuBOIS-REYMOND, the distinguished psychologist of Berlin, died December 26. He was born in that city in 1818. He began studying theology, but abandoned this for natural science. After a sojourn at Bonn he returned to Berlin and studied anatomy and physiology under Jean Muller, and on his advice undertook his researches in animal electricity, on which subject he published several works. In 1868 he replaced his master as professor of physiology at the University of Berlin, and was named in 1869, Perpetual Secretary of the Berlin Academy of Sciences.

CHARLES HEITZMANN, M.D., Vienna, 1859, died in Rome, Italy, Dec. 6, 1896, aged 60 years. He was a native of Hungary and a practitioner of New York City, where he was a neurologist of note, and for three years president of the German Medical Society.

LOUIS LEON DESAULNIERS, M.D., a prominent character in Canadian public life, is the subject of a brief memorial note in the *Montreal Medical Journal*. "We regret to have to record the death of Dr. Desaulniers, which occurred on October 31 last, after a few days' illness. He was born at Yamachiche, P. Q., in 1823, and graduated in medicine from Harvard University in 1846. He was inspector of prisons and asylums for twenty-eight years and for many years chairman of that board. He was well known in political circles, having been elected member of the Canadian House of Assembly in 1854, and member of the House of Commons in 1867 and again in 1878. He was a Justice of Peace and also a Lieut.-Colonel of Militia."

JAMES HEDDEN TRUMBULL, M.D., died in Iquique, Chili, South America, November 12. He was a graduate of Yale, 1848, and of the College of Physicians and Surgeons, N. Y., 1852. He immediately went to Chili after graduation and almost from the first became prominent in his profession.

JAMES S. SERRIN, M.D., Medical College of Indiana, 1881, died in Indianapolis, December 13, aged 65.

SELDON W. JONES, M.D., Bowdoin, Me., 1853. A native of Boston, Mass., died December 16, in Leavenworth, Kan., where he had long resided.

FREDERICK ARNOLD MANNING, M.D., born in Eddyville, Ind., May 4, 1859, died in Denver, Colo., of tuberculosis, Dec. 3, 1896. He was a graduate of Yale College in 1881 and of the College of Physicians and Surgeons, N. Y., 1884. After serving on the surgical house staff of the N. Y. Hospital he practiced a while in New York City and served on the visiting staff of several hospitals but was obliged in 1895 to seek recuperation of his health in Colorado. He was a member of the N. Y. County Medical Association. His remains were interred in South Coventry, Conn.

GEORGE URQUHART, M.D., Jefferson Medical College, 1850, died at his residence in Wilkesbarre, Pa., Dec. 19, 1896, aged 68 years.

JAMES W. COLE, M.D., Jefferson Medical College, 1881, died of pneumonia Dec. 15, 1896, aged 35 years.

JAMES W. ROBINSON, M.D., Jefferson Medical College 1889, died in Philadelphia, Pa., Dec. 13, 1896, aged 51 years. For a number of years he was pastor in a Presbyterian church.

MISCELLANY.

R. M. Eames, M.D., of Seattle, has been appointed a member of the Washington State Board of Health and Bureau of Vital Statistics.

The "General Practitioner."—The *General Practitioner* of St. Louis has been sold to Dr. James Moores Ball, who will publish it in connection with the *Tri-State Medical Journal*. The consolidated publication will bear the name of *Tri-State Medical Journal and Practitioner*.

A Basis for Expert Opinions.—In an action to recover damages for maltreatment alleged to have resulted in a miscarriage, the supreme court of Wisconsin says, Nov. 24, 1896, *McKeon v. C., M. & St. P. Ry. Co.*, that it perceives no error in allowing the experts, who had heard the plaintiff give part of her testimony in court, and then heard the balance of her testimony read to them by the court reporter, to testify what, in their opinions, was the cause of the miscarriage, assuming the testimony of the plaintiff to be true.

The Scotograph.—This is a desk so arranged that a couple of rods cross the writing table from side to side. It is designed for the use of the blind, who write between the rods while the paper is held and moved along by an ingenious device. It is much simpler than the typewriter for those unaccustomed to it, who have learned to write before they became blind. In some recent experiments with it at the Blind Asylum at Amsterdam, children of 6 learned very rapidly to write with the assistance of the scotograph, which is the invention of Dr. Nord, but it is especially designed for the use of scholars, etc., who have become blind late in life and still wish to continue their literary activity.—*Annales de la Soc. Med.-Chir. de Liège*, November.

Dr. Squibb's Misfortune.—It is with great regret we learn that Dr. Edward R. Squibb of Brooklyn, to whom the medical profession has in the past owed so much, was recently obliged to submit to amputation of his left hand in consequence of an affection which threatened blood poisoning. The anesthetic was administered by his own hand. Dr. Squibb seven years since passed the allotted limit of three-score and ten, but is yet active and interested in all that pertains to medicine and medical science and it is to be hoped that he will be spared to us for many years to come. It is with profound sorrow that we hear of his affliction, which is really a sequel to severe injuries received thirty years ago from the explosion of a vessel of ether.—*Medical Age*.

Not Insurer of Quality of Food.—A restaurant keeper, according to the decision of the supreme court of Illinois, handed down Nov. 9, 1896, in the case of *Sheffer v. Willoughby*, is not an insurer of the quality of the food which he serves. If he

fails to exercise ordinary care in the furnishing of food to his patrons, or conducts his business in a careless or negligent manner, and damage results, he is liable therefor. But as to food served at a restaurant, such as oysters, ice cream and the like, the court says that it is not aware that there ever existed a rule establishing liability similar to the one which makes innkeepers presumptively liable for losses which happen to the goods of their guests.

Shorthand for Medical Men.—Mr. William Thomson, F.R.S.I., President of the Royal College of Surgeons in Ireland, in a recent address gave his estimate of the value of stenography to professional men as follows: "I can not leave this part of my address without telling you of another advantage which you ought to acquire. I allude to shorthand. Last year we held in London the first meeting of the Society of Medical Phonographers, under the presidency of the distinguished physician, Dr. Gowers. That society now numbers nearly three hundred members. We have a monthly medical journal, printed altogether in shorthand, and full of admirable information. I can not now enter as fully as I should wish into the great benefits which a knowledge of this art will confer upon you. I am glad to know that there are many in this school who have acquired it, and I urge others to set about learning it. Do not be frightened by its apparent difficulty. I assure you that it is simplicity itself if you set about it properly. It will save you in the end three-fourths of your time in note-taking, and you will soon find out what that means. I have written it since I was a lad, and it has enabled me to do with ease duties which I could not have accepted in an otherwise laborious life."—*The Scalpel*, December.

Admissibility of Expert Evidence.—Who is entitled to be considered as an expert in regard to any question of science or skill, the court of errors and appeals of New Jersey holds, Nov. 16, 1896, in *New Jersey Zinc and Iron Co. v. Lehigh Zinc and Iron Co.*, can not be determined by any precise rule, but from the nature of the case, must be left very much to the discretion of the trial judge; and his decision is conclusive unless clearly shown to be erroneous in matter of law. The interest of an expert witness affects the weight, not the legality, of his testimony. Books of science are generally inadmissible in evidence to prove the opinions contained in them; but, if a witness refers to them as an authority for his own opinions, they may be received for the purpose of contradicting him. The admission of almanacs, mortuary tables and perhaps some other scientific publications of undisputed accuracy, seems to form an exception to the rule.

Nervous Functions of the Suprarenal Capsules.—Dominicis has already published various studies of the functions of the suprarenal capsules, and a recent article by him in the *Gazzetta d. Osp. e d. Clin.* of November 22, throws new light upon their connection with the nervous system. The experiments he describes on dogs and rabbits consisted in the transplantation of one capsule, after ligating its pedicle, to the internal and anterior surface of the kidney, leaving its point of attachment intact. The animal remained in the same health as before. Ten to fourteen days later, he removed the other capsule, and in every case the animal died in three hours with the same symptoms as when both capsules are removed at once. The transplanted capsule showed no traces of degeneration, anatomically nor histologically, and seemed to be perfectly normal. Its function, however, was evidently suspended, and it was unable to take the place of the other capsule when it was removed, as occurs in the case of glandular organs with an internal secretion, when they are transplanted or ingrafted, the thyroid gland for instance. He adds his experience that section of the spinal cord below the level of the capsules invariably retards death for eighteen to twenty-six hours when both capsules are removed at once. These facts demonstrate that we must look elsewhere than to an exclusively glandular function in ascribing a rôle to the suprarenal capsules.

Cruelties Toward Deformed Children.—The lame, the halt and the blind have little consideration in this world; how they will come off in the next is a matter for conjecture. Great riches are subscribed in England for charitable purposes, but it is beyond understanding why an institution could not readily be found for the poor little daughter of Annie Sheldon, who is now doing her three months for sending the child out to beg. It was stated that she "had deformed hands and feet like lobster claws." Nothing is more revolting than the exposure of wounds and deformities, especially when they serve for begging purposes. So thought Mr. De Rutzen, who was horrified by the fact that no institution could be found to take her without money; he thought that such a society as the National Society for the Prevention of Cruelty to Children might stretch a point in this case. To the surprise of all, Mr. Moreton Phillips stated the society was not rich, but was £13,000 in debt; this seems remarkable after so much has been done for it, and such a society can hardly commend itself to those who always contrive to live within their means. If we all worked on the same principle what would become of us. A private society with an income of £60,000 derived from the charitable, should keep out of debt and set an example to smaller ones. Perhaps the N. S. P. C. C. is doing too much and is like the little pig who tried to grunt before it could squeak.—*The Scalpel*, December.

Why Morton Failed.—It is the feeling of many medical men that the failures of Morton and of Jackson to score a greater success in the introduction of ether-anesthetization were due to the intrusion of the mercenary element in the matter. A letter just published in the *Boston Medical and Surgical Journal*, from the pen of Dr. Wm. Henry Thayer, formerly of Brooklyn and still earlier of the old Berkshire Medical School, brings out this feature in an unmistakable light, as follows: "In 1846 I was admitting physician to the Massachusetts General Hospital, saw the first administration of ether there and have a vivid recollection of the professional interest in the successful experiment. If Wm. T. G. Morton had presented the subject to the medical profession in the manner in which scientific men and physicians are accustomed to publish a discovery or an invention—as something that belongs to science—making no concealment or false pretence, the credit of his discovery would have been unanimously awarded to him. But his experiments were purely in mercantile interest. He wished to conceal the nature of the substance he was using. He came to the hospital surgeons with a false statement. He had colored the ether and stated that it was a composition whose ingredients were his own secret. He called it 'letheon.' He wished to secure the endorsement of the medical profession, but reserve for himself control over its use. Medical men surmised that it was simply sulphuric ether, which he was soon obliged to allow. There is no question that the use of sulphuric ether as an anesthetic at that time was due to the enterprise of Morton; and he would never have found it necessary to make any claim for the credit of it, if he had conducted himself honorably in relation to it."

An Accident of Tubal Pregnancy.—According to the *Scalpel* for December, at the last meeting of the West London Medico-Chirurgical Society, Mr. Mansell Moullin read a paper on "Intraperitoneal Hemorrhage in Connection with Tubal Pregnancy." Arrest of the fertilized ovum in the Fallopian tube was of much more frequent occurrence than was generally supposed, and was the most common cause of hemorrhage in the peritoneal cavity. Hemorrhage was not necessarily due to rupture of the tube. More frequently a more or less gradual loss of blood took place from the "ostium abdominale," and thus slowly effused, coagulated with the formation of a tumor. In some instances the tumor was limited by the neighboring organs, bound together by adhesive peritonitis. In other

instances the outer layer of the clot became organized, constituting a limiting membrane, as pointed out by Mr. Taylor of Birmingham. These conditions might be combined. As a rule the hemorrhage occurred at a very early date, within from ten to fourteen days from the arrest of the ovum in the tube. The ovum almost invariably perished at the same time. Dr. Mansell Moullin then drew attention to the leading symptoms of this condition, illustrating them by reference to cases which had been under his care in the West London Hospital, and urged the advantages of early operation in all cases where a considerable hemorrhagic tumor was present.

Accident Insurance in Relation to Physicians.—A recent *Bulletin* of the Fidelity and Casualty Company of New York refers to the fact that two other accident insurance companies have followed the course taken by it in raising the rate on physicians and surgeons. The company years ago became satisfied that these useful men do not properly belong in the preferred class, and rated them accordingly; they are exposed to septic poisoning from slight scratches or cuts, harmless in themselves, and "a doctor can not well do without transportation and he becomes the victim of that most productive instrument of disabling injuries, the horse, which, by runaway or collision, is responsible for more claims upon accident companies than any other single cause we know of." The insurance editor of the *Independent*, in this relation, treats of the hazards of the bicycle, a means of locomotion so largely used by our profession, as a question that is still undetermined among the companies. It says the possibilities of injuries are always against the cyclist. Necessarily one assumes exposure to a special class of hazards when he mounts the wheel, but he escapes some others; thus, he can not then be injured by being a passenger on any public conveyance, nor can the ceiling fall on him. Mutual accident companies have been somewhat disturbed about the assumed additional risk and are disposed to either put an extra upon general policies, or make a deduction in case the injury occurs while wheeling; but the stock companies have taken no united action, and the Fidelity Company has not found it necessary to take any action, saving that racing, on track or on road, is not covered. As yet the hazard, while real, has not assumed such relative proportions as to make any action seem needful.

Etiology of Cancer.—The articles presented and the discussions at the recent Italian Surgical Congress agree that up to the present our knowledge of the cause of cancer is limited to the fact that certain bodies are found in malignant neoplasms and nowhere else, which produce general inflammation when inoculated into rabbits, guinea pigs and mice, and neoplastic formations in the larger animals. They resemble the blastomycetes morphologically, and show the cellulose reaction like them when inoculated into animal tissues, which demonstrates that they are not evolved from the degeneration of the tissues. They are always found also accumulated around the edges of the neoplasm, where the vital growth is most prolific and never in the degenerated elements of the center. They stain by certain methods and taken either from man or animals are readily cultivated. The blastomycetes produce in man and animals septicemia, suppurations and chronic inflammatory neoplasms of the granuloma type, but so far, neither cancer nor sarcoma has been produced by them experimentally, and until we are able to produce the same neoplasm experimentally in animals, we are not justified in assuming that these bodies are the actual cause of the neoplasm, and this has not been accomplished to date. Roncali stated that the blastomycetes can not be regarded, however, as casual accompaniments of neoplasms, as they are always found in the younger peripheral parts, associated with karyokinetic formations and that their distribution in the cells and connective tissue tends to prove their genetic connection with the neoplasm. He also asserted that certain

kind of ferments have produced experimentally in dogs chronic tumors with the same characteristics as in man. He is inclined to deny the existence of a nucleus in the ferment cell, but others stated that this has only a botanical significance, and may vary with different kinds of ferments. It was generally conceded, however, that the almost invariable presence of these bodies in malignant neoplasms, their frequency in the latest growing parts and their excessive numbers in neoplasms of especially rapid evolution are facts of great etiologic significance.—*Cbl. f. Chir.*, December 12.

Construction of an Exemption Law.—The fifth section of the New Jersey law of 1894, found on page 354 of Laws of 1894, exempts "all colleges, academies seminaries of learning, . . . buildings used as asylums or schools for the care, cure, nurture, maintenance and education of feeble-minded or idiotic persons and children, provided such institutions are duly incorporated under the laws of this State, and the land whereon the same are situate, necessary to the fair use and employment thereof, not exceeding five acres for each one, the furniture thereof and the personal property used therein," etc. Under this law, the supreme court of New Jersey holds, in the case prosecuted by the Home for the Education and Care of Feeble-minded Children against the Collector of the Township of Landis, Nov. 5, 1896, that the foregoing institution is entitled to exemption from taxation for every building used for the purposes of its creation, and also for so much of the land upon which each building is erected as is necessary to its fair use and enjoyment, not in any case exceeding five acres to the building. The assessor had considered that all that he ought to exempt under the law was five acres and the buildings thereon, though it did not appear that five acres could be so set off as to contain all the buildings on the 120-acre tract owned by the institution.

Cincinnati.

THE STATE BOARD OF MEDICAL REGISTRATION has secured an important decision relating to their discretionary powers and their right to compel a physician to register after having practiced ten years or more. The supreme court decided that the board had the right to pass on the issuing of certificates to this class of practitioners, and the courts could only interfere when this discretionary power, was being abused. This decision firmly upholds the constitutionality of the law, and active prosecutions against those who have not been duly qualified will be at once instituted.

THE ANNUAL REPORT of the Health Department shows the death rate to be 16.90 per 1,000, which is a decrease of 1.39 over the previous year.

THE MORTALITY REPORT for first week in January: Zymotic diseases 15, phthisis pulmonalis 17, other constitutional 9, local 61, developmental 11, violence 4, total 117; corresponding week in 1895, 117; 1894, 125; 1893, 134. Under 5 years 33.

THE FORTIETH ANNUAL REPORT of the Ohio Institution for Feeble-minded Youth shows that the balance on hand at the opening of the past fiscal year, together with the appropriation amounted to \$187,214.82, amount disbursed \$124,623.05, leaving a total balance Nov. 15, 1896, of \$62,591.77. The number of pupils during the year was 1,031. Twenty boys and nineteen girls have been discharged. Dr. Doren emphasizes the necessity of the establishment of a custodial department for the weak-minded, and calls attention to the fact that many of them marry and raise children, who inherit their parents' weakness. He says that a custodial department would not only prevent this, but would render its inmates self-supporting.

THE ANNUAL REPORT of the Toledo Insane Asylum shows that there were under treatment during the year 1,635 persons, of whom 87 were discharged cured, 92 as improved, 30 as unimproved and 5 discharged as not insane, a remarkable reflection on the authorities who committed them; remaining at the end of the year 1,308. Total per capita cost of inmates, \$127.35.

Washington.

WEEKLY REPORT OF THE HEALTH DEPARTMENT.—The report of the Health Officer shows that the city's death rate during the last week ending Jan. 2, was 18.2 per 1,000 inhabitants. The average rate for the last month was 17.5. This is 6 per 1,000 below the annual average of the city, which is 23.5. The deaths reported to the Health Department numbered 98, of which 70 were white and 28 colored. Of the total mortality acute lung cases numbered 17 and 11 cases of consumption, compose 28.5 per cent. There were 3 deaths from diphtheria, and the new cases reported fell from 25 in the previous week to 20; houses released from quarantine 18, against 32 the week previous, and premises still isolated were reduced from 56 to 48. New cases of scarlet fever reported numbered 5; cards removed, 6; premises remaining placarded, 15. Of heart-maladies there were 9 deaths, an increase of 2 over last week, and those from affections of the kidneys rose from 2 to 8.

THE X RAY IN THE PENSION OFFICE.—In a doubtful pension case an X-ray photograph was accepted as evidence by the department, showing an injury to the bones of the forearm which previously was not accurately determined.

CHEMICO-PATHOLOGICAL SOCIETY.—The annual meeting of this society, recently held, resulted in the election of Dr. A. A. Snyder, president; Drs. E. L. Tompkins and D. O. Leach, vice-presidents; Dr. R. T. Holden, secretary; Dr. T. Clarke, treasurer, and Dr. N. M. Ellison, corresponding secretary.

WASHINGTON JOURNAL CLUB.—The annual meeting of the Washington Journal Club resulted in the election of Dr. H. A. Robbins, president; Dr. F. P. Morgan, treasurer, and Dr. D. W. Prentiss as an honorary member. Dr. Prentiss was president ten years ago.

MEDICAL SUPERVISORS.—The board of medical supervisors held a meeting at the health office and decided to meet on the second Thursday in January for the examination of applicants who desire to practice surgery in the District of Columbia. The members of the board are: Drs. J. B. C. Custis, C. H. A. Klineschmidt and Thomas Robinson, and J. J. Darlington and John Ridout. Where the examinations will be held has not been determined. Under the law the examinations must be both written and oral.

HEALTH OFFICE RECORDS.—Upon the reassembling of Congress the Commissioners will report to that body a bill requiring all persons getting a transcript of the records of the health office to pay a fee of 50 cents. It is thought that a revenue of \$1,000 per annum will be realized through this tax.

MEDICAL APPOINTMENTS.—The Commissioners have appointed Drs. Jesse Shoup and A. W. Boswell as physicians to the poor, the appointments of each to date back to June 1, last. The resignation of Dr. George W. Wood as physician to the poor was accepted and Dr. Francis P. Morgan was appointed to succeed him.

THE GEORGETOWN COLLEGE ALUMNI SOCIETY, which has been organized since 1872, gave its first reception to the faculty of the college on the 29th ult. About two hundred members of the society gathered in the parlors of the college, with the members of the law, medical and academic faculties. Music was provided and a lunch served until 10 o'clock.

REVIEW OF THE HEALTH REPORTS FOR THE YEAR 1896.—The health of the city during the calendar year 1896 has been favorable, as compared with the several preceding years. There were 5,834 deaths, estimating the last days of December. This represents an annual death rate of 20.7 for the total population, while the average rate for the District of Columbia is 23.5. The first portion of the year embracing the last winter and early spring months passed with no marked outbreak of disease. Typhoid fever, which had expanded into dimensions approaching epidemic in the preceding fall months, suddenly declined to almost zero. During this time there were but few fatal cases, and this condition continued.

until the last autumn months. There was then a return of this malady, which caused about eighty deaths, again declining as before. The grip again paid its yearly visit, this time appearing in the spring months of April and May, coming suddenly and as suddenly departing, causing 53 fatal cases. The diseases of children under 5 years of age, embracing the summer maladies of cholera infantum, diarrhea and enterocolitis and kindred affections, were less in virulence than for a number of years. The deaths in this class were but 291, while in the previous year they numbered 468. During the last fiscal year 2,094 children under 5 years of age died out of a total mortality of all ages of 5,904. Of these, 1,524 were under 1 year old, mostly under six months of age. The figures show that about one-third of all who died in the District of Columbia are young children under 5 years of age, and one-fourth are infants under a year old. Many of these die of marasmus and inanition and congenital debility. During the same time there were 705 deaths from consumption, of which 335 were white persons and 370 colored. The death rate for the whites from this malady was 1.79 and of the colored 4.21, and for the whole population 2.6, counting the inhabitants of the District of Columbia at 187,600 whites, 87,900 colored and 275,500 in all. These statistics show that about 12 per cent. of all who die are carried away by this dread disease. Diphtheria prevailed to some extent during the year, but in a comparatively mild form. According to the last reports there were 326 cases thereof, of whom 76 died. This shows a mortality of a fraction over 23 per cent. The average rate of mortality, heretofore, both in this city and elsewhere throughout the country, has been about 33 per cent. of all cases. There were 198 deaths from violence during the year, of which 40 were from suicide. Five of the suicides occurred in November. The principal methods by which people take their own lives are pistol shot, narcotic poison and corrosive poisons. One occurred by jumping from a third-story window. All were whites with one or two exceptions. During the year the health department gave much attention to relief of the poor people who were sick. Nearly sixteen thousand patients were treated and 2,500 office consultations given, with an expenditure of nearly \$3,000 for medicine furnished free to this class. Over five thousand children were reported as having been born and 2,300 marriages were officially reported. The year closed with a very low death rate, thus indicating a favorable state of health at the beginning of the new year. Cases of diphtheria and typhoid fever were tending to the minimum. No new diseases indicate a tendency to spread, and an almost total absence of other contagious diseases or malarial troubles give cause for congratulation. Coroner Hammett has investigated more than six hundred deaths during the year. This number includes suicides, homicides and all accidental deaths and every death which occurred from violence and all sudden deaths where no physician was in attendance. There was one legal hanging in addition to several suicides in which hanging was the means employed to cause death. Then there were suicides committed by taking poison as well as by the use of the pistol. In all there were 39 cases of self-destruction, while the number of homicides was fourteen, an average of more than one a month. Sixty-eight of 95 stillbirths reported represented the daily finds of dead infants on ash piles, in sewers or on doorsteps. The other 27 cases were known. There were 81 accidental deaths, and in this number were included victims of railroad accidents. Other causes of death given were: Measles, 1; Bright's disease, 3; congestion of lungs, 7; cholera morbus, 1; sunstroke, 7; heart disease, 63; alcoholism, 14; consumption, 10; pneumonia, 28; senility, 13; drowning, 17; poisoned, accidental, 3; epilepsy, 1; meningitis, 4; and congestion of brain, 4.

CLASSIFICATION OF TUMORS.

COMPREHENDING MALIGNANT AND NON-MALIGNANT NEW GROWTHS, AND CYSTS.

We republish from the last Revised Nomenclature of the Royal College of Physicians (1896), their Classification of Tumors, as it differs materially from that of the previous revision in common use among English speaking physicians. Our own ASSOCIATION long ago adopted the Nomenclature, which, we suppose, carries with it the adoption of the subsequent revisions, unless otherwise ordered by the ASSOCIATION.

In deference to the needs of the various Registration author-

ities, a distinction has been made in the general and local tables between malignant and non-malignant new growths. The tumors are, however, here classified according to their structure and the type of normal tissue they most closely resemble. To facilitate returns under the general tables, the malignant growths are here marked by two asterisks. In certain cases malignant and non-malignant growths are unavoidably associated under one head, as for instance, under Sarcoma; the name is then marked with one asterisk.

Cysts are placed in a separate class, and may be returned severally among the local affections of organs; or among new growths (if connected therewith); or as malformations (if congenital); or as parasites (if parasitic).

CLASSES.

- I. Tumors composed of one of the modifications of fully developed connective tissue.
- II. Tumors resembling in structure, more or less closely, one of the more complex tissues or organs of the body.
- III. Tumors composed of cells of an embryonic type sometimes tending to develop into one of the forms of connective tissue—Sarcoma.
- IV. Tumors composed of epithelial cells arranged in the spaces of a stroma of more or less perfectly developed and vascular connective tissue—Carcinoma.
- V. Cysts.

Class I.—Tumors composed of one of the modifications of fully developed connective tissue.

(The name of the typical normal tissue is printed first in each case, that of the tumor second.)

1. ADIPOSE TISSUE. Lipoma. Fatty Tumor.
 - a. Circumscribed.
 - b. Diffuse. *Synonym*, Fatty out-growth.
 - c. Multiple.
 - d. Nævo-lipoma.
 - e. Fibro-lipoma.
2. FIBROUS TISSUE. Fibroma.
 - a. Firm or hard fibroma, Desmoid tumor. Fibrous epulis. Fibrous polypus of nose. Fibroma of nerves. *Synonym*, False neuroma. Keloid.
 - b. Soft or areolar fibroma. Molluscum fibrosum.
3. CARTILAGE. Chondroma.
 - a. Ossifying. *Synonym*, Spongy or cancellous exostosis.
 - b. Non-ossifying. *Enchondroma (when growing in bone). Echondrosis (when growing from cartilage).
 - c. Myxo-chondroma (when undergoing mucous softening).
4. BONE. Osteoma.
 - a. Developing from cartilage. Cancellous, or spongy exostosis.
 - b. Developing from membrane. Compact or ivory exostosis.
 - c. Of teeth.
 - (1.) Growing from the cement. Dental exostosis. Hypertrophy of cement.
 - (2.) Growing from the dentine. Odontoma.
5. MUCOUS TISSUE. *Myxoma. Mucous polypus.
6. NEUROGLIA. *Glioma.

Class II.—Tumors resembling in structure, more or less closely, one of the more complex tissues or organs of the body.

(The name of the typical tissue or organ is placed first, that of the tumor second.)

1. MUSCLE. Myoma.
 - a. Unstriped. Leiomyoma. Fibromyoma. Uterine fibroid. Fibroid tumor of prostate.
 - b. Striped. Rhabdomyoma. *Myosarcoma.
2. NERVES. Neuroma or True neuroma.
 - a. Medullated. Plexiform neuroma (in part). Bulbous nerves. *Synonym*, Amputation-neuroma.
 - b. Non medullated.
3. BLOOD VESSELS. Hæmangioma, Angioma, or Nævus.
 - a. Capillary. *Synonyms*, Port-wine stain, Mother's mark, Teleangiectasis.
 - b. Venous. *Synonym*, Erectile tumor, Cavernous nævus.
 - c. With adipose tissue. Nævo-lipoma.

4. LYMPHATIC VESSELS. Lymphangioma, Lymphatic nævus. Congenital cystic hygroma of neck. Macroglossia.
5. LYMPHATIC GLANDS. Lymphadenoma. Hodgkin's disease.
6. PAPILLÆ OF SKIN OR MUCOUS MEMBRANE. Papilloma.
 - a. Squamous papilloma, Wart.
 - b. Columnar papilloma, Villous growth: Of rectum. Of bladder.
7. SECRETING GLANDS. Adenoma.
 - a. Racemose adenoma (spaces lined with glandular or spheroidal epithelium).
 - (1.) Resembling normal gland tissue. True adenoma.
 - (2.) With excess of firm fibrous stroma Adenofibroma, Adenoid tumor.
 - (3.) With stroma of imperfectly developed fibrous tissue. Adeno-sarcoma.
 - (4.) With stroma containing mucous tissue, Adenomyxoma.
 - (5.) With large cysts throughout the tumor. Adenocysto-sarcoma, Cysto-sarcoma. With simple cysts. With intra-cystic growths.
 - b. Tubular adenoma (spaces in tumor lined with columnar or cubical epithelium).
 - c. Adenoma of ductless glands, Thyroid adenoma.
 - d. Ovarian Adenoma.

Class III.—Tumors composed of cells of an embryonic type sometimes tending to develop into one of the forms of connective tissue.

*SARCOMA:

1. Composed of small round cells.
 - a. With homogeneous intercellular substance. Granulation sarcoma. Encephaloid sarcoma.
 - b. With reticulate stroma. Lympho sarcoma.
 - c. Ossifying sarcoma, Osteoid sarcoma (Osteoid cancer).
 - d. Chondro-sarcoma (Malignant chondroma).
 - e. Glio-sarcoma.
2. Composed of large round cells. With alveolar stroma. Alveolar sarcoma.
3. Composed of oval cells. With mucous intercellular substance. Myxosarcoma.
4. Composed of large spindle-cells (Fibro-plastic tumor).
 - a. Ossifying.
 - b. Chondrifying.
5. Composed of small spindle-cells.
 - a. Developing into fibrous tissue. Recurrent fibroid tumor.
 - b. Ossifying.
6. Composed of round and spindle-cells.
7. Containing giant cells. Myeloid sarcoma.
8. Melanotic sarcoma, Pigmented sarcoma.
9. Plexiform sarcoma, Cylindroma.
10. Psammoma, Brain-sand tumor.

Class IV.—Tumors composed of epithelial cells arranged in the spaces of a stroma of more or less perfectly developed and vascular connective tissue.

**CARCINOMA OR TRUE CANCER.

1. Glandular or Spheroidal Carcinoma.
 - a. With little stroma and abundant vessels. Encephaloid cancer.
 - b. With dense fibrous stroma. Scirrhous or hard cancer. Variety: Atrophic cicatricial scirrhous.
 - c. With colloid degeneration of cells. Colloid cancer (Reticular or alveolar cancer) in part.
 - d. With myxomatous stroma. Carcinoma myxomatodes.
2. Squamous Carcinoma. *Synonyms*, Epithelioma, Squamous epithelioma.

Note.—Chimney-sweeper's cancer is to be returned under Squamous Carcinoma.
3. Rodent cancer or Rodent ulcer.
4. Columnar Carcinoma. *Synonyms*, Columnar epithelioma, Adenoid cancer.
 - a. With colloid degeneration of cells. Colloid cancer in part.
 - b. Arising in ducts. Duct cancer.
5. Thyroid Carcinoma. Resembling in structure the Thyroid gland.

Class V.—Cysts.

1. CYSTS ARISING FROM THE DISTENSION OF PRE-EXISTING SPACES.
 - a. Spaces lined with secreting epithelium, Retention cysts.
 - (1.) Acinous or glandular cyst of breast, pancreas, and other glands.

- (2.) Duct cyst of the breast, pancreas, testicle and other glands.
- (3.) Galactocele.
- (4.) Spermatocoele.
- (5.) Mucous cyst. Ranula. Labial cyst.
- (6.) Sebaceous or atheromatous cyst, Wen.
- (7.) Ovarian cyst from Graafian follicles.
- b. Spaces lined with flattened endothelium. Distension or exudation cysts, Lymphatic cysts.
 - a. Bursal cysts.
 - b. Ganglion.
 - c. Serous cysts.
2. CYSTS IN WHICH THE FLUID IS CONTAINED IN A SPACE OF NEW FORMATION.
 - a. Blood cyst. Apoplectic cyst in brain.
 - b. Degeneration cyst. In brain. In tumors.
3. CYSTS OF CONGENITAL ORIGIN.
 - a. Inclusion-cyst. Dermoid cyst.
 - b. Cysts arising in the remains of fetal structures.
 - a. Unobliterated branchial clefts. Deep cysts of neck.
 - b. Unobliterated canal of His. Sub-lingual cysts in part. Sub-hyoid cyst in part. Cysts in front of larynx.
 - c. Remains of Wolffian body. Encysted hydrocele in male (in part). Cysts of the broad ligament in female (in part).
 - d. Partially unobliterated processus vaginalis testis, Encysted hydrocele of cord.
 - e. Partially unobliterated canal of Nuck. Hydrocele of canal of Nuck.
 - f. Cysts of post-anal gut.
4. PARASITIC CYSTS.

Change of Address.

ORIGINAL ARTICLES.

A RÉSUMÉ OF MEDICAL HYPNOTISM.

Read before the Louisiana State Medical Association, May 13, 1896.

BY RANDELL HUNT, M.D.

SHREVEPORT, LA.

The wonderful and marvelous facts that have been evolved within the last twenty years through hypnotism, are such as to attract the attention of the most skeptical, and fill those who believe in and practice the science with veritable awe. Science, with its brilliant light of logic and truth, is rapidly dispelling the darkness of mystery and doubt, and men are no longer looking helplessly to the supernatural for the solution of a problem above their individual ken. They realize that all in nature is natural and subject to natural laws, and when a phenomenon can not be explained, readily admit that it is through their failure to comprehend those universal principles that govern the cosmos.

Educated people demand a little more of the scientist than mere arbitrary statement. They wish to know the reason of the faith that is in him, and rightly, for the scientist should meet the issue squarely, face to face, and in such manner that any sound mind can grasp the solution he offers. Finite mind needs finite reasoning and in this practical age the world wants demonstration, for it has the courage of its convictions and inductively refuses to accept anything upon revelation alone. Hypnotism, to be acceptable to the thinking world of today, must be brought from the realm of mystery, charlatany and empiricism, and standing unflinchingly in the light of scientific investigation, in no particular be found wanting. Its history is almost connate with the history of the world, for we find evidences of spiritualism in Babylon; while in Israel the Witch of Endor conjured the shadows of the dead.

In the eighth book, chapter 2, of the "Antiquities of the Jews," Josephus says: "God enabled Solomon to learn that skill which expels demons, which is a science useful and sanative to men. He composed such incantations also by which distempers are alleviated. And he left behind him the manner of using exorcisms, by which they drive away demons so that they never return, and this method of cure is of great force unto this day, for I have seen a certain man of my own country whose name was Eleazar, releasing people that were demoniacal in the presence of Vespasian and his sons and his captains and the whole multitude of his soldiers. The manner of the cure was this: He put a ring that had a root of one of those sorts mentioned by Solomon to the nostrils of the demoniac, after which he drew out the demon through his nostrils; and when the man fell down immediately, he abjured him to return into him no more, making still mention of Solomon and reciting the incantations which he composed."

In the temple of Ceres there was a well at the bottom of which there was a mirror; in this the priests saw the faces of those who came to be cured.

For forty centuries hypnotism has been practiced in Egypt by taking a porcelain plate and drawing two triangles in it crossing each other, in the center writing a cabalistic word, which when gazed at steadily for some minutes produces trance. The Eber papyrus, in the history of Egyptian medicine 1552 years before Christ, gives the laying on of hands as part of the treatment of disease, and we see the same thing later in the cures of the Emperor Vespasian.

Hypnosis from fixation has been practiced for thousands of years by the Persian magi, the fakirs and yogis of India, and also in certain convents of the Greek church, notably the Omphalopsychics of Mount Athos, by gazing at the umbilicus.

The next revival of hypnotism, under the name of animal magnetism, was by Mesmer, who believed in a universal magnetic fluid, and gathered many patients about him in Paris. Greatrakes, in 1662, claimed to have had divine revelations to the effect that by the laying on of hands he could cure many diseases. This he succeeded in accomplishing and soon his fame became so great that people came to him from all directions. Gasner, an ex-monk, 100 years later, performed many miracles and at last settled in Regensburg where, by the aid of exorcism, he gained fame and at one time had as many as 10,000 patients. Abbot Faria spent many years in India and in 1815 taught that the cause of trance and somnambulism was due to forces in the subject, not in the magnetizer, and that sleep could not be produced against the subject's will.

To James Braid of Manchester, belongs the honor of not only doing much to clear hypnotism of its mysticism and of naming the science, but of hinting at its most important factor, suggestion.

In the hospital of La Salpêtrière in 1878, Charcot and his pupils began to demonstrate hypnotism, but neither he nor his pupils have as yet any very satisfactory theory to advance. In 1866 Liebault, the real and true father of the therapeutics of suggestion, wrote a book on the subject, but it remained little known and the author was laughed at by his confrères. Professor Bernheim of Nancy, adopted Liebault's views and a great rivalry took place between him and Charcot and to this day the rivalry continues, though Nancy is gaining ground.

It was not until 1893 that a working hypothesis was formulated for the scientific demonstration of hypnotism. Like the flash of a meteor the brilliant genius of Hudson burst forth and gave to the world light in the logical presentation of one of its fundamental laws. His theory of the duality of mind is so clear that I shall employ it in this paper, and for the sake of explanation call, as he does, one phase of mind objective, with its seat in the upper brain and the other sub-

jective and located in the lower brain. The objective mind from its post of observation in the cerebrum, takes cognizance of the objective world through the media of the five physical senses, is under the control of reason, and develops what we know as common sense. This is the mind we are using at this moment, the mind we instruct at school, inform and polish by travel and in a thousand ways teach, the mind of the scientist and scholar. In normal man it is not controlled against reason by the suggestions of another, for it reasons both inductively and deductively and refuses to accept anything in opposition to achieved results.

The subjective mind, that of the lower brain (pons, medulla and cord) perceives, not through the physical senses, but by intuition, is the seat of the imagination, of memory, and, as is proven through the phenomena of hypnotism, controls the functions of the body. This is the mind whose ascendancy gives us the musician, the poet, the artist in any line, and when "exquisitely balanced" with the objective mind, as Mr. Hudson so beautifully shows us, a Shakespeare. That the subjective mind is always amenable to suggestion is the law that Mr. Hudson demonstrated to us so clearly.

To make the difference between the two minds plain I will give this illustration: Blind Tom had no objective force, but if Von Bulow or any other great musician played in his presence a most intricate and difficult composition, Tom could sit down and without trouble reproduce the whole. From this we see that perfect memory is a factor in the grand aggregate of the subjective faculties, while mere recollection and not true memory it is that belongs to the objective faculties.

The charge so commonly made by the uninformed that crime and immorality may result from improper suggestion from evil-minded operators, is met by the statement, fully proved through satisfactory experiment, that strongest of all suggestions is auto-suggestion. The suggestion of a crime is rendered abortive by the instinct of self-preservation acting through auto-suggestion, while the suggestion of immoral or indecent action is met by the counter auto-suggestion arising from strong convictions of right and the habits of a lifetime. To a really pure hearted, modest woman virtue and honor are more than mere existence, aye, they are divine glory and constitute her greatest ideality to man, and the insistence of an operator upon a suggestion opposed by auto-suggestion would result in hysterical distress and a speedy restoration to consciousness.

Anatomy and physiology prove the duality of mind, for Surgeon-General Hammond in a paper entitled, "The Brain not the Sole Organ of Mind," relates how he removed the brain of a frog and after waiting for the shock to pass, put it in water, when it immediately began to swim. He placed his hand so as to stop it and its efforts ceased; taking away his hand, it again commenced to swim. Pflüger removed the entire brain of a frog and applied acetic acid to the thigh over the inner condyle. The animal immediately rubbed the spot with the foot of the same side, making a voluntary movement and showing his appreciation of the locality of the irritation. The foot was then amputated and the acid was again applied, when the frog made an ineffectual effort with the amputated member and failing after a few movements, rubbed the irritation with the other foot. This experiment,

with its demonstration of sensation and volition, is certified to by Prof. Austin Flint, who says he has often successfully produced the same phenomenon.

"In certain monsters born without a brain, or with important parts of this organ absent, we have interesting examples of the persistence of instinct." "Syme describes one of these beings which lived for six months. Though very feeble it had the faculty of sucking and the several functions of the body appeared to be well performed. Its eyes clearly perceived the light and during the night it cried if the candle was allowed to go out. After death the cranium was opened and there was found to be an entire absence of the cerebrum, the place of which was occupied by a quantity of serous fluid contained in the arachnoid." "Ollivier d'Angers describes a monster of the female sex which lived twenty hours. It cried and could suck and swallow. There was no brain, but the spinal cord and medulla oblongata were well developed." "Saviard relates the particulars of a case in which there was no cerebrum, cerebellum, or any other intracranial ganglion. Yet this being opened and shut its eyes, cried, sucked and even ate broth. It lived four days. Some of these movements were reflex, but others were clearly instinctive and adapted to the preservation of life." "But all these instances as well as experiments referred to as having been performed on lower animals, show that instinct does not reside in the brain."

Methods employed to produce hypnosis vary with each individual hypnotizer, though all use fixation with or without suggestion.

Mesmer generally sat opposite his patient, stared him in the eyes and held his hands for ten minutes, then made fourteen or fifteen gentle passes over his head, chest and body; but later on in the height of his triumph, when all fashionable Paris came to him, he lessened his labors by using magnetized tables and the baquet.

Braid fixed the attention on a bright object situated about three inches above the root of the nose, which caused the eyes to converge and the muscles to soon tire.

Charcot has modified Braid's method by placing the piece of glass gazed at near the bridge of the nose and suddenly striking a loud gong which causes catalepsy. But as Dr. Tuckey remarks, "Such sleep is analogous to that shock produced in waking moments by sudden fright, which paralyzes and transfixes with terror."

Suggestion, as employed at Nancy, acts as a sedative to the brain and softly woos a condition analogous to natural slumber. The person hypnotized is placed on a bed or in a large chair, told to think only of going to sleep, to be passive, not to move, and to look the hypnotizer steadily in the eyes, while the following formula is repeated: "Your eyelids are growing heavy, your eyes begin to wink, you can not see distinctly, you are growing so sleepy your eyelids are almost stuck together, a torpor steals all over your body, your eyes are closed, you are sound asleep, you can not feel anything, you can not move your arms or legs, you are sound asleep. Sleep, sleep, sleep." By this time the patient is generally hypnotized; but in case he is not, continue to vary the suggestion and success will usually follow.

As passivity is an indispensable factor to successful hypnotization, it follows that an unwilling subject is an impossibility. Advise hypnotism when indicated

and wait the patient's full and eager consent. By taking this course success will invariably follow and the practitioner will avoid the delay, worry and failure that will inevitably result from the perversity of an ignorant and stubborn patient.

Classification of the stages or degrees of hypnotism vary, but for the sake of convenience and brevity four shall be employed, viz.: Suggestion without sleep, light sleep, profound sleep and somnambulism.

Suggestion without sleep is a wonderful illustration of the power of the mind over the body and shows that through imagination and mental concentration every action and sensation can be controlled. A few rapid passes for psychic effect will sometimes, in the most susceptible, produce loss of sensation in the arm, hand or face and, in like manner, a catalepsy of any limb. There is no loss of individuality and though the patient may be unable to open the eyes, he will say that he can not understand his inability to do so.

In the second degree there is light sleep and general muscular relaxation; the eyes remain closed and the patient not only hears the voice of the hypnotizer, but any conversation within his hearing and, as a rule, remembers all.

Profound sleep is characterized by catalepsy. If the arm is lifted it remains in the position in which it is placed and while the voice of the operator is heard and remembered, conscious relationship with others is only obtained by verbal suggestion.

Somnambulism is marked by complete loss of consciousness of the outside world and, though suggestion is obeyed, there is no recollection of anything that happens during sleep. Some curious physiologic phenomena have been observed by those who practice medical hypnotism, such as increased circulation, respiration and muscular rigidity, though the two former disappear in a short time and therefore may be ascribed to excitement. Through suggestion circulation can be signally affected and by a mere word of command the cardiac function so influenced as to notably increase or decrease its pulsations. Suggestion also affects the temperature and the vasomotor system. In certain cases red spots and even blisters can be made to appear on the arm, chest, or any part of the body, by using a magnet, piece of paper, or a coin, and intimating the result desired.

Hypnotism will materially increase our knowledge of the functions of the brain, for the condition is entirely psychic and can not as yet be explained by physiology. Tucket quotes Brown-Sequard as saying that when one cerebral center or function is used to excess the others become, for the time being, paralyzed or inhibited and this is particularly true in the induction of hypnotic sleep, for the mind is then engrossed with one idea, and the eyes being fixed on a bright object soon cease to perceive it and the brain is consequently left in a state of vacuity. Dr. Barwise considers the condition brought about by mental and visual tumult and by cerebral anemia, the throwing back of the head interfering with circulation and producing a condition analogous to natural sleep.

Bernheim's views are more in accord with my limited experience. He thinks it due to the fixation of vision and the power of suggestion, particularly the latter; for many persons are easily hypnotized without assuming an unnatural posture, or even a fixation of gaze. In fact, it is nothing but a certain mental

state in which the patient is susceptible to suggestion.

To obtain success in hypnotic treatment it is most important to impress the mind of the patient with its great and lasting power to produce effects. Dr. Moll assures us that any patient who goes to Lourdes with the faith of a good Roman Catholic meets a far different result than he who goes without faith. Under ordinary circumstances it is impossible for the practitioner to engender such belief, but it becomes easy with the aid of hypnotism to place the subjective entity in a condition of receptivity and faith.

The diseases that yield most readily to therapeutic suggestion are the following: Chronic alcoholism, tobacco habit, morbid delusions, hypochondriasis, bad habits, neurasthenia, insomnia, megrim, epilepsy, functional paralysis, hystero-epilepsy, writer's cramp, stammering, chorea and menstrual irregularities. "Dr. Björnström of Stockholm asserts that from 1850 to 1860 hypnotism was used on a large scale by Dr. Esdaile, head surgeon at the hospital at Calcutta. In six years he performed 600 operations on hypnotized Hindoos and a committee of surgeons and physicians, appointed by the Indian government, testified to his great success, which was chiefly derived from the fact that the most difficult operations could usually be made without a sign of pain from the patients."

Many interesting cases treated and cured by hypnotism could be related, but as the scope of this paper will not permit it, I shall have to be satisfied with calling your attention to such names as Dr. Gerald Yeo the physiologist, Professor Bernheim of Nancy, Professor Charcot of La Salpêtrière, Voisin, Wetterstrand, Björnström, Velpeau, Dumontpallier of Hotel Dieu, Richet of Paris, Tuckey of London and Albert Moll of Berlin.

In October, 1895, Dr. T. E. Schumpert, surgeon of the Charity Hospital of Shreveport, in the presence of Dr. J. F. Griffin of the same city, operated upon Allen Coates, age 53, suffering from chronic ulcer of the leg. The ulcer was curetted and skin-grafted under hypnosis without pain to the patient. He also performed circumcision on John S. and George Fields under hypnosis without causing pain and without memory, when they awakened, of what had been done.

The following is an extract from some notes handed me by Dr. T. G. Ford of Shreveport: "My experience with hypnotism, although limited, has been a happy one, using it upon one case of nausea from pregnancy with success, three cases of sick headache with relief, and one aggravated case of hysteria. In the latter I used almost every anodyne without benefit and at last resorted to suggestion, which acted most satisfactorily, and I now consider the condition of my patient much improved under its use."

The following recital of some of my own experience with hypnotism is presented to you with hesitancy, owing to its very limited scope, and only in the hope that in the event of any among you being without personal experience, it may serve to encourage you to try this most powerful and beautiful therapeutic agent. Some time ago a lady suffering from an attack of megrim sent for me and being afraid of contracting the morphine habit, she implored me not to give her an opiate, a request I respected. I then stated the benefits to be derived from hypnotism and as she was eager and willing, catalepsy was soon induced and suggesting that the pain was gone and

would not return, in a few minutes I had the pleasure of arousing her free from all pain. On another occasion a young lady came to my home office suffering from acute ovarian neuralgia and in the presence of my wife I hypnotized her and in four minutes she left smiling and well.

George Anderson, negro, aged 35 years, had facial neuralgia and had undergone agony for three weeks, in spite of medical treatment administered by one of our best physicians. Knowing the excellent ability of his former doctor and feeling that the treatment could not be improved upon, I urged him to let me produce hypnosis and, at last consenting, in a few minutes he was entirely cured.

In September I was called in consultation to see a woman who had been sick in bed for three months with hystero-epilepsy, and the week preceding my visit she had had nine seizures. After a careful examination the ovaries were found painful to touch and very much congested, so much so that the examination induced an attack, during which I succeeded in hypnotizing her and affirmed in a loud tone that all pain had passed away and that she would have no more trouble, but in the morning would be sitting up and would assure her physician of her great improvement and her certainty of soon being entirely well. A few weeks later I met the doctor and he told me that all had happened as I suggested and that she had an uninterrupted and extraordinarily rapid recovery.

In January of this present year there came to me a young woman addicted to the morphin habit, taking, according to her own statement which I afterward verified, eight grains daily. I at once placed her upon a mixture containing strychnia, caffeine and cinchona, giving it every four hours and decreasing the morphia so as to have her off the drug in two weeks. For the next four weeks I continued the mixture, giving an occasional dose of phosphate of codein, and whenever great depression occurred, or any nervous pain, I would hypnotize her and obtain instant amelioration. One interesting feature of this case was that the diarrhea which always follows the withdrawal of the drug, and often proves so troublesome, was absolutely and entirely controlled by therapeutic suggestion. I have also the gratification of informing the Association that the patient is now well and in excellent spirits.

I have also found hypnotism successful in the following diseases: Intercostal neuralgia of eight years' standing, abolishing pain, increasing menstrual flow, filling and crowning teeth, dipsomania and chorea.

Before I close I should like to recall to the minds of my brother physicians the struggle that vaccination had to undergo before it was admitted as a reliable prophylactic agent; that it has not been long since electricity was taken from the hands of empirics and charlatans and that massage was ridiculed and laughed at, but at last, in spite of conservatism and inexperience, behold their triumph.

Nearly every village in Germany has one regular practitioner who, in addition to regular practice, employs the science of suggestion. Only a few months ago the Illinois Medical College appointed a chair of psychiatry and hypnotism in its curriculum, and less than three weeks ago an arm was amputated under hypnosis in the largest hospital in Baltimore.

The following preamble and resolutions were agreed to at the first First International Congress of Physicians and Jurists on Hypnotism held in Paris, 1889:

WHEREAS, This Congress recognizes the danger of public exhibitions of magnetism and hypnotism, and deeming that the therapeutic application of hypnotism has become a branch of the science of medicine, that its official teaching is the province of psychiatry, votes the following resolutions:

Resolved, Public exhibitions of hypnotism and magnetism should be forbidden by the administrative authorities in the interest of public hygiene and public morals.

Resolved, The employment of hypnotism as a curative agent should be subject to the laws and restrictions which regulate medical practice generally.

Resolved, It is desirable that the study of hypnotism and of its therapeutic application be introduced into the curriculum of medical sciences.

The advice of this Congress is not to be disregarded, for while the morally pure are safe from error, there is a large mass of humanity whose ethical nature is an unknown quantity and with a moral equilibrium that might easily be disturbed by adverse or criminal suggestion. Such being the case, it at once becomes imperative that proper legislation be enacted for the protection of such people and that this powerful agent be taken out of the hands of charlatans and empirics. Hypnotism used as a therapeutic measure is commendable, but care should be taken that no suggestion be made except relating to the cure desired, for inadvertent and unscientific suggestion when repeated daily for a great length of time, results not only in auto-hypnosis, but also in lasting hallucinations. These dangers, however, are easily avoided by judicious and quieting assertions and by never giving to the hypnotized subject any suggestion other than one necessary for his cure. If this advice be followed, Professor Bernheim and Prof. R. Von Kraft-Ebing assure us that no mental or physical detriment can result and that only good can come from medical hypnotism and therapeutic suggestion.

HOW THE ESTABLISHMENT OF A PERMANENT CENSUS BUREAU WILL IMPROVE THE VITAL STATISTICS OF THE UNITED STATES.

BY CRESSY L. WILBUR, M.D.

DIVISION OF VITAL STATISTICS, DEPARTMENT OF STATE,
LANSING, MICH.

The establishment of a permanent census bureau has long been advocated by those most familiar with the numerous practical defects of our antiquated census system, both on grounds of greater economy and of improved results. Under a joint resolution of the first session of the present Congress, Hon. Carroll D. Wright, United States Commissioner of Labor, was directed to make a report on the advisability of placing the preparations for the census of 1900 upon a permanent basis, and the results of his labor are now before Congress in the form of a "Bill to provide for a permanent census service."

The bill contains provision for an enumeration of the population at the quinquennial periods intermediate between the present decennial enumerations, thus making general the means of verifying our knowledge of the population of the country every five years. It is unnecessary to point out how indispensable such frequent censuses are for the computation of accurate vital rates. All rates for intercensal years are based upon estimated populations, and when the estimation is continued for seven, or eight, or nine years after an official census, deductions based thereon may become entirely misleading. Indeed, so evident had the too infrequent character of our National cen-

suses become, that many of the States have already established censuses of their own in order to obtain data at quinquennial periods.

It was not my intention, however, to dwell upon the commendable features in the general census bill proper, but rather to call attention to the special provisions relating to the very important subject of vital statistics. The text of the bill as originally reported to Congress¹ is as follows:

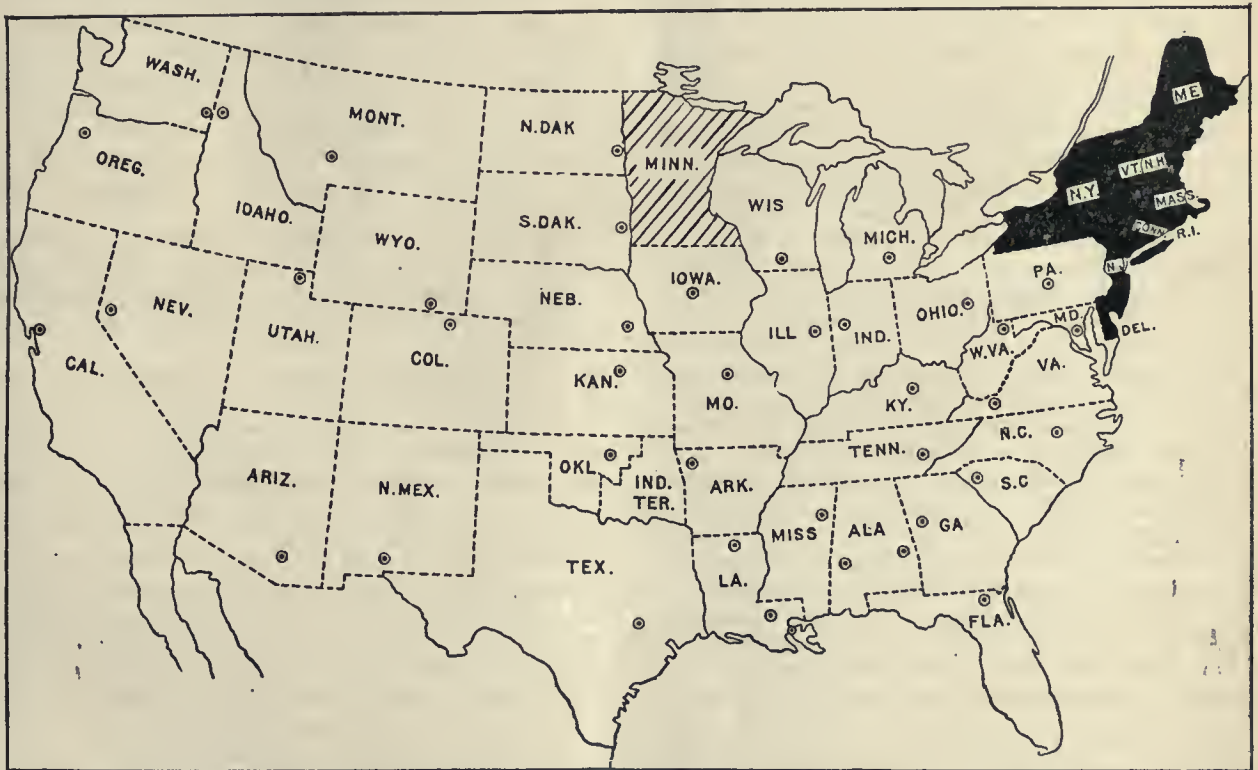

"There shall be a collection of statistics of deaths and of births for the year 1900, and annually thereafter, the data for which shall be obtained from the registration records of those States and municipalities possessing such records. At the time of the decennial enumeration of the population such data may be obtained from representative localities not having such records, at the discretion of the Director of the Census."

Upon this Col. Wright comments as follows:

"The collection of vital statistics every ten years, as now carried on, does not furnish material of value commensurate with the cost. The reliance of the decennial censuses has been upon the data collected from those States and municipalities

country not having a registration system. Ultimately under this provision the whole country would come into line with the States already having their registration provided for."

The United States may be conveniently divided for purposes of vital statistics, as under the last census, into registration and non-registration States. The assured registration States, comprising all of the New England States, New York, New Jersey and Delaware, occupy a comparatively small portion of the territory of the Republic (about 4 per cent.), although nearly one-fifth of the entire population of the country is contained in them. All of the other States of the Union are included in the non-registration class, although several of them have had systems of vital statistics in operation for many years. Their results, however, are not sufficiently accurate to determine their true death rates, with possibly a single exception. Minnesota has had a system of mortality statistics based upon certificates of death since the year 1887, and the results obtained under it are claimed to

having a registration system—that is, a compulsory system—under which physicians and others must make returns of births and deaths, and clergymen of marriages, the municipal authorities in States having a registration system making returns to the State. These are the only valuable vital statistics in the Federal census. All others, gathered from the people themselves by means of questions on the population schedules, are of no particular value for scientific purposes. When it is understood that the most accurate statistics we have in this country are from 5 to 10 per cent. away from the truth, it seems a useless expenditure of money and a needless irritation of the people to tax the enumerators with questions relating to births, deaths and marriages. Again, the value of vital statistics is increased more than tenfold by having them collected annually. It would be comparatively an inexpensive matter to collate the vital statistics of the United States, so far as registration States and municipalities are concerned, from the reports of such States and municipalities. By the adoption of such a system those States not having a registration system would gradually adopt something of the kind; so the bill under consideration authorizes the Director of the Census to collect vital statistics from representative localities in parts of the

be reliable. In the chart showing the registration area in black and the non-registration area unshaded,² Minnesota is partially shaded and should, perhaps, be included among the full registration States.

1. The registration States will be benefited by the annual compilation of their data, which is an important feature of the proposed law, and which will undoubtedly bring out many valuable comparisons. Something similar has already been undertaken by the registrars of the six New England States in the quinquennial "Summary of the Vital Statistics of the New England States." In the case of Michigan, which I trust may become a registration State by act of the present legislature, we shall be very glad to devolve the higher statistical treatment of our vital statistics upon the bureau of the general government, which alone can handle them to the best advantage;

² The division is made on the basis of mortality statistics alone. New York has imperfect returns of births and marriages. Several of the so-called non-registration States have excellent systems of marriage statistics.

¹ Senate Executive Document No. 5, Fifty-fourth Congress, Second Session.

sufficient for the State registration bureau will remain in the thorough administration of the law for the collection of data, the primary compilations, and the issuing of timely information in the shape of bulletins or otherwise for the benefit of the public health service. What is true of the State systems of registration is even more true of the municipal systems, especially those situated in non-registration States. There are few if any satisfactory compilations of their vital data, and a central bureau competent to act as a general clearing-house for municipal systems of registration is greatly needed. It is not enough to accept and publish the mere statements of city authorities. The accuracy of registration must be examined and standardized, population must be properly estimated, and such a general supervision be exercised over the conduct of registration that the results, when published by the government bureau, shall be known to be reliable.

2. Even greater advantages will accrue to the so-called non-registration States, which include about 96 per cent. of the area and four-fifths of the total population of the country. It is not feasible to institute a general system of registration in these States, but the bill provides that "data may be obtained from representative localities not having such records, at the discretion of the Director of the Census." The bill at present limits such collection of vital data from the non-registration States to "the time of the decennial census;" this, however, is an oversight which will be amended before passage. The reasons for a continuous registration of vital data in non-registration States are as strong as those for an annual collection of data from the registration States, or even stronger, since the data from the latter are accessible at present, while the proposed representative data will depend for a time entirely upon the census bureau.

In the chart certain circles with central dots represent the locations of agricultural experiment stations in the United States. It is planned, under the power intrusted to the Director of the Census, to establish vital statistics observation stations, or rather districts, in much the same way. Selected counties from each State, carefully chosen with reference to geographical situation and representative character of population, will give reliable information in regard to the vital movement of each State. Reliable representative birth rates and death rates will at last be obtainable. For years the sanitary workers in the great central West have been handicapped by the absence of reliable mortality data. When the way is shown, and the people shall actually see the benefits resulting from accurate registration among them, undoubtedly an increase in the number of State systems will result. Of course it may be necessary to have several registration districts in the same State, if a large one, or having great diversity of population; perhaps three or four districts will be sufficient on the average.

It will be very necessary to select districts having an average distribution of urban and rural population. One of the chief objections to the vital statistics of the cities of the non-registration States at present is their failure to represent the average degree of density of population. Statistics obtained from the country as well as from the city would be less objectionable in this respect.

Taken altogether, the provisions of the proposed bill relating to vital statistics seem well adapted to introduce a system of partial but thoroughly repre-

sentative registration, whose results will be vastly superior to anything we have previously derived from the census investigations. All of the details of collection of data and the specific limits of the inquiry are, of course, not yet worked out. Enough of promise appears, however, in the draft of the organic census law to enlist the interest and assistance of physicians, sanitarians and sociologists in behalf of the measure, and I sincerely trust that active efforts will be made to assist its passage by all who desire better vital statistics for the United States.

THE EFFECT OF THE EXTRINSIC POISONS ON THE EYE.

Read before the New York Academy of Medicine, General Meeting, Oct. 15, 1896.

BY J. HERBERT CLAIBORNE, M.D.

Adjunct Professor of Ophthalmology in the New York Polyclinic, Instructor in Ophthalmology in Columbia University, Assistant Surgeon New Amsterdam Eye and Ear Hospital, Member of the New York Academy of Medicine, etc.

In presenting this subject I recognize fully the difficulties I encounter. The list of agents which when taken into the system produce disturbances of vision is a long one. I do not hope, therefore, to present them all. I shall select those that are most frequent and interesting and show in fact only the skeleton of the subject, leaving to you the task of clothing it with beauty and with flesh.

In the beginning I desire to express my indebtedness to Dr. G. de Schweinitz¹ and Dr. Casey M. Wood² for the assistance I have received in preparing this paper from their works entitled "The Toxic Amblyopias."

By the term toxic amblyopia I understand an interference in vision produced by certain drugs or substances that have been absorbed by the human system. Following Dr. Wood I divide them into two great classes: 1, those that directly affect the optic nerves; 2, those whose symptoms are unattended by retinal or optic nerve lesions.

The first class should be divided into two divisions: (a) those that produce a retrobulbar neuritis; among these tobacco, alcohol, tobacco-alcohol, carbon bisulphid, hashish, iodoform and arsenic are chief; (b) those that produce other forms of optic nerve and retinal disease, such as lead, quinin, salicylic acid or the salicylate of soda, venom of poisonous reptiles, silver, mercury, ergot, nitrite of amyl, the oxid of nitrogen gas, male fern and pomegranite. We will first take up the study of those agents that produce either retrobulbar optic neuritis or neuroretinal disease.

Among the agents that produce retrobulbar optic neuritis, alcohol and tobacco occupy first and second place respectively. It has been held, and at the first blush it appears not without reason, that these agents separately produce no toxic effect on the optic nerve. But upon careful examination of the literature that bears on this subject it is now obvious that there is an amblyopia dependent upon each of these. There can be no doubt that they are more frequently combined than separate in their action on the optic nerve, but I repeat it has been sufficiently proven that each one alone produces in toxic doses amblyopia dependent upon retrobulbar optic neuritis.

As far back as 1777 Plenck³ recognized alcohol alone as a cause of amblyopia. Doebblin⁴ has argued this in a thesis published in 1850.

It is highly probable that dilute alcoholic drinks in the form of beer and wine taken in moderation pro-

duce no effect on the function of vision. It has been claimed by Hutchinson⁵ that the adulteration of alcohol by amyl alcohol, empyreumatic oils or the essences of the liqueurs such as wormwood in absinthe, hydrocyanic acid in maraschino, etc., are peculiarly apt to produce amblyopia. This point has not been by any means established. To any one who has made any observations on this subject it must be clear that the habit of taking many small drinks during the day and particularly before meals, is conducive to the causation of amblyopia. In fact it is the "nipper" and not the "spreer" whom we find the subject of amblyopia from the abuse of alcohol.

I myself have found it frequently among bar-keepers who are accustomed to take a large number of small drinks during the hours of duty.

In alcohol as in all forms of poisoning the greatest difference exists in persons as to susceptibility. There are those who have drunk strong undiluted drinks constantly from youth all the days of their lives who have never shown signs of amblyopia, and there are others who show the signs after a very limited indulgence for a small number of years. Idiosyncrasy is a factor beyond any doubt. Nevertheless one rarely finds a case of amblyopia from either tobacco or alcohol or both combined under 40 years. Uthoff has shown by a compilation that by far the greatest number of amblyopics from tobacco and alcohol are found between the ages of 40 and 50 years. There can be no doubt that the male sex has a decided monopoly of amblyopic symptoms from these two agents. Men are more given to smoke and drink in excess than women. In Uthoff's compilation of 135 cases all were men. If women used tobacco and alcohol as much and as frequently as men there is no doubt that amblyopia would be found as frequent among them as among men. I have under my care at present a woman of 26, who for years has been addicted to tobacco and alcohol in great quantities and whose vision is reduced to 3—200 from retrobulbar neuritis. I should say that women would be more subject to amblyopia from tobacco and alcohol than men, all things being equal, owing to their more delicate nervous system. I have seen one case of tobacco amblyopia in a Portuguese man between 30 and 35 years. One case of amblyopia from dipping snuff has been reported by Blitz⁶. I can not altogether agree with those who think that occupation is a predisposing factor except in the case of bartenders. It has been said that workmen and especially farm hands are predisposed, owing to their rising very early and the temptation which this habit brings of drinking and smoking on an empty stomach. My experience does not confirm the accuracy of this opinion. The strength and amount of the tobacco smoked and the strength and "neatness" of the liquor drunk certainly have a bearing on the subject. Those who drink neat whisky and brandy on an empty stomach and those who smoke short-stemmed pipes, strong tobacco and strong cigars are more liable to amblyopia than those who do not. It has been my fortune to see but two cases of amblyopia in which cigarettes had been smoked. One was the case of the woman referred to, whose case was complicated by alcohol, and the other was that of the Portuguese under 35. He did not drink to excess and smoked only cigarettes. One of the worst and most rapidly developing cases of amblyopia I ever saw was that of an Englishman of powerful frame, who told me that for twenty years he

never was without a pipe in his mouth and frequently drank more than a quart of brandy in a day. He was a ranchman in Australia. It would be interesting to know the experience of those present in regard to amblyopia from cigarette smoking.

I am not at one with those who claim that it is possible to make a difference between the signs and symptoms of the amblyopia from tobacco and that from alcohol. Since I hold this view I shall refer to their symptoms and signs together. Patients are apt to tell you as the first symptom that their vision is misty. A mist, they say, seems to hang over the print and it always apparently affects both eyes. They are apt to come to you and demand a stronger pair of glasses.

It is worthy of note that they rarely suspect the cause of their trouble. Perhaps the most distinctly characteristic symptom is the inability to recognize the colors red and green at the macula lutea. This is called central color scotoma. This is not always present in the beginning but is certain to be present later. The color perception outside of the region of the macula is normal. Hence the patients are never conscious of this defect till it is shown to them. In severe cases there is absolute scotoma at the macula, *i. e.*, there is no recognition of any object in the small area in the field corresponding to the macula. The field of vision as a rule is unimpaired in uncomplicated cases. In the beginning the ophthalmoscope reveals a congested optic nerve. As the neuritis goes on the optic nerve as a rule assumes a pallid appearance to the outer side where the fibers destined for the macula lutea lie. This sometimes has a triangular shape. Uthoff found this sign in 63 out of 100 cases. For my part I have never failed to find it when the central scotoma for red and green was marked and certainly always when the central scotoma was absolute.

It is a question whether this form of optic neuritis alone ever goes on to complete blindness. It is always well to look to syphilis as a complication, since tobacco, alcohol and syphilis are a frequent trigeminal combination. Recovery is apt to occur only when the disease is recognized in its incipiency and the patient has the character to jugulate the habit.

I have no faith in the word of chronic smokers and drinkers. Their mental inhibition seems to be diminished. I think it may be said that as a rule these cases do not recover but retain enough vision to go about with difficulty, although not able to read or engage in any useful pursuit.

Quite a large number of cases of amblyopia from the effect of carbon bisulphid have been reported. This agent is a colorless, highly refracting liquid of a peculiarly disagreeable odor. It is very volatile in the arts and is chiefly used in the manufacture of vulcanized rubber goods. In this manufacture it is always associated with the monochlorid of sulphur. It has been thought that this latter agent has some influence on the development of amblyopia but this point has not been proved. The Committee of the British Ophthalmological Society appointed to investigate this subject came to the conclusion that it was the inhalation of the vapor and not the contact of the hands with it that produced the poisonous effects. The earliest symptoms are frontal and temporal pain as if the head was being squeezed. There are numerous other symptoms such as vertigo, loquacity and intoxication followed by depression. At first vision is misty as in the tobacco and alcohol amblyopia, then

vision is greatly impaired, there is central ring-shaped scotoma for colors and at times an absolute central scotoma. The optic nerve often becomes pallid. The prognosis as far as sight is concerned is good if the occupation is given up. Of twenty-four cases reported upon to the above-mentioned society about one-third recovered perfect vision, one-third improved a good deal and the remainder continued as they had been. Delpech⁷ first described this amblyopia in 1856.

In addition to its well-known effects, haschisch or Indian hemp produces inconstant symptoms of amblyopia. The drug is taken by the natives of India in the form of leaves which are smoked, a conserve which is eaten or an oily mess made with melted butter which is sipped. Ali⁸ has reported a number of cases as occurring in Persia. James Oliver⁹ noticed dimness of vision and weakness of accommodation. Cassicia's¹⁰ case developed mydriasis with hallucinations of vision. Werner¹¹ reports a case of cloudy violet vision in a small, nervous woman. The various reports hardly entitle cannabis indica to a place among the amblyopia-producing intoxicants.

Hirschberg¹² seems to be the first to publish a case of iodoform poisoning with this symptom. His patient was a young girl whose hip joint had been dressed with iodoform. There was intoxication and the vision was lowered to 1—20 and 1—30 in the right and left eye respectively. There was also a decided central scotoma for form. In eight days recovery was complete. E. Hutchinson¹³ and Priestley Smith¹⁴ have reported two more cases. In both of these cases iodoform was given internally. In Smith's case there was absolute central scotoma with greatly diminished vision, but in Hutchinson's case there was greatly diminished vision without any scotoma. Both cases recovered in a few months.

It is well known that those who work in arsenic, such as painters and paperhangers, as well as those who take arsenic medicinally and habitually, suffer from eczema, edema and pigmentation of the external ocular appendages. In addition to this, however, it is well established that arsenic in poisonous doses produces well-defined effects on the optic nerve. Liebrecht¹⁵ reports a case in which a man who took arsenic for psoriasis to the point of vomiting and headache evinced great deterioration of vision, *e. g.*, in the counting of figures at eight feet. There was also well-marked paracentral scotoma for red and green together with temporal pallor of the optic disc. Dana¹⁶ reports a case of an American who took increasing doses of Fowler's solution till he developed sensory and motor paresis and a well-defined optic neuritis. He recovered on discontinuance of the medicine. Derby¹⁷ reports a case of a man who had severe arsenical poison from the fumes of the wallpaper in his library. He found double optic neuritis with a hemorrhage in one eye.

I shall now leave the poisons that produce chronic retrobulbar optic neuritis and shall take up the consideration of those that produce other forms of optic nerve and retinal disease.

Among these agents lead and quinin stand preëminent. Plumbism does not always affect the eyes in the same manner. The commonest sign is said to be optic nerve atrophy, which comes on slowly. The disc is pale or grayish with contracted arteries and dilated veins. It commonly goes on to total blindness, and when that is not the case there are defects

in the center and periphery of the field with much diminished visual acuity. Uthoff describes the case of a color-mixer who had retrobulbar optic neuritis with absolute central scotoma and vision reduced to 8—200 in one eye and 7—200 in the other. De Wecker¹⁸ and Massalon say that retrobulbar optic neuritis is common in lead poisoning and that if the poisoning continues there will always be absolute central scotoma. Gowers¹⁹ shows that optic neuritis with retinal hemorrhages, in fact the picture of neuroretinitis hemorrhagica, occurred in his case. Finally a condition of amblyopia fugax has been observed without fundus changes.

In chronic lead poisoning the other well-known systemic symptoms persist as a rule for a long time before amblyopia is observed, although Samelsohn has shown that sometimes ocular symptoms are observed first and in such cases the prognosis seems to be good. The prognosis is favorable when vision is but slightly reduced and the fundus lesions are slight or recent. Other ocular symptoms have been observed in lead poisoning, especially paralysis of one or more of the extrinsic muscles. Landesberg,²⁰ Von Schroeder²¹ and Wadsworth²² report such cases. Dr. Pooley has recently called my attention to a case reported by Lagleyze²³ of Buenos Ayres, which is, I believe, unparalleled. A man of 45 shot himself in the palm of the right hand with a fowling piece. (*La Clinique Ophthalmologique*, August, 1896.) Several shot were taken away, a few came away by suppuration, but seventeen remained encysted. Without going further into the details of this case, suffice it to say three years afterward there was a paresis of the internal rectus of the right eye which after several months became a paralysis. During these three years he was subject to symptoms of colic and spasms of the abdominal muscles.

I regret very much I have not more time and space at my disposal to discuss more fully quinin amaurosis. The subject is certainly interesting and important. In consideration of the great amount of quinin that is yearly prescribed, particularly in malarial countries, it is curious that not more than fifty-five or sixty cases of amaurosis are on record. In referring to the toxic effect of this drug on the vision, we always use the word amaurosis and not amblyopia, because it produces blindness.

Giacomini²⁴ reported the first case. The amount necessary to produce amaurosis varies greatly. I myself have cited a case in which 15 grains produced total blindness lasting a number of hours, and it is recorded by Vorhees²⁵ that one person took 1,300 grains before blindness set in. I am inclined to believe that idiosyncrasy is a factor when small doses produce blindness, and that any one may become blind from excessive use of the drug. Atkinson²⁶ has made a masterly review of the subject and I would refer you to his work for details as to the literature and symptoms of quinin blindness.

Dr. Knapp,²⁷ in 1881, thus describes the signs and symptoms of quinin amaurosis: "Marked pallor, general weakness, twitching of the mouth and extremities, total blindness and deafness associated with loud tinnitus aurium. The pupils are widely dilated and do not react to light, but do to accommodation. The patient often loses consciousness to a greater or less degree. The ophthalmoscope shows an absolute anemia of the optic nerve and retina. The papilla is chalky white and no trace of a blood vessel in that or

the retina is to be seen. This²⁸ state of things is seen in every case." Over against this statement I desire to place a case I have reported. After a large but undetermined dose of quinin a man of 45 became delirious and finally exhibited total blindness. He recovered to the extent of seeing white objects in a dimly lighted rooms. Two years afterward his optic nerves were dead white, but the arteries and veins could be distinctly traced on the disc and into the retina. I can not refer to this subject without bringing before your notice the monumental work of Dr. G. de Schweinitz,²⁹ who has shown by feeding quinin to dogs that the same signs and symptoms as occur in man can be produced in them. Microscopic examination of the optic nerves after death showed the characteristics of true atrophy. The prognosis is said to be good, as a rule. The blindness persists from a few hours to years. The central vision returns to normal after some days, weeks or months according to Gruening,³⁰ but the peripheric blindness remains. My case is the only one on record in which the blindness remained for as long a period as two years. I hope I will be pardoned for presenting the conclusions I drew in 1894 from a study of this subject:²⁸

1. Quinin in toxic doses may produce blindness.
2. The dose is distinctly indeterminate.
3. The duration of the amaurosis varies largely.
4. The field of vision remains contracted.
5. Central vision usually returns.
6. There is color blindness at first; the color perception is ultimately within the central field.
7. The ophthalmoscopic picture is that of white atrophy.
8. Experiments on dogs show that there is atrophy of the entire optic tract.
9. The same experiments show that the cells of the cuneus are probably not affected.

The only remaining statistics in this class that I shall discuss are the venom of reptiles, mercury, ergot, and the anthelmintics, male fern and pomegranate. It seems certain that in several instances blindness has resulted from the bite of venomous reptiles. Amaral states that this frequently occurs in South America. De Magalhaes³¹ of Rio reports the case of a negro who became totally blind after a snake bite. The poisonous agent is an albuminoid in the secretion of the venom sac. It is said that the poison of the cobra is a cycloplegic when applied to the eyes of fowls.

Staderini³² and Addario found that a 2 per cent. collyrium of toad poison produced anesthesia of the cornea that lasted four of five hours. In this connection I can not refrain from mentioning what is to me very interesting: Dr. Lambert, an American missionary to China, stated in a letter, that when cocain first came out he removed a foreign body from the cornea of a Chinese lady painlessly in the presence of a Chinese physician. The latter expressed no wonder at the result and said that his people had known that agent for 1,000 years, and that it was made from the eye of the toad.

I think mercury can be dismissed in a few words. Amblyopia from the absorption of mercury is beyond a doubt very rare. The only two cases that seem to me to be worthy of consideration are those of Galezowski, who reported an example of optic atrophy, and Square,³³ who reported one of optic neuritis due to the poisoning from this drug.

Ergot presents a much more interesting field. Transitory amblyopia has been attributed to poisoning

from this drug, but the most important rôle that ergot plays in affections of the eye is that of causing cataract. The interest centers in South Germany and Russia, where a great deal of rye bread is eaten. Ignaz Meier,³⁴ in 1857, saw twenty-three cases of cataract in the epidemic of rye poisoning in South Germany. A wet summer produced disease of the rye and the peasants ate bread made from the diseased rye in spite of warnings. Two hundred and eighty-three cases were affected by ergotism. Meyer saw twenty-three cases of cataract the following year among these people, of which fifteen were women and eight men. The form of cataract was the senile form and it progressed slowly. The remaining structures of the eye were healthy. Kortnew³⁵ saw a number of cases in Russia during the epidemic of 1889-90. Two thousand people were affected with ergotism. About two months after the beginning of the epidemic the eye symptoms were noticed. He divides the symptoms into two groups, the intermittent fugacious amblyopia and cataract. It affects both young and old. The cataracts formed slowly, growing from the center toward the periphery. The operation of extraction was successful, except that there was an unusual loss of vitreous.

Male fern has produced amaurosis and amblyopia in several well authenticated cases. One case reported by Eich³⁶ died. In several cases in which the patient survived, optic nerve atrophy resulted with total blindness. Zimmerman³⁷ publishes a case of bilateral optic nerve atrophy from a dose of 10 grams and Fritz³⁸ one of unilateral atrophy with sudden blindness. His case was that of a servant girl of 18, affected with tenia, who took 6 grams of the extract in as many hours. She fell in convulsions and coma and when she recovered was blind in both eyes. After several months her right eye recovered normal vision, but the left remained amaurotic with atrophy of the optic nerve.

Pomegranate can be dismissed with a line. Jacobson records a case in which there was paresis of accommodation and amblyopia from the development of latent hypermetropia.

We come now to Class 2—Those poisons whose amblyopic symptoms are unattended by any retinal or optic nerve lesions. With Wood, I divide these into three subdivisions:

1. Those agents that produce mydriasis as their chief symptom. Among these the most important are the solanaceæ, belladonna, hyoscyamin, daturin, duboisin, etc. Their effect on the pupil is well known; they produce mydriasis and paralysis of the accommodation. I am inclined to place cocain among them, for it certainly dilates the pupil and slightly affects the accommodation. These agents have their most marked effects when introduced as solutions in the conjunctival sac, but they may likewise produce them when introduced in toxic doses into the system. It is to be remembered that atropia is apt to produce glaucoma when used in adults, and that severe toxic general symptoms have frequently been observed to follow the instillation of a solution of duboisin in the eye. I do not believe that cocain has any tendency to produce glaucoma. On the contrary, my experience has taught me that it reduces the tension of the eyeball.

The ptomaines and leucomains to be found in decomposed or "high" food, affect the eye as the mydriatics, namely, by producing dilatation of the pupil and paresis of the accommodation. Among such

foods may be mentioned uncooked tainted meat, rotten sausage, rotten fish, poisonous fungi and shell fish, mussels in particular. In mussels the poison is found in the liver and is similar to curare in action.

An American physician, says Wood, observed a case of mydriasis and paresis of the accommodation from eating turkey. He assumed that the bird had eaten the berries of the deadly nightshade. It is far more reasonable to assume that the turkey was "high" and the poisoning was due to tyrotoxin. The extrinsic muscles have likewise been paralyzed and ptosis, or drooping of the lid, has been frequently observed. Grienouw³⁹ recites the case of several members of a family who ate raw ham; all had mydriasis and cycloplegia. The ham was fed to mice, which it killed in twenty-four hours.

2. Agents that produce myosis or a contracted pupil. Among these are opium and its preparations, chloral and its hydrate, eserine, pilocarpin, strychnin and nicotin. The effect of opium upon the pupil is well known and is a strong diagnostic sign in poisoning by this drug. Physostigma venenosum or calabar bean with its preparations, and jaborandi and its preparations, which are decided myotics when applied directly to the eye, generally cause mydriasis in systemic intoxication. Eserine and pilocarpin have the effect of decreasing intraocular pressure when applied to the eye, and hence are used in the treatment of glaucoma. By some delicate subjects eserine is not borne, as in such cases it congests the eye, gives supraorbital pain and produces vomiting. For such cases pilocarpin is better, though its effects are more transient and less powerful.

3. Poisons that produce irregular eye symptoms: This list is a long one. Those that are most worthy of notice, it seems to me, are santonin, the anilin dyes, emanation from pitch and coal, naphthalin and the bromid of potash. Santonin, picric acid and amyl nitrite may be grouped as triplets, producing colored vision, generally xanthopsia or yellow vision. There are several theories to account for these visual disturbances. Helmholtz has thought that it is due to the direct action of the drugs on the nervous elements of the retina. Others think it is due to a tingling of the media of the eye, as the urine is colored in such cases. This phenomenon was first observed by Hufeland in 1806. De Martigny⁴⁰ has made some interesting observations on this subject. He found in some cases that the yellow passed into other colors. A dose of .3 grams was followed by xanthopsia, .6 grams caused red vision, which turned into orange and then into yellow. Another patient saw green and still another blue. It seems quite certain that anilin, which is the base of the beautiful dyes of commerce, produces amblyopia, photophobia, muscæ volitantes and headache. The workmen in dye factories often complain of these symptoms. Akin to this is the effect produced upon workmen by the emanations from pitch and coal. The fine powder from these substances fill the pores of the skin, choking the sweat ducts and pass into every cavity of the body. The poisonous emanations are mainly phenol and anilin and the result of their being absorbed into the system is analogous to those of anilin. Naphthalin likewise is a product of coal distillation, and the chief interest that centers round its absorption into the system is the probability of its causing cataract in the human being. Experiments have proved that it produces cataract when fed to rabbits. I refer you to a

paper by H. Magnus⁴¹ for information on this point. Notwithstanding the large doses of bromid of potash taken by epileptics it is significant that but few instances have been recorded in which this drug has produced visual disturbances. Rubel reports a case of a patient who took 235 grains daily. One day he became suddenly blind. Examination showed pallor of both discs and contracted retinal arteries. The bromid was stopped and vision returned.

It is difficult to draw any other than general conclusions on such a broad subject as this. I think, however, the following are permissible:

1. There are certain poisons which when introduced into the human system produce characteristic toxic symptoms in the eye.

2. These poisons are divided into two grand divisions: *a*, those that produce organic changes in the optic nerve and retina; *b*, those that produce no organic change in the optic nerve and retina, in short, those whose effect on the eye is a functional one.

3. The majority of these poisons are found in the list of medicinal remedies.

4. In view of these facts it is obviously important that practitioners of medicine should be intimately acquainted with the toxic effect of these poisons on the eye.

Experimental Investigations of the Effect of Certain Purgatives in Achoilia.—Stadelmann tied and resected part of the ductus choledochus and made a biliary fistula in dogs, thus preventing the passage of any bile into the intestines. Certain purgatives administered then failed to produce any effect, among them podophyllin, podophyllintoxin and scammonium, while others, including calomel aloes, aloin, gamboge and jalap produced the usual effect.—*Nouv. Remèdes*, December 8.

GONORRHEAL OPHTHALMIA—REPORT OF CASE.

BY HENRY W. WANDLESS, M.D.

Consulting Oculist and Aurist of Parkland Hospital; Chief Surgeon
Dallas Charitable Eye, Ear, Nose and Throat Infirmary;
Consulting Oculist and Aurist to the
M. K. & T. and G. C. & S. F.
Railways.

DALLAS, TEXAS.

T. F. S., a strong, robust young man, contracted a typical case of gonorrhoea. As he did not regard it with much anxiety, and as it was no unusual thing with him, he began treating himself. On the eighth day of its progress his left eye became inflamed and in three hours, at which time I saw him, his eye was violently inflamed, discharging profusely and very much swollen. He told me his story and I saw that I had a serious case to handle. I decided that heroic treatment was demanded at once. I lost no time, after cleansing the eye, in applying a nitrate of silver solution, 40 grs. to the ounce of water, thoroughly to both upper and lower lids; after allowing it to rest a few moments, cleared off the excess with solution of acid boric 4 per cent. and common salt. I then put him in a recumbent position and applied to closed lids hot solution of mercuric chlorid, 1-2,000, continuously for one hour. I then cleansed eye again with solution boric acid, bandaged it well and ordered him to return at 6 o'clock P. M., it then being 3 P. M. When he returned, to my great surprise, I found very much less discharge, swelling considerably reduced and very little pain. My first thought then was that it was not a case of gonorrhoeal ophthalmia; but without taking any chances, I continued my treatment as outlined—anti-gonorrhoeal. I flooded the eye with bichlorid of mercury solution, 1-5,000, instilled a 6 per cent. of cocain, bandaged the eye and ordered him if pain returned or discharge became profuse during the night, to send for me at once. I ordered hot fomentations before bedtime for one hour, consisting of Pond's extract, boric acid and water, and told him to return at 8 o'clock next morning. He showed up on time, greatly improved, with bandage off. He reported following my directions to the letter and said that he went to sleep at 10 o'clock and slept all night. He did not open his eyes until 5:30, when he got up and bathed the eye in the solution used before retiring, the eye having glued together during the night. I applied a solution of zinc, 5 grs. to the ounce, after profusely flooding it with boric acid solution. I saw no further need of silver. He returned at noon when I repeated the morning treatment and at night I did the same thing. At this time there was some ecchymosis in lower lid and considerable in conjunctival membrane. I ordered hot fomentations of salt water and a weak solution to be allowed to enter between the lids. He again showed up at 8 o'clock the next morning, after having had a good night's rest. The eyelids did not adhere the night previous and only a moderate quantity of pus remained in the corners. I continued the previous day's treatment, morning, noon and night. He returned the next day very much improved, with only a slight discoloration about the lids and conjunctiva, and I considered the eye well. He came for a few days for inspection rather than treatment. I had made up my mind by this time that the inflammation was non-gonorrhoeal and that the urethritis was not of gonorrhoeal origin. The young man assured me that he knew what he was talking about and pointed to the very moment when he

inoculated his eye. He bathed his eyes as a precautionary measure, but evidently failed to dislodge the virus, as results show. To satisfy myself I had Dr. J. B. Shel mire make a microscopic examination of the urethral discharge, which revealed gonococci in the pus cells in great numbers. I then became convinced that I had dealt with a true case of gonorrhoeal ophthalmia. Had I had presence of mind I could have had the discharge from the eye examined microscopically, as I afterward did the urethral discharge, and verified my diagnosis; but in my great anxiety my only thought was that of saving the eye. It was not till after danger had passed that I thought of the microscopic examination.

I report this case for three reasons: 1, because of its rapid and most violent onset; 2, for its complete and rapid recovery; 3, because it required only one application, 40 grs. to the ounce, of nitrate of silver to eliminate its characteristic symptoms.

It is not necessary to go into detail and give all the different oculists' treatment; but I think I am safe in saying that the general drift of opinion is in favor of less heroic treatment.

The less heroic treatment does well in children under 3 years and for infants, but in adults and older children we need something heroic—something which by its severity more nearly counteracts the disease. In one case of a little girl, 3 years old, after having used milder treatment for several days with no appreciable good, I applied nitrate of silver, 40 grs. to the ounce at one time which completely put the disease under control. The ulcer on the cornea began to heal at once.

Every oculist who has been so unfortunate as to have a case of gonorrhoeal ophthalmia to treat, knows what it means; and if I could by the report of this case arm him with more effective means of combating this dreadful disease, I shall feel that I have done good.

There were no bad results in this case, not even the least infiltration of the cornea.

INTRACRANIAL ABSCESS.

A paper read before the Wayne County Medical Society, Oct. 15, 1896.

BY HAL C. WYMAN, M.Sc., M.D.

PROFESSOR OF SURGERY, MICHIGAN COLLEGE OF MEDICINE AND SURGERY.
DETROIT, MICH.

Recent improvements in surgical technique enable surgeons to open the cranial cavity with much less danger than formerly attended operations of this class. Anesthesia, antiseptics, better instruments and more knowledge of surgical history and news, make the foundation on which this improvement rests. The art of diagnosis keeps pace with the advance in surgical methods. The general forward movement along the whole line of medicine has helped to crowd the cranial cavity with industrious investigators. The bony envelope of the brain is no longer a Chinese wall against research and discovery concerning the function and aberrations of the organs of the mind.

The common cause of abscess, infection, operates on the same principle in the cranial cavity, but under different conditions from those which obtain in other parts of the body. For example, the swelling incident to an infection of the knee-joint occurs in consequence of the yielding character of the joint tissues under the pressure of inflammatory processes. In the

skull, however, infection can not show itself by swelling and tumefaction because of the unyielding character of the skull wall. The different anatomic conditions under which infection and abscess occur, will therefore yield symptom phenomena of diverse and varying kinds, but their significance and interpretation will not be the less unvarying and constant. Thus, swelling in the skull will yield the symptom phenomena of brain compression, with an aberration, impairment and loss of function in the part of the brain compressed. Infections commonly proceed along certain channels, for which they seem to manifest a well-defined preference. The lacerated and bruised finger when infected will, in most instances, show that infection by pain, redness and swelling of the lymph channels of the forearm and arm. If abscess results, it will generally be found in the connective tissue lymph spaces of the forearm or arm. If an infection follows an injury to the Eustachian tube or middle ear, it will be quite certain to travel, with pain and swelling, along the lymph spaces adjacent to the lateral or sigmoid sinuses. If abscess succeeds, it accumulates in the mastoid, cranial or aural cavity. The symptoms of this infection will be, 1, a history of injury to some part of the auditory track; 2, pain in the region of the ear or side of the head; 3, impairment or loss of function of some part or parts of the brain, delirium, convulsions, paresis, coma, paralysis. There may or may not be a record of abnormal temperature, but there will surely be found the constitutional symptom of inflammation and of abscess, although the chill, classical in the history of abscess, may not be clearly defined. The degree of primary inflammation may not afford an accurate index of the amount of the brain function impaired. It may not be sufficient to cause much pain, loss of sleep and appetite, and yet produce when choked within the bony walls of the skull, delirium, convulsions, paralysis, coma, death.

Intracranial abscess, in so far as its primary symptoms are concerned, may give rise to the same phenomena as intracranial hemorrhage, effusion or depressed fracture. Certain drugs may also produce those symptoms. They are whisky, opium, gelsemium and other narcotics including those derived from coal tar. The differential diagnosis can generally be made by a careful study of the history of the case. The character of the onset. The certain finding of the infectious entrance in some part of the face, head or neck, with the symptoms of impairment of brain function and the persistence of the symptoms after time has been allowed for the elimination of drugs, will make a quite safe foundation for a diagnosis. I do not mean to dispute the unusual fact that an infection entrance, in brain abscess, in parts of the body remote from the head and neck, may be found. I have found, postmortem, a large abscess of the right frontal lobe of the brain in which the symptoms leading to it followed an injury of the foot, but such remote sources of intracranial infection are not the rule. The particular part of the intracranial contents which is the seat of abscess may vary, and I know of no external sign that is infallible of the location of an intracranial abscess. Abscesses having their origin in throat or ear inflammations may be looked for in the region adjacent to the lateral and sigmoid sinuses, and obstruction of the blood current in those vessels should be looked for. Sometimes it is found as a hard, cord-like mass extending into the internal jugular vein, which can be felt

deep in the neck below the angle of the lower jaw, but this is only sometimes. In other cases the obstruction will cause the blood to dam back and choke the vessels of the conjunctiva and eyelids on the affected side. The ophthalmoscope may reveal the presence of obstructed venous circulation under the circumstances. Other times the abscess may be deeply seated in the brain tissue and not affect directly the membranes or their vessels. Then its presence may be recognized by the impairment of function which follows destruction of brain cells and fibers, but so little is known of the local functions of the brain that no great accuracy can be expected from this source. A patient may have a paralysis or paresis limited to certain sets of muscles of face, arm or leg and in consequence the abscess be looked for in some part of the fissure of Rolando. The motor areas of the cerebral cortex are quite well defined and peripheral feebleness or paralysis can be located with reasonable precision. Likewise, certain sensory areas can be limited. Paths of white fibers leading to these areas may be the seat of inflammation and abscess and then this loss of function will have the same diagnostic and localizing significance common to all neurotic symptoms, which are stated rather crudely as follows: Loss of function or nerve energy in the parts supplied by a nerve indicates that a lesion exists in some one or all of the parts known as the ending, trunk or center of the nerve. Now, when by exclusion we have traced a lesion to the cavity of the skull, we may still be in doubt as to whether it is located in the cortex or white substance. Of course, we know that the wider the field of loss of function, the greater the probability of the inflammation or abscess being located in some of the narrow paths where large numbers of communicating fibers are associated, for example, the internal capsule. And when there is a loss of function in parts supplied by well known cortical areas, we have little trouble in making a differential localizing diagnosis. But suppose, as often occurs, the well known cortical areas and sensory and motor paths are not specifically affected, that the loss of nerve energy as shown by paralysis and coma, is general, where will we look for the products of inflammation? Bearing on the solution of this question which, I think, must be settled by a careful and discriminating interpretation of the history of all the phenomena as they have developed from hour to hour, we must not forget that a small inflammatory lesion in the cortex or any part of the brain may impair the function of the whole brain or of limited areas of it, much more extensive than the anatomic boundaries of the lesion. Particularly is this true when the lesion involves the blood supply to parts of the brain. The physiologic relation of blood and brain to nerve energy can be compared to a sponge and water. Compress or otherwise obstruct the flow of blood through the brain or any of its parts, and you drive the nerve energy out of the brain as the water is driven from a wet sponge when it is squeezed in the hand. We have already spoken of inflammatory lesions involving the cerebral sinuses. The obstructive phenomena which we would naturally expect to follow the development of a large inflammatory thrombus in the lateral and sigmoid sinus, does not commonly occur for the reason that the outlet for blood through the jugular foramen on the opposite side of the skull is competent to empty the skull of venous blood as fast as it is produced, but usually, however, it is slow in adapting itself to the increased

work, and in consequence the quality of nerve energy developed from the brain cells is more or less impaired. Hence the varying degrees of delirium, mania, paresis, convulsions, coma, which sometimes accompany a case of intracranial abscess, and a few of the difficulties in bringing it within reasonable reach of a surgical operation. I think it a sound surgical procedure to open the skull when we are satisfied that pus or other inflammatory products are pent up in its cavity, and no one would think of disputing it if I could with precision say where those products could be found, so that an operation would surely be followed by an immediate discharge of them. This, however, in the nature of things can not be. But the opening in the skull can be used to search for the abscess or other products of inflammation. Often abscesses are located between the dura mater and the brain; then the trephine, if applied directly over the place where these morbid fluids are located, will permit their immediate evacuation.

Trephining is an exploratory operation generally, although the simple removal of a piece of the skull wall may give vent to pent-up fluids and change the character of blood and lymph circulation so that curative process may commence. Sometimes in the search for the inflammatory nidus after opening the skull, a probe pushed beneath the bone in the direction of the supposed location of the inflammation, will find it and establish a channel for the discharge. Healing of the wound and the cure of the patient, however, will generally be better accomplished by removing a strip of bone over the inflamed and suppurating area, sufficient to secure good drainage. For this the trephine should be supplemented by the use of some of the bone-cutting forceps or rongeurs. One devised by Dr. De Vilbiss of Toledo, Ohio, is well adapted for the purpose. Chisel and mallet and drills are often used, but I do not like the idea of pounding the skull with a mallet, consequently always use a small trephine, which removes a button of bone three-fourths of an inch in diameter. Through the opening made with it, the point of the finger can be introduced and the membranes palpated. The same valuable information as regards pulsation, density, resistance and temperature can be learned about the brain in this way that can be learned by the sense of touch applied to other parts of the body. If the membranes bulge into the opening we know there is excess of pressure; if there is absence of pulsation we know that circulation has, in part at least, ceased beneath our finger. The dura mater should be incised when there is abnormal pressure beneath it, and always with great caution against infection. If epidural inflammatory areas are discovered, the dura mater should not be opened lest the arachnoid space be exposed to infection. At first the opening in the dura mater should be made with a fine needle, preferably a hypodermic needle, which can be used to exhaust some of the fluid for examination. If found purulent, it should be at once evacuated through an opening in the dura mater large enough to hold a short drainage tube about the size of a lead pencil. One end of the tube should be inserted beneath the dura and the bone far enough to hold, in the direction from which the pus appears to come. The other end of the tube should barely project from the scalp so that it can be easily covered and protected by the dressings. Unless the cavity is large, the writer does not find it necessary to resort to irrigation. In his

experience, as a rule, a daily change of gauze absorbent dressings has sufficed to keep the wound clean and promote healing. In a case of abscess of the frontal left lobe following a compound fracture, and in which the abscess was recognized and located by the occurrence of convulsions followed by coma, I operated at the Emergency Hospital; used the trephine at the lower angle of the fracture, broke through the inflamed and lymph-covered membranes with point of scissors and penetrated and evacuated an abscess which was apparently in the white substance, a full half ounce of pus discharged; a gauze drain was used and removed daily, all untoward symptoms gradually disappeared and the patient was cured well and sound. A man aged 24, whom I trephined for epilepsy of almost daily occurrence, was doing well in the Emergency Hospital on the tenth day after the operation. The scalp had healed. Because of hemianopsia preceding the epilepsy in the aura, I trephined on the left of the torcular Herophili and removed a strip of bone three-fourths of an inch wide and two inches long, upward obliquely at an angle of 45 degrees to the left lateral sinus. I also opened the dura and discharged some fluid. A few days after reaching his home the patient became stupid; when roused said his head ached, lost his appetite, rolled his eyes up, became very restless and muttered in delirium. His temperature rose to 104 degrees F. His pulse and breathing were very irregular, alternately fast and slow. I suspected abscess. Without anesthetic I reopened the wound, scooped out the new tissue in the bone and penetrated the membranes. The cortex did not pulsate. It felt hot and resistant. An exploring needle was pushed in the direction of greatest resistance and penetrated an abscess cavity at the depth of one-half inch. Two ounces, approximately, of pus discharged, after pushing a dressing forceps through the cortex alongside of the exploring needle. A drainage tube one and one-half inches long was introduced. The outer end of it was sutured in the scalp when the flap was replaced. A sterilized gauze dressing was applied daily. The patient recovered. His epilepsy did not recur until four months after this operation and then in much milder form. No water or other fluid was used to irrigate the abscess cavity.

I have mentioned these cases because they illustrate the existence of abscess of the white substance. In neither case was there any paralysis nor paresis of a localizing character. I found the abscess by exploring for it. The intracranial abscesses which follow nose, throat or ear infection is much more frequent and is almost always meningeal. It should be operated early to avoid general meningitis. The opening for the purpose should be made through the skull near the base of the mastoid. Care should be taken when operating early, to not saw into the lateral sinus. I have never known serious hemorrhage from the sinus when wounded in the course of an operation for inflammation of the parts adjacent to it, but I believe in taking every precaution compatible with removal of a button of bone from contact with the sinus. With ordinary skill in operating and selection of cases in which general infection of the subarachnoid space has not occurred, one may reasonably expect most of the cases of intracranial abscess to recover.

Let us have a Department of Public Health!

SOCIOLOGIC REFORMS.

Opening address, read before the State Conference of Charities and Corrections at Springfield, Nov., 12, 1896.

BY ARTHUR R. REYNOLDS, M.D.

PRESIDENT OF THE BOARD OF STATE COMMISSIONERS OF PUBLIC CHARITIES OF ILLINOIS.

The Board of State Commissioners of Public Charities were moved to call this conference, feeling that there was a growing demand for knowledge of our institutions, and an increasing interest in the care of dependent persons. There seems, also, to be an awakening among charitably inclined people, as to how best to help those who can not help themselves. It is true, that our board publishes every two years a report of their doings, so also do the larger institutions, but they are read by comparatively few persons.

The amount of money paid out directly by the State, to support persons unfitted by nature or disease to support themselves, is very large, but when we come to consider the amount expended by the several counties and municipalities, and the sums subscribed, through churches and other public bodies of organized charity, together with the amount expended in private work, of the same kind, the total amounts to enormous figures.

It is to the credit of the tax-payers that there is never any complaint against paying a liberal allowance for the care of the sick and needy, and however heavy the total burden of taxes may be, there is no one that would have it lightened, if the retrenchment would bear upon the scanty portion of the poor.

Notwithstanding all the treasure that has been lavished upon the unfortunate, there seems to be an increasing demand that it should go on and on. There are many indications to warrant the belief that the increase of dependents is in greater proportion than the increase of population. In spite of the efforts made toward relief, the increase of those who need care grows faster than the increase of the means to care for them. Some even go so far as to say the race is in danger of being overwhelmed, and fear for the future of the State and society.

As we ponder on the subject, the conviction grows that there is something wrong in our methods of dealing with the question. We ask ourselves whether or not it be wise to continue forever harvesting this crop of human tares; if it would not be wiser to follow the example of the prudent husbandman, and prevent the unprofitable seed from taking root; if it would not be wiser still to expend more time and toil preparing the soil for the sowing, that there may be economy in the gleaning.

We can not escape the fact that a large number of criminals and those with a susceptibility to mental and physical disease, and even the paupers, are foredoomed to their fate before they are born, and should not have been born at all.

It may not be practicable for an officer of the State to sit in judgment upon those who would marry, and properly foretell the exact physical and mental mold of the progeny. The State, however, can and should be able to do as much for the breeding of men and women as is done for the breeding of the beasts of the field. The passage of a just law for the regulation of marriage, with skilled officers to enforce it, would call the attention of the public to the question most forcibly. Once it becomes a matter of serious thought and study, by the people, the cure will be near at hand. There are none but would recoil from the thought of

begetting offspring that would be lacking in any respect, if the question were brought home by a law that required them to pass muster before competent authority. While I firmly believe in proper selection for marriage I do not think this is the whole evil. More criminals, paupers and dependents generally are made after they are born than before. The children of vicious parents can be trained in the ways of righteousness if the training begin at the cradle, and the child of the good and wise can be spoiled if trained by vicious and indolent hands. We need more kindergartens and social settlements for the babies in the congested tenement districts of cities, before we add more universities for adults. If we can for one generation give to all children the proper environment and judicious training, we will have less need for penitentiaries, jails, bridewells, police stations and criminal courts. Indeed, such training is even a most rational cure for the withering blight of inebriety, and the endless train of degenerating evils, that follows in its wake.

If the proper training of children is of such moment, the greatest protection must be thrown around the sanctity of the home, for it is in the home and only in the home that the very best training can be had. The home, to be sacred, must be segregated, for indiscriminate crowding and association develops the evil propensities of a child rather than the good. Nowhere can the homes of the poorer people be segregated so well as in the country. Orphan asylums may be necessary and the right thing in their way for the present, but they are at best but a makeshift for the real remedy. The children of today will be the home builders of tomorrow. A child raised in a public institution learns nothing of this art, and will not take kindly to it after leaving the institution.

If the money spent in the support of orphan asylums were used to find individual permanent homes among the farmers for dependent children, in the great majority of cases a robust and normal adult would be the result. The direct saving of money, if this were the rule, must be great, and the gain to the State by improving the chances of the descendants is beyond estimate.

In our day the almighty dollar is the magnet that draws all mankind. To possess it is a passion with almost all kinds and conditions of men. It holds a despot's sway in the heart of every man, whether he be high or low in society's scale. It is a powerful entity that must be reckoned with in sociological science. So strongly developed is the desire for money, and the power it brings, and so keen is the struggle to obtain it, that rest, food, raiment, honor and even life itself are sacrificed on its altar.

Men crowd into a decade the labor that should be spread over the three score years and ten. Men and women suffering constantly from overwork and nervous strain can not reasonably be expected to beget children that are robust and normal, yet the world marvels that so few of the great have offspring that can fill the parent's sphere in the world. We are too apt to forget the fact that our men with the greatest minds and the strongest bodies have been reared almost wholly in the country.

The drift of population of late years has been toward the cities and away from the country. Efforts should be made to stop it, and transplant the surplus population of cities on the broad acres. But if we are to move the surplus out from the cities to the

country, our wise men must, if they can, make the dollar as easy to obtain in the country, as it is in the city, for the possession of money is the goal that all are striving to reach. Those economic features that best foster the profit of the farm, then, must play an important part in the welfare of the race, and should be carefully considered by our statesmen, as well as by students of sociology.

The State of Illinois has established, under supervision of the Board of State Commissioners of Public Charities, fourteen institutions, caring for more than 12,500 persons annually at a cost of about \$133 per year each. Four of these are hospitals for the insane, affording care and treatment to 4,600 males and 3,000 females. Two other hospitals for the insane are in course of construction, one at Rock Island to accommodate 600, and one at Peoria to accommodate 200.

There are still about 1,000 insane in poorhouses, and in jails of the various counties, while Cook County maintains an insane hospital for the accommodation of about 1,300; there is also an asylum for insane criminals with 125 inmates; the Eye and Ear Infirmary with about 150 patients; the Industrial Home for the Blind, with about 75 inmates, who are furnished an opportunity to earn a portion of their living at least, and are freed from the feeling of utter dependence. There is a home for feeble minded children, with over 600 inmates, and as many more on the outside who should have the care of a similar home. The Soldiers and Sailors Home with 1,300 inmates; the Soldiers' Orphans Home, with 400 and over; the Home for Soldiers' widows with 20 inmates; the school for the blind, with 150 pupils; the school for the deaf and dumb, with over 300 pupils; the home for juvenile female offenders, with 75 inmates.

The management of all the State's institutions in the humane, scientific and financial aspect, is well abreast of the times. In addition to the supervision of the State institutions mentioned, the Commissioners of Public Charities are commanded to visit "each of the poor houses, or other places where the insane may be confined at least once each year." There are 102 counties in the State, each of which has a poorhouse. To do all this work and do it well, requires almost the entire time of all five commissioners. The State asks that this service be rendered without salary, the State only paying the actual cash outlay made.

There is a pressing need for a Home for Epileptics, and this conference would do well to ask our Legislators to provide it. To my mind, the greatest need of all, is another well equipped home, capable of receiving all the feeble minded children in the State, where those capable of receiving instruction may be made in some degree useful, and where the others can have ample custodial care, and where all, as they grow older, can be so segregated that they will not leave any descendants to inherit the blight that makes them a reproach to our civilization.

I venture to suggest the propriety of so enlarging the scope of our State Board of Health, as will permit it to do at least as much for the development of man as is now being done for the development of dumb brutes. The Board of Health will not have reached its limit in sanitation till it will have prevented human beings from being born with a susceptibility that invites the attack of the deadly disease germs. The first necessity of human beings is good health. It is not enough that a State Board of Health should

point out the way to the individual, so he can avoid contact with a germ that may eat him up. It could, if it would, point out the way to develop a being so vigorous and so strong, that the dreadful germ will itself be destroyed in the contest. Perhaps, too, our higher educational institutions might enlarge their usefulness if they would add to their curriculum of study a year at the forge, the lathe, the work-bench, the loom, or even a year on a farm doing the routine duty of the hired man, and working from sun-up till the darkness drives him from the field. A thorough grounding in the duties of the farm is to learn the foundation of all industries. Indeed, I pity the man who knows nothing of rural life; he is seriously handicapped, no matter into what sphere his fate may lead him. It is on the farm that a young man can better than anywhere develop a strong body, and a robust and normal intellect. It is there that a ruggedness of character can best be developed, that will later on make him spurn an evening at the club over wine and tobacco, where ribald jest is mistaken for humor. It will make him shun such perverted pastimes that too often lead to a degeneracy of his descendants.

Perhaps, too, such institutions of learning might with profit teach in a more practical way the physiology of man, to the end that none of their graduates would ever append their signatures to a document certifying to the wonderful virtues of Dr. Balsam's liniment. It is but fair that they should learn enough on the subject to drive out of them any superstitious notions they may have upon the cause and treatment of disease, for, "the proper study of mankind is man."

In conclusion, I beg to suggest the need of this conference, making a permanent organization and meeting at least annually to study the great problems that are embraced in the broad field before us. I can not think that the philanthropic spirit—the practical logic of the students of social law—the public spirit of the great commonwealth of Illinois, will be behind other States in this respect. She will take her place in this, as she has in so many other things, having no competitors but leading all, in the fullness of her destiny.

WHO WAS THE FIRST TO ILLUMINATE THE SIGMOID CAVITY?

Read in the Section on Surgery and Anatomy, at the Forty-seventh Annual Meeting of the American Medical Association held at Atlanta, Ga., May 5-8, 1896.

BY J. G. CARPENTER, M.D.

STANFORD, KY.

At Winchester, Ky., June, 1886, the author read a paper before the Kentucky State Medical Society on ulceration of the sigmoid cavity—Inversion of Trunk, Electric and Reflected Light in Diagnosis and Treatment, which was published in the *American Practitioner and News*, Vol. 11. New Series, No. 17, August 21, 1886, at Louisville, Ky.

On November 30, 1885, the writer visited J— Mc. at Crab Orchard, Ky., who had had an attack of acute dysentery in August, 1885, and had made an incomplete recovery, and had been treated by his physician for chronic dysentery from September 18 to November of that year. Age of patient was 20 years, good family history, former health good, habits and morals good, and the following general and local conditions existed, viz.:

The patient was pale, weak and anemic; the tongue had a yellowish-white coat; the bowels were tympan-

itic and painful in the left iliac region, especially on pressure. Dysentery had been present since August, the stools averaging from three to six per day, and containing a little muco-pus with some blood. Each stool was preceded by pain in the tract of the sigmoid flexure. The pulse was ninety-six; temperature and respiration normal. Digital and ocular examination found the anus and rectum in a normal condition, though the latter contained an abundance of scybala, broken-down pus, epithelium and blood. A rectal injection of warm salt and water, as hot as could be borne, half a gallon in quantity, was given, the trunk being inverted at an angle of from seventy to eighty degrees with the bed. The object of this procedure was to wash out the descending colon, sigmoid flexure and rectum. The injection was retained for twenty minutes, when the patient resumed the sitting posture, and passed it. The bowel having been cleansed, the patient was placed on his left side and the trunk again inverted to an angle of seventy to eighty degrees, whereupon the abdominal and pelvic contents gravitated toward the diaphragm.

Sims' speculum was now inserted into the anus, which being dilated and the nates widely separated, the patient was directed to make prolonged expirations. Under these maneuvers the rectum became inflated, the distension being so great as to temporarily efface the folds of its mucous lining. An electric lamp was now introduced into the rectum, and an ulcer, one inch by two, was seen in the sigmoid flexure, ten inches by measurement from the anus. This was swabbed with absorbent cotton, and to it nitrate of silver, grs. xl to water 3j, was applied. During the next six days, injections of water, as hot as could be borne, were given night and morning, with the trunk inverted but inclined toward the left side. These were for cleansing and soothing effects. In each instance after the first injection had passed, another of tannin, grs. x, laudanum, gtt. xx, was administered for its astringent and anodyne effects, and to give rest to the ulcerated bowel. These injections were given invariably with the trunk inverted. Applications of nitrate of silver, grs. lx to water 3j, were made every six or eight days, the injections being continued during the intervals until restoration was complete.

All subsequent ocular examinations were made with reflected light from the head mirror of a laryngoscope, sometimes by the sun, sometimes by the coal-oil lamp, both of which illuminated the ulcerated surface and lining of sigmoid flexure and rectum sufficiently for all practical purposes.

The constitutional treatment consisted of liquid nutritious food, rest in a recumbent posture, and massage night and morning. Mr. Allingham speaks of making rectal examinations with the hips elevated, the trunk in the prone position, and by aid of reflected light from the head mirror of a laryngoscope; but neither Erichsen, Bryant, Holmes, Ashhurst, nor Ashton or any other writer mention inversion of the trunk at an angle of seventy or eighty degrees, and the use of the electric lamp for exploration of the rectum and sigmoid flexure; and an entirely different posture to Dr. Sims' and original with the writer, and should be called "Carpenter's Posture or Method." Mr. Bryant, however, states (Surgery, p. 566) that Mr. Allingham advises the prone position with the hips well elevated upon hard pillows to such an inclination that the intestines will

gravitate toward the diaphragm, so that when expiration takes place the rectum will become patulous, and the surgeon can see distinctly as far as the sigmoid flexure. This mode of examination, he informs us, was suggested by Dr. Marion Sims' "Diseases of the Rectum, 1882."

I was not aware of the fact that Dr. Sims had resorted to this mode of examination until my patient had recovered, when I found the above item in a search of a literature of the various methods of rectal examinations. But it should be noted that, in addition to reflected light, I used the electric light. I have employed this means of illumination in oral, throat, nasal, aural, and rectal examinations with such entire satisfaction as to convince me that no other light can surpass it. Sunlight reflected is to be accorded the second place in the order of excellence.

In obscure cases of diseases of the rectum and sigmoid flexure, inversion of the trunk seventy to eighty degrees, dilatation of the anus with Sims' speculum, inflation of the bowels and electric or reflected light (the former is preferable), are indispensable to a thorough ocular examination and diagnosis.

When the ulcer is situated in the descending colon, a rubber tube can be inserted into the bowel through the anus, to the distance of one or more feet, and a medicated injection passed through it to the diseased surface. In such cases I have used a rubber tube, eighteen inches long, with good results. By inversion of the trunk seventy or eighty degrees, the pelvic and abdominal contents gravitate toward the diaphragm; a vacuum is formed in the rectum and sigmoid which become inflated with air under forced expiration; the mucous folds are effaced, and the bowel has almost the appearance of a straight tube; on inspiration the bowel collapses and presents a curved tube, the mucous folds resuming their normal position.

The upper end of the rectum is much smaller than any other part of it, and presents a cavity closed from the sigmoid flexure by virtue of the fact that the circular muscular fibers of the latter act as a sphincter, except during forced expiration and defecation; at such time the rectal cavity and lower part of the cavity of the sigmoid flexure seem one.

Gray's Anatomy, page 806, states that the sigmoid flexure is the narrowest part of the colon. It is situated in the left iliac fossa, commencing at the termination of the descending colon opposite the crest of the ilium, and ending in the rectum opposite the left sacro-iliac symphysis; the distance from crest to the symphysis is three or four inches on the skeleton. The rectum is the terminal part of the large intestine, and extends from the sigmoid flexure to the anus; it varies in length from six to eight inches, and has received its name from being less flexuous than any other part of the intestinal canal. It commences opposite the left sacro-iliac symphysis, passes obliquely downward from left to right to the middle of the sacrum, forming a gentle curve to the right side; it then descends in front of the lower part of the sacrum and coccyx, presenting a curve with its concavity forward, and near the extremity of the latter bone inclines backward to terminate at the anus. The rectum is cylindrical, not sacculated like the rest of the large intestine; it is narrower at its upper part than the sigmoid flexure, gradually increases in size as it descends, and immediately above the anus presents considerable dilatation. It is capable of acquir-

ing enormous size; when distended it is funnel-shaped.

The bill of Sims' speculum is two to four inches long, convex on the outer, concave on the inner surface; the lower third of the rectum is one to one and a half inches long; after passing forward in the manner of the middle third, it passes backward to the anus; it is therefore easy to see if the sphincter ani is dilated or weak and dilatable, how with the speculum the anus and the lower part of the rectum can be retracted posteriorly, making the posterior wall comparatively straight; then a blunt sound or applicator (the bladder being empty) may be passed along the anterior wall of the rectum, pressing it forward, or by inflation on expiration, thus removing the convexity of its posterior surface, which naturally, or during normal respiration, fits into the concavity of the anterior surface of the posterior rectal wall, and making the anterior or recto-vesical wall straight; still holding this wall forward, it being quite mobile, and, holding it also out of the way with the recto-vesical wall at the same time, light is readily reflected into the rectal and sigmoid cavities. "The sigmoid flexure has great mobility; with the hand introduced into the bowel a point above the umbilicus has been reached." In the discussion of the case of ulceration of the sigmoid flexure reported by me at Winchester, Ky., Dr. Pinckney Thompson "thought the claims of the reporter almost impossible," viz., that he could see the sigmoid flexure or pass a tube or bougie beyond this point. Dr. David Yandell thought it impossible, Drs. Wathen and Wm. Bailey thought it possible and the procedure feasible, and that Dr. Carpenter had illumined and seen into the sigmoid cavity. Mr. Wales, in *Gaillard's Medical Journal*, p. 385, Vol. xxxii, No. 4, April, 1884, states that O'Bierne, Rilliet, Cadge, and Simon, concluded that a bougie could not pass into the descending colon. Wachmuth, on the other hand, claims to have reached a depth of 166 to 195 centimeters, or five feet five inches, to six feet five inches. Storer reported cases in which he believed he had reached the cecum, after five feet (151 centimeters) of a bougie had passed into the anus.

Mr. Wales further states: "I have rarely failed to pass it through the sigmoid flexure to near the termination of the descending colon, and on the cadaver I have demonstrated the practicability of penetrating beyond this point; the difficulty arises from the meso-colon fastening the lower end of the descending colon almost immovably in the lumbar region, while the sigmoid flexure from this point curves sharply to the right before plunging into the pelvis. When the bougie attains a depth of forty centimeters its point can be felt in the neighborhood of the umbilicus, especially if the flexure, as sometimes happens, is unusually long and mobile, far away from the locality where the flexure merges into the descending colon. The bougie has, in fact, stretched the sigmoid curve upward and to the right, thus rendering the angle it makes with the colon altogether sharper and quite impassable. In order to arrive at this angle with the bougie, it is necessary to depress its point into the left lumbar region by one hand externally to the abdomen, while using the other hand to propel the instrument." Dr. George Hunn, of Junction City, Ky., had a patient, a boy, with intra-pelvic tumor. The latter pressed on the sigmoid flexure, making it impossible for the patient to pass a stool, or even gas,

without passing a hollow tube into the colon daily to give temporary relief. Injections were given through this tube, and all gases, liquids and feces escaped through it. The tube on its distal end, or head, had the form of a snake's head, was slightly flexible, and curved so as to readily take the direction of the descending, transverse and ascending colon, after passing the sigmoid flexure; it was three feet six inches long and half an inch in caliber.

Dr. Hunn continued this treatment daily for many weeks, the colon and sigmoid flexure were greatly distended, one or more times the normal caliber of each. The tube passed easily and could be felt in different parts of the colon, even to the cecum, by the hand on external palpation. The patient finally died of exhaustion. Ocular examination of the cavities of the rectum and sigmoid flexures, though one is expert in handling instruments and focusing reflected light on the parts to be seen, is no easy feat to accomplish. The subject to be examined should be slender and lean or emaciated, and willing to bear some slight pain and discomfort in the accomplishment of inspection; the sphincter ani should be previously dilated or relaxed and dilatable, as was the case with my patient. If sunlight is reflected into the rectum the head of the patient should be toward the sun, if gas or coal oil light be employed it should be to one side—the left is preferable. The trunk must be inclined to the left side and inverted to an angle of 70 or 80 degrees and the thighs flexed; both should be supported on hard pillows. The speculum (Sims') is introduced into the anus and rectum, retracting the former, the lower and about half of the middle third of the latter, with the coccyx. The nates must also be retracted. The anterior rectal wall, or retrovesical wall, and anterior wall of sigmoid flexure are to be pressed forward by the blunt-pointed sound or applicator, or by inflation of air, out of the way, the retraction of the anus and rectum pressing the anterior rectal wall and anterior wall of the sigmoid flexure forward. The reflection of light or use of the electric lamp introduced within the bowel must be done simultaneously with forced and prolonged expiration. Mr. Mc. was examined in all ten times by this method; the last examination was on April 1, 1886. After my return from Winchester, Ky. (Kentucky State Medical Society) the patient was again examined. Neither sunlight nor electric was available this time, and lamplight had to be reflected into the bowel. The afternoon was hot, and the room had to be darkened, which increased the heat. The patient was much stronger and fleshier than on previous examinations. The sphincter ani was also stronger and more difficult to retract. Mr. Mc. complained greatly of heat, pain in anus, difficulty in breathing, and had profuse epistaxis as well as free diaphoresis. This inverted position of trunk in persons who are old or have atheromatous blood vessels, diseased lungs or heart, might lead to disastrous consequences. The examination was not completed and no more will be made in this way during the hot weather. Frequent examinations of the above reported case justify the following statements: 1. The function of the sigmoid flexure is a receptacle for the feces as they pass from the descending colon, being closed at its lower end by circular muscular fibers separating the sigmoid cavity from the rectum. 2. The shape of the sigmoid flexure lessens or breaks the force of gravity in the feces downward; if the bowel at this point was a straight

tube the intestinal contents would descend at once to the anus and cause continual inclination to defecate in the sitting or erect position. 3. When the sigmoid flexure becomes filled normal reflex action by the spinal nerves is produced, causing contraction of the circular muscular fibers and retraction of the longitudinal muscular fibers, by which the length and lumen of the bowel are made less above; the circular muscular fibers of the lower end of the sigmoid flexure and those of the rectum, the sphincter ani included, relax, and with the volition of the patient defecation is accomplished, the lungs being inflated, and the diaphragm and abdominal muscles contracted, thus lessening the contents of the abdominal cavity. 4. Physiologically the rectum is a closed and empty cavity (except during forced expiration and defecation), and separated from the sigmoid cavity above by contraction of the circular muscular fibers of the latter at its lower end. 5. The rectum has the following mucous folds, viz.: The longitudinal fold at the lower part of the bowel, and Houston's folds, each being a half inch wide and semilunar in shape, generally three or four, sometimes only two. One is situated on the right side of rectum near its upper end; one on the left side lower down. The anterior and largest one on the anterior rectal wall, opposite the base of the bladder, the posterior fold on the back wall of the rectum an inch from the anus. 6. These folds, with the circular muscular fibers of which the sphincter ani is composed, together with the levator ani and coccygeus muscles, support or act as a pillar to the sigmoid flexure when it is filled with fecal matter. 7. When defecation is postponed, though the desire is present and urgent, and feces have passed into the rectum, the latter by contraction of its circular and longitudinal muscular fibers (the mucous folds acting as valves or elevators) returns the feces to the sigmoid cavity. 8. After the desire to defecate is passed, the rectum is found to be empty. 9. But, should defecation be habitually postponed from day to day, or two or three times a week, though demand is urgent, the bowel gets habitually distended after a time, fails to contract or retract, and the rectum then, instead of being physiologically empty, becomes pathologically distended and relaxed. 10. Constipation or diarrhea would then cause the same relaxation of the involuntary muscular fibers. 11. Distension of the bladder causes its posterior or recto-vesical wall to project far into the concavity of the sacrum and rectum. 12. When the suprapubic operation of lithotomy is done, the rectum is filled with sponges to push the floor of the bladder (recto-vesical wall) up, or raise the bladder upward and forward, thereby causing the distended viscus to rise high above the pelvis, drawing the peritoneum out of the way and increasing the space for the suprapubic incision. Both of the latter conditions prove the ease with which the anterior wall of the rectum can be moved and held out of the way in ocular inspection of the bowel.

We want to deal fairly and justly with Dr. Kelly, but are at a loss to know why he should have remained silent eleven years on the knee-chest posture (Sims) and never published anything, though claiming to have done work in this line eleven years ago. For sake of argument; allow that Dr. Kelly was using reflected light in the rectum, eleven years ago, still Dr. Sims has the priority of one or more years and is the originator of the knee chest posture, and rectal illumination with reflected light. The writer's or Carpenter's

position of examination and illumination of the rectum and sigmoid cavity is new and entirely original with him; worked out on a new and independent line of thought and originality, peculiar to himself, different in position of patient and different light used, viz.: electric and sunlight reflected from head mirror; Sims' nor Kelly mentions electric or sunlight, and in 1882-3-4 electric light was not used for diagnosis in medical and surgical practice.

From Nov. 30, 1885 to April 1, 1886, the rectum and sigmoid cavity were illumined and seen into ten times by the writer in ———, 1896, the writer in consultation with Drs. Ramsey and Caldwell, of London, Ky., illumined the rectum and sigmoid cavity; patient Mr. Y. in the Carpenter posture with entire satisfaction to himself; Drs. Ramsey and Caldwell saw twelve inches and measured fourteen inches into sigmoid; instruments used every time in the Carpenter posture are Sims' speculum, a sponge holder with long handle and long wire applicator, head mirror and sunlight, electric light or coal-oil lamp, position easy and simple, no harness used, instruments few, plan original and feasible.

Prof. Howard Kelly states in *Annals of Surgery*, April 1895: "For the past eleven years I have been in the habit of examining the rectum by means of a speculum and reflected light with patient in the knee and chest posture." This same method was used by Dr. Sims in 1882, and confirmed by Messrs. Allingham and Bryant, and said position was original with Dr. J. Marion Sims and not Dr. Howard Kelly, for Dr. Kelly's first publication was a preliminary one, was in the Johns Hopkins Hospital *Bulletin*, December, 1894. We learned that Dr. Kelly did not publish anything until twelve years after Dr. Sims had published the knee-chest posture for rectal examination, and nothing is said by either gentlemen of having illumined and seen into the sigmoid cavity, but to the sigmoid cavity by Dr. Marion Sims; the writer wrote Prof. Howard Kelly for his first article on rectal illuminations, and in reply received his article published April, 1895, *Annals of Surgery*.

In the *Annals of Surgery*, 1895, Dr. Kelly titles his paper "A new method of examination and treatment of diseases of the rectum and sigmoid flexure," but really this was not a new method, for Dr. Simms suggested it in 1882, and the writer, Dr. Carpenter, demonstrated his method, and which was entirely new and original with himself, Nov. 30, 1885, read before the Kentucky State Medical Society in June, 1886, and published in the *American Practitioner and News* in August, 1886; nine and ten years respectively before Dr. Kelly recorded in print his or the Marion Sims posture.

LETTERS TO DR. J. G. CARPENTER:

BALTIMORE, May 22, 1895.

Dear Dr. Carpenter:—I have read your article with great pleasure, and wish I could meet you personally, and talk over the many things which interest us in common. I was particularly interested to see the way in which you diagnosed and treated your case of rectal ulcer. It fully bears out all you say about originality and genius of men who are thrown on their own resources.

Sincerely yours,

HOWARD A. KELLY.

Dr. Kelly has misquoted from my letter. I wrote him of "Ulcer in Sigmoid Cavity;" neither of my patients had "rectal ulcer." It is unfortunate for Dr. Kelly and myself both that he should have substituted "rectal ulcer" for sigmoid ulcer, as some reader might think I had written him of the former, instead

of the latter, and might think Dr. Kelly was first to see into the sigmoid cavity, instead of the writer.

BALTIMORE, June 13, 1895.

Dear Dr. Carpenter:—It will give me pleasure to refer to your original work in the field of rectal examination and treatment the next time I write about the subject. I think we will have to share the discovery together, as, if you will notice the first line in my article, I stated that I have been using the method of examination for eleven years past. It is clear that we, both of us, independently of each other and about the same time, arrived at a very important means of diagnosis and treatment in an obscure class of diseases.

Sincerely yours, HOWARD A. KELLY.

In Dr. Kelly's second letter, he again misquotes and refers to my "original work in the field of rectal examination and treatment," when he should have stated "original work in the field of sigmoid examination and treatment."

The writer can not see why Dr. Kelly should want to share the discovery with him (Dr. Carpenter), when the latter published his discovery more than eleven years ago, and Dr. Kelly claims to have done this about eleven years ago, but did not announce his until December, 1894, Johns Hopkins Hospital *Bulletin*, and April, 1895. Why he should have kept his light under a bushel for eleven years is certainly a mystery to the profession. Furthermore, what Dr. Kelly claims, belongs to J. Marion Sims of New York, 1882, who suggested examination of the rectum in the knee-chest posture, with reflected light. Only the guy-posts, the hobbing bandage, kicking straps are original with Dr. Kelly.

We are surprised that he has not added a surcingle with an over-check, or martingales, to complete the outfit of surgical harness, all of which are entirely unnecessary in the Sims or Carpenter posture.

It is very clear that Dr. J. Marion Sims suggested rectal illumination and the knee-chest posture in 1882. It is also clear that Dr. Carpenter made his discovery Nov. 30, 1885, independent of Drs. Sims and Kelly, before he had read Allingham's work on diseases of rectum, or Bryant's Surgery. Again, it is clear that Dr. Carpenter did not know that such a man lived by the name of Dr. Howard Kelly, until 1887 (June). But it is not clear that Dr. Howard Kelly was in the habit of examining the rectum by means of a speculum, with patient in the knee-chest posture with reflected light. This is Sims', not Kelly's originality, and it is clear that Dr. Carpenter did "arrive at a very important means of diagnosing and treatment in an obscure class of cases." If Dr. Kelly did, he has not proven it, and has only made an assertion which yet remains to be proven. Dr. Kelly graduated in 1882, and doubtless was not practicing rectal specialism before he graduated.

CERTIFICATES.

I, Joseph McClure, do hereby certify that on Nov. 30, 1885, I was inverted on my head and left shoulder, hips elevated, by Dr. J. G. Carpenter and his assistants of Stanford, Ky., who with the aid of the electric light and head mirror, was enabled to illuminate the bowel, and see an ulcer located in the sigmoid cavity ten inches from the anus, and treated the same; and that these examinations and illuminations of sigmoid cavity, ocular inspection, and applications were made to the ulcer with a long applicator, and that coal oil light and sun light were also used for illuminations at different times.

April 28, 1896.

JOSEPH McCLURE.

Witness: J. H. Hutchings.

To Whom it May Concern:—This is to certify that I was present along with Dr. J. G. Carpenter of Stanford, Ky., examined Mr. Tilfred Yaden; and that we were enabled to see into sigmoid cavity twelve inches, and with applicator to measure fourteen inches, by illumination of same with head mirror light from an oil lamp, the patient being inverted, resting upon

head and left shoulder, and nates suspended in air by elevation with pillows.

R. T. RAMSEY, M.D.
Sec'y Southeast Kentucky Medical Society.

DISCOVERIES.

From reading of Dr. W. Rubeska's Criticism on Prof. Howard Kelly and his discoveries in the Domain of Urinary Diseases:

It appears that Professor Kelly has appropriated to himself catheterization of the ureters, which was done by Pawlik at Prague in 1887, taught Professor Kelly there in 1888, and showed him (Kelly) his (Pawlik's) different metallic and elastic ureteral catheters, made by Leiter of Vienna. Pawlik also explained to Professor Kelly his (Pawlik's) new and then unpublished method of inspection of the female bladder. In the year 1889 Kelly was again a guest at Professor Pawlik's clinic and he then became acquainted with the endoscopy of the female bladder as practiced at that clinic. Kelly, after he had become acquainted with Pawlik's method, now also began to busy himself with this subject and published a series of papers in which he gradually appropriated Pawlik's urethral catheter and also endeavored to represent Pawlik's cystoscopy as his own invention. It is this which induces me to stand against Kelly and to defend the work of Pawlik as the property of his genius.

And in the *Annals of Surgery*, 1895, he has endeavored to represent J. Marion Sims' rectoscopy as his own invention. The writer has not added a slit, or handle, or changed the point; added a stopper, or chained it to any instrument; nor straightened or curved one and called it his own. All gentlemen should and can only stand on the truth. We are told the glass catheter and so-called Kelly pad are foreign inventions, only introduced into America by Professor Kelly; the strap on the pad may be his.

Since Dr. Kelly has appropriated Professor Pawlik's discoveries and inventions to himself, also Dr. Sims' rectoscopy, it is self-evident to the writer that he wants to claim Carpenter's sigmoidoscopy, and perhaps the earth. We pause in astonishment and ask, should Professor Kelly find Noah's ark and make a new window in it, would he not call the ark Professor Kelly's. Should he catch the dove that brought the olive leaf, and pluck a feather, would he not call it Professor Kelly's dove? We leave the reader to decide whether the Johns Hopkins professor or the Kentucky backwoodsman is the author of sigmoidoscopy.

Professor Kelly's sigmoidoscope are Fergusson's old uterine cylindrical speculums made with an obturator reduced in size and elongated, or the urethrasopes enlarged and lengthened, and handles placed on them, all of which are unnecessary to do sigmoidoscopy and rectoscopy.

Kelly's conical sphincter dilator and his sigmoidoscope are non-essentials, superfluities of instrumentation, and seem to be only a freak of Professor Kelly's imagination. The surgeon who knows how to do rectoscopy and sigmoidoscopy does not need Professor Kelly's modifications of other men's instruments; and he who can not do this line of work without these should not engage in this practice.

The great essentials in rectoscopy and sigmoidoscopy are: 1, the Carpenter posture, no anesthetic is required; 2, the J. Marion Sims' speculum or Harry Sims' speculum; 3, one long-handled sponge holder; one long wire applicator; 4, head mirror; 5, sun or artificial light; 6, dilated or dilatable sphincters.

ADDENDUM.—The writer thought Dr. Howard Kelly would have been present in the surgical Section of the AMERICAN MEDICAL ASSOCIATION and contended in debate for originality in sigmoidoscopy and rectoscopy had he been entitled to it. But Professor Kelly left Atlanta about twelve or twenty-four hours before the writer's paper was read. Here in the surgical Section was the place to settle the priority of claims and originality of sigmoidoscopy in the presence of surgeons and physicians who could see, think and hear for themselves, and must be our judges. We are reminded of the adage, "He who fights and runs away lives to fight another day." We are of one conclusion, that Professor Kelly did not have, nor has he, the facts to sustain him as the author of sigmoidoscopy and rectoscopy, and that rather than suffer defeat he folded his tent and silently went away.

BALTIMORE, Oct. 14, 1896.

Dear Dr. Carpenter:—I am just writing an article including some account of rectal examinations for the *Centralblatt f. Gynaekologie*, which has the widest distribution of any gynecological journal in the world. In it I shall make careful note of your original work published in the *Cincinnati Lancet-Clinic*, Feb. 23, 1895. I am sorry not to have been able to give the matter more prominence at an earlier date, but it is utterly impossible for me to get through the work which is driving me every hour of the day, and important matters sometimes do have to wait.

Remember that I shall always be glad to see you and show you any courtesy I can here in Baltimore, and when I treat the subject of rectal examinations before my classes your name will always occupy a prominent position as a pioneer.

Sincerely yours, HOWARD A. KELLY.

Cincinnati Lancet-Clinic, Feb. 23, 1895, is the second publication of my sigmoidoscopy, the first publication being June, 1886, and August, 1886, before the Kentucky State Medical Society and in the *American Practitioner and News*.

A SYSTEM FOR THE RATIONAL TREATMENT OF INJURIES BY FOMENTATIONS.

BY CHARLES DEWEY CENTER, M.D.

LATE HOUSE SURGEON PRESBYTERIAN HOSPITAL, CHICAGO, ILL.
QUINCY, ILL.

The treatment of injuries by applications of either hot or cold moisture is not a new procedure. There has been, however, a revival of this practice in the past ten years. Listerism is largely responsible for the renewal, and the development of our bacteriologic knowledge combined with our clearer physiologic insight, has given it the impetus toward the position it now holds. These applications of moist heat or cold were formerly known as stupes, but this term is now confined more especially to applications of turpentine, etc., or perhaps a better way to express it, to medicated fomentations applied to strictly medical cases.

There is no doubt that wound treatment by moisture is sometimes overdone, that it is often used with plain empiricism; that hot moisture is used where cold is indicated and *vice versa*, for very little has been written to guide the practitioner, and a doctor does not collect knowledge of fomentations and their uses by intuitional imbibition any more readily than he does other information of a professional character. Hydrotherapy has much of value concealed among its masses of uselessness and harmfulness. All believe that a kidney well flushed each day is of more benefit to the individual than one clogged with urinary salts. We do not doubt that a clean, well bathed skin is

both more useful and more ornamental than a greasy, dirty one, whose pores are filled with disfiguring blackheads. So wound treatment by moisture is rational and has come to stay, since it is based on physiologic and therapeutic facts.

The healing and cleansing properties of water have long been known; so long, in fact, that animal instinct teaches our four-footed and two-footed friends its virtues. We have merely added the knowledge of the difference in action between the hot and the cold. Dogs have been often seen to resort to water in case of injuries. One instance, reported by a reputable doctor, is on record. His dog, belonging to the spotted coach variety, was run over one day by a wagon. The dog was pushed along in front of the wheel for some distance, lacerating the soft tissues of the legs and the hips, but owing to an unevenness of the pavement, had no bones broken. Howling with pain the animal ran to a stream near by, waded into the shallow water, lay down and could not be persuaded to leave it for about seventy hours. The record is made complete by the statement that no inflammation resulted from the wounds and that the dog made an extremely rapid recovery. Water in some form is being used more and more extensively in fevers. Where once the family doctor sternly and solemnly assured the anxious family that cold water, either internally or externally, meant death to the patient, in one case by driving the fever in and the other by driving it out, there is heard now the command to sponge, or cold pack, or ice pack, when the temperature passes a given point. Permission is given to drink as freely as desired. If water, either hot or cold, or both, are useful in systemic inflammations why not in local ones. In one the disease is general, in the other local, and if there is any virtue in the water one would certainly look for its greatest benefit in the local ailment.

There is one feature of this modern hydrotherapy to bring out more clearly: the difference in the action of hot and cold moisture, and a caution against using either indiscriminately. Moist heat acts on inflamed tissue the same way as the removal of a rubber band from the finger acts on the throbbing sensation present before the removal. It dilates the cutaneous vessels, softens the general mass of tissue, allowing the capillaries and arterioles clogged with red and white corpuscles, to free themselves, permitting the process of osmosis to be enacted backward this time, and causing the intercellular stasis of serum or lymph to disappear.

Either heat or cold at first touch, acts as a constrictor or constringer of tissue, causing momentary pain in the congested area. Either the moderate, continued, hot application or the cold one dilates cutaneous vessels. The intermitting, long continued form of either constricts them. Moist heat promotes activity of the leucocytes by increasing their ameboid movements, and hastens suppuration in this way. Then, too, in an inflammation the fixed tissue cells proliferate and accompany the leucocytes in their tissue infiltration. Pathogenic microbes find the artificially warmed atypical area a fruitful spot, consequently suppuration speedily and easily ensues. Of course, in some cases this tissue infiltration reaches such an extreme that a true avascular area is caused by the pressure, and a patch of necrosis results, a frequent condition in the pathologic condition known as furuncle. Here also moist heat is favorable to resolution, since it hastens the separation of the necrotic tissue.

The cold fomentation, while intrinsically perhaps more valuable than the hot one, will in the practice of many find a more restricted usefulness, since cold must be used when inflammations are young or before the inflammatory process has commenced. The matter of cold for local calor is not a serious one, although patients frequently mislead the doctor by insisting that there is so much heat in the inflamed part. Local temperature is rarely any higher and usually not so high as body heat. It is caused entirely by increased blood supply to the part, in all cases where the systemic temperature does not also rise, the latter being caused by the toxicity of ptomaines, or by the not understood physio-chemic product, fibrinogen.

Application of cold is dangerous in cases of extreme congestion, in strangulated hernia and in any instance where the blood supply is already diminished or shut off. The Thompsonian doctrine that, "heat is life," must be believed and practiced in these cases. Cold acts in much the same way as elevation of a part. It reduces the amount of blood in the deep vessels, assisting the return of this diminished amount by dilating the cutaneous ones. Cold decreases vitality and all the vital processes, a fact recognized in our using heat instead of cold in shock. Where heat hastens suppuration cold retards it by constricting tissue; also by delaying or inhibiting the action of pus microbes.

There is no absolute and undeviating rule for the use of hot and cold fomentations. Idiosyncrasy plays a large part; mental impressions or dislikes a smaller one. Some time ago a case of appendicitis came under my notice. He had been complaining of pain for three days; had a temperature of 102.4 degrees F., there was considerable rigidity of the abdominal muscles, dullness on percussion in the region of McBurney's point. An ice bag was ordered for this spot, absolute quiet enforced and to make him think something was being done for him, as much as for any other reason, he was given benzo-naphthol, 5 grains, three times a day. For six days he lay on his back with the ice bag over his affected locality, and he got well. Some time after, another patient with appendicitis came in. It was in the beginning of her attack also. The ice bag was ordered again, but this time the patient declared it increased the pain, increased the vomiting, and it had to be left off. The only explanation that can be given for these cases, is, that there are exceptions to the rules governing the effect of heat and cold on the vaso-constrictors and vaso-dilators, as well as to all other rules.

One proof of the constricting effect of cold upon deep blood vessels is the test of Brown-Sequard. Ice placed over the lumbar region and kept there, first checks and afterward stops the secretion of the kidneys. The laity know of this effect of cold without knowing how it is obtained. They say a warm bath opens the pores and that the bather will catch cold unless he follows with a cold plunge or sponge, which closes the pores. They also know that cold fomentations, or an ice bag, are good for incipient tonsillitis. On the other hand, the backache of many women is relieved by a hot bath along the spine, the ache being the result of cord anemia and the heat producing a physiologic congestion. The opposite condition and result obtain with the use of ice in cerebral congestion.

Concerning the value of medicated fomentations, and by this term is meant those of boric acid, acetate

of aluminum, sulphate of aluminum, bichlorid of mercury, sulphate of zinc, carbolic acid, lead and opium, or opium alone, this may be said: Theoretically they are all right. The boric acid more nearly fills the requirements of all cases than any other. It has the advantage of not being dangerous. Carbolic acid is decidedly untrustworthy under all circumstances as a fomentation. One case where it was used comes to mind. The patient was a man of ordinary intelligence. He had a boil at outer end of right eyebrow. It was opened, the compartments broken up with the end of finger and washed out with 2 per cent. carbolic solution. Then, having nothing else by me, I put on a hot wet dressing of the same solution, telling him to remove this when he reached home, only four blocks, and to apply fomentations of hot water until he went to bed. The carbolic acid made his aching face feel so good he decided no improvement could be made, so left the dressing on all night. Result, considerable superficial necrosis and sloughing. The acetate of aluminum enjoys a good but narrow reputation. Senn advocates it above all other fomentations, and it is at once non-toxic and seemingly has no effect on idiosyncrasy. Sulphate of aluminum had better be left alone. It has an insidious way of removing the body of skin down to the rete, giving no sign of doing so beyond a slight tingling sensation on the part of the patient. Bichlorid of mercury must be employed very cautiously and its use not continued. Sulphate of zinc, unless used in a very dilute solution, is extremely painful to the patient when used over broken skin. Lead and opium are not used so extensively as they were some years ago. The combination is an incompatible on its face. Whether they became unfashionable preparations or whether some untoward results were obtained we do not know. There is no literature on the subject. The employment of the lead and opium wash in hot fomentations gives this result: The lead acetate hinders the conversion of uric acid into urea and favors the deposit of sodium urate about the joints. If long continued about open joints or open bone injuries, there is an increase in the diameter of the bone, or in fractures an unusual amount of callous, which later becomes infiltrated with osseous material. The opium, on the other hand, gives local results that are very desirable, if it is used in small amounts moderately; it must be used early before any degree of inflammation has been reached, for like cold it raises arterial tension, helps to maintain the blood current and hinders the migration of the leucocytes.

Fomentations of one or another kind are frequently preferable to submersions, because of the greater convenience; because submersion, if long continued, tends by great absorption of the fluid to an edematous, spongy condition of the part, and because fomentations allow the patient greater freedom of position.

In conclusion, it may be said that it is just as necessary to make an accurate diagnosis of the existing condition, for the successful use of fomentations, as it is for the successful use of any drug or of an operative procedure.

527 Lind Street.

The number of medical students in France has materially decreased since the more stringent regulations went into effect this year, dropping from 8,996 to 8,485, a difference of 511. The new regulations were described in the JOURNAL August 22, page 450.

OBESITY AS A CAUSE OF STERILITY.

Read before the Second Pan-American Medical Congress at the City of Mexico, Nov. 17, 1896.

BY JOHN V. GAFF, M.D.

TUCSON, ARIZONA.

In all ranks of life there are two well marked forms of senile decay; and every one will at once, I think, recognize the truth of the following sketch by Paget:

"Some people, as they grow old, seem only to wither and dry up—sharp featured, shriveled, spinous old folks, yet withal wiry and tough, clinging to life and letting death have them, as it were, by small instalments slowly paid; such are the 'lean and slippered pantaloon' and their shrunk shanks declare the prevailing atrophy."

Others, women more often than men, as old and as ill nourished as these, make a far different appearance. With these the first sign of old age is that they grow fat, and this abides with them till, it may be, in a last illness sharper than old age, they are robbed of even their fat. These too, when old age sets in, become puffy, short winded, pot-bellied, pale and flabby; their skin hangs not in wrinkles, but in rolls and their voice instead of rising toward childish treble, becomes gruff and husky.

Now these classes of old people may represent the two forms of atrophy. Atrophy by decrease and that by degeneration of tissue, to which we shall find nearly every part of the body liable.

Given an obese woman, we will find an excessive accumulation of fat in the adipose tissue, hindering and finally rendering impossible the function of the various organs of the body.

The distribution of this accumulation of fat is seldom uniform, being sometimes in one part of the body and sometimes in another. Particular organs may be greatly encumbered, while others experience very little impediment.

But there is a close relationship between the condition of the internal cavities and that of the subcutaneous areolar tissue, so that an extensive accumulation of fat beneath the skin may be accepted as sufficient evidence of a similar internal burden.

Under normal physiologic conditions of nutrition, the adipose tissue of the body stores up only that amount of fat which is needed for the continuous supply of fatty matter to the tissues of the body. Adipose tissue is present or may be formed wherever there is connective tissue, except in the lungs, spleen, sheath of the penis and in the brain. In the normal condition, it forms about one-twentieth of the total weight of the body.

According to Lyman, the physiologic store of fat is normally recruited from the fats that enter the circulation, either in the form of an emulsion or in derivative combination, forming glycerophosphoric acid, fatty acids and soaps. A portion of the fat is held in solution by the soaps that are formed through the action of fatty acids upon alkaline bases in the small intestines.

Glycerin and the fatty acids are produced by the action of the pancreatic juice and bile upon fat. The liberated glycerin enters into combination with phosphoric acid that has been displaced from the alimentary phosphates by the hydrochloric acid and soap of the gastric juice. Thus formed the diffusible glycerophosphoric acid and soap pass readily into the general circulation, while the emulsified fats find their way through the lacteals and the thoracic ducts into the

venous current of the blood. Reaching the tissues, the glycerin and fatty acids are readily oxidized, while the stable emulsified fats are deposited in the adipose tissue for a more gradual disintegration.

If the fat be introduced into the system beyond the capacity of the soaps and other alkaline salts to hold it in solution, the surplus remains suspended in the form of minute oil globules, giving to the circulatory fluid an oily appearance. This excess constitutes what is termed lipoemia. Under such circumstances, at the ordinary rate of oxidation within the tissues, the surplus fat can not be oxidized and it accumulates in the cells, in and around the uterus, ovaries and other organs and adipose tissues.

When the supply of fat in the blood is too great to be disposed of by immediate oxidation or by deposit in the adipose tissue, it must find its way out of the body. The sebaceous glands of the skin excrete excessively, hence that disagreeable greasy appearance of the hair and skin and eruptions of eczema and acne in the anemic and victims of irregular menstruation.

Among the causes of obesity, Blanchard has noted excess of eating and drinking in about 40 per cent. of the cases; in about 37 per cent. there was a deficiency of exercise, but in 20 per cent. the exercise was extraordinary, and in 10 per cent. the quantity of food was less than the normal amount.

Hereditary influences play a very important part in the evolution of obesity, 50 per cent. of such cases being due to this cause. Hereditary influences that predispose to arteritic disease, retardation of nutrition due to rheumatism, gout, gravel, biliary lithiasis, asthma, acid dyspepsia and kindred diseases. Through many successive generations these diseases may be traced, either associated at the same time in the same subject or occurring in alternation with each other, leaving numerous obese and sterile women in their wake. The preponderance of opinion is with the idea that more frequently an excessive amount of adipose tissue is caused by the ingestion of saccharin and starchy food than by the consumption of fat; in many cases it can be traced to acid dyspepsia, since the action of the pancreatic juice is greatly impeded by excessive acidity in the small intestines; the fats are then absorbed in the form of an emulsion instead of being split up into glycerin and fatty acids. Emulsified fats have a great tendency to become more or less permanently stored up in the adipose tissues, and favored by sedentary habits, malt liquors, etc. Lyman says that the development of anemia and obesity is favored by small but frequent losses of blood; the diminished current of blood can not transport a sufficient amount of oxygen; the exchanges upon which nutrition is dependent are consequently retarded and obesity developed. In like manner the disease frequently accompanies pregnancy, excessive menstruation and lactation, especially if the patient leads a luxurious life and gratifies an appetite for alcoholic beverages and sweet articles of diet. An insufficient oxidation of that in the tissues has been made prominent as one of the causes of obesity. As a consequence of obesity, the internal organs like the uterus, tubes, ovaries, kidneys and pancreas may be completely buried in masses of fat. The liver is enlarged, its borders lose their sharpness, its color is pale and oil oozes from an incised surface; the hepatic cells are gorged with fat, but they are not in a condition of fatty degeneration, and the connective tissue by which they are surrounded is not invaded by fatty particles.

The secretion of bile is greatly diminished, and the gall bladder and large ducts are often found empty, or contain nothing but mucus. The diaphragm is forced upward by the immense masses of adipose tissue that crowd the abdominal cavity. The thoracic cavities are also diminished by the presence of fat in the mediastinal spaces and under the pericardium and pleura. A proper expansion of the lungs is thus prevented, lessening the amount of oxygen given to the blood and thereby increasing the existing condition. Owing to the minute particles of undissolved fat, the amount of oil in the blood may be four or five times greater than it should be, or five or six parts per thousand of the circulatory fluid. The amount of hemoglobin in the red blood corpuscles do not fall below the normal limit.

The blood can not take up and transport a sufficient supply of oxygen under such conditions, and consequently a sense of breathlessness, wheezing, etc., is often experienced.

I have thus given a pen picture of the general condition and have thus described the condition of the liver more closely, to show by comparison the condition of the ovaries which are in exactly the same state, except that the anatomic construction is somewhat different, yet the cause and the results are the same.

The uterus, tubes and ovaries will be found firmly packed into the pelvis and surrounded by layers of fat; the fat cells interspersed between the unstriped muscle fibers and connective tissue surrounding the follicles are so thick and cause so much pressure that it is impossible for the ovum to escape from the ovary; large masses of fat crowding down upon the cervix, bend the canal of the uterus forward, producing an aggravated condition of ante flexion and thereby effectually preventing the entrance of semen to the uterus.

During copulation, the uterine round and broad ligaments by their concerted action cause a suction from the vagina toward the ovaries, greatly facilitating the movement of the semen. When they become encumbered with large quantities of fat, they are then no longer able to perform that function, the semen is then retarded or is lost on its way toward the junction with the ovum in the tube or ovary.

Compression of the tubes by masses of fat obstructing the passage way through the ovarian tubes is another fruitful cause of sterility.

The menstrual blood from fat women is usually pale, scant, watery and poor in fibrin. Amenorrhea and scanty menstruation probably have their origin in the anemic condition of the blood found in obese women who have been afflicted for a long period. The sexual appetite rapidly fails and is often entirely extinguished. Among young girls who exhibit the disease, menstruation usually appears at a precocious age. It is generally irregular, and alternating conditions of amenorrhea are not uncommon, and an increase in the size of the abdomen often leads to an erroneous idea of conception.

The prospects for offspring will depend more upon the menses than upon the amount of fat, which in turn depends upon how great a fatty change exists in the blood, uterus and ovaries. The life of the poorer classes tends to leanness, which calls to mind the old adage "A poor man for children." Leanness only results in sterility when due to starvation or chronic disease.

An obese woman menstruates in varying degrees from a discharge which will soil three or four napkins

daily and continue from one to three days, to only the slightest stain of a serosanguinolent nature, which by its color would be difficult to distinguish as menses. It is nearly always less than normal and in most cases consists of a bloody serum containing a few epithelial scales.

Kish has enumerated over two hundred cases of obesity associated with amenorrhea and sterility. In many of the cases there was no other cause to which he could attribute the sterility, but to obesity. Philbert has described five cases wherein pregnancy occurred through adopting a thorough and vigorous system of hydropathic and dietetic treatment. Their ages ranged from 21 to 27 years. Abortions in obese women are frequent. Stoltz has cited a case of an obese woman who had five consecutive abortions to which he could attribute no other cause. Goubert cites the case of a very fleshy woman, having had eight consecutive abortions from the same cause. McKee sums up the subject in the following well chosen words. "Nutrition takes an abnormal direction and the nutritive elements destined to support the product of conception are directed to other points."

The most favorable cases for treatment are subjects under 30 years of age, and who have not been exhausted from frequent child-bearing. Bunson has shown that the offspring from fat women lack vitality, and many if carried to full term do not survive the teething period. The following description of a few cases may prove of interest:

Miss S., aged 16, began menstruating when 14 years old. After menstruating regularly for about one year she began to take on flesh and the flow of menses grew somewhat less, and just two years from the time they were first observed they suddenly stopped. During the last year she had been confined very closely at the bedside of a sick mother and had been eating largely of sweet confections, etc., until her weight had increased in one year from 120 pounds to 200 pounds; the abdomen was quite prominent; and becoming dyspeptic from the abuse of diet she was adjudged pregnant by her family, a nurse and the neighbors. Her step-brother was accused and confessed to having cohabited with her for the past year; they were duly married and in three months the menses again made their appearance, no pregnancy having occurred. Mrs. H., aged 27, married three times, four children by first husband; began to grow fleshy until she attained a weight of 260 pounds. The menses had lessened to half the quantity and from five days to two days duration. Exercise and dietetic treatments reduced her weight to 225 pounds. She then married for the third time. Treatment was continued until her weight was 190 pounds, when she was compelled to desist on account of the extreme weakness, loss of appetite, etc., together with the great annoyance caused from an eruption of pruritus about the genitals, which on account of the intolerable itching made life anything but pleasant, and which refused to yield to remedies until the diet had been changed. The menses increased both in quantity and duration but pregnancy did not occur.

Mrs. B., age 27, weight 215 pounds, married seven years, never been pregnant, began treatment one year ago. Moderately restricted diet, eating very little bread or starchy food, exercising in the open air both by walking and the use of the bicycle and the administration of Parke, Davis & Co's desiccated thyroids. The commencing dose was three-fourths of a grain and gradually increased to 6½ grains, three times daily; her weight was reduced to 147 pounds and she is now pregnant; is enjoying good health with the exception of a slight feeling of languor and weakness.

Mrs. R., age 26, weight 200 pounds; inclined to be fleshy from birth, weight 165 pounds when married at 17 years of age; she has gradually increased in weight until three months ago, or for about nine years. The menses at the time of marriage were regular and large in quantity, but have continued to grow less and less until at the present time she is often in doubt as to whether she has passed the monthly period or not, on account of the extreme scantiness and want of color in the menstrual fluid. The treatment was begun about three months ago, with desiccated thyroids, with the advice to eat little bread or food of a starchy nature and take regular exercise by

walking or the use of the bicycle or both. According to her own words she has eaten whatever she pleased and taken only moderate exercise by walking, but has taken the medicine very regularly; commencing dose was $\frac{3}{4}$ of a grain and was gradually increased until at the present time she is taking $5\frac{1}{2}$ grains of the thyroids three times daily, before meals. She has not experienced any discomfort and has lost ten pounds. There is no perceptible change, but she says she can take much more exercise without so much fatigue and shortness of breath as before the treatment was begun.

I could describe a number of other cases that have come under my observation, but think these four cases which I have described will be sufficient to demonstrate the theory that obesity is a frequent cause of amenorrhea and sterility owing to mechanical pressure and the physiologic changes resulting from an excess of fat in the blood tissues, and is amenable to treatment in well selected cases.

WHAT CAN BE DONE BY ELECTRICITY TO AVOID SURGICAL OPERATIONS IN GYNECOLOGY.

Read before the American Electro-Therapeutic Association at Boston, Sept. 28, 1896.

BY G. BETTON MASSEY, M.D.

PHILADELPHIA.

This is a very extensive subject, even when it is narrowed down, as I have done, to the avoidance of surgical operations in the diseases of women; so extensive indeed as to be capable of only a general discussion in the time at my disposal, leaving the detailed proof of the greater comparative value of electricity to other occasions. A number of books have in fact been written on the subject since the publication of my own work and the only purpose that can be subserved in a single paper is to call renewed attention to the subject and to give additional reasons for a faith that needs the fervor of a missionary crusade among practitioners of medicine. That there is need for a pause and self-examination on the true relation of surgery to the diseases of women is the first point to be established, the second question being the claims of electricity as a superior remedy in the treatment of certain affections.

Surgery appeals to the human mind as a brilliant, spectacular and lucrative occupation; it appeals to the professional mind as a means of cutting out an otherwise incurable disease and remedying mechanical faults quickly and in the best manner. As to which of these motives has predominated in the production of the remarkable surgical furor now prevalent among gynecologists, must be decided by those who care to study motives. The evidence of overwhelming interest in surgery by those calling themselves gynecologists is evident on every hand. Beside numerous special institutions exclusively devoted to this work, many of the greatest general hospitals in this country are given over almost entirely to the performance of major operations on the pelvic organs of women, in some of them four or five such operations being done to one equally grave operation in the combined operative fields of men, children and the other parts of woman. Why is this so? It surely can not be that the pelvic organs of woman are so many times more dead, damnable and useless than all other organs of men, women and children.

Without pausing to consider the motives that have resulted in this remarkable activity, or even the insidious steps by which it has gradually grown to be considered by most of us as the legitimate work of prac-

tioners supposed to be engaged in curing the diseases of woman, but little thought is required to show that it is based on a regrettable misconception of the true nature of these affections and of duties as physicians in their remedy.

The uterus and ovaries of woman possess nerves, blood vessels and lymphatics like other organs of the body; are subject to the same vital activities; vulnerable to the same disturbing agencies, whether traumatic, microbic or reflected; and are blessed with the same defensive armament against depressing and morbid influences. Why then should they be treated as so much carpenter work in which the principles of mechanics alone are to be considered?

The stress laid upon displacements of the uterus as a primary lesion, for instance, not only violates the pathologic facts in omitting consideration of older intrinsic changes in the organ itself, which may better explain the symptoms, but is an anachronism in perpetuating a theory of the origin of engorgement or inflammation which has been superseded by the germ theory of disease.

For it is in the germ theory of tissue degradation, coincident with lowered vital resistance, that we have a key to more than half of the pelvic diseases of women, particularly those accompanied by engorgement and proliferation of the parenchyma of the organs and relaxation and fatty degeneration of their supports. The field of electro-therapy in such conditions is an extremely important one, for the true curative agency is one that stimulates the natural defences and rebuilders of tissue—the phagocytes and trophic nerves—to a renewed activity in removing lingering debris and consequences of the germ-phagocytic contest. It is not that electricity does this by virtue of proven germicidal powers at this stage, but rather by a stimulation of vital processes, and in so doing a vast number of otherwise refractory cases may be permanently remedied.

Per contra, it may be asked in what way are propping, stretching, cutting and sewing operations antidotal to the non-suppurative consequences of microbic invasion?

But if pessaries, slitting, stretching and sewing were the worst indignities that modern surgery inflicts upon these organs they would still be left to the curative efforts of the electro-therapist, and many such have finally been restored to health. Unfortunately the pessimism engendered by the failure of these purely mechanical theories of relief has at last produced its fruit in the shape of therapeutic nihilism, which blindly destroys the very organs themselves. Succeeding and accompanying the cyclonic wave of ovarian destruction and removal, we have another wave of uterine removal, the sacrificial operations of this nature attaining proportions at present that stamp Jack the Ripper as a novice in his work. But two criticisms need be made on this latest evidence of the dangers of specialism unaccompanied by judgment: The final conclusion of the surgical gynecologist to destroy an organ for mere enlargement and displacement is without a parallel in any other department of medical or surgical effort, and demands justification on the two-fold ground of the failure of non-destructive methods as well as its own success; secondly, since it has been found necessary to remove the uterus in the same class of cases for which removal of the uterine appendages has been vaunted as a cure-all, what organ or set of organs will next fall under

the ban when these cases return to the surgeon for a third operation, minus ovaries, tubes and uterus?

To us, wielding artificially a force strained from the circumambient ether, a force that is equally concerned in the chemical affinity of the minutest atoms, the metabolism of organized bodies and the world movements of the universe, such expedients are unspeakably gross. Our efforts may be equally crude and blunt in the eradication of cancer, though I will not even grant this, but when the trouble is a mere errant nutrition, a cellular hyperplasia, representing the disordered condition of a battle-devastated district, the purifying, stimulating and reconstructive effects of electricity are most interesting.

In a word, the advantages of electricity over surgery in all that class of cases due to more or less remote inflammatory conditions, lies in the fact that it is a far-reaching stimulus to tissue cleansing and reconstruction, by which alone a restoration of normal functions is attainable. And this group of cases is by no means small, including as it does endometritis, metritis, salpingitis, ovaritis, pelvic peritonitis and most of the conditions accompanied by displacements of the uterus and ovaries and relaxation of pelvic supports of non-traumatic origin.

On the other hand, surgery is indicated where a true abscess (not a mere collection of mucus in a Fallopian tube) has formed, and then the relaxation of the perineum or of the vaginal walls is due to puerperal lacerations.

Turning to neoplasms, it may be proven that the mortality from fibroid tumors is almost entirely due to surgical operations for their removal. It is impossible to give the exact statistics of this operation. One of the most recent and authoritative works on the subject, that of Pozzi, calculates the percentage of deaths as 28.2 per cent. for the intra-peritoneal method and 25 per cent. for the extra-peritoneal method, the list being made up from the reports of the most skillful operators only. Even if the lowest admitted figures be taken, they mean that one out of every four patients is sacrificed in an unnecessary attempt to remove a benign lump of flesh. This is surely as bad as the celebrated bean drawings of early Texas days when those who drew black beans were shot, the selection of the victims being probably as uncertain. And this three-to-one ordeal is offered as the only alternative when over nine to one, or about 85 per cent. of all such cases can be practically cured in the removal of the symptoms and reduction of the growth by electricity. And it may be added that the remaining 15 per cent. not favorably affected by the electric treatment are still capable of being treated by surgical method, if thought advisable, without the least disadvantage due to the application of electricity.

But this is not all. Referring again to the four cases in which the tumor is removed, one of which ends fatally and three recover, what is the subsequent condition of the three cases that recover from the immediate effects of the operation? In each case the remaining portions of the uterus and both ovaries have been removed, thus destroying the peculiarly feminine characteristics of the individual. They are necessarily neuters in the social economy. Each case is also liable to a rupture of the abdominal wall at the site of the incision, producing a tumor far more troublesome than the original growth, and each is liable to obstruction of the bowels from the operation,

and some suffer from pain, nervous disturbances and even insanity.

We look in vain for such after-effects of electric treatment, which almost invariably restores the patient to robust health, even if some portion of the harmless fibrous mass remains in its original situation.

The ultra-surgical enthusiasm should be halted also in the too prevalent method of treating dysmenorrhea, or as I prefer to call it, menorrhagia, by forcibly tearing apart the muscular and fibrous tissues of the cervix uteri. This treatment is also based on a discarded theory which attributed the pain to a mimic labor to expel accumulated fluid. It has been proven that no such accumulation exists, and the presumption now prevalent is that the pain or cramps is a neuralgic expression of nerves called upon to functionate in the presence of hyperesthetic, congested, inflamed or merely undeveloped organs. While this operation is not deadly, it gives trouble at times, and is far too violent and unscientific a procedure when the abnormal conditions are so easily curable by intra-uterine, or even at times vaginal, applications of electricity. If the pain is due to inflammatory conditions of either the uterus, tubes or ovaries, as it so often is, this operation will aggravate the patient's condition, a number of instances of this unfortunate result having been observed by me.

I shall mention but two other frequently performed operations as additional evidences of too much surgery in diseases of women, capable of simple cure by electricity. The repair of but moderately lacerated cervix receives but little mention in literature at present, but in practice is still too often performed; and the same may be said of the use of the sharp curette. The symptoms in the conditions for which both of these operations is oftenest performed are due to chronic hyperplasia of the uterus, with or without leucorrhea, and are easily curable by electricity if the habit of performing important and expensive operations were not so prevalent.

REPORT OF A CASE OF ACROMEGALY COMBINED WITH GIANTISM.

BY JAMES W. WALKER, M.D.

HOUSE PHYSICIAN, COOK COUNTY HOSPITAL,
CHICAGO.

Since 1886, when Dr. Pierre Marie first named and described this interesting pathologic condition, the literature of the subject has grown progressively larger each year, and the disease is no longer the rarity it was once believed to be, there being now over 130 authentic cases on record. The particular nature of the malady however, its etiology, pathology and clinical course are yet so imperfectly understood it is the duty of all observers to place on record an exhaustive history of each case with which they meet.

J. McL., male, age 16, was admitted to Cook County Hospital, Chicago, Ill., July 16, 1895, to the service of Dr. Jacob Rosenthal, who has kindly permitted me to report the case.

Family history is good. Father, mother, five sisters and three brothers are living, healthy and normal in appearance. All the patient's relatives are of full normal size, none are remarkably large.

Personal history. (This is supplemented by the statements of the mother and an elder brother.) He was born in Illinois of Irish-American parents, and at birth weighed thirteen pounds. The weight of his

brothers and sisters at birth varied between nine and ten pounds. The mother says that nothing remarkable was observed until the patient was 6 years old, when, after an attack of measles, he began to grow at an unusually rapid rate, the development of his hands and feet being especially noticeable. His appetite became ravenous and has continued so to the present time. When 8 years of age he began to suffer from asthenopia, which was progressive in the right eye, so that he was blind in that eye when 14 years old. He is a frequent sufferer from supraorbital neuralgia, and is also subject to attacks of urticaria. He is habitually constipated. During the past six months he has been passing an unusually large quantity of

able to clean clocks and watches and put the parts together, repair shoes, etc.

PHYSICAL EXAMINATION.

Weight	111.13 kilos (245 lbs.).
Height	196.5 cm. (6 ft. 5 1/8 in).
Girth of head at level of eyebrows	62.5 "
" " " mento-parietal	72 "
" " " occipito-bregmatic	61 "
" " neck	37 "
" " chest in expiration	102 "
" " " inspiration	116 "
" " abdomen	112 "
Span of extended arms	215.5 "
Length of hand	26 "
" " middle finger	14 "
Girth of index finger	9.5 "
Length of foot	36 "
Width "	16 "
Girth of great toe	12.5 "

J. McL.—Acromegaly.

Acromegalic giant and dwarf, both 13 years old.

urine, having to urinate several times during the night. He says he has lost about thirty-five pounds in weight during the past twelve weeks. His physical strength has always been disproportionately small in comparison with his size and with that of boys of his age. He perspires profusely, especially at night. His appetite for sweet articles of food, and for candy, is marked. He has never used tobacco. He has not received any education, being now unable to read or write; nor has he had any regular industrial employment. He has some musical ability, playing a few instruments indifferently, but only by ear. This natural gift is possessed by two or three other members of the family. He has also some natural industrial dexterity, being

The general nourishment of the patient is good. The panniculus adiposus is of average amount. The face is more boyish in expression than the age warrants. The general impression given by the patient is that he is a simple, good-natured, overgrown boy. Intellectually he is behind his age by several years. There is nothing indicating imbecility; but his views, his interests and his delights betoken delayed mental development. Seeing him as he towers above those of average stature, with his puerile expression and irresponsible manner, he seems almost unhuman, and one is unconsciously reminded of the monster in Mrs. Shelley's Frankenstein. In temperament he is decidedly phlegmatic. He is docile, obliging and courteous in disposition. He sleeps about eight hours each night and an hour or two each afternoon. There is

no true incoördination in his gait, but he "rolls," in walking.

His forehead is well shaped. The predominating feature of it is the excessive prominence of the superciliary ridges, which gives a receding appearance to the forehead. The mastoid processes are unduly large; the cheek bones are slightly prominent, the lips a little full and the nose a trifle larger than the proportionate size. It is worthy of especial note that the lower jaw is perfectly proportionate in size to the head and is normal in shape. There are twenty-seven sound teeth, which are small; the incisors and canines are not in contact laterally; none of the wisdom teeth are erupted; the dental arch is markedly narrowed in front; the tongue is of normal size; the hair is brown and soft. Eyes blue; ophthalmoscopic examination

Acromegalic giant when 13 years old.

reveals an optic nerve atrophy in the right eye. The chest is well formed and is symmetric; auscultation and percussion fail to show anything abnormal; Erb's dullness is not present; there is a kyphosis in the cervico-dorsal region of the spine. The hands, as the measurements previously given show, are extremely large; they are very thick and broad; the bones and soft parts seem to be equally increased in bulk; the fingers taper slightly; the nails are long and filbert-shaped, not short and broad as is usual in acromegaly; the soft tissues have a peculiar softness and the normal lines are deepened. The feet are enormously large in every way; the toes are proportionate and not deformed in any way; the plantar surface is flat, the normal arch being absent. The patient wears a spe-

cially-made shoe of flexible leather, with thin, flexible soles. His physical strength is below normal as tested by the hand dynamometer and by lifting weights. The skin on the right side of the abdomen shows a brown discoloration like that of pityriasis versicolor, which is sharply limited by the median line. The lower part of the abdomen, which protrudes somewhat, is marked by lineæ albicantes; there are no other scars on the body; the body is devoid of hair except in the genital and axillary regions; over the anterior and posterior surfaces of the thighs are numerous reddish-brown macules about the size of a lentil; the veins of the legs are varicosed; there is no enlargement of the lymphatic glands. The genital organs are under-developed; the testes are almond-sized and are quickly retracted on manipulation; the penis is very small; the hair on the pubis is of the feminine type, being limited by a horizontal line above; sexual desire is not developed. The nervous system is normal; reflexes are present and there are no sensory disturbances. The amount of urine passed in twenty-four hours averages 12,600 c.c., or over eight times the normal amount for an adult; the specific gravity ranges between 1.036 and 1.040; color pale; reaction acid;

Feet of patient with Acromegaly, and the author's.

the fermentation test shows 6.25 per cent. of sugar; no albumin. An estimation of the number of red corpuscles per cubic mm. gives 3,865,200; white corpuscles in normal proportion; hemoglobin present in about 75 per cent. of the normal. On admission to the hospital he had an infected finger, which healed readily after incision and evacuation of pus.

The following will show graphically how the case under description compares favorably with Dr. Maximilian Sternberg's tabular list of symptoms given in *Zeitschrift für Klinische Medizin*, Berlin, 1895:

1.—OBJECTIVE SYMPTOMS.

a. Constant.—Enlarged hands and feet, present; lengthening of face, absent; enlarged eyelids, absent; excessive enlargement of nose, slight; prominence of cheek bones, slight; enlarged lips, slight; enlarged chin, absent; prominent jaw, absent; kyphosis, present; thickening of bones of thorax, (?); abdominal respiration, present.

b. Inconstant.—Prominence of supraorbital arch, present; exophthalmos, absent; optic nerve atrophy, present; hemianopsia, absent; impaired hearing, absent; anosmia, absent; disordered taste, absent; enlarged larynx, absent; depth and roughness of voice, absent; Erb's dullness, absent; atrophy of testicles, present; enlargement of penis, absent; enlargement of abdomen, slight; atrophy of muscles, absent; reflexes, present; enlargement of heart, absent; increased rate of pulse, absent; varicose veins, present; enlarged lymphatic glands, absent; impotence, present; sweats, present; polyuria, present;

glycosuria, present; disordered sensibility, absent; pigmentation, present; warts and moles, absent.

2.—SUBJECTIVE SIGNS.

a. Constant.—Loss of sexual instinct, undeveloped; polyphagia, present; polydipsia, present.

b. Inconstant.—Headaches, present; palpitation, absent; dyspnea, absent; paresthesia, absent; vasomotor neuroses, present.

GENERAL AND PSYCHIC SYMPTOMS.

General weakness and ennui, present; melancholia, absent.

Of especial interest in the case is the combination of the two conditions, acromegaly and giantism. The exact relation these bear to each other, or the precise way in which they differ, is a subject yet under discussion; the weight of opinion, however, seems to be in favor of accepting them as distinct entities, giantism being regarded as physiologic and acromegaly as a disease. Virchow claims that there is a sharp distinction between them. Dana speaks of a case of giantism in which one side of the face alone was affected by acromegaly. Langer says that the findings about the heads of so-called giants require two classifications to be made, normal and pathologic. Individuals of unusual size with normal skulls are strong and healthy and usually live to be old, while those with abnormal skulls are weakly and die young. Klebs says that both conditions have the same causes, and are disturbances of the development. Sternberg says, in summing up this subject: "Giantism and acromegaly are two different things. Giantism is an anomaly of development which has no connection in itself with disease. Enlargement of hypophysis, enlarged jaws and the like do not occur in giantism, but in acromegaly, which is a disease with a sharp differentiation. Giantism, however, has with it a disposition to the occurrence of general dystrophy, and in particular acromegaly: This is shown by the fact that about half the cases of giantism are fatal from the development of acromegaly."

I have personally seen nine undoubted cases of acromegaly, all males. All of these have been of more than average body size, but the one under present notice is the only one over 183 cm. (6 feet). In the remaining eight, all of whom were adults, giantism does not come under consideration, but a boy of 16, measuring 196½ cm. and weighing 111.13 kilos, may, I think, be regarded as a giant. He furnishes me a statement of his height and weight at different periods during the last ten years, but as it is given from memory and has not been systematically kept, it is not sufficiently reliable for publication. It is, however, reasonably safe to assume that the development of the acromegaly and the giantism has been contemporaneous. Sternberg says that of the 130 authentic cases of acromegaly described in recent literature, only eighteen have been over 177 cm., of which number he gives a list. Only four have been taller than the subject of this paper, these being the case of Dana, 200 cm.; Haskorec, 200 cm.; Hutchinson, 204.2 cm., and Alibert, 205.7 cm.

It is also worthy of note that in this patient the lower jaw is not enlarged. Sternberg places this enlargement among the constant symptoms. It is the first case in which I have seen it lacking. Of its entire absence there is no room for doubt, as the profile photograph shows. On the other hand, the prominence of the supraorbital ridges, which he places among the inconstant symptoms, has been present in all of the nine cases I have examined.

SOCIETY PROCEEDINGS.

Chicago Academy of Medicine.

Stated Meeting, November 10, 1896.

CASEY A. WOOD, M.D., in the Chair.

(Continued from page 125.)

Dr. EMIL RIES read a paper on

NODULAR FORMS OF SALPINGITIS.

The conclusions at which he arrived are as follows:

1. Nodular enlargement of the tube can be caused by a number of different pathologic conditions.
 2. Clinical examination does not enable us to make a diagnosis of the pathologic conditions existing in an individual case of nodule of the tube.
 3. The diagnosis of the nature of a tubal nodule can only be made with the microscope.
 4. The conditions causing nodular enlargement of the tube are congenital or acquired, non-inflammatory or inflammatory.
 5. Each of these conditions can exist without the production of nodules.
 6. The nodules can be found in all parts of the tube and taking the peculiar anatomy of each part of the tube into account show the same structure.
 7. The enlargement can be caused by epithelial or epithelioid formations, connective or muscular tissue or round-cell infiltrations or combinations of two or more of these.
 8. The epithelial formations originate in the epithelium of *a*, the tubal mucous membrane (salpingitis pseudo-follicularis, adenomyoma originating in the tubal epithelium); *b*, the accessory tubes (intraparietal parasalpinx and hydroparasalpinx); *c*, remnants of the Wolffian body (adenomyoma).
 9. The epithelioid formations originate in the peritoneal epithelium (peritoneal growths under "relative heteropy").
 10. The excess of formation of connective tissue is a consequence of inflammatory conditions of the tubal wall (salpingitis interstitialis, Zweifel).
 11. The hypertrophy of the muscular tissue is *a*, non-inflammatory (adenomyoma); *b*, consequence of inflammation, Kaetenbach's case.
 12. The accumulations of round cells a direct evidence of inflammation: *a*, non-specific (salpingitis interstitialis disseminata, salpingitis abscedens) or, *b*, specific (salpingitis tuberculosa or salpingitis gonorrhoeica).
 13. The epithelioid formations can occur whenever pseudo-membranes cover organs lined with a serous coat.
 14. Extrauterine pregnancy (abdominal or tubal) produces epithelioid formations by causing pseudo-membranes to form, not by any irritation peculiar to the pregnancy.
- Dr. T. J. WATKINS—I feel extremely fortunate in having had so thorough and scientific examination made of some of the nodular growths which I removed. It was a great surprise to me to learn the character of the growths because I had always considered them inflammatory. I believe the majority of operators consider these nodules inflammatory. Some authorities do not consider these growths adenomata, because the tubes do not contain glands. Dr. Ries believes some of the adenomata develop from the tube and not from the Wolffian body. I would like to be informed how an adenoma can develop from non-glandular tissue.

Some of the practical advantages which arise from a recognition of these nodules as adenomyomata are the possibility of saving the tube and the preservation of the functions of the organ. If these nodules are inflammatory it would be dangerous to leave the tube because points of infection might be left which would cause subsequent trouble; but if these nodules are recognized as non-inflammatory it is possibly safe to leave the tube.

The case referred to by Dr. Ries where I resected was one where a nodule had developed in the tubal wall near the horn of the uterus. About one inch of the tube was resected. The interstitial portion of the tube was excised and the end of the tube was stitched into the excavation which remained. The other tube contained pus and it was removed along with the ovary. The patient menstruated twice after the operation. Two or three months later she wrote me that she thought she was pregnant; that she had skipped two menstrual periods, and that she had symptoms of pregnancy, and wanted to know if there was any danger of allowing pregnancy to continue. I advised her there was not and requested her to report to me regularly. Unfortunately she has not reported and I have not her address.

In another case a nodule had developed in the tubal wall

about two inches from the uterus. I excised the nodule with the intention of reuniting the tube, but could not find the canal of the tube in the incision, and so passed a probe in from the abdominal ostium of the tube, and was very much surprised to find the tube still intact. So it would seem advisable, wherever we find these nodules, to enucleate them and to pass a probe in from the abdominal ostium to see whether we have injured the canal or not. If the nodule occurs near the uterus there is no objection to cutting the tube off and stitching it to the uterus as above mentioned. In cases where the abdominal ostium has become closed from accumulations of serum in the tube and resultant adhesions, it is possible to amputate the distal end of the tube. Quite an efficient abdominal ostium can be made by cutting the serous and muscular layers of the tube which will cause the mucous membrane to become everted.

I have been highly gratified in listening to Dr. Ries' paper, and heartily congratulate the doctor upon his scientific and practical production.

Dr. LUDVIG HEKTOEN—I can add nothing to what Dr. Ries has already brought out. I admit that I am not able to exactly understand the drawing nearest to me, assuming that the condition originates from proliferation of the tubal epithelium. I have been thinking of similar conditions in other parts of the body where proliferations from similar structures occur. The only somewhat similar condition I have thought of is in the bile ducts. In the bile ducts of rabbits, coccidia may produce similar proliferations of the epithelium, resulting in formations not unlike those shown in one of the drawings. It would seem to me that proliferation of the epithelium like we see here might give rise to carcinoma, supposing the study of early tubal carcinoma might throw light upon these apparently benign proliferations. Concerning the proliferations of the peritoneal endothelium described, I would mention the fact that in chronic leptomenigitis very marked proliferation of the endothelial cells of the lymphatic spaces occur that are not unlike some of the pictures we notice in one of these plates.

Dr. WM. H. RUMPF was called on. He said: I want to congratulate Dr. Ries on his excellent contribution. I know how much work it represents, because I had the privilege of seeing a great deal of it and to see several of the specimens. From seeing them I can perhaps form a better picture than a great many of the Fellows. I agree thoroughly with his conclusions. It is exceedingly difficult to say much about a comparatively new pathologic condition like this, because so little is known about it, and unless one has made investigations of his own concerning it, he can not discuss it or refute any of the facts that have been brought forth. As regards the practical outcome of these investigations, I think we have here a comparatively new field, and that Dr. Watkins' operation is a step in the right direction. I do not know that I could add anything that would be of benefit in the discussion of the subject. Whether the facts set forth by the essayist are established must be shown by future investigations.

Dr. T. J. WATKINS—I would ask Dr. Ries a question. Inasmuch as these nodules are usually associated with inflammatory conditions of the uterus or appendages, is the inflammation by irritation or infection an etiologic factor in the development or growth of adenomyoma of the tubes?

Dr. RIES (closing the discussion)—Many of the points brought out in the discussion I have answered in my paper. I could not discuss them in the short review that I gave of my paper. As regards Dr. Watkins' question regarding the origin of the adenomyoma in the tubal epithelium, I have tried to prove this from observations of direct communication between epithelial masses in the wall and the epithelium of the tube. I have further been able to prove this on a specimen which showed a nodule with a well developed tubal mucous membrane in the center and obliteration of the tubal cavity at both ends of the nodule. There were no epithelial formations in the walls at both ends, but where there was well developed tubal epithelium there were numerous epithelial formations in the wall. This is of interest to us because this origin has been considered impossible, because the tube contains no glands. I tried to refute this by showing that this communication was not a gland, but a diverticulum, properly speaking. It is not a thin process, but a great depression in the mucous membrane. The growing of the tumor I did not discuss in the brief review of my paper. Where the growth originates in epithelial masses belonging to the Wolffian body, it must be assumed that primarily the Wolffian body has not undergone the degree of atrophy which it generally undergoes, and that on account of its abnormally good preservation in extrauterine life these epithelial formations by their presence and activity have caused the irritation of the surrounding

tissue which gave rise to the hypertrophic growth and the formation of the tumor. As soon as this hypertrophic growth of muscular tissue begins the epithelial formations participate. That is the theory to which I have arrived as well as von Recklinghausen. With regard to Dr. Hektoen's remarks I believe it is very appropriate to mention a similar occurrence in other organs. I have searched high and low for them, because analogies have to serve instead of experiments. We can not experiment, but we can observe the experiments which nature has made, and in this light I should regard occurrences of such formations in other organs. A somewhat similar formation has been described as occurring in the ureter, the processes of the epithelium of the ureter sometimes entering into the wall of the ureter. There we have to assume that the epithelium in the wall has to be derived from the epithelium of the ureter, because there is no Wolffian body ready to take the responsibility of these growths.

Professor Klebs mentioned the question of the formation of carcinoma from epithelial masses which have become misplaced. Recklinghausen has observed two clear cases of formation of carcinoma in the wall of the uterus without connection with the epithelium of the uterine cavity and attributes these carcinomas to the Wolffian body. He also described a case of adenoma in the wall of the cervix which originated in Gartner's duct. The transportation of epithelial masses into distant localities is a subject which is of very great importance to the gynecologists at present. This transportation becomes important in the formation of a tumor originating in the epithelial investment of the chorionic villi. The first metastases of these tumors are found in the lungs, not in the neighborhood of the uterus or in the glands. The transportation goes along the blood vessels and epithelial cells belonging to the chorionic villi, resembling to all intents and purposes the epithelium of the chorionic villi, have been found in the liver, the lungs, the spleen, where there was not the slightest other sign of carcinoma. But as Professor Klebs has said, epithelium observed in a place where epithelium is not ordinarily found does not necessarily mean carcinoma.

Another point which Professor Klebs advanced was interesting to me because I discussed it in the paper, namely, the origin of the solid masses of "peritoneal growths" in the endothelium and eventually in the lymphatic vessels. I do not accept this theory because I did not find these masses arranged in the way in which endothelial growths are arranged; that is to say, I did not find the shape of rosary as we find it in carcinomatous infiltrations of lymphatic capillaries. It is not one bead arranged next to the other—dilations and constrictions. There are no bifurcations and I can follow them to the surface to the endothelial covering of the tube. Of course the endothelial covering of the tube is practically the lining of a large lymph sac. The peritoneum is a large lymph sac and if you wish you can call these growths endothelial. But these endothelial growths show an undoubted similarity to the germinative epithelium which, looked at from an embryonic standpoint, is comparatively easy to explain. The germinative epithelium and the endothelium covering the rest of the peritoneum are originally one and the same. The germinative epithelium has preserved the size and activity of the embryonic stage. We find in other tumors that cells reassume activity and functions which they possess only in embryonic life. We always speak of the re-assumption of embryonic activity when we speak of the formation of carcinomas and of other tumors. Why not in this case?

A case of pachydermia of the larynx, as described by Professor Klebs, is very much like the cases of abnormal growth of epithelium of the chorionic villi in the uterus after myxomatous degeneration of the chorionic villi or retention of non-degenerated villi. I have some specimens where not the slightest sign of carcinoma existed in the uterus, yet I find distinct growths of epithelium belonging to the chorionic villi. The cases were those of endometritis post abortum and were cured on account of the hemorrhages. I examined them microscopically and found eventually chorionic villi and decidual masses. Sometimes the epithelium of the chorionic villi embedded in the decidual masses is not atrophied or degenerated, but has started to grow. That may be the first stage of deciduoma, but it is not necessarily that.

The malformation of the tubes in this case would not only be a double formation, but a fourfold or sixfold formation. This is theoretic. Double accessory tubes are comparatively frequent. If you pay attention to these conditions after operations you will find them much more frequently than you expect, especially if you resort to the precaution of observing your specimens when floating in water. Very frequently you do not see the accessory tubes if you do not use this precaution, because they are so small that they escape observation.

With regard to the frequency of the nodules, you will find them more frequently after your attention has been directed to them. Before I examined them microscopically I did not find them frequently. I believe that in my four years' work at the Strassburg University Woman's Hospital I did not see more than two or three cases, but since I have paid special attention to these nodules I have found them in a large number of cases. The nodules I described are not sacculated or occluded parts of the tube, occluded by inflammatory masses or inflammatory constrictions, but are real thickenings of the wall. Inflammatory sacculated nodules occur in the tube, but that is not what I designated as a nodule. It is a different condition.

SELECTIONS.

Experience with Behring's "Hellsrum."—Dr. Haase of Strassburg, in *Aerztliche Rundschau*, October, reports his experience with the curative serum of diphtheria in an unbroken series of 291 cases. He had ten deaths, all advanced cases when first seen by him, or less than 4 per cent. "The inoculations included one of 3,000 units of immunization pro dosi, and another successful case was that of a child only two days old, into which I injected 1,000 units of immunization. In the latter case it is possible that either I or the nurse communicated the disease, but in spite of a very high fever and violent symptoms of stenosis at first, within twenty-four hours the well-known shriveling of the diphtheritic membrane on the ulterior pharyngeal wall and the tonsils commenced. The child was completely cured within six days. The injection was unaccompanied by any bye-effects. The child exhibits constant increase in weight, and is in good health. For the information of opponents to the serum therapy I would mention that in all doubtful cases diphtheritic investigation was undertaken, and on each occasion the presence of true diphtheria bacteria was demonstrated. The extremely favorable results which I have obtained undoubtedly do not depend entirely upon the use of serum, but concomitant circumstances have contributed thereto. For instance, a large majority of the cases were tonsillar diphtheria, and in consequence of the instructions given to the sisters and nurses it was nearly always possible to carry out injections in the first stages of the diphtheritic attack."

The Study of Medicine a Perennial Delight.—One of the pithiest of recent addresses is that of Dr. D. W. Cheever, given in the *Boston Medical and Surgical Journal*, December 24. He treats of the study of medicine, as contradistinguished from its practice, in a luminous way; also, one or two other points which we will quote below, with our thanks to the writer, and the thanks of our readers in advance.

"The study of medicine is one delight from beginning to end. You begin with anatomy, and what is more delightful than the study of that subject for a year or two, in which you can see almost every mechanical law and mechanical device demonstrated; then you pass on from that to physiology, and see all the most delicate functions; and when you go on still further and notice them in sickness, and can reason on the causes and conditions of disease far better than you could before, and then apply remedies that will regulate and give relief; what study is more delightful? The horizon of knowledge ever recedes. You are just as much a student when you are 80 years old as when you are 20. Surgery lately has advanced so far and so fast that it has distanced medicine, and is now, since the application of antiseptics, the most attractive thing; and this, of course, is limitless; but meanwhile, even now at this moment and henceforward, I am sure that medicine is going to resume its own place, and by and by maintain its supremacy, which it always should have over surgery. I have always said that the physician is superior to the surgeon; that he has a broader field to look over; that his knowledge must be more

extensive to make him a good physician than a good surgeon. Now the physician is coming back; and he is coming back through the great advances being made so rapidly through the discovery of the antitoxins and of bacteriology. In ten years, I will venture to say, that medicine will be on as high a plane as it ever was. The resources of our profession are endless in delight; and if you find in the beginning that you love it, you will never cease to be happy in its pursuit.

"No suit of malpractice should be condoned or settled in any way, but should be fought out. As a rule, however long it is fought, the doctor will win his case. It is rare in Massachusetts that the jury will go against the doctor, in the long run, unless he proves to be a man of disreputable character. As a rule, the law is lenient, the law is just; and the interpretation put on it by most of our judges is rather on the side of the physician. It reads somewhat in this way: 'The doctor is not obliged to be possessed of extraordinary skill; if it can be shown that he has ordinary skill, that he did his best to use the skill which he had, that the skill that he used on his patient was what is averaged by the medical profession in his vicinity; if it can be proved that he did not neglect his patient, that he did the best he could, he can not be cast in damages in a suit for malpractice.'" I have looked over the records very carefully, and the judges are uniformly fair, in their charges to the doctor. We are all liable to be sued on the slightest provocation, and we must defend it. We are not the only ones who suffer; if you look at the records for actions of tort, as they are called, you will see that the courts are loaded down with them. Corporations, municipalities, individuals, merchants, business men, contractors and employers, are constantly blackmailed in the most shameful way; many of these cases they settle without allowing them to go into court. So that our profession is not alone or peculiar in this respect; only it seems to us very hard, when we have done the best we could, that we should be for a long while kept in a state of uncertainty and forced to pay in the end, although we get a verdict triumphantly in our favor. Now here comes in sometimes the importance of consultation, because if the patient has been seen in the beginning by other doctors; if they all agree; if they are sure what was the matter with him, and that what ought to have been done for him was done, this would have great weight, and will possibly prevent a suit from being brought. That I have known to be so in some cases. But you can not allow these suits to go without attending to them, because if a person yields to blackmail, all the hungry throng of sharks will mark him out as a prey, and he will have suit after suit brought against him, and soon will be entirely ruined. Moreover, on account of his self-respect he must stand for his rights. I do not think that any suit for malpractice will hurt a young doctor; in fact, sometimes it is an advertisement. It is not altogether an unmitigated hardship.

"The doctor is a victim of the interviewer and reporter; they not only pursue the doctor, but haunt the house of the sick, and even the chamber of death. There is no privacy, no respect for the patient's feelings. If any person, in a public position, happens to be sick or dying, the papers want it all, and without regard to the feelings of the friends. Now, what course must the doctor take when pursued in this way? Reporters come from his own town, or from distant cities, and claim that the illness of this person, and whether he is to live or die, is of great importance to the public. Why? Because it may affect some political deal; because it may affect the stock market; certain changes may take place if he is about to die; and so on. To whom is this man's reputation and life so important as to his own family? How can the doctor presume to give away that knowledge which belongs to the family? It seems to me the only answer for a physician to make, is to say: 'If you will bring me a note from the nearest relatives requesting me to give you such knowledge as I can of this patient, you shall

have it; otherwise I shall say nothing; and you may place whatever interpretation you please on mysilence.' "

And in conclusion :

"Ours is the noblest profession that exists; it is, above all, the most humane; it can not be otherwise; we seek daily, and give our lives, to make people happier, to make them better, to alleviate their sufferings in every possible way. This reacts upon us; we share their joy; and we frequently also get more credit than we deserve for unexpected results; and although sometimes we have a great many anxieties in the event of unexpected deaths, yet these are evenly balanced by seeing others convalesce. In England a Medical Defence Union is in vigorous existence. It assumes the risks of suits for malpractice and defends them. It is a mutual insurance company of medical men. Here, an attempt was made in 1895 to secure the assent of the Massachusetts Legislature to the establishment of a Medical and Surgical Branch of the Employers' Liability Insurance Company. It failed, however. It is the opinion of some lawyers that the existence of such an association to defend the doctor would turn the jury against him. Exorbitant fees injure the standing of the profession. Liberal fees, in consultation, are a protection to the attending physician. Small fees to the poor—but some fee—are the true course for the young doctor. McClelland on Civil Malpractice (p. 15) says: 'Among practitioners of the different schools consultations can not be held, for the reason that there is a radical difference between them either as to the medicines to be used, or the manner of using them; hence, if the practitioners be honest in their several beliefs, no good can accrue to the patient, this being the sole object.' Now, when does a doctor want a consultation to protect himself? In doubtful injuries; with ill-minded people, contentious people, people who are likely to make trouble, people who are never satisfied with anything that is done for them. The doctor soon estimates that class of people; he sees a great many of them; he can select them and differentiate them in about five minutes after he is called—and that is the class against which he is very wary. The doctor is not obliged to go when called; the only law which binds him is the obligation of humanity. Thus, if in an isolated community and no other physician were to be found, he might feel obliged, while he would not in a city or town where there were other doctors. Fatigue, sickness, overwork, other engagements, are sufficient excuses. Were it otherwise, he would soon die of exhaustion. He may decline, day or night; he can select his patients as he chooses; but if he goes, he feels obliged to continue."

PRACTICAL NOTES.

Antifebrile and Analgesic Effect of Citrophen.—E. Homberger announces that the results of his experience with citrophen in tuberculosis have been that in doses of 0.5 gram, citrophen rapidly reduces the temperature in febrile tuberculosis, without producing any secondary inconveniences. The same dose repeated four times in twenty-four hours in cases of acute rheumatism and neuralgia has given good results. In a large number of cases the citrophen increased the appetite, and as the odor recalls that of citric acid, patients enjoy taking it.—*Nouveaux Remèdes*, December 8.

Thymic Asthma.—The diagnosis of this disease is usually made after the death of the patient. In the case of a child described recently, who suffered from intense dyspnea, tracheotomy was performed without result and it was decided that the cause must be some compression by a tumor or hypertrophied thymus gland. Extending the incision, the thymus gland was found extremely enlarged and was removed. At once the respiration became normal and the child was completely cured. Siegel, who reports the case, suggests that it would be more appropriate to designate this trouble as thymic stenosis of the trachea or bronchi.—*Province Méd.*, December 12.

Operative Treatment of Stones in the Ductus Choledochus.—W. Braun reviews the 124 cases on record in his Göttingen thesis, finding that the proportion of women to men affected is as 4 to 1. Thirty-five patients died, a mortality of 28 per cent. In about 10 per cent. it was found that the operation had not been radical and that stones still remained after it. In four cases patients with extravasation of bile recovered, while in

four other cases it was the cause of death. In eighteen of fifty-nine cases the suture held, and in nineteen it gave way. Thirty-nine cases have been seen recently and no relapses have occurred among them, showing that they are rare.—*Cbl. f. Chir.*, December 19.

Comparative Nutritive Value of Nutrose and Peptone.—Bornstein has been investigating the comparative values of these substances and finds that nutrose (Rhörmann and Liebrecht), is superior to peptone (Liebig) in every respect. It is agreeable to the taste while peptone is not; it is almost completely absorbed without producing any irritation in the alimentary canal, while the irritation caused by the continued use of peptone is so severe that it is impossible to take a large amount for any length of time. Nutrose also is completely utilized, even more than meat; peptone on the contrary is assimilated less perfectly than meat. The price of the nutrose is no higher than that of peptone.—*Nouveaux Remèdes*, December 8.

Dermatol as an Antidiarrheic.—N. Klimeneko announces as the conclusions from his observations in sixty cases of diarrhea which he has treated with dermatol that it deserves more attention than it has hitherto received as a remedy of great efficacy in diarrhea. Many cases yielded to it that had resisted all other treatment. It was equally effective whatever the cause of the diarrhea, and as it has no taste or odor, it is readily taken by the patients. No inconvenience of any kind followed its use, and some claimed that their colics were also cured by it. He administered it in powders of 0.25 to 1 gram at a time, from 2 to 8 grams in all during the twenty-four hours. When there was a severe cough beside he administered simultaneously morphin, opium or codein, but in other cases he gave the dermatol alone. The diarrhea was caused by existing tuberculosis in sixteen cases, by typhoid fever in six, including one case with fever and peritonitis from perforation; grippe in four, nephritis in four, chronic intestinal catarrh in twenty-seven and three infants.—*Nouv. Remèdes*, December 8.

Iodoform Solutions for Subcutaneous Injections.—Dinkler states that the solution of iodoform in almond oil (5 per cent.) is readily decomposed by the light and produces irritation owing to the crystallization of the iodoform under the skin. It is rapidly absorbed and easily gives rise to toxic phenomena. It is advisable to reduce by one-half the usual dose of 1-10 gram. Iodoform triturated with paraffin (5 per cent.) decomposes easily and only the fresh preparation should be used. No toxic phenomena were observed from its use. Iodoform triturated with glycerin (5 per cent.) is quite soluble. Absorption is slow; the iodoform is not distributed evenly under the skin and the injections are painful. Iodoform triturated with wheat starch finely pulverized (5 per cent.) is to be recommended. Protected from the light in air tight bottles, it keeps for five to eight days without alteration of any kind, the iodoform suspended throughout the mass. Injections of this do not produce irritation; absorption takes place slowly and uniformly and is complete in three days.—*Nouveaux Remèdes*, December 8.

Hemol.—Kobert's hemol is produced by mixing thoroughly pulverized zinc with blood and then removing the zinc just before it dries. It forms a brownish powder, with a slightly brackish odor. It is prescribed for chlorosis as a powder, with or without chocolate, 0.3 to 0.5 of a gram of each; in pills made with depurated licorice juice in compressed tablets of 0.25 gram; and in chocolate pastilles of 0.5 gram. It contains 0.2 per cent. of iron and dissolves gradually in the intestines, where it is slowly absorbed. J. Bartlett reports in the *Therap. Month.* of October thirty chlorotic patients treated with hemol (in powders of 0.25 to 0.6 gram, twice a day) with excellent results. Even when continued a long time it produced no secondary annoyance; the teeth were not blackened,

there was no constipation and the appetite remained the same or was improved. It is practically a blood extract, and contains so little iron that it is supported by the weakest stomachs. He recommends the combination of arsenic with the hemol whenever arsenic is indicated, 1 to 100. This combination seems to be free from the inconveniences that frequently attend the administration of arsenic alone.—*Nouv. Remèdes*, December 8.

On Removal of Foreign Bodies from the Esophagus.—Since the article on this subject was published October 17, in the *JOURNAL*, the cathode ray has been improved to such an extent that the location of coins, etc., in the esophagus, has become an easy matter, and then by opening down to the esophagus, the foreign body can be palpated and manipulated upward (without making an incision into the esophagus), until it can be reached through the mouth and withdrawn with a pair of Mathieu forceps with corrugated blades. Foreign bodies as large as 15 millimeters are easily swallowed by children; they are usually arrested at the narrowest portion of the esophagus, and if they stand upright it is difficult to recognize their presence by the usual methods, if the children continue to drink and swallow and do not complain of pain. In these cases radiography is of the greatest advantage, as it shows the exact location of the object. An incision down to the esophagus then will allow the object to be forced upward and extracted through the mouth, avoiding an incision into the organ and thus not interfering with alimentation afterward.—*Bulletin de l'Acad. de Méd.* December 8.

Lymphadenoma with Marked Pigmentation.—At the Medical Society of London, Dr. de Havilland Hall showed a case of lymphadenoma in a patient aged 21 years, who in January, 1894, complained of indisposition for exertion for eight or nine months and a "dreadful cough." There had been no expectation, no hemoptysis and no night sweats, but he had lost nearly a stone in weight. Impaired resonance at the left apex anteriorly and posteriorly with respiration of a cogged-wheel type, was the only abnormal state found. In March, 1895, great glandular enlargement in the cervical and supraclavicular regions of the right side was noted and there was a similar enlargement on the left side, but less marked, and an enlarged gland in the axilla. The left chest was dull to the third rib, and the breath sounds were absent over the dull area. In June, 1895, there was a diminution in the size of the glands and the patient had gained slightly in weight. In May, 1896, the patient had lost eight pounds in weight; there was a dullness at the base of the left chest with deficient entry of air; the glands were about the same size as before; there was a mass of enlarged glands over the upper part of the sternum and the spleen was palpable. The skin was much pigmented. On Nov. 7, 1896, there was dullness all over the left lung, with almost entire absence of respiratory murmur, and there was a great increase in the size of the glands. Dr. Hall commented on the difficulty of diagnosis in the first instance, on the slow progress of the disease while the patient was taking arsenic and on the marked pigmentation; and he raised the question whether the pigmentation was due to the arsenic or to the involvement of the solar plexus and adrenals in a mass of enlarged abdominal glands.—*The Scalpel*, December.

Pneumectomy.—F. Terrier in the *Progrès Méd.* of December 12, reviews the record of this operation to date, which has been performed on man for tuberculosis, cancer and pulmonary hernia. In tuberculosis the three successful operations reported were circumscribed lesions in otherwise sound lungs and bodies, and it is more than probable that they might have been cured without surgical intervention. Block's patient died under his hands and he committed suicide to escape criminal prosecution. Surgical intervention in neoplasms when due to cancerous infection elsewhere, has been unsuccessful,

owing to the presence of several foci which it was impossible to find and exterminate entirely. In two cases when a cancer in the thoracic wall had spread into the pleural cavity, Krönlein and W. Müller operated with success, although one patient relapsed four years later, when a second operation was required which was similarly successful. In these cases the surgeon must not hesitate to resect the number of ribs necessary to open up the intra-thoracic extension of the neoplasm. In cases of hernia from stabs, etc., when the lung simply protrudes to close mechanically the incision, all that is needed is to disinfect the wound as thoroughly as possible and suture the serosa. The reduction must be made as early as possible and the opening closed if the tissues are not already degenerated. If they are, resection of the gangrenous portion and reduction of the pedicle is the only procedure. It has secured two satisfactory recoveries. In case of actual hernia, Tuffier incises the tumor, reduces the herniated lung with resection of the sac and débridement of the orifice, detaching the wound all around, and suturing the ring. Experiments on animals have shown that the partial and even total resection of a lung is possible and even easy in many animals, but Milton of Georgia, he states, was the first to perform pneumectomy on man. The surgical operation on the lungs most frequently required is for traumatic hernia with pulmonary parenchymatous complications.

Application of the Schleich Method of Infiltration Anesthesia.—The results of 118 operations performed in the Breslau clinic are described in the *Cbl. f. Chir.* of December 12. It was found perfectly harmless; transient inconveniences were only observed in two cases, probably due to some individual intolerance of cocain. In the first two cases treated with it, it was not successful, owing to lack of familiarity with the technique, but after that in thirteen cases it produced partially satisfactory results and in all the rest it was absolutely successful. It is delightful, the author states, to witness how insignificant an operation becomes with it—even what are called the great operations. Miculicz removed fifty-two tumors with it, from the size of an egg to that of a child's head. The operation of sectioning the vas deferens was performed eight times; ligating the vena saphena, exploratory laparotomy and for strangulated hernia, each twice; thoracotomy for empyema of the pleura once, and gastrotomy ten times. The method is especially advantageous in these last operations, as the patients are always in an enfeebled condition and general narcosis is hazardous. With this they can arise from the operating table and go about without inconveniences. Infiltration is especially valuable in incarcerated hernia, as it is only necessary to anesthetize the outer surface of the abdomen. There is no pain from cutting into the peritoneum and intestine and no anesthetic is required for them. Miculicz intends to use it in still more important operations, gastroenterostomy, resection of the pylorus, etc. He combines it with Esmarch's method of driving the blood out of the part (described in the *JOURNAL*, Vol. xxvii, page 89), but he finds it necessary to anesthetize first and expel the blood afterward. Otherwise the injection into the distended part is painful and the blood can not be driven out so easily as before. The actual time required for an operation is lengthened five to ten minutes, although Miculicz has recently been modifying Schleich's method somewhat, proceeding on the assumption that there is less danger of infecting the deeper layers when the anesthesia is produced by one instead of a number of injections. In other respects he follows Schleich's instructions to the letter. The *D. M. Woch.*, of December 10, also reports equally favorable results with this method in eighty-eight operations performed by Steintal, especially in abdominal operations, chiefly as the danger of vomiting is avoided. The necessity of overcoming the psychic shock by encouraging words and demeanor is insisted upon, as also the extra care required if general narcosis is resorted to later in the course of the operation. The instructions in the Schleich book are all that is necessary to perform the anesthesia successfully. The solution No. II was used most frequently. (Cocain mur. 0.1; morph. mur. 0.0025; dissolved in 100 water.)

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the Association living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, JANUARY 23, 1897.

THE ANTIVIVISECTION BILL.

So many resolutions have been formulated and adopted by medical men as members of local, State and National associations, and so much has been printed in the lay as well as in the medical press, concerning the "Antivivisection Bill," now before the United States Senate, that it seems almost needless to refer in these columns to the arguments against it.

The bill, S. 1552, entitled "A bill for the further prevention of cruelty to animals in the District of Columbia," was favorably reported to the Senate by Mr. GALLINGER, May 26, 1896, from the Committee on the District, although the AMERICAN MEDICAL ASSOCIATION had entered an earnest protest against its passage "unless it shall first be shown by an impartial investigation that cruel and unnecessary experiments are being performed in the District of Columbia and that existing laws do not provide suitable punishment for cruelty to the domestic animals." From this it might be inferred that the investigation made by the Senate Committee had demonstrated the inadequacy of existing laws to cope with abuses. The medical profession of the District, together with the men in high Governmental positions more or less related to medicine, and the representatives of the educational institutions, took exception to the report of the Senate Committee and appointed a joint committee to present to the Senate and House of Representatives their views on the subject. On this committee the best men in their line of work were appointed

including among others, Dr. S. C. BUSEY, representing the Medical Society of the District; Surgeon General GEO. M. STERNBERG, U. S. Army, representing the Biological Society; Dr. D. E. SALMON, Chief of the Bureau of Animal Industry, representing the Agricultural Department, and Surgeon WALTER REED, representing the Medical Department of the Army. This Committee has presented a memorial to Congress protesting against the proposed legislation, and suggesting that the favorable report presented by Mr. GALLINGER was based on a misunderstanding of the facts relative to experimentation on animals, and without due consideration of the benefits to mankind and to animals which are derived from such experimentation.

The memorial claims that the scope or purpose of the bill is much more comprehensive, radical and destructive to scientific research than is admitted by its advocates. It states that the reasons of the joint committee for protesting against the proposed legislation, are briefly summarized in the resolutions adopted unanimously by the AMERICAN MEDICAL ASSOCIATION at its meeting in May 1896, and these resolutions are cited in full. As apposed to the statement in the Senate Committee's report that there is a sharp difference of opinion among medical men as to the value of vivisection, it invites attention to the resolutions adopted by sixty-eight National, State and prominent local medical and scientific associations, and cites the memorial of the Association of American Physicians and Surgeons as follows:

The voice of science and of medicine, so far as it receives authoritative utterance, is overwhelmingly opposed to legislation of any kind which would take in any measure the direction of experimental medicine and physiology out of the hands of those who, on account of their special fitness, have been chosen by the authorities of our higher institutions of learning and of research, to convey instruction and to conduct investigations in these departments.

The report of the Senate Committee advocating the bill, states that multitudes of educated, humane physicians have learned by patient research and large experience the value of other methods to secure the results that have been obtained by biologic experimentation. The memorialists of the District of Columbia profess themselves ignorant of these other methods; and we confess that withstanding our editorial acumen, we can not enlighten them. It is suggested that the other methods must involve experiments on the human subject, and that if there is a question of preventing cruelty to animals it might be well to inquire which animal had better be selected as the object of Congressional legislation, the man, the woman, the beloved child, or the dog, the cat, the rat, or the guinea pig, etc.

The advocates of the bill also deny that any real advance has been made in medical knowledge in the laboratory of the biologist. The reply to this is a

reference to the knowledge possessed by every educated physician of the great discoveries made by biologic methods during the past twenty-five years. A summary of these is presented, beginning with the identification of the bacillus of anthrax by DAVAINÉ in 1850, and PASTEUR'S subsequent discovery of the method of protecting animals by inoculations with attenuated virus. Advances in our knowledge are cited in relation to relapsing fever, typhoid fever, trichinosis, pneumonia, consumption, glanders, cholera, tetanus, diphtheria and the bubonic plague. The protection to human life by immunizing against infectious diseases is also stated, and citation is made of the many benefits to domestic animals that have been derived from biologic experiments conducted in the District of Columbia by the Bureau of Animal Industry.

We might say a great deal more on this subject, but editorial space is limited. In concluding, however, we must not forget to suggest that now is the time for action against this bill, which would so handicap the progress of scientific research as now conducted for the benefit of mankind. When this was written, Mr. GALLINGER was in New Hampshire looking to his reelection; but on his return to Washington, Senate Bill 1552, with its favorable report from the committee, will no doubt be promptly called up for passage. We would suggest that members of the AMERICAN MEDICAL ASSOCIATION who have influence with Senators or members of the House of Representatives, communicate their views on this subject to their friends in the National Legislature, that the advance of medical science may not be unnecessarily impeded.

Incidentally we venture to suggest that some of our New Hampshire brethren should have looked after Dr. GALLINGER.

RUSH—HAHNEMANN—PASTEUR.

The proposition which was made at the meeting of the AMERICAN MEDICAL ASSOCIATION in the city of Washington in the year 1884, that a monument should be erected by the physicians of America in the capital of the United States to some great medical hero of the Revolution, as typifying the part that the profession of medicine had taken in the establishment of the Republic, was enthusiastically received and unanimously indorsed from the venerable President, AUSTIN FLINT, Sr., to the youngest member of the body. It was admitted by every one that in a city where there were memorials of the eminent men of other callings, who had risked their lives in the struggle for National independence, it was but fit that the profession of medicine should have its representative among these heroic figures, and all agreed that there was one man justly entitled to the distinction of having his effigy handed down to posterity as that of a physician who had discharged all the duties of his vocation while fulfilling all the obligations of a citizen in the most

trying period of his country's existence. There are other names of medical men affixed to the Declaration of Independence, but Dr. BENJAMIN RUSH stands alone as an eminent physician in active practice, who without sacrificing his duties to his patients, took a conspicuous part in the political events of the day. It is superfluous to repeat here the long record of his meritorious works. Two years after his death it was stated by a historian of the times (in 1815): "Considered in relation to the entire composition of his character, as a practitioner, a teacher, a philosopher and a writer, Dr. RUSH must be acknowledged to have been the *most distinguished physician that America has produced*. In no quarter of the globe has it fallen to the lot of many individuals to occupy so extensive a sphere and to comply with duties so numerous and diversified"—and another declared that his conduct was such that all humanity should erect a statue to him.

Nevertheless the project, for reasons difficult to understand, has made slow progress. At every annual meeting it has been enthusiastically reindorsed and resolutions have been adopted, year after year, urging its speedy completion. Meantime, the little body of homeopaths have set out to erect a monument at Washington to their founder, and albeit a foreigner, in no way associated with the history of the country, they have succeeded in raising a very large fund for this purpose, and the model which has been adopted, after competition by the ablest sculptors, is evidence that it will be the most elaborate artistic work of the kind in this country. Perhaps a rivalry of this sort was to have been expected, since under no possibility can there be concert between the two parties.

But the present year has witnessed still another monumental enterprise for the erection of a statue of PASTEUR in the city of Paris, France. The State Board of Health of Pennsylvania has transmitted to the public press a series of resolutions, that "WHEREAS, this board has been applied to by the Supervising-Surgeon-General of the United States Marine Hospital Service to secure its coöperation in aid of the international subscription for the erection at Paris of a monument to M. PASTEUR, *therefore*¹ Resolved: That the chairman of the executive committee be authorized to receive contributions for this purpose, and transmit them to the treasurer of the PASTEUR Monument Committee at Washington."

If ever charity should begin at home it should do so in this instance. After American physicians shall have honored at home the remarkable man, who did so much to elevate medicine by teaching and example, it may be well for them to aid in building monuments in foreign countries. If a single medical man, who has but a few dollars to contribute to one such project, is induced to give it for a monument in Paris, rather

¹ Italic is ours.

than for that to his own illustrious countryman in his own capital, just to that extent will injustice have been done to the commendable project initiated at Washington in 1884.

It is significant of the lapse of time that of the nine men first associated with the RUSH monument proposition, six, Dr. AUSTIN FLINT of New York, Dr. JOSEPH M. TONER of Washington, Dr. HENRY H. SMITH of Philadelphia, Dr. ROBERT A. KINLOCK of Charleston, South Carolina, Dr. JOHN H. MURPHY of St. Paul, Minnesota, and Dr. MORRIS H. HENRY of New York City, have died, only three surviving, Dr. GIHON, the chairman, Dr. ROHÉ, the secretary, and Dr. S. C. GORDON of Portland, Maine.

If it were true in 1884 that BENJAMIN RUSH was "the greatest physician this country has ever produced," it is still true today, and the obligation to honor his memory is greater by the twelve years that have elapsed. Hence, the members of the profession in America are urged by every consideration of duty and justice, pride and patriotism, to give whatever they may be able to contribute to this monument at Washington, which shall commemorate not so much the individual, BENJAMIN RUSH, as the ideal patriot physician of the Revolution.

PROPOSED HEALTH DEPARTMENT FOR THE GREATER NEW YORK.

It is proposed in the new charter for New York City and vicinity to perpetuate the montrosity that at present exists under the name of a Board of Health. New York is about the only large city except Chicago in the civilized world that is so handicapped that a medical sanitarian can not rise to the head of its administration; a plumber, a ward "healer" or stock-broker can become the head of the Board, but all physicians however competent are excluded. To say that this results in a montrosity is to use a mild term, at least so it will seem to any medical audience. The chapter devoted to health preservation has eight principal subjects, namely; 1, the powers and duties of the department, its officers and administration; 2, marriages, births, deaths; 3, duties of physicians and others; 4, legal proceedings and punishment for disobedience of orders and ordinances; 5, reimbursement of expenses; 6, abatement by suit; 7, tenement and lodging houses; 8, pension fund.

Under the first head it is announced that there shall be a health department, of which the board of health shall be the head. The board will consist of the president of the board of police, the health officer of the port and two officers, to be called commissioners of health, one of whom shall have been a practicing physician for not less than ten years preceding his appointment. The president of the board is not to be a physician. The commissioners are to hold office for four years.

The authority of the board of health under the new

charter will stretch to the quarantine limits. The board will make an annual report of its operations to the mayor of the greater city. It may grant bills of health to masters of vessels and may order and enforce repairs to buildings where the public health demands it. Under the head of extraordinary expenditure the board is authorized to use a sum not exceeding \$80,000 in excess of the annual expenditure if any emergency should arise demanding it.

Two bureaus are provided for, the sanitary superintendent to be chief of one and the registrar of records of the other. Branch offices are to be established in all the boroughs with assistant sanitary superintendents and assistants registrars. Chief clerks are to be appointed in each borough with powers similar to those of the secretary of the board. There are to be fifty inspectors and possibly fifty-eight. The present sanitary inspectors are to be continued in office. A sanitary squad of police consisting of fifty men, who have been on the force for five years, is to be formed. Every officer must pass a civil service examination in the sanitary laws and ordinances.

Certain offensive trades are to be supervised by the department and such apparently trifling details as yards and cellars will also come under its notice. The board is given unlimited authority to take discretionary measures for the prevention of disease and it is stipulated in the charter that any person violating the rules in this direction may be fined a sum not exceeding \$150 or to be imprisoned for a period not exceeding six months or both. Any violation of the sanitary code is to be treated and punished as a misdemeanor.

The board is empowered to continue or organize a corps of vaccinators and of physicians in order to effectually prevent the spread of smallpox by the thorough and systematic vaccination of all unvaccinated persons and for the relief of persons residing in greater New York suffering with diphtheria and other infectious diseases.

The reporting of births, deaths and marriages promptly and systematically is provided for in the charter, and the duties of physicians and others working under the board are carefully pointed out.

A pension fund is established under the department. All money paid for searches and transcripts of records and all fines and penalties for violation of the sanitary code as well as those inflicted on officials of the department will go to make up this fund. Pensions are provided for physicians and other employes permanently disabled in the discharge of their duty at a rate not to exceed half the salary of the pensioner. A \$300 pension for widows of such employes is also provided and another for twenty years service.

AN UNFORTUNATE CREATURE MALTREATED.

During the past week the newspapers of the whole world have made the most of the sensational escapades of an evidently mentally unbalanced woman of Amer-

ican birth, married to a titled foreigner. The public, that is that part of it that enjoys social scandals and to which the scandal-mongers cater in their publication, does not probably read between the lines of the misled woman's interviews the evident symptoms of want of mental balance that are so clearly suggested to any one accustomed to the vagaries of those who are on or over the borderland of insanity. The scandal in itself is not such an unusual one so far as the immoral element is concerned in the class to which this particular delinquent has allied herself—according to a popular English novelist recently deceased, irregularities of a certain sort are the special privilege of the aristocracy—but in this particular case the fact that she is an American, that she has allowed herself to be generally interviewed and has otherwise exhibited a special desire for notoriety and has given utterance to wild and incoherent statements as regards her social and moral ideas and intentions, and the further fact as it appears, that very prominent personages are in fear of her revelations, have created more than a usual interest in the case. If her insanity is not generally suspected abroad it is perhaps due to extravagant notions held there as to the possibilities of American customs and manners; but to an impartial observer in this country with a knowledge of the published facts in the family history the evidences are sufficient to more than merely suggest mental aberration as a charitable supposition in the case. In this point of view it has a medical interest and the outcome will be worth noting in case the unfortunate woman continues to court publicity as at present.

THE EMPLOYMENT OF X RAYS FOR THE RELIEF OF SOME FORMS OF BLINDNESS.

It is not unreasonable to hope that many new uses will be found for the X rays, both in the arts and in the sciences. The possibilities of the range of application to which the recently discovered force is susceptible are yet beyond intelligent conception. Whether we have to do with a new force or with merely some modification of an already familiar force remains to be determined. In any event we have had placed in our hands by ROENTGEN'S discovery an agency capable of doing what has heretofore been considered impossible.

There has been exploited of late rather noisily in the newspapers the idea that the blind might be made to see by means of the X rays. It was not expected by intelligent minds that vision of any kind could be restored when atrophy or degeneration or other form of destruction of optic nerves, centers or tracts had taken place. An Austrian physician, EMIL BOCK (*Wiener medizinische Wochenschrift*, Dec. 19, 1896, p. 2269), however, has recently made an ingenious suggestion in this connection, which on its surface appears plausible and capable of practical application.

In a word, the proposition is made that it may be possible by means of the X rays to imprint visual images upon the retinae of persons possessing a healthy nervous optic apparatus, with preservation of the light-sense, in whom vision has been destroyed through irremediable opacities of the refractive media.

Experiments have already shown the idea to be theoretically correct and practically feasible. All that is necessary is to make an impression with some material impervious to the X rays upon substances through which the rays will pass. It is not to be hoped that any degree of permanent vision will thus be restored, but it is possible that the procedure may prove serviceable in the instruction of blind persons who have previously had the use of their eyes, in the recognition of legal documents, in the identification of individuals, etc.

ABOLITION OF REFLEX VOMITING AS A SYMPTOM OF HYSTERIA.

Cutaneous anesthesia has long been recognized as one of the stigmata of hysteria, and associated loss of sensibility has often been observed on the mucous surfaces. Anesthesia of the pharynx especially has been looked upon as a characteristic phenomenon and to this has been attributed the absence of reflex vomiting so commonly noted in hysterical subjects. In turn, when this reflex act is found to be wanting, the fact is usually accepted as evidence that the pharynx is anesthetic. With the object of determining whether this peculiarity is due really to sensory impairment, to motor impairment or to disturbance in the reflex arc, KATTWINKEL (*Deutsches Archiv für klinische Medizin*, B. lvii, H. 5, 6, p. 549) undertook the examination of 104 cases of hysteria at the medical clinic of the University of Munich, and found absence of the reflex act of vomiting following irritation of the pharynx in one hundred. In only a small proportion was the sensory function of the mucous membrane of the pharynx deranged in any way, and then in association with corresponding derangement of cutaneous sensibility. In not one were the motor functions of the pharynx at all interfered with. There is thus left only the conclusion that the absence of reflex vomiting in cases of hysteria is due to disturbance in the reflex arc and that such abolition may be viewed as an hysterical stigma.

THE DANGER OF EYE INFECTION BY SPECTACLES.

It has for some time been a growing custom for ophthalmologists and opticians to lend London smoked or other tinted coquille spectacles to patients under mydriasis. The spectacles are returned after the passing of the mydriasis and are again lent to other patients. It is a dangerous custom that should be stopped. The writer has known of cases of infection

not readily explainable except as due to wearing glasses that others have used. As these tinted coquille glasses cost the optician but a few cents, we advise oculists either to give patients outright the pair required, or suggest that they be bought. Doubtless the better class of opticians would be willing to give their regular patients such glasses free of charge. But in all cases the patients should be warned against the use of second-hand, possibly infection-smear'd articles.

CORRESPONDENCE.

Antileprous Serum.

NEW YORK, Jan. 18, 1897.

To the Editor:—Will you kindly state in your paper that I am considering the propriety of starting a Carrasquilla Institute in New York city. I have received from Dr. Carrasquilla of Bogota, Colombia, six consignments of antileprous serum, seventy-two bottles in all. Further consignments will be forthcoming at short intervals. Of the above consignments, I have sent a portion, respectively, to Dr. Hansen, Norway; Dr. O. Petersen, Inspector General of Leprosy for Russia, St. Petersburg; and the President of the Hawaiian Board of Health, Honolulu. These gentlemen will experiment with the serum and make a report of results obtained at the first Leprosy Congress, to be held in Moscow, August 19 to 26, 1897.

Carrasquilla, in his latest letter to me, dated Dec. 13, 1896, says: "The efficacy of the antileprous serum tried for one year, on a large number of patients, leaves no doubt, as you will find out yourself. The process gives all kinds of securities, which makes me hope that you will recommend it to the attention of others and persuade them to study it."

The above-named countries, Norway, Russia and the Sandwich Islands, have had the following experiences with leprosy: In Norway, 1856, there were 2,877 lepers; from that to 1891 there were 4,758 additional cases, in all 7,635. In 1885, the mixed isolation law, that is, isolation in hospitals and in families, was passed. Under that law leprosy has decreased to 800 cases, which is the present number. Is it any wonder that the physicians of Norway believe in contagion?

In Russia, whose population is 124,000,000, during the period in which it was generally believed that the disease was not contagious, the leper hospitals were closed; leprosy increased apace. In 1879, Professor Münch of Kiev, and Professor Petersen, began to study the disease, and reached the conclusion that climate, situation and food have nothing to do with its spread. In 1894, a commission having been appointed by the government to study the question of leprosy, reported that they had come to the conclusion that leprosy is contagious; they consequently advised the segregation of *all* lepers. According to Dr. Petersen, there are 5,000 lepers in European Russia.

In the Sandwich Islands, leprosy was imported in 1848, or 1819 as some say. Before 1848, at any rate, the disease was very rare, or else it worked unknown to the inhabitants. Hildebrand, in 1853, was the first to report a case of leprosy. In 1861, there were six lepers in the neighborhood of this original case. From that time, the disease spread in an unheard of manner. In 1865, there were 230 lepers in a population of 45,000. In 1881 and 1882, there were 4,000 lepers. Thus in thirty-five years, one-twelfth of the population had become lepers. *Et nunc erudimini*, says Dr. Robelin, from whose work (*Es o no Contagiosa La Lepra*) I quote these figures as to Hawaii, strict isolation laws came at last, in 1865. Today there are only 1,250 lepers.

While the New York County Medical Society had these facts before them, or could, or ought to have had them before them,

yet they have approved a report of their committee on leprosy, composed of the Health Commissioner of New York, and several professors of dermatology, to the effect that leprosy is not a dangerous disease, and that isolation is not necessary.

In Colombia, while there was no isolation, leprosy increased in forty years from 400 to 27,000 cases. The government now is very much alive to the situation. The church has raised \$200,000 for a National Lazaretto. It is believed there generally that the solution of the problem is either the Carrasquilla serum cure, if it shall prove effective, or absolute isolation, and the question is taken very fearfully to heart; they can not afford there to declare jauntily that leprosy is not dangerous.

The lepers are, at the present time, crowding Bogota, to receive the possible benefits of Carrasquilla's treatment. Their crowding there has become a real nuisance.

According to the report of the Health Commissioner of New York, there is no danger of the spread of leprosy in New York climate. Therefore this is the place for starting a Carrasquilla Institute for the treatment of the lepers in the United States. The different States, Minnesota, Wisconsin, etc., will be very glad to unload their leper populations into this favorable climate, if a chance of cure by Carrasquilla's serum is offered to them here. I should be disposed to inoculate any patient who shall be sent to me by the State Boards of Health, free of charge.

As soon as the bars are down, and the three lepers of North Brother Island are discharged by our Health Commissioner, when every pretense of isolation shall have been given up, and leprosy officially recognized as *not being dangerous*, no one can have any objection to the coming to New York of all the lepers of this country.

ALBERT S. ASHMEAD, M.D.

Chlorid of Sodium.

BOSTON, Jan. 13, 1897.

To the Editor:—Salt in excess of what occurs in natural food appears to be necessary with the human family as it is with animals. Both a deprivation of it and a large excess of it, especially in the absence of vegetable food, works evil to the body, producing various sorts of disease both in body and in mind. Salt exists in all the fluids of the body. It appears to stimulate every tissue and have an influence over the metabolic changes in every part, and at all times. Yet how far these changes can be usefully modified by diminishing or increasing the ordinary amount of salt is not settled. Sure it is that some cases in practice have been improved by decreasing the salt supply, while others have gained on increasing the usual daily amount of it. Küss says it is indispensable to the formation of bile and the pancreatic and gastric juices. Animals grow better and fatten on it. They have more glossy and thicker hair, have a more healthy appearance and are more sprightly and active; while the potassium salts have the opposite effect and are more or less serious in their consequences. Salt stimulates the kidneys, and all the proteid qualities have a peculiar dependence on the presence of the various salts. Common salt promotes secretion, aids osmotic action, promotes fluid diffusion throughout the entire system. It stimulates nervous action as a whip stimulates a horse and clears and brightens the eyes.

Now, can it be that an agent which has so general influence throughout the body, in exciting the nerves and promoting secretions and the various metabolic physiology, should fail to have a more or less direct effect upon the organs and functions essential to procreation? This is a question which presented itself in the case of some friends of mine.

The two women concerned were well educated and of excellent character, but both were feeble and more or less invalids when married. Both married clergymen, were equally well and tenderly cared for. They both found plenty exercise, were were of studious habit and helpful to their husbands. The husband of one conceived the idea that his wife would be

stronger and better in health if she took more common salt than she was accustomed to take. More salt was put in her butter, on her meats and in the milk she used. Often he added to her regular proportion of salt in the water she drank. The result has been that she is a very well woman—a woman of great efficiency in the work as an aid to her husband, and she has increased the household by a daughter and a son. They are still young people. The other husband took contrary views in reference to salt and denied to his wife as much as he could, thinking it injurious to use much salt. The result in her case is that she has remained weakly, nervous, neuralgic, etc., and can not spare strength for the ordinary household duties. Her lungs have become weak and her throat so sensitive that he is obliged to take her to the South for the winters. She has never been pregnant and has passed the age when women are likely to conceive. For one I am sure he has made a mistake. They have greatly desired a child. I have mentioned the other case to him and jokingly told him that I believe he has not salted his wife enough.

E. CHENERY, M.D.

Stomach Movements.

PARIS, ILL., Jan. 14, 1897.

To the Editor:—Regarding the stomach's emptying itself (see JOURNAL, page 83) I wish to say that Professor Freer demonstrated the movements of the stomach by vivisections, and that the contractions proceeded from right to left along the lesser curvature, rounded the cardiac end and proceeded from left to right along the greater curvature, moving its contents in that direction. When it reached the pylorus the latter opened and allowed a small quantity of liquid food to pass into the intestine. After a short rest the contractions began and proceeded in the manner described. In one case there were three distinct revolutions. Respectfully,

W. H. TEN BROECK, M.D.

"Thoraeoplasty in America."

PHILADELPHIA, Jan. 15, 1897.

To the Editor:—I see in your issue of January 9, an article by Dr. A. H. Ferguson on "Thoraeoplasty in America," in which he states that the Bureau of American Medical Literature at Washington, D. C., informed him that they were unable to find any case of Schede's operation performed in America. I beg to state that in the *Annals of Surgery*, June 1895, p. 721, I published a case with successful result, which was done without any knowledge that Schede had preceded me.

Yours very truly,

W. W. KEEN, M.D.

SOCIETY NEWS.

The Twelfth International Medical Congress.

PRELIMINARY PROGRAMS OF THE SECTIONS.

[Translated for the JOURNAL.]

SECTION I.—ANTHROPOLOGY, NORMAL ANATOMY AND HISTOLOGY.

I. *Anthropology*.—1. Measures to be taken to collect the largest possible number of exact data in regard to the anthropologic types among the Russians and the allogeneous population of Russia.

2. The most characteristic peculiarities of the Mongolian skull. Which Mongolian or other race presents these peculiarities most frequently and most pronouncedly?

3. How far does the cranial type of the present population of Russia differ from the ancient type of the Kourgan period? How can this modification be explained if found to exist?

4. Prof. Sergi's typical skulls. Their importance in the classification of the shapes of skulls.

5. Anomalies in the skeleton and external tissues. Have any of these anomalies a racial significance and can they be considered phenomena of atavism?

II. *Anatomy*.—1. Is the Latin nomenclature in anatomy elaborated by the German Anatomical Society to be adopted internationally?

2. By what means can uniformity of nomenclature in anatomy be introduced into Russian works on the subject?

3. Is polydactylia to be regarded as a division or a phenomenon of atavism?

4. Homology of the upper and lower members.

III. *Normal Histology*.—1. Comparison of the value of the various theories and hypotheses in regard to the structure of protoplasm in general.

2. Importance of the blastomeres in the segmentation of the ovum. Post-regeneration. Development of the interstitial and cuticular substances.

3. Importance of the centrosomes, spheres and supplementary nuclei. Importance of direct division (amitotic).

4. Genesis of the cell, *i. e.*, evolution of the constituent parts of the cellular organism.

5. Innervation of the glands.

6. Different modes of termination of the nerves depending upon certain mechanical conditions.

7. Development of the nerve fibers and cells; best methods of studying them.

8. Place and mode of the first development of the organs of the genito-urinary system.

9. Importance and genesis of the third constituent of the blood (Bizzozero's plaques), and their connection with coagulation.

10. Is there a physiologic migration of the leucocytes? Where does it take place? In what proportions? What is the principal rôle of these elements in the body?

11. Secretory ducts of the salivary glands, pancreas and liver, especially the initial capillary tubes.

12. Is it not possible to create a better classification of the animal tissues than those that now exist, based as far as possible on the largest number of facts?

13. Genesis of the encephalon in the vertebrates, man included.

14. Mechanical principles of the development of organisms.

15. Structure of nerve cells and their reciprocal relations in the nerve centers.

16. Modifications in the structure of the cells of the glands during repose and during the activity of the corresponding cells or glandular formations.

17. Termination of the sensory nerves in the heart.

18. Termination of the nerves in the nerve cells of the spinal ganglia.

19. Sensory nerves of the muscles (smooth and striated muscular fibers).

20. Forms and extent of elastic tissue in the animal organism, and its importance.

21. Structure and presence of the basement membranes in the animal body, and their importance to it.

SECTION 2.—PHYSIOLOGY AND PHYSIOLOGIC CHEMISTRY.

1. Importance of physiologic psychology in medical education.

2. Rôle of nitrogenous alimentation in the transformation of substances and forces in the animal organism.

SECTION 3.—GENERAL PATHOLOGY AND PATHOLOGIC ANATOMY.

1. Genesis of the different forms of diabetes.

2. Pathologic physiology of thrombosis.

3. Pathologic physiology of myxedema.

4. Theories in regard to immunity. Production and influence of antitoxins in artificial immunity.

5. Rôle of the vessels and parenchyma in inflammation.

6. Constancy of the various species of pathogenic bacteria considered in regard to their botanic classification and the specification of diseases.

SECTION 4, A.—GENERAL THERAPEUTICS.

1. Serum therapeutics and prophylactic inoculations.

2. Organ therapeutics.

3. Appreciation of the present methods of alimentation (artificial alimentation, forced alimentation, koumyss cure, grape cure, substitutes for alimentation employed in therapeutics).

4. Methods of treating fever.

5. Present methods of antiphlogistic treatment (phlebotomy, etc.).

6. Hydrotherapeutics.

7. Climatotherapeutics (seashore climate, mountain climate, sea voyages, etc.).

8. General therapeutics of the different organs (for example, new methods of treating diseases of the heart).

9. Electrotherapeutics.

SECTION 4, B.—PHARMACOLOGY.

1. Rapid and certain local treatment of severe erysipelas (epidermic method).

2. Rapid and certain treatment of epidemic cerebro-spinal meningitis (hypodermic method).
3. Treatment of pneumonia with guaiacol, applied externally.
4. Calomel as a medicament for the heart.
5. Treatment of recurring erysipelas.
6. Treatment of typhoid fever.
7. Value of the methods of using water in hydrotherapeutics: frictions and ablutions, fan douches and sitz baths.
8. Climatotherapeutics of pulmonary phthisis.
9. Disintoxication.

SECTION 4, C.—PHARMACOGNOSY AND PHARMACY.

1. *Amanita phalloides*: its botanic varieties, geographic distribution, chemic composition and physiologic action.
2. Classification and histology of the simple drugs of practical importance. Study of new, already known drugs, the knowledge of which is yet insufficient.
3. Organic and inorganic pharmaceutical medicines deserving special attention on account of their practical importance.
4. Best methods of determining the medicines of heroic action, from a chemic-legal point of view: the alkaloids, glucosids, so-called bitter substances, etc.
5. Cultivation of narcotic plants. Value of the medicinal preparations obtained from them.
6. Most certain methods of distinguishing the alkaloids in narcotic medicaments.
7. Best methods of preparing the bitter almond water.
8. Necessity of strict standard amounts of specific substances and of the alkaloids in extracts, tinctures and other medicaments of heroic action.
9. Establishment of an international standard for the Galenic preparations (*Galenica internationalia*).
10. The drugs of domestic medicines considered histologically and chemically.
11. The serum and organ therapeutic medicaments from the pharmaceutical point of view.
12. Water from the hygienic and pharmaceutical point of view.
13. Microscopic examination of the identity and the actual value of the most important medical powders.
14. Products excreted by plants.
15. Most certain means to distinguish anatomically and chemically between the true *illicium* (*illicium verum*, Hooker) and the false (*illicium religiosum*, Siebold).
16. Difference between the structure of the testa of black mustard (*sinapis nigra* L.), Russian mustard, called *sarepla* (*sinapis juncea* L.), and white or yellow mustard (*sinapis alba* L.).

SECTION 5.—INTERNAL DISEASES.

1. Essential causes of chlorosis.
2. Are the different forms of malarial fevers caused by Laveran's parasites or by still other species?
3. Climatic treatment of tuberculosis.
4. Relations of nervous dyspepsia to general neuroses—its symptoms and their pathogenesis.
5. Clinical classification of nephritis.
6. Pathogenesis of chronic nephritis.
7. Clinical forms of hepatic cirrhoses.
8. Pathogenesis of chronic lesions of the valves of the heart.
9. Pathogenesis of obesity.
10. Pathogenesis of gout.

SECTION 6.—DISEASES OF CHILDREN.

1. Diagnosis of pulmonary tuberculosis during early infancy.
2. Diagnosis of tuberculous meningitis.
3. Whooping cough complicated with influenza (grippe).
4. Diarrhea accompanying diseases of the respiratory organs.
5. Affections of the lymphatic system during childhood.
6. Normal properties of the blood and their modification in diseases of different ages.
7. Results of serum treatment of diphtheria and other diseases.
8. Results of "belt puncture" in hydrocephalus.
9. Arrhythmic action of the heart in children.
10. Results of laparotomy in tuberculous peritonitis.
11. Organization and results of the work of Russian foundling asylums, or asylums for abandoned children in general.
12. What is the difference between natural and artificial alimentation of children from the standpoint of physiology and pathology.
13. Hereditary syphilis.
14. Hemorrhagic diathesis and geographic distribution of rhabdomyositis.
15. Influence of school work on the physical development of children.

SECTION 7.—NERVOUS AND MENTAL DISEASES.

I.

1. Pathology of the nerve cell (normal microscopic anatomy and pathologic lesions).
2. Pathogenesis and pathologic anatomy of syringomyelia.
3. Pathogenesis and treatment of tabes dorsalis.
4. Operative treatment of diseases of the brain.

II.

1. Hallucinations and fixed ideas.
2. Pathogenesis of the general paralysis of the insane; delimitation of this disease from kindred morbid manifestations.
3. Hypnotism and suggestion in relation to mental diseases and medical jurisprudence.

SECTION 8.—DERMATOLOGY AND VENEREAL DISEASES.

1. Cutaneous actinomycosis.
2. Primary cutaneous tuberculosis.
3. Cutaneous arthritis.
4. Cutaneous sarcomatosis.
5. *Acanthosis nigricans*.
6. Pathogenesis of *area Celsi sive Jonstoni*.
7. Gonorrhoeal dermatoses.
8. Mercurial dermatoses.
9. Cutaneous paludal eruptions.
10. Treatment of simple scleroma (scleroderma).
11. Treatment of Frisch's scleroma (rhinoscleroma).
12. When should the treatment of syphilis with mercury be commenced? How long should it be continued? Should syphilis be treated at the time when the syphilitic accidents make their appearance, or should the treatment be provisional without waiting for the appearance of the syphilodermis.
13. Modifications in the elements of the blood in syphilitics during the condylomatous period.
14. Syphilis and serum therapeutics.
15. Treatment of syphilis with soluble and insoluble mercurial preparations.

SECTION 9.—SURGERY.

1. Methods of treating infected wounds.
2. Methods of treating malignant neoplasms without operating, especially the results of treatment with serum therapeutics.
3. Cerebral surgery in cases of tumors and Jacksonian epilepsy. Results of operative procedures.
4. Surgery of the lungs, principally from the standpoint of the formation of tuberculous caverns and of gangrene of the lungs.
5. Treatment of cancerous strictures of the esophagus, pylorus and rectum. Results of the different methods of treatment.
6. Gonorrhoeal and syphilitic affections of the articulations.
7. Principles of the construction of protheses of the lower extremities in affections of the articulations, paralyzes, congenital luxation of the femur and after amputation.

SECTION 9, A.—DISEASES OF THE TEETH.

1. Nature and treatment of pyorrhoea alveolaris.
2. Hygiene of the oral cavity and of the teeth.

SECTION 10.—MILITARY MEDICINE.

1. In what respects should the Geneva Convention be examined again to avoid differences of interpretation of its various articles, and what changes should be made in it on account of the transformation of armaments and the increase in the number of combatants?
2. Organization of the search for the wounded on the battle field.
3. First dressing for bullet wounds. What is the best?
4. Most convenient surgical case for the treatment of fractures caused by firearms.
5. Best styles of litters for the wounded.
6. Most convenient and inexpensive ambulances for the transportation of the wounded. Transportation of the wounded.
7. Transportation of the wounded in narrow gauge railway field cars.
8. The supply of drinking water for armies in the field.
9. In what way and to what extent can uniformity in the military medical service be secured?

SECTION 11.—DISEASES OF THE EYE.

1. Operative treatment of myopia (Fukala's method).
2. Trachoma and its treatment.
3. Therapeutic value of sub-conjunctival injections.

SECTION 12, A.—DISEASES OF THE EAR.

1. Inflammation of the middle ear in new-born infants.
2. Classification of the inflammations of the middle ear according to the products of the inflammation.
3. Physiologic importance of the special parts of the labyrinth, especially in regard to the question whether complete deafness is caused by a partial alteration of the labyrinth.

4. Treatment of attico-mastoid suppurations and of the subsequent intracranial affections.
5. Contribution to the study of cholesteatoma.
6. Diseases of the ear originating in inflammation of the cranial sinuses (maxillary, frontal or sphenoidal).
7. Comparison of the value of simple trephining and the large opening of the cavities of the ear in chronic otorrhea.
8. Surgical treatment of sclerous otitis and its therapeutic value.
9. Acute adenoiditis in adults.
10. Study and treatment of internal complications in purulent inflammation of the ear.
11. Primary affections of the bony walls of the labyrinth.
12. Therapeutic importance of exercises of the ear for deaf persons and the deaf and dumb.
13. The dimensions of the auditory cavities regarded as a predisposing cause of diseases of the ear.
14. Pathology and treatment of sclerosis of the tympanic cavity (its difference from other similar lesions of the labyrinth).

SECTION 12, B.—DISEASES OF THE LARYNX AND NOSE.

1. Suppuration of the nasal sinuses (the maxillary excepted). Diagnosis and treatment.
2. Cancer of the larynx. Diagnosis and treatment.
3. Causes and treatment of loss of voice in singers.
4. Progress realized since the last Congress in the local treatment of tuberculosis of the larynx.
5. Autoscopy of the larynx.
6. Laryngo-straboscopy.
7. The X ray applied to rhino-laryngology.
8. Esophagoscopy.
9. Photography of the larynx.
10. Report of the committee in regard to obligatory standards in the construction of rhino-laryngoscopic instruments and apparatus.

SECTION 13.—OBSTETRICS AND GYNECOLOGY.

I. OBSTETRICS.

1. Symphysiotomy.
2. External exploration.
3. Serum therapeutics in puerperal septicemia.
4. Connection between gonorrhoeal infection and puerperal affections.

II. GYNECOLOGY.

1. Colpotomy in cases of inflammation of the uterine adnexa, in displacements and neoplasms of the uterus.
2. Gonorrhoea and its treatment in non-pregnant women.
3. Surgical treatment of peritonitis.
4. Comparison of the operative methods of treating cancer of the uterus in regard to their prevention of relapses.

SECTION 14.—HYGIENE, ETC.

This program will be announced later.

SECTION 15.—LEGAL MEDICINE.

1. Creation of an institute to instruct physicians in medical jurisprudence and consequent modification of the conditions of medico-legal instruction. Necessity of requiring a special diploma of medico-legal experts.
2. The necessity of a more extensive application of the method of microscopic investigation in legal medicine. Application of bacteriology to legal medicine. Medico-legal demonstration of the presence of gonococci.
3. Present status of the question of ptomains in legal medicine.
4. Present status of the question of vital proofs and the conditions which affect their reality.
5. Value of the indications of death from asphyxia. Conditions favorable to the genesis of sub-pleural ecchymoses. Ecchymoses and their relations to strangulation.
6. The glycogenic function of the liver in its relations to medico-legal expert testimony.
7. Anatomico-pathologic indications of death caused by cold.
8. Medico-legal investigation of death caused by chloroform.
9. Caulerizing action of arsenious acid and its salts.
10. Responsibility of hysteric subjects.
11. Penalty to be applied to crimes in the sphere of the sexual functions.
12. The criminality accepted by the Lombroso school. Does it exist?
13. Death from shock.
14. Cadaveric rigidity.
15. Peculiarities of the decomposition of the cadaver of the fetus and the new-born infant.
16. How to distinguish human blood from the blood of mammals in medico-legal investigations.
17. Criminal morcellement of the cadaver and means to determine the particulars of the cutting process and the length of time that has elapsed.

Association of Military Surgeons of Ohio.—In response to a call of the Surgeon General of the State, the medical officers of the Ohio National Guard met in the retiring room of the House of Representatives, in the State House, Thursday afternoon, Dec. 17, 1896. A constitution and suitable by-laws were adopted, forming the "Association of Military Surgeons of the State of Ohio," with active members consisting of the medical officers of the Ohio National Guard, associate members consisting of ex-medical officers of the Ohio National Guard and ex-medical officers of the United States Volunteer service and honorary members. The following officers were elected: President, Brig. Gen. J. E. Lowes, surgeon general of Ohio, Dayton; vice-president, Maj. L. T. Guerin, surgeon Fourteenth Infantry, Columbus; secretary, Maj. H. M. W. Moore, surgeon First Light Artillery, Columbus; treasurer, Maj. Frank Bain, surgeon Second Infantry, Kenton; executive committee, the foregoing officers and Maj. E. C. Farquhar, surgeon Eighth Infantry, Zanesville; Capt. Gilbert I. Cullen, assistant surgeon First Infantry, Cincinnati; Lieut. (junior grade) C. W. Newton, surgeon First Battalion, Naval Brigade, Toledo. Lieut. Col. William E. Walters and Capt. James E. Pilcher, of the Army, were elected honorary members.

NECROLOGY.

WILLIAM WALLACE, M.D. of Brooklyn, died December 22, in consequence of an attack of locomotor ataxia of about three months duration. He was born in Cork, Ireland, in 1835, and studied at Rothesay, Scotland, and at Foyle College in Londonderry. In 1851 he took up the study of medicine in Edinburgh, in 1856 was graduated from the Royal College of Surgeons and in 1860 from the Royal College of Physicians. During the year 1855 he acted as an assistant surgeon in the royal navy in the Russian war. It was in 1864 that Dr. Wallace came to Brooklyn to pursue the practice of his profession. Three years later he married Miss Ellen Louise Ladd of Throggs Neck. During his residence in Brooklyn Dr. Wallace was actively engaged in educational and philanthropic work. He was attending physician to the outdoor department of the Long Island College Hospital, and was visiting physician to the Long Island College Hospital, St. John's Hospital, Home for Consumptives, consulting physician to the Long Island Hospital and St. Mary's Hospital, and later, medical director of the college dispensary. He was also appointed a member of the council of the Long Island College Hospital, of the hospital committee of St. Mary's Hospital and of the board of managers of the Church Charity Foundation. He was at one time president of the Pathological Society, censor of the Kings County Medical Society and a delegate to the State Medical Society. Dr. Wallace leaves a widow and two sons, one of whom is a physician and was associated with his father in practice. Dr. Wallace was a man of sterling worth and wide popularity.

JOHN D. BRUMLEY, M.D., New York Medical College, 1858, died in Newark, N. J., January 8, aged 62 years. He became a Union army surgeon in 1863, and his first assignment was with the Seventh Michigan Volunteer Infantry, just before the "seven days' fight." He was captured and confined in Libby prison for a month. After his release on exchange he served to the end of the war. He was afterward a United States examining surgeon for pensions and for years the commandant of the New Jersey Home for Disabled Soldiers in Kearney. He held several public offices in Newark, was a member of several medical associations of New Jersey and Essex County and a member of the Society of the Army of the Cumberland.

BENJAMIN F. KETCHUM, M.D., New York University Medical College, 1860, formerly surgeon of the Twelfth Vermont Infan-

try, U. S. V., and mustered out Oct. 4, 1862, died suddenly of angina pectoris at the Brooks House, Brattleboro, Vt., January 9. He was born in Troy, N. Y., Dec. 25, 1837.

PATRICK H. BRYANT, Passed Assistant Surgeon, U. S. N., died at Newport, R. I., on board the training ship *Constellation*, Dec. 29, 1896.

BOOK NOTICES.

The Diary of a Resurrectionist 1811-1812, to which are added an account of the resurrection men in London, and a short history of the passing of the Anatomy Act. By JAMES BLAKE BAILEY, B.A., Librarian of the Royal College of Surgeons of England. 8vo. Cl. Illustrated. Pp. 184. London: Swan, Sonnenschein & Co., 1896.

The student of medical history can not fail to be interested in the story of the troubles of William and John Hunter, Matthew Baillie, the elder Cline and Sir Astley Cooper in the matter of anatomy. That interesting work by Bransby Cooper, "Life of Sir Astley Cooper," refers in several places to the diary which is now reprinted by the Librarian of the College of Surgeons, to which institution the MS. was presented by the late Sir Thomas Longmore, who during his pupilage was dresser to Bransby Cooper.

The diary itself is of little intrinsic value, but as a collateral reference to the times immediately preceding the passage of the British Anatomy Act, it is of great interest. The gruesome details of the accounts of Mr. Josh. Naples, the chief resurrectionist, belong to the chapter of horrors fortunately closed by the more enlightened legislation of the last half of the nineteenth century, whereby the trade of the resurrectionist was relegated to the pages of history.

The reader will find in this volume, among other interesting matters gathered by Mr. Bailey, a copious extract from Southey's "Surgeon's Warning." After the surgeon died, notwithstanding his elaborate preparations to prevent the dissection of his body, the "prentices" finally got his body in a bag.

"So they carried the sack pick-a-back,

And they carved him bone from bone,

But what became of the surgeon's soul

Was never to mortal known."

The Surgery of the Chest. By STEPHEN PAGET, M. A. Oxon., F. R. C. S. Illustrated. New York: E. B. Treat, 5 Cooper Union. Pp. 479. 8vo cloth. 1897.

This is a timely contribution to the literature of thoracic surgery. The author's interest in the subject is profound and it has led him to produce a monograph that for suggestiveness and at the same time true conservatism has few equals.

We are pleased that Mr. Paget has the courage to state the case fairly against the great mutilations which have lately come into vogue, and to reassert the advantages of the classic Greek practice in cases of empyema.

Full credit is given to our American authors on this subject and indeed it may be fairly claimed that few recent important articles written on this side of the water have escaped him. But little note, however, has been taken of the American or English systematic treatises on general surgery, many of which contain reference to cases, but ancient and medieval literature have been thoroughly examined and modern medical periodicals exhaustively searched.

The work is of great value to every general practitioner of medicine and surgery.

Two Health Seekers in Southern California. By WILLIAM A. EDWARDS, M.D., and BEATRICE HARRADEN. 16mo, cl. Pp. 144. Philadelphia: J. B. Lippincott. 1897. Price \$1.00.

Dr. Edwards says in the preface, "I have long felt that an impartial account of Southern California, devoid of the fulsome praise of guide books and land office advertisements, would be of interest and help to a large class of health seekers. If invalids would bear in mind that no climate is

perfect, much disappointment would be saved. Again, if physicians would explain to their patients the absolute necessity of coming earlier in their disease, much suffering could be avoided."

Dr. Edwards has given his conclusions after a residence of eight years and Miss Harraden after two and one-half years' sojourn.

The style of the book is pleasant and the conclusions, we doubt not, are accurate. The work will be of good service in teaching the valetudinarian what to expect from the Southern Californian climate.

The Retrospect of Medicine. A half-yearly journal containing a retrospective view of every discovery and practical improvement in the medical sciences. Edited by JAMES BRAITHWAITE, M.D., London, assisted by E. F. TREVELYAN, M.D., B.Sc., M. R. C. P. Volume 113. January to June, 1896. 8vo, cl. Pp. 464. London: 1896, Simpkin, Marshall, Hamilton, Kent & Co., Ltd. Price 6s. 6d.

This volume is fully up to the standard of its predecessors and we are pleased to see that American literature is given a large space in the work. "Braithwaite" is one of the most popular, comprehensive and useful in the collection of "year books" that come to our table.

PUBLIC HEALTH.

Health Statistics in Family Archives.—A writer in the *Journal d'Hygiène* suggests that if families would preserve in their archives full records of the important illnesses, accidents, operations, etc., as they occur in them, with detailed reports of necropsies, "which should be more frequent," they would possess immense scientific and historic value and interest in time and prove of great service to the health of future generations. He cites the queen mother of Henry IV., who left commands that her head should be dissected in order to discover the cause of her frequent severe headaches, that the information thus obtained might be applied to prevent the same trouble in her children.

Anthrax at Sing Sing Prison, New York.—A convict in Sing Sing Prison has recently developed a case of malignant anthrax, the result of scratching a pimple on his neck with his finger nails. He had been handling curled hair, such as is used in upholstery work, and it is supposed that the anthrax spores had collected under the nails. He has had violent hemorrhages from the nose and mouth, and his left side is completely paralyzed, but Dr. R. T. Irvine, the prison physician, thinks his chances of recovery are good. It is said that only about a dozen cases of this disease in man have heretofore been reported as occurring in New York State.

Origin of Epidemics of Cholera.—The *Progrès Méd.* of December 12, quotes Courtellement, who has just returned from a trip to Mecca, that epidemics of cholera do not originate there, but that it is brought from India by Indian pilgrims, who flock in great numbers every year, attracted as much by commercial interests as by religious sentiment. Protégés of England, they come to sell English products, which explains the consideration with which they are treated at Bombay and Aden. Arrived at Mecca, the cholera they bring attacks the crowds of other pilgrims there, exhausted by their travels, while according to M. Courtellement, it could be easily stamped out if the simple necessary precautions were taken on the arrival of the pilgrims from India.

Memorial to Michigan Members of Congress, Relative to a Permanent Census Service of the United States.—At the regular meeting of the Michigan State Board of Health at Lansing, Jan. 8, 1897, the following preamble and resolutions were unanimously adopted:

WHEREAS, The bill "to provide for a permanent census service" reported to Congress by Hon. Carroll D. Wright, will

be of great usefulness to the sanitary service of this State, as follows: 1. By providing a more frequent statement of population, thereby affording a basis for reliable vital rates and the more accurate calculation of intercensal populations, upon which such rates depend. 2. By providing means for ascertaining, for the first time in the history of the census, a reliable representative death rate for the State which will be comparable with those of other States and countries, Michigan being now a so-called non-registration State. 3. If Michigan shall become a registration State by act of the present Legislature for the immediate registration of deaths, by providing an annual comparative compilation of its data in connection with those of other registration States, thereby greatly increasing the usefulness of the Michigan statistics; therefore be it

Resolved, That the Michigan State Board of Health, at its quarterly meeting held at Lansing, Jan. 8, 1897, urgently recommends the passage of the bill for a permanent census service, on the ground of the improvement that will result therefrom to the sanitary interests of the country; and further,

Resolved, That a copy of this resolution be sent to each Senator and Representative from Michigan in Congress, with the request that they labor for the passage of the measure.

HENRY B. BAKER, Secretary.

MISCELLANY.

A Milwaukee physician has forwarded \$5.00 in currency to Dr. Henry P. Newman, Treasurer, without enclosing his name. The amount will be properly credited if he will send in his name and give date of transmittal.

The President of the Republic of Brazil was recently operated on for vesical calculi by Professor Alfonso of Rio Janeiro, with an uneventful recovery.

Prognosis by the Servant Girl.—Sick man: "Is this the West-end Sanitarium?" New Girl (mystified): "This is Dr. Brand's house." "Yes, but doesn't he take sick people to nurse sometimes?" "Oh! maybe he does. There's two or three skeletons in the back office."—*Philadelphia Record*.

The Largest of Coffins.—One of the strangest coffins ever told of is that for which the British War Department is said to be responsible. The story is told that a workman engaged in casting metal for the manufacture of ordnance in the Woolwich Arsenal lost his balance and fell into a caldron containing twelve tons of molten steel. The metal was at white heat and the man was utterly consumed in less time than it takes to tell it. The War Department authorities held a conference and decided not to profane the dead by using the metal in the manufacture of ordnance, and the mass of metal was actually buried and a Church of England clergyman read the services for the dead over it.—*Notes and Queries*.

Sickness Does Not Excuse Tenant Holding Over.—The fact that a member of his family is sick and it would endanger the life of the latter to be moved, the appellate division of the supreme court of New York holds in the case of *Herter v. Mullen*, Nov. 6, 1896, does not furnish a valid excuse for a tenant holding over after the expiration of his lease, so as to relieve him from the operation of the rule of law that where a tenant holds over, without the consent of the landlord, the landlord may elect to treat the holding over as creating a new lease for another year, and it will not make it otherwise for the tenant to notify the landlord in advance that he does not propose to keep the property another year.

Separate Account Books for Patients.—It is not probable that any great number of physicians keep separate account books for different patients. But the case of one who did comes to light where he filed a claim for medical services to the decedent, *in re* *Fulton's Estate*, upon which the supreme court of Pennsylvania passed Oct. 5, 1896. Here, when proof of the claim was to be made, a separate book was produced, containing no charges except against the decedent. The physician explained that this book was so kept at the decedent's request. Its character, however, the supreme court holds to be an

insuperable objection to the book, which it rejects as not being one of entries in the regular course of business. The regularity of an account as to its place in the ordinary books of the business, the court says, is as necessary as its regularity in other respects.

Dr. Colden's Coach.—In 1732 there was but one vehicle on Manhattan Island that bore any resemblance to a coach, and forty years afterward there were only half a dozen coaches. There were several chaises, but carts were the common conveyance. In 1772, according to authentic local history, there were five private coaches in use here. One belonged to the Governor, one to Lieutenant Governor Cadwallader Colden, M.D., one to William Walton, one to Mr. Murray, for whom Murray Street was named, and the fifth was the property of Mrs. Alexander. Carpets were unknown in New York at this period, for "all the houses were sanded with white or silver sand, in figures and devices."—*New York Tribune*.

The Beginning of a Medical Code for Austria.—After a long and animated discussion, the Medical Chamber of Vienna has at last adopted the following recommendations as to the mutual relations of physicians, patients and the public. The first article, referring to the intercourse of physicians between themselves, declares that the maintenance of the honor and dignity of his profession is the medical man's first duty. Misunderstandings as a rule arise from the fact that patients seek further advice without previously informing the practitioner already engaged. If a medical man knows that a patient who consults him is already under the care of another practitioner, he ought to decline further attendance and ought not to express an opinion as to the diagnosis or treatment of such a case unless he has conferred with his colleague who has first been called; he should not refuse a consultation on the ground of the alleged inferior position or attainments of the proposed consultant. If two physicians do not agree a third is to be called. Fees ought to be claimed at the time; gratuitous treatment is only admissible in the case of poor patients. A medical man is not obliged to attend a patient, but he ought not to withhold assistance in urgent cases. Reticence as to the patients' confidences is already prescribed by law.—*London Lancet*.

Location of Hospital.—Under chapter 157, General Laws of Minnesota of 1895, entitled "An act to create a commission to locate, acquire land and prepare plans for a fourth hospital for the insane," the supreme court of Minnesota holds, in the case of *State v. Bondy*, Nov. 19, 1896, that the location of a site within the meaning of the act signifies and includes not merely a determination as to that part of the State where it should be located, but also a selection and designation of the precise tract or parcel of ground upon which the hospital should be located, and until this was done the location was incomplete, and therefore the commission still had the power to reconsider any partial or tentative action which it had taken upon the subject. The court further holds that conceding, without deciding, that after the commission had once located a site, its power would be *functus officio* and therefore without power to reconsider or change its location, yet upon the facts appearing in the record in this case, the *viva voce* vote on the location of a site, by which the commission voted to locate it at Hastings, did not amount to a complete location or selection of the site within the meaning of the act, nor did it amount to such an acceptance of the offer of the city of Hastings as to make it a binding contract between the parties and hence it was within the power of the commission to locate the site elsewhere.

Italian Surgical Congress.—The seats of learning and scientific research in Italy are not centralized as in most countries, but all over the land are small groups of enthusiastic investigators clustered around some progressive professor, constantly at work according to the most advanced methods of modern bacteriology, experimental pathology, etc. The Congress at Rome

in October brought out numerous communications of the results attained, which time may possibly prove to be of great importance. We notice among them Salomoni's report of some experimental surgery of the heart on dogs, which survived wounds into the heart—sutured by the usual methods—and showed only slight pericardial adherences when killed two to three weeks later. Farina recently sutured successfully the left ventricle of a patient who was recovering when a fatal intercurrent disease occurred. Sgambati has secured one success in his experiments on dogs to ascertain if normal epithelial tissue implanted in the pulmonary arteries would continue to grow and proliferate like abnormal cancer tissue. He used the skin of the submaxillary gland and of the testes, in an endo-venous injection after soaking them a while in salt solution at 38 degrees C. The dogs were killed afterward and the hemorrhagic infarcts found in the lungs examined. Most of the results were negative, the embolic elements being found in a more or less advanced stage of degeneration, but in one case the experiment had succeeded and the epithelial elements from an organized thrombus in the testicular epithelium had located and proliferated presenting the picture of a tubular adenoma. These experiments are the first by the embolic method although Cohnheim and Maas have transplanted embryonal tissue and observed its reproduction *in situ*. Gangitano also announced that numerous experiments have shown that occluding the cystic duct by tying it or closing the lumen with aseptic small stones was invariably followed by atrophy of the gall bladder. On the other hand, if septic substances were introduced, such as non-sterilized stones, saliva, etc., into the gall bladder after the cystic duct was tied, hydrops invariably followed. He considers therefore that hydrops in man is due not only to the obstruction of the duct but also to infection. He advises consequently in cases of gallstones when the biliary passages are free from infection and otherwise normal, not to perform cholecystostomy or cholecystectomy, but merely to tie the cystic duct.

—*Cbl. f. Chir.*, December 19.

A Delirium of Loquacity.—The *British Medical Journal*, December 5, has a cautionary word about orators, political and other, that may profitably find lodgment in this orator-ridden country. It says in part: "We live, in fact, in a whirlwind of words, a delirium of talk; and this unwholesome environment leads to the development of a neurotic condition of the political and social organism which is fraught with the gravest danger to the commonweal. More than once in recent years the excitement of oratory has led to attacks of hysteria affecting large numbers of the public, and it is conceivable that a state of acute National frenzy might be brought about by the same cause. It is hardly too much to say, therefore, that the mere orator is a danger to society. Dr. Le Bon has told us what the madness of crowds may lead to, and the orator has the power of engendering this madness and stimulating it to the highest pitch of destructive fury. Not only does the orator act upon the crowd, but it reacts upon him. He becomes intoxicated with the exuberance of his own verbosity, and is carried into excesses of speech which, when translated by those whom he has influenced into action, he would in his saner moments deplore. A curious illustration of the possible dangers of oratory was afforded recently by the lunatic who lectured on his own disease at Vienna. The lecture, we are told, was admirable as a display of oratorical art; the wealth of ideas was only equaled by the brilliancy of expression. The effect of such a discourse on a popular audience may easily be imagined. The speaker might in this country have carried on a campaign against the lunacy laws, the iniquities of 'mad doctors,' and the horrors of madhouses, which would have led to an agitation for the setting free of all lunatics and the abolition of asylums. And if 'a tale told by an idiot, full of sound and fury, signifying nothing,' could do this, what might not a course of inflammatory orations by a master of the art of mak-

ing the worse appear the better reason, on subjects as to which the people are without authoritative guidance, accomplish? Plato banished poets from his republic, and we are inclined to think that it would be for the good of mankind if a similar course were adopted with orators."

Not Bound to Employ Physician or Avoid Hysterical Outbreaks.—In a personal injury case it was asked that the jury be instructed: "If the plaintiff was injured by the collision, he was bound by law to use ordinary care to render the injury no greater than necessary. It was therefore his duty to employ such medical assistance as ordinary prudence in his situation required, and to use ordinary judgment and care in so doing." This, the supreme court of Illinois holds, in the case of *Chicago & Erie Railroad Co. v. Meech*, Nov. 9, 1896, stated a correct but abstract rule of law, which, because it was likely to mislead the jury for want of directions in regard to its proper application to the case in hand, was properly refused. It points out that the jury would probably have understood from such an instruction that although there was culpable negligence on the part of the defendants, and consequent injury to the plaintiff, yet if any aggravation of injurious consequences was caused by subsequent negligence of the plaintiff, then there was no cause of action, even for such consequences as necessarily resulted from the injury. The doctrine, it affirms, is that where, after the occurrence, the plaintiff by his own negligence increases the damage, then the defendant is liable only for the consequences of his own acts and not for those of the plaintiff, or of those of a third person, which are separable from the results of his own acts. The court also holds in this case that the fact that a plaintiff or defendant or witness, or any other person, suddenly swoons or faints, or gives vent to hysterical exclamations, or breaks down with hysteria, does not call for the granting of a new trial, though, of course, if it appeared that the dramatic occurrence that took place in the midst of the trial was intentional and for an improper motive, it would afford ground for setting aside the verdict.

Placental Vestigial Origin of Uterine Tumors.—Dr. Adami in the *Montreal Medical Journal* discusses the influence of placental tissue upon the uterus, finding reason for holding that portions of the fetal epiblast that may be left behind after the separation of the placenta may continue to grow and assume the characters of a definite tumor growth. That uterine tumors may thus develop from placental relics is now pretty well recognized by pathologists. "The placenta is in the main a fetal structure, nourished by the maternal blood, and being in the main fetal, it is possible that such tumors can be of fetal origin. Meyer has described an epitheliomatous growth which followed the removal of a hydatiform mole, in which the resemblance of the invading columnar processes to chorionic villi was especially noticeable. Meyer, it is true, did not venture to describe the growth as entirely fetal, but imbued with the present German view, suggested that the epithelial element was of maternal origin and that the chorionic villi had protruded into it, a view which our present knowledge of placental structure renders eminently improbable. But Fränkel has published a case of 'carcinoma developing from chorionic villi.' Here also malignant disease of the corpus uteri followed removal of a vesicular mole. This growth had a papillary form, invaded the deeper tissues and gave rise to metastases. Microscopically it was shown to have originated from the remnants of chorionic villi left after the removal of the mole, since the structure of the uterine glands was still recognizable and its histologic appearance was quite different from that of cancer of the endometrium of the corpus uteri. The writer has been unable in a hurried search to discover other cases of this nature, but these two would seem to support the view that (not only can cells derived from one tissue invade others and form metastases, but also that) cells originating from

another individual—the embryo—are capable of assuming similar powers of invasion and metastatic growth. That this process of invasion should be developed by the multiplication of parasites within those cells seems to me most unlikely, when it is remembered that these same cells of the chorionic villi, under physiologic conditions manifest this same power of invasion to a considerable, if strictly limited, degree; or otherwise these facts brought forward by Professor Young seem to be wholly in accord with the argument adopted by me in the article to which I have already referred. A consideration of another most interesting form of tumor of placental origin—the so-called malignant deciduoma—must be left for another occasion. To discuss the various theories propounded as to its nature would unduly prolong this article. Sufficient has been already brought forward to show that a fuller knowledge of the placental structure materially advances our views in many directions."

The Teaching of Pediatrics in London.—At this season of the year it is usual for the various medical schools in London to attract by advertisements and prospectuses as large a number of new students as possible. We, as a journal devoted to the diseases of infants and children, are concerned only in that particular branch of the student's education, probably the most important, and, in London at any rate, the worst taught of any of the numerous subjects which the student has to study during his hospital career. It can hardly be disputed that, in the interests alike of the public and of the profession, every newly qualified man should commence practice with a thoroughly practical knowledge of the diseases of infants and children; not only because children's ailments constitute a very large percentage of the work of the general practitioner, but because of the livelong influence for good or evil which the medical treatment effects upon their future existence—nor indeed can it be maintained that the physical examination of children, which is so necessary for accuracy in diagnosis, is an easy accomplishment, or one which is likely to be mastered without considerable practice. It is then obvious that the General Medical Council of Great Britain should insist upon each and every examining body thoroughly testing the student's practical and theoretical knowledge of pediatrics before granting him his diploma, and that the authorities of every medical school should be called upon to provide facilities for its pupils to obtain the requisite tuition. We at any rate are disposed to regard the diagnosis and treatment of children's diseases as among the most difficult of the varied duties of the general practitioner, to be learned thoroughly only by special training, and it consequently behooves us to call attention to the attitude at present adopted toward this question by the examining and teaching authorities in London. We must confess to a feeling of the keenest disappointment that none of the examining bodies in London insist upon the student taking out a course of special study of pediatrics, and as we find that this grave omission in their schedules leads to an almost total neglect of the subject in the medical schools, we propose in future numbers to criticize the very imperfect arrangements which at present exist at the different general hospitals in London, and to suggest reforms which we consider are urgently required.—*Pediatrics*, November.

Liability of Non-resident Specialists.—The decision of the supreme judicial court of Maine, in the malpractice case of Feeney v. Spalding, which was rendered April 8, 1896, is now accessible to the public. It grants the defendant's motion for a new trial. He is a physician and oculist, practicing in Portland. In the summer of 1891, while on a trip to Machias, to visit patients, he stopped over a short time at Cherryfield. While he was there, the plaintiff, at that time a girl seven years old, who had been cross-eyed in one eye since she was a year and a half old, was taken to him by her father for exami-

nation and operation if thought desirable. After an examination by the physician, he performed the usual operation for a difficulty of this kind, bandaged the child's eye, gave certain directions to the father, and proceeded upon his journey. Prior to the operation, it was alleged, that the sight of this eye was, at least, fairly good; that, in fact, no defect whatever in the vision had ever been complained of by the plaintiff or observed by her parents or teacher; and that, after the operation, the sight of the eye operated upon was entirely gone, which result, it was alleged, was caused by the ignorance and want of skill of the defendant, and by his carelessness in the performance of the operation. But the court holds that before the plaintiff was entitled to recover a verdict, it was incumbent upon her to prove that the injury complained of was caused either by the defendant's want of that degree of skill and knowledge which is ordinarily possessed by physicians who devote special attention and study to the treatment of the eye, or by his failure to exercise his best judgment in the application of his skill to the particular case, or by his failure to use ordinary care in the performance of the operation, and in giving such instructions as should have been given by a surgeon who was only to perform the operation, and who was temporarily in the locality where the patient lived. At the trial, the plaintiff relied almost entirely upon the result which it was contended followed the operation. As to this, the evidence was conflicting. The expert testimony upon the part of the defense was to the effect that an examination of the eye showed conclusively that the defective vision had existed from birth, and that it was as good at the time of the trial as it ever had been. And not only was there no evidence of any want of the requisite skill, knowledge or care upon the part of the defendant, but the evidence on his behalf was that the operation was a proper one, skillfully performed, and incapable of causing the injury complained of. Under such circumstances, the court holds a verdict for the plaintiff not authorized.

Journal of Experimental Medicine.—The November number of this journal is fully up to the standard of its preceding issues and contains the following: "Histological Lesions of Acute Glanders in Man and of Experimental Glanders in the Guinea Pig." After a series of experiments, the author concludes as follows:

"The glanders nodule in the class of cases studied by us is in no sense analogous to the miliary tubercle in its histogenesis and our studies afford no support to Baumgarten's views. The primary effect of the bacillus of glanders on a tissue we found to be not a production of epithelioid cells, which undergo necrosis and invasion by leucocytes, as happens in the cases in which the bacillus of tuberculosis is concerned, but to be the production of primary necrosis of the tissue, followed by inflammatory exudation, often of a suppurative character. Degenerative changes rapidly ensue in the inflammatory product."

A report of "Two Cases of Sarcomatosis with Purpura Hemorrhagica" by C. F. Martin, M.D., and W. F. Hamilton.

John Lovett Morse, A. M., M.D., gives an interesting study of the "Changes Produced in the Kidneys by the Toxins of Staphylococcus Pyogenes Aureus." As the result of experiments made upon rabbits which were injected with the toxin, Dr. Morse says:

"The lesions of the kidneys produced by bacteria have been carefully studied by many investigators during the last ten years. Ribbert has devoted especial attention to those produced by the staphylococcus aureus. Pernice and Scagliosi injected guinea pigs with filtrates of the anthrax bacillus and of the bacillus pyocyaneus. The animals were killed in forty-eight hours. In general the results were almost negative. In some cases, however, hemorrhages were found in the interstitial tissue. The epithelium was as a rule unchanged. Here and there, however, it showed granular degeneration. The epithelium of some of the straight tubules was desquamated and in some cases the walls were collapsed. With this exception, I am unable to find that any attempt has been made to study the renal lesions produced by bacterial toxins alone.

Certainly no one has made a careful study of the effects of continued and repeated injections of such toxins. The positive results obtained in these three animals seem sufficient to prove that a chronic interstitial process may be caused in the kidneys by the action of the toxic products of bacteria. It must be admitted that the human kidney is more or less constantly exposed to the action of chemical substances produced by bacteria. Hence it would seem justifiable to assume that a certain proportion of the cases of chronic interstitial nephritis in man may be due to the action of such substances."

C. C. Stewart contributes an article on the "Influence of Acute Alcohol Poisoning on Nerve Cells." This series of experimentation is in extension and confirmation of Dehio's researches, and the bacteriologic procedures are very minute.

F. S. Locke's article on "The Action of Ether on Contracture and Positive Kathodic Polarization of Vertebrate Voluntary Muscle" is subdivided into four parts: 1, the action of ether on veratrinized muscles; 2, the action of ether on muscles under the influence of physiologic salt solution; 3, the action of ether on dehydrated muscles; 4, discussion of results, and concludes with some remarks regarding positive kathodic polarization of vertebrate voluntary muscle.

"The Regeneration of the Blood," by Winfield S. Hall and Marion Eubank, comprises twenty pages devoted to: Methods of observation; the withdrawal of blood; the course of the blood; the microscopic observations, and transfusion of an artificial serum or of a physiologic salt solution. The authors conclude with the following summary:

a. The blood of apparently normal animals undergoes considerable variations within physiologic limits.
b. After a loss of blood the regeneration is more rapid if there has been a transfusion of an artificial serum.
c. Regeneration after transfusion is less rapid during the first half of the regeneration period than during the second half.
d. The regenerative processes once stimulated into activity carry the blood, qualitatively; considerably beyond the established normal. Otto observed a similar phenomenon.
e. The quantity of hemoglobin per volume of red blood corpuscles is not constant.

f. The volume of red blood corpuscles varies as the product of the average volume of individual corpuscles and the number of corpuscles per unit volume ($V \propto v \times n$).

g. When the number of the corpuscles increases the size decreases, and conversely ($n \propto 1/d$).

h. The quantity of hemoglobin varies in general with the number of red blood corpuscles per unit volume ($Hb. \propto n$).

Dr. G. F. Novy's conclusions in an article on the "Immunizing Power of Nucleohiston and Histon" are as follows:

1. Nucleohiston does not protect against a separate and subcutaneous injection of tetanus toxin, diphtheria toxin, hog-cholera bacillus, or anthrax bacillus.

2. Mixtures of nucleohiston and either tetanus toxin or diphtheria toxin lose their specific action—the latter much more readily than the former. Animals that recover after inoculation of such mixtures are not rendered immune.

3. In a mixture of nucleohiston and anthrax bacillus the latter is unaffected, even after a lapse of eleven days.

4. The destruction of specific toxins in a solution of nucleohiston, though in part due to sodium carbonate, is probably chiefly due to nucleohiston.

5. Histon does not protect against a separate and subcutaneous injection of tetanus toxin, diphtheria toxin, hog-cholera bacillus, or anthrax bacillus.

6. In a mixture of histon and diphtheria toxin the latter is destroyed in a few minutes. This action is in part, if not wholly, due to the acidity of the histon solution. Similar mixtures of closely related bodies, serum globulin or albumoses, in Witte's pepton, give analogous results. The animals that recover from such inoculations are not rendered immune. Histon does not destroy the tetanus toxin as readily as the diphtheria toxin.

7. Histon possesses decided and marked toxic properties which are not due to the hydrochloric acid present.

Dr. G. W. Fitz reports a "Study of Types of Respiratory Movements." He concludes as follows:

1. Children of the two sexes differ very little in the character of their respiratory movements.

2. Between girls and women and boys and men there is little or no difference in respiratory type.

3. Childbearing does not permanently affect respiration.

4. The natural type of respiration for both sexes is one in which the movement is fairly equally balanced between chest and abdomen, the abdominal being somewhat in excess.

5. In typical unobstructed individuals the chest contributes about the same bulk of air as does the abdomen.

6. Constricting dress causes preponderance of thoracic movement in ratio to its restriction of abdominal movement and to the sensitiveness of the nervous coordination.

Syphilology in Early English Drama.—Some weeks ago the JOURNAL called attention (Volume xxvii, page 1252) to the ludicrous blunder of a commentator who, destitute of even popular medical knowledge, distorted the Hippocratican facies Shakespeare so beautifully illustrated in Falstaff's death into bizarre absurdities. Senator Lodge, in his "American Slang in Shakespeare," makes a similar amusing blunder when he remarks:

"In the soup' to express defeat and disaster, is apparently very recent, yet it is singularly like the language of Pompey (Measure for Measure, act 3, scene 2) when he says 'Troth, sir, she hath eaten up all her beef, and she is herself in the tub.'"

The tub reference was a sly allusion to the "occupation diseases" afflicting the procuress of whom Pompey was speaking. The "tub" was a sweating apparatus employed in venereal disease by Herodotus in the second century (Dupouy, *Histoire de la Prostitution*) and later advocated by Cornelius Agrippa, whence the appellation "Cornelius tub." This "tub" is still employed in syphilis at Hot Springs and elsewhere. The patient, according to Ambrose Paré, who gives (*Works*, Edition 1575, p. 598) a figure of this tub, was seated inside on a perforated stool, beneath which were hot bricks or stones. Through a trap door in the side of the tub, a mixture of vinegar and brandy (to which mercurials and aromatics were sometimes added) was thrown upon the heated bricks. The steam was confined by a sheet fastened around the neck. In England, as Dr. R. Fletcher shows (*Alienist and Neurologist*, 1895) the tub used for salting or "powdering" meat was thus employed. Rabelais was an advocate of its use. His attention was early attracted to syphilis because of a kindly disposition which drew him toward all neglected invalids. In 1538 he made great efforts to reform (Dupouy, *Medicine in the Middle Ages*) the treatment of these patients who had been abandoned by physicians to quacks, who terribly abused mercurial inunctions. Rabelais had "often seen syphilitics when greased with mercurial ointment; their faces on edge like a knife and their teeth clacking like the keyboard of a broken down organ." In the treatment of syphilis Rabelais employed the hot air and other baths, which had long previously been used by Torella. Rabelais, believing that ere the discovery of America, syphilis ravaged Europe, made a tutor of Gargantua die of it in 1420.

"In fourteen hundred and a score,
Did pox come to him full sore."

To the use of sweating in syphilis, Rabelais makes a most pungent allusion in his explanation of why the sea is salt.

"The earth at this time was so exceedingly heated that it fell into an enormous sweat, yea, such an one that made it sweat out the sea, which is therefore salt, because all sweat is salt, and this you can not but confess to be true if you will taste your own or of those that have the pox when they are put into a sweating, it is all one to me."

The tub or bath (for tub was then as now an accepted English synonym for bath) treatment for syphilis was very popular in Shakespeare's time, as witness Timon's cynical advice to Phyrne and Timandra, the courtesans (Timon of Athens, act 4, scene 4).

Make use of thy salt hours;
Season the slaves
For tubs and baths: bring down rosy-cheekd youth
To the tub fast and the diet.
Consumption sow in hollow bones of men; strike their sharp shins
And mar men's spurring: crack the lawyer's voice
That he may never false titles plead.
Down with the nose.
Down with it flat; take the bridge quite away;
Make curly headed ruffians bald.

Strict diet, as Shakespeare implies, was enforced. Dry food, especially overdone mutton from the neck, was alone allowed. Beaumont and Fletcher (Knight of the Burning Pestle, act 3, scene 5), in a burlesque on Spenser's Faerie Queene, imprison a knight and lady in a cave by a giant who tortures them. The Knight, who has carried off his "lady dear" from Turnbull Street (then notorious for houses of prostitution) thus tells his tale of woe.

Man.—I am an errant knight that followed arms,
With spear and shield; and in my tender years
I stricken was with Cupid's fiery shaft,
And fell in love with this my lady dear,
And stole her from her friends in Turnbull Street
And bore her up and down from town to town
Where we did drink and eat and music hear,
Till at the length at this unhappy town
We did arrive and coming to this cave,
This beast us caught and put us in a tub
Where we this two months sweat, and should have done
Another month if you had not relieved us.

Woman.—This bread and water hath our diet been
Together with a rib cut from a neck
Of burned mutton; hard hath been our fare.
Release us from this ugly giant's snare.

Man.—This hath been all the food we have received
But twice a day for novelty,
He gave a spoonful of this hearty broth,
To teach of us through this same slender quill.
[pulls out a syringe.]

Beaumont and Fletcher in another comedy (Honest Man's Fortune) thus reproach a libertine:

All women that on earth do dwell thou lovest,
Yet none that understands loves thee again
But those that love the 'spital. Get thee home
Poor paluted butterfly; thy summer's past;
Go sweat and eat dry mutton.

Middleton (Michaelmas Term, 1607) predicts the like fate to another rake:

He'll be laid shortly;
Let him gorge venison for a time, our doctors
Will bring him to dry mutton.

Lustic alopecia early lead to numerous allusions to "French crowns and nightcaps." In "A Fig for Momus" (the oldest satire in the language) occurs the following stanza:

Last day I chaunst in crossing of the street
With Divilus, the lunkeper, to meet,
He wore a silken nightcap on his head,
And looked as if he had been lately dead,
I asked him how he far's; not well, quoth he,
An'ague this two months hath troubled me,
I let him pass and laught to hear his abuse
For I knew well he had the pox by Luce
And wore his nightcap beribbl'd at the ears
Because of late he sweat away his heares.

Middleton (Your Five Gallants, 1603) remarks:

"He is in his third sweat by this time, sipping of the Doctor's bottle or picking the pluch part of a rack of mutton dry roasted, with a leash of nightcaps on his head, like the pope's triple crown, and as many pillows crushed to his back."

George Farquhar has the following high opinion of the value of the "powdering tub" in lues:

You will revive, the pox expire
Then rise like Phoenix from the fire.
The metal's stronger than's once soldered
And beef keeps sweeter once 'tis powdered.

Armin's "Nest of Ninnies," 1608 says anent the students:

And when they should study in private with Diogenes in his cell, they are with Cornelius in his tub.

Cornelius was thought popularly to be a corruption of Diogenes who thus naturally offered the following mark for the satirist in Cotgrave's English Treasury of Wit and Language (1655):

As for Diogenes, that fasted much
And took his habitations in a tub
To make the world believe he loved a strict
And severe life, he took the dyet, sir, and in
That very tub sweat for the French disease
And some unlearned apothecary since
Mistaking name, called it Cornelius tub.

Dietetic treatment was an early favorite, Gandy's Arabian dietetics, so popular in the first decades of the present century, and even now, were in use in the reign of Charles II. of England. Gandy's diet consisted exclusively of dry biscuits, nuts, dried almonds, figs and raisins. An infusion made from sarsaparilla, China root and cloves was freely given and a mercurial pill was administered thrice daily. Mrs. Aphra Behn, the most pornographic novelist of the time describes this procedure in (1660) the following doggeral "Letter to a Brother of the Pen in Tribulation." (Tabernaclers were street preachers who

preached from casks or tubs and thus furnished another sly allusion to the "tubbing" of luetics:

Poor Damon art thou caught. It's even so,
Art thou become a Tabernacler too,
When sure thou dost not mean to preach or pray
Unless it be the clean contrary way.
This holy time I little thought thy sin
Deserv'd a tub to do its penance in.
O, how you'll for the Egyptian flesh pot wish
When you're half famished with your lenten dish,
Your almonds, currents, biscuit, hard and dry
Food that will soul and body mortally
Dammed penitential drink that will infuse
Dull principles into thy grateful muse.

A powerful method of sweating then in use that would have greatly pleased the advocates of the dry earth treatment, is described by D'Avenant (The Wits, 1636, act 4, scene 1):

Though I endured the diet and the flux,
Lay seven days buried up to the lips like a
Diseased and Indian, in warm sand, whilst his
Afflicted female wipes his salt foam off
With her own hair, feeds him with buds of guacum
For his sallad and pulp of salsa [seaweed] for
His bread; I say all this endur'd would not
Concern my face. Nothing can decline that.

Massinger (The picture, 1620, act 4, scene 2) plays two rivals, Ubaldo and Ricardo, against each other. Ubaldo first backbites his rival to Sophia, with whom both are in love:

Sophia.—How, is he not wholesome?

Ubaldo.—Wholesome, I'll tell you for your own good he is
A 'spital of disease indeed
More loathsome and infectious; the tub is
His weekly bath. He hath not drank this seven years
Before he came to your house but composition
Of assafraas and guaicum and dry mutton,
His daily potion. Name what acratich soever
Can be got by women and the surgeon will resolve you
At this time or that, Ricardo had it.

Sophia.—Bless me for him.

Ubaldo.—'Tis a good prayer, lady,
It being a degree into the pox
Only to mention him; if my tongue burn not hang me
When I but name Ricardo.

After Ubaldo had been dismissed by Sophia Ricardo is introduced, who thus rewards his friend's kindness:

Ricardo.—He did not touch your lips.

Sophia.—Yea, I assure you
There was no danger in it.

Ricardo.—No, eat presently
Those lozengers of forty crowns an ounce
Or you are undone.

Sophia.—What is the virtue of them?

Ricardo.—They are preservatives against stinking breath
Rising from rotten lunge.

Sophia.—If so, your carriage
Of such dear antidotes, in my opinion,
May render yours suspected.

Ricardo.—Fie, no; I use them

When I talk with him. I should be poisoned else,
But I'll be free with you; he was once a creature
It may be of God's making, but long since
He is turned to a druggist's shop, the spring and fall
Hold all the years with him; that he lives he owes
To art not nature. She has given him o'er.
He moves like the fairy king on screws and wheels
Made by his doctor's receipts and yet still
They are out of joint and every day repairing.

He's acquainted

With the green-water, and the spitting pill's
Familiar to him; in a frosty morning,
You may thrust him in a pottle pot; his bones
Rattle in his skin like beans toas'd in a bladder
If he but hears a coach. The fomentation,
The friction with fumigation can not save him
From the chine-evil. In a word he is,
Not one disease but all; yet being my friend
I will forbear his character, for I would not
Wrong him in your opinion.

Venereal disease in the sixteenth and seventeenth centuries had many popular synonyms. In the fifteenth century (Les Cents Nouvelles Nouvelles, 1456) it was called the "spite" (that predecessor of the toasting-fork), which was easily converted into the "Devil's Spit for Rakes" of more than one author. In the thirteenth century in France and Scotland, it was termed the "grand gorre" or "pocky pork."

In a Scotch version of the French "XXIII Kinds of Vulgar" appears the following ("Sibbald's Chronicle of Scottish Poetry," 1802):

Now cursit and waret be their wyrd
Quhyll [while] they be levand on this erd
Hunger, sturt and tribulation
And never be but [without] vexation.
The paneful gravel and the gutt.
The gulsech [jaundice] that they never be but [without]
The strangolis and the grit glengor.

A later English translation of the French version is:

That they may be
Itchy, poked and apostumed,
Dug with ulcers, badly rheumed

By gout and gravel pained; by jaundice sapped
That they may be also clapped.

Strangolis was strangury produced by venereal infection. Fracastor, first called venereal disease syphilis (*syphilis sive morbus Gallicus*) from sus, pork, and philos, love. Gorre (meaning pork in Romance) was applied by pirates to the women sold as slaves and hence easily drifted into a designation of prostitutes whose ranks were largely recruited in this way. Fracastor to avoid national prejudice (which made the Turks call syphilis the "Christian disease;" Germans, Italians and Spaniards the "French disease;" Frenchmen, Dutchmen and Scotch, the "Spanish disease" and Poles the "German disease") translated the Romance term into Greek and made it popular. In England (as Dr. Fletcher remarks) one of the oldest terms in the copious popular nomenclature of syphilis is the "Winchester goose." In early London, the Bankside, a row of brothels near the river, was under jurisdiction of the Bishop of Winchester. The victim who suffered the usual consequence of a visit to this tainted locality was called a "Winchester goose." The term was finally applied to the disease itself. The old writers very frequently use it. John Taylor, the Water Poet (intimately acquainted with all river-side customs and phrases), calls it

A groyne, or a goose from Winchester.

The Nomenclator (an English dictionary of 1585), defines it as "a sore in the grine or yard, which if it comes by lletcherie, it is called a Winchester goose or a botch."

Ben Jonson (Underwoods) says:

And this a sparkle of that fire let loose
That was rak'd up in the Winchesterian Goose
Bred on the Bank in times of popery
When Venus there maintained the mystery.

Shakespeare makes more than one stage use of the term. Pandarus (*Troilus and Cressida*, act 5, scene 2) in what is clearly intended to be an epilogue, employs the term as a stage trick to avoid being hissed.

Pandarus.—Some months hence my will shall here be made.
It should be now but that my fear is this:
Some gall'd goose of Winchester might hiss;
Till then I'll sweate and seek about for ease
And at that time bequeath you my disease.

In *Henry VI* (part 1, act 1, scene 3) Humphrey, Duke of Gloster, applies the term to the Cardinal Bishop of Winchester, the ruler of the Bankside:

Duke of Gloster.—Stand back, thou manifest conspirator,
Thou that givest whores indulgences to sin.
Winchester.—Gloster, thou'lt answer this before the pope.
Gloster.—Winchester goose.

Webster ("Westward Ho") has an elaborate explanation of the origin of the term identical with that already given. To be "bitten by the Winchester goose" was in popular speech, to have syphilis. As the pigeon as well as goose meant in slang a gull, "Winchester pigeons" were like "Winchester geese" victims of syphilis.

Bone-ache is another synonym for syphilis, used by both Nash and Shakespeare. Nash (*Pierce Penniless*, 1592) says:
But cucullus non facit monachum; 'tis not their newe bonnet will
keep them from the old boan ache.

Shakespeare (*Troilus and Cressida*, act 5, scene 2) employs this term in the same sense. Another synonym bore reference to the supposed origin of lues at the siege of Naples. In Motteux's English translation of Rabelais, Friar John says: "He looks as if he had been struck over the nose with a Naples cowl-staff."

That the relationship between genital infection and constitutional results should be so early recognized by dramatists may seem strange to those who believe Hunter discovered the chancre called by his name, and who fail to recognize that printer shops, publishing medical works as well as general literature, were the haunts of poets and dramatists in search of material. This was excellently shown by Dr. R. N. Hawley in a paper read before the Milwaukee Medical Society (*N. W. Lancet*, December, 1892). While admitting Shakespeare's debt for medical lore to his friend Dr. Helden, and to his own son-in-law, Dr. Hall, Dr. Hawley pointed out that Helkiah Crooke pub-

lished what was probably the first great work on anatomy published in English. It contains over one thousand pages imperial quarto and is illustrated by numerous drawings of anatomic subjects. It contains beside anatomy, various references to physiology and psychology. In this work the brain membranes are well described. W. Jaggard of the Barbican, London, printed the works of Crooke. He was the printer for Shakespeare. Within easy walking distance from the Globe Theater (the scene of Shakespeare's managerial glory) was the printing office of Jaggard, where the plates and letter press of Crooke would for a long time be the most remarkable press-work of the time. To that office the indefatigable playwright would often be drawn by his own business. There he could hardly fail to see unfolded before him the anatomy of man from a sure source in just the form that would most readily appeal to his ever-absorbing mind. The closer this book and the plays are read together, the more clearly, Dr. Hawley remarks, it is detected where and how the dramatist became the student of anatomy.

Long before Hunter, both Fallopius and Ambrose Paré (*Buret, History of Syphilis*) had recognized the constitutional prognostic significance of the hard chancre.

Washington.

THE MEDICAL SOCIETY ELECTS OFFICERS.—At the annual meeting of the Medical Society held on January 6, Dr. Samuel C. Busey was elected president by acclamation. This is the fourth time he has been thus honored. The other officers elected were Drs. J. D. Morgan and Stone, vice-presidents; Dr. C. W. Frangoni, treasurer; Dr. T. C. Smith, corresponding secretary; Dr. S. S. Adams, recording secretary; Dr. Hayes, assistant secretary, and Drs. Kleindschmidt, Acker, Richardson, King and Winters, censors. The society formerly issued the licenses to practice medicine in the District, but a recent act of Congress transferred that power and created the Medical Examining Board, who now perform that function.

MEDICAL ASSOCIATION.—An adjourned meeting of the Medical Association was held on January 12 to consider a report from a special committee appointed to investigate the subject of free dispensary abuses. Several valuable recommendations were adopted. The fee bill, which has been in vogue for many years, was revised and a special committee of three appointed to cooperate with the other societies in the suggestion of a plan for checking the frauds practiced by patients on physicians. Washington has been a Mecca for "beat" and "rounder" patients.

FEES FOR HEALTH TRANSCRIPTS.—Senator McMillan has introduced a bill on the recommendation of the Commissioners, authorizing the charge of 50 cents for issuance of transcripts from the records at the Health Department. Health Officer Woodward's letter, accompanying the bill, states that these transcripts are asked for in great numbers for private purposes, especially by applicants for insurance. He would have the money derived from this source turned over to the collector of taxes. Mr. Babcock introduced a similar bill in the House.

MEDICAL LICENSES.—The Board of Medical Supervisors has decided not to issue licenses to physicians connected with the army, navy and marine-hospital service. They are exempted by the act.

MEDICAL SOCIETY.—At the regular weekly meeting of the Medical Society held on January 13 Dr. W. K. Butler read the essay of the evening, entitled "Syphilitic Ophthalmia," and presented cases and specimens. Dr. Jos. Taber Johnson reported a case of extra-uterine pregnancy and presented the specimen.

MONEY FOR THE FREEDMEN'S HOSPITAL.—Mr. McMillan has given notice in the Senate of an amendment to the District of Columbia appropriation bill which he proposed to make. The amendment provides: "For Freedmen's Hospital, for sub-

sistence, \$22,500; for salaries and compensation of superintendent, not to exceed \$3,000; for clerk, engineer, matron, nurses, laundresses, cooks, teamsters, watchmen and laborers, \$15,000; for rent, hospital buildings and ground, \$4,000; for fuel, light, clothing, bedding, forage, transportation, medicine and medical supplies, surgical instruments, electric light, furniture and other absolutely necessary expenses, \$11,500. Total appropriated by this amendment is \$53,000." The amendment also provides that hereafter the incorporators of this institution shall have full control and management thereof. This is a very proper amendment. It gives the same rights to this institution which are enjoyed by all the other hospitals in the District and removes the obnoxious political control which has been so objectionable in the past.

TO REGULATE EXPERT TESTIMONY IN LOCAL COURTS.—Senator Morrill has introduced a bill in the Senate to regulate the employment of expert testimony in the courts of the District. It bestows the power upon the trial judge, subject to review by the appellate court, to decide whether a person is competent to testify as an expert. Further provision is made in insanity cases for the appointment of a commission of three medical officers, one to be named by the government, one by the defendant and one by the court.

SECRETARY MORTON'S CRITICISM OF THE MEDICAL SOCIETY'S ANTI-ADULTERATION BILL.—Secretary Morton of the Department of Agriculture has written to Mr. McMillan, chairman of the Senate committee on the District of Columbia, in reference to Senate bill, 3,485, relative to the adulteration of food and drugs in the District of Columbia. Mr. Morton says he takes liberty to submit a few comments on certain portions of this bill which, it seems to him, would be benefited by further consideration. In the definition of adulteration of drugs, he says, it should be stated that only in cases in which they profess to be in harmony with the United States pharmacopeia should they comply with its requirements. He says it would probably be very difficult to pass any bill with the provision relating to patent medicines as provided in the measure under consideration on account of the active opposition of manufacturers and dealers in patent medicines to such a provision. He says the whole bill would probably be defeated with this clause left in. Mr. Morton says it seems to him it would be far better, instead of trying to define standards by statute, to simply state that all the articles of food should conform to standards to be established by the Commissioners of the District of Columbia and to be approved by the Secretary of Agriculture. The legal fixing of standards, he says, is attended with many difficulties, and is not a proper subject of legislation. In case these standards are fixed, however, by Congress the description of one for cream should be inserted. There is probably more fraud practiced in the District of Columbia, he says, in the selling of cream than in any one article. If the standards to be used in the bill are to be retained that for cream, he says, should certainly be inserted, and the butter fat therein should not be less than 20 per cent. He says the whole description of flour in the bill is of such a nature as to cause all samples of buckwheat, rye flour, Indian corn flour and rice flour to be regarded as adulterated. He says no attempt should be made in describing flour to fix the limit of protein matters, as the cereal from which the flour is made may contain from 7 to 17 per cent. of such material. He says the provision that the analysis should be done in the presence of the owner or his agent is wholly unnecessary, inasmuch as the presence of strangers in a laboratory where analysis is going on can only impede the work, and such persons not being professionals can have no idea of the processes which are used. It is presumed, Mr. Morton says, that the District Commissioners will have their analyses made by competent experts and need not be watched by persons who are utterly ignorant of what they are doing. Mr. Morton says that the provision found in line 69 of the bill will tend to invalidate the efficiency of the law. It is not sufficient, he says, that the seller make known orally to the purchaser the character of the goods. The character of the goods sold should appear plainly written or printed upon the package, otherwise there would be confusion between what the purchaser says was said and what the seller says was said in all such cases. Mr. Morton concludes that the whole bill appears to be rather loosely drawn and without an adequate conception of the purpose for which such a bill should be enacted. He says the provision which repeals all other laws on the same subject might affect very seriously the standing of the oleomargarin and the filled cheese acts, especially in regard to color, when it is considered that under the present bill the coloring of butter is not permitted.

Cincinnati.

THE LAURA MEMORIAL Medical College and Presbyterian Hospital contemplate improvements to the extent of \$100,000.

A LABORATORY for vivisection has been presented to the Laura Memorial College by Mr. Alex. McDonald, and elaborate researches will be carried on in this work despite the threatened protest and prevention by the Humane Society.

THE WOMAN'S MEDICAL ASSOCIATION convened recently at the residence of Dr. Amelia J. Pryor. Dr. Julia Carpenter made an address upon "The Trend of Medicine." The annual election of officers resulted as follows: President, Dr. A. J. Pryor; vice-president, Dr. Henrietta Buchanan; secretary, Dr. Emma Batchelor; treasurer, Dr. E. J. Dickey. Dr. Bertha Glaeser will read a paper upon "Appendicitis" at the next meeting.

THE PUBLIC SERVICE.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for two weeks ending Jan. 16, 1897.

P. A. Surgeon M. S. Guest, detached from the "Massachusetts" Jan. 9 and ordered to the "Vesuvius" Jan. 12.
 P. A. Surgeon L. W. Atlee, detached from the "Richmond" on relief and ordered to the naval hospital, Philadelphia.
 P. A. Surgeon W. F. Arnold, detached from the "Enterprise" and ordered to the "Richmond."
 P. A. Surgeon R. P. Crandall, detached from the "St. Mary's" and ordered to the naval hospital, Norfolk.
 Asst. Surgeon Lewis Morris, promoted to P. A. Surgeon from June 27, 1895, and ordered to the "Essex."
 Medical Director H. M. Wells, retired Jan. 20.
 Medical Inspector J. R. Tryon, ordered to examination for promotion Jan. 11.
 Surgeon G. P. Bradley, ordered to examination for promotion, Washington, D. C., Jan. 18.
 Medical Inspector J. C. Wise, relieved from duty at the Museum of Hygiene.
 Surgeon A. C. H. Russell, ordered to the "Lancaster" per steamer of Jan. 27.
 Surgeon C. T. Hibbett, detached from Norfolk navy yard Feb. 1, and ordered to the "Independence."
 P. A. Surgeon F. W. Olcott, detached from the "Independence" on reporting of relief, and ordered to the Puget Sound naval station.

Change of Address.

Bennett, Alice, from Wrentham, Mass., to Thomasville, Ga.; Bouton, W. C., from 320 to 248 E. 57th Street, Chicago, Ill.; Bouton, J. F., from Galesburg to Peoria, Ill.; Boyer, J. S., from 3203 Cottage Grove Ave., to 3765 Rhodes Ave., Chicago, Ill.
 Henley, A., from Fairmount, Ind., to Melbourne, Ind.; Holmes, E. L., from 1216 Milwaukee Ave., to 206 Cass Street, Chicago.

LETTERS RECEIVED.

Anderson, Winslow, San Francisco, Cal.; Atkinson, W. B., Philadelphia, Pa.; Alma Sanitarium Co., Alma, Mich.
 Bates, C. B., Santa Barbara, Cal.; Brown, Caleb, Sac City, Iowa; Banks, W. H., Keokuk, Iowa; Brokaw, A. V. L., St. Louis, Mo.; Bishop, S. S., Chicago, Ill.; Braislin, W. C., Brooklyn, N. Y.

ORIGINAL ARTICLES.

PAIN AND ITS THERAPEUSIS.

BY S. V. CLEVINGER, M.D.

Allenist and Neurologist of the Alexian Brothers' and Michael Reese Hospitals, Chicago; formerly Medical Superintendent of the Illinois Eastern Hospital for the Insane, and Pathologist of the Cook County Insane Asylum; author of "Spinal Concussion," "Comparative Physiology and Psychology," etc.
CHICAGO, ILL.

What is pain? The question to the mass of suffering humanity would appear absurd. The one who has experienced pain fancies that he knows what it is, just as

"The primrose by the river's brim
A yellow primrose is to him,
And nothing more."

But to the philosopher, and especially to the physiologist, the nature of pain, in common with the nature of all other life phenomena, has a significance unknown to those not given to such analysis.

Consciousness is requisite in pain appreciation as well as any kind of feeling. The suppression or blunting of consciousness notoriously suppresses or blunts pain. The cognizance of pain being a cerebral process involving consciousness, cutting off the route to the brain by which pain is conveyed to consciousness disposes of the pain, but not of the cause originating it. Too many pain alleviators are mere deadeners of sensation. The inebriate "drives dull care away" with his dram, but awakes to a realization of having intensified his troubles by the means adopted to escape them. Schopenhauer holds that pains are positive and pleasures are negative experiences; that pleasures are due to the absence of pain and the intensity of one is often in proportion to the other feeling that preceded. Susceptibility to painful impressions increases with development of the nervous system in the ascending scale of life from lower animals to man and in the ratio of intellectual growth, and enjoyments are correspondingly multiplied and intensified. The pains and pleasures of the intellect are both qualitatively greater with its development.

The major anesthetics act upon pain by extinguishing consciousness in general, other chemicals arrest the pain consciousness alone, and in rare cases ether and chloroform have unexpectedly allowed intelligence to be preserved during the painlessness induced by them, while intermediate states between total and partial abolition of consciousness occur from insufficient anesthesia, to that which is called the surgical degree. Shock to the nervous system is more likely in the former case, and it sounds strange to say that, other things equal, death during an operation is more likely to occur from imperfect than from full anesthesia.

The philosophic claims of pleasure being not only antithetical to pain but due to pain absence, finds justification in the universal prevalence of care, which is essentially a painful state, and the fools' paradise to

which the drunkard is conveyed by his anesthetic alcohol. Further, in parietic dementia there are both physical and mental anesthesia; the tactile sense impairment, akin to what is found in locomotor ataxia, is accompanied by the loss of care, indifference to what otherwise would cause grief, or other degrees of mental pain. The consequence is the feeling of well being, *bienfaisance*, and upon this is erected the "delusion of grandeur" which takes the direction of assertions of great wealth, strength, or powerfulness in some form, according to the ideals usual to individuals of different classes.

So parietic dementia and the complacent megalomania stage of paranoia may be put in the category of pathologic mental anesthetics, all the more properly as both disorders indicate impending total destruction of the organ of the mind.

Many bodily functions, such as digestion, assimilation, etc., are unfelt, conveying nothing of their workings to consciousness until some fault in their process render them apparent; induces discomfort, anxiety, or pain.

Interference with customary nerve action may, under certain conditions, be the basis of painful sensations. In all life relations that which occasions the least effort impresses consciousness least. Changes from usual experiences may entail effort, greater expenditure, more labored heart and blood vessel impulses; more heat is evolved, tissues are consumed and require more repair than usual. Mosso shows that thought is no exception to the rule, for blood pressure and temperature are raised in this kind of brain activity, and the wear and tear of cerebral structures in worry, grief, anxiety, can be as actual as from some mechanical destruction such as a tumor or direct injury could induce.

Effort of any kind has in it the constant menace of pain, and relaxation the promise of release therefrom, though inactivity sometimes may also become painful if maintained by effort.

Life itself is activity, whether in rest or in labor. Molecular or mass motion must proceed in varying degrees, asleep or awake, toiling or recuperating. And the law of relativity complicates considerations of activity and inactivity by making effort and rest impossible to classify under all conditions. What would be labor to one person is not such to another. Ease to one individual would be torture to another, and accompanying circumstances may convert what would be pleasure at one time into pain at another.

Pain also is relative, for a certain nervous molecular activity may be over-stimulation in one person and normal in another.

For the proper maintenance of nerve function there must be continuity of the conducting organ, a normal degree of pressure thereupon not to be exceeded; heat above a certain level and within definite limits; a suitable supply of nutritive material usually secured from

the circulation, and that it should be suitable refers to both quality and quantity.

Pain may result from interrupted continuity, from irritation or pressure upon nerves or their centers, from heat or cold extremes and from defective nutrition, provided that the sensory portion of the nervous system is not disabled from conveying intelligence of such changes to consciousness.

Great organic destruction may proceed unrecognized as such until the sensory nervous distribution is in some way appraised; so while pain may in a general way serve to warn of danger, it may fail to do so, or prove unreliable in making a great disturbance over an imperfect tooth while failing to inform the drunkard of the slow destruction of his liver or brain. History also abounds in instances of universal hubbub over trifles and apathy concerning matters of the greatest importance.

Hunger is a form of pain which disappears in the extremity of starvation. One may freeze unawares but suffer acutely during warmth restoration.

Local blood quantity may increase or decrease emotional, intellectual or sensory faculties. Nerve stimulants raise the spirits and make sensations keener. Sedatives diminish mental pain as they do physical. Only broad generalizations are practicable in determining what would be pleasurable or painful, for so many modifying factors complicate both extremes of these sensations that experiences when repeated may fail to act as before, or pain may become pleasure or pleasure pain. And what would afford pleasure to one person may be annoying to others. The color blind and tone deaf persons are merely bored by what others enjoy.

Dean Stanley actually suffered from listening to music, yet Jennie Lind once told Max Müller he paid her the highest compliment she had ever received. Stanley was very fond of Jennie Lind, but when she staid at his father's palace at Norwich he always left the room when she sang. One evening Jenny Lind had been singing Handel's "I Know that My Redeemer Liveth." Stanley, as usual left the room, but he came back after the music was over and came shyly up to Jenny Lind.

"You know," he said "I dislike music; I don't know what people mean by admiring it. I am very stupid, tone deaf, as others are color blind. But," he said with some warmth, "tonight when from a distance I heard you singing that song I had an inkling of what people mean by music. Something came over me which I had never felt before, or yes, I had felt it once before in my life." Jenny Lind was all attention. "Some years ago," he continued, "I was at Vienna and one evening there was a tattoo before the palace performed by 400 drummers. I felt shaken, and tonight, while listening to your singing, the same feeling came over me; I felt deeply moved."

"Dear man," she added, "I know he meant it, and a more honest compliment I never received in my life."

What savages consider musical the civilized could not tolerate, and the untrained ear is wearied by classical music as is the untrained mind by discourse beyond ordinary understanding. For this reason, as Herbert Spencer claims, wisdom always has appeared and always will appear to be folly to the ignorant.

The special sense nerves have been excluded by some physiologists from among conveyers of pain, but blinding light, disagreeable sounds, odors and tastes are analogous to tactile pains, and are induced by

over-stimulation or other comparable interruption to the customary nerve workings.

As frequently more than a single factor enters into the creation of pain and its exacerbations, the withdrawal of one of these elements may modify or even relieve the suffering. For example it is told that a professor lectured through his hour unconscious of a cinder in his eye which made itself felt immediately afterward. Referring to the use of derivation such as blisters, hot foot baths, cathartics, etc., in relieving pain by reducing circulation in the painful part, enables the relief obtained by the professor to be explained as blood supply withheld from the point of irritation while the blood was contributing to brain functions.

In parietic dementia and megalomania the false happiness engendered by the brain destruction, and the disappearance of hunger when dissolution is begun, may serve to explain the *spes phthisica*, or hopefulness of consumption, through blunted pulmonary afferent impressions. Thus the reverse of pain accompanies anesthesia, or absence of sensation, and it is the thoughtless who are gayest and freest from care.

Lucretius, Seneca and Homer allude to what modern psychologists call the luxury of grief (Spencer), pleasure in pain (Ribot), and the pleasure of pain (Boullier). There are pleasures derived in some morbid conditions from physical and others from moral pain. Jerome Cardan wrote that he could not endure existence without pain and he resorted to self-torture to secure enjoyment. Krafft-Ebing discusses such flagellants as a recognized type of sexual perverts. The melancholy of lovers (spoken of by an Irishman as "sweet pain"), that of poets and artists is included in pleasureable pains. Spencer ventures the explanation that the feeling is one of pleasure in deserving more than has been received.

Depression of vital functions is involved in ordinary pain. Melancholia is a "psychical neuralgia," according to Krafft-Ebing.

The coupling of pleasure with what is beneficial and pain with what is detrimental, originated with Aristotle, but it is far from being a universal rule, for pain may be far more useful as a life-conserving than pleasure, and the latter may indicate dissolution, while both may be associated in apparently outrageous fashion in pathologic instances.

Susceptibility to pain may persist in spite of anesthesia, though analgesia is a common accompaniment of loss of sensation. In locomotor ataxia anesthesia and the terrible shooting pains co-exist.

Hyperalgesia can be considered as an aggravated hyperesthesia. The zone of irritability parallel to that of anesthesia on the chest of one with spinal cord disease, can be explained by the hyperesthesia being due to central nerve root irritability as a forerunner of the more serious cause of the associated loss of sensation in the adjacent nerve distribution.

If this irritability involved the blood supply reflex of the spinal cord gray matter, pain is intensified and is induced by ordinary stimulation of the implicated nerves.

In a work entitled "Comparative Physiology and Psychology" (1884), I detailed reasons for the existence of what could be called a "nutrient reflex," whereby blood was instantly impelled to localities in the body that had undergone waste through action, and were hence in need of repair. The mechanism consisted in an intimate association of the vaso-motor nerves with the cerebro-spinal nervous system as seen

in the rami communicantes running from the spinal to the sympathetic system of nerves and their ganglia. It is only by introducing nutrient reflexes into consideration of all the higher vital processes that they can be even approximately understood. The regulation of the caliber of blood vessels, the swiftness of the current of blood and the amount supplied to parts in proportion to their needs in such parts; by a harmonious working of the vaso-motor nervous system with the cerebral and spinal, when carefully considered, clear up many an obscure point in nerve and brain physiology and consequently in psychology. Failure of this relationship will also account for pathologic phenomena explicable in no other way.

Thus in hysteria, instead of proper vascular workings, blood is withheld from cerebral centers, giving rise to aphonia, deafness, blindness, etc., and when impelled to inappropriate parts an inversion of the emotional exhibitions may result in pleasant impressions starting the weeping mechanism, and laughter following upon unpleasant impressions.

Cramped vascular and other renal channels sufficiently account for hysteric urinary suppression, and relaxation of these parts induces the copious *urina spastica*, or vast quantities of limpid urine, passed after a hysteric attack.

Ordinary toothache induced by alveolar abscess is lessened by whatever draws blood from the painful part and is increased by hyperemia. The irritation of the carious tooth starts the pain, but the battle of the phagocytes and microorganisms induces an increased blood accumulation, which by mere pressure may intensify the agony. Relief through evacuation of the abscess points to the blood pressure as the aggravator of the pain.

When pain is relieved by a mental impression it can best be accounted for through derivation. Some other portion of the cerebral or other organ drains away the overplus blood, with corresponding relief. Some headaches dependent mainly, though secondarily, upon too much blood, or erratic blood distribution in the brain meninges, can be relieved by whatever will determine blood elsewhere, whether by full or partial hot bath, a mustard plaster, a changed current of thought, or a mental impression. Conversely an anemic headache may disappear upon lying down or by heart stimulation.

That the circulation participates in suffering either as a cause or consequence is readily observable.

Congestion may induce tactile pain, offensive odors, ringing in the ears, flashes of light or perverted taste, according to the nerve distribution affected; the extreme congestion can obtund or even cut off special sense appreciation, inducing anesthesia, deafness, blindness, inability to smell or taste, through pressure, and the opposite extreme of bloodlessness can set up identical defects.

The old saying that "pain is the cry of the nerve for purer blood," is in a restricted sense true. Impure blood may induce pain through acting as a foreign substance and through reducing the quantity of blood proper. Pain may be the cry for less blood also.

Headache from bad air is a toxemia, ordinarily relieved by fresh air. The insufficient oxygenation renders this qualitative a quantitative condition. Headaches caused by tumors, especially the grinding luetic headache, are through meningeal nerve pressure and irritation. Similarly meningitis and injuries to the head that involve the brain and its covering,

when inflammatory conditions follow, depend upon the vascular troubles associated with such inflammations. Reducing the blood supply to the head modifies the pain and destructive processes.

Irritation of ordinary sensory nerves suffices to cause pain, as when an amputation stump cicatrix includes a nerve and neuromatous growths are formed. That the circulation contributes to the pain is evident through the desire to elevate the stump and by gravitating the blood therefrom allay the suffering.

Normal irritation of nerves produces the feeling of general comfort, free breathing, and tactile impressions generally. Hunger, thirst, malaise, horror, fatigue are due to nerve terminal irritation. Mechanical, chemic, thermal and electric stimulation may cause pain if transcending certain limits, or if intense enough may destroy sensation altogether, and beyond this the *anesthesia dolorosa* may appear. Pains are not always definitely located, through irradiation, or may be referred to the wrong source of origin, as when amputation pains are felt to be in the lost member.

Varieties of pains are in proportion to the intensity of the stimulus, and massiveness regards the number of nerves involved.

Most of the differences described by the words piercing, shooting, cutting, boring, burning, pressing, gnawing and acute, are due to the intermittent or continuous molecular changes in nerves or their centers, but the throbbing and dull pains usually owe their peculiarities to arterial or passive congestion. The headache known as angio-paralytic has been often relieved by pressure upon the carotid supplying the aching part and the angio-spastic kind should be treated by means calculated to relieve spasm, such as amyl nitrite inhalations. In the one case there is the hyperemic throbbing arterial impulse, and in the other intense constriction of vessels inducing localized anemic pains.

In inflammatory affections of the skin hyperalgesia may be so extreme that a breath of air or light touch produces pain. The blood superabundance in the nerve terminals here is plainly the cause.

The disordered sensations called paresthesiæ including chills and burnings, creeping, itching, formication, are related to pains, and may become so intense as to become such. Causalgia and erythromelalgia are described by S. Weir Mitchell as burning sensations and reddenings due to central nerve irritations.

Neuralgias, with shooting pains transmitted the length of the nerve affected, primarily or secondarily involve blood distribution, and inflammation of nerve roots frequently give rise to neuralgias. The inflammation may not be the cause of the original disturbance, but even though produced by the same irritation that induced the neuralgia it is an aggravating factor, and when this inflammation is controllable a step toward possible cure is taken.

The structural commotion recognized as pain can only be maintained by blood presence, as nutrition is necessary for prolongation of any vital phenomenon.

When the vascularity of a point of irritation, such as the amputation end of a nerve, is relieved of blood supply by gravitation or pressure the pain is lessened. Anesthesia often accompanies bloodless peripheral states and the numbness of freezing depends upon the constriction of blood vessels and other circulatory reduction in the frozen part which visibly whitens through being deprived of blood.

Inflammation of a spinal nerve root or in the sensory neuroglia of the spinal cord causes the lightning pains of neuralgias, ataxia and sciatica. Relief of the inflammation necessitates more than mere temporary alleviation of the pain, for the primary cause of the irritation that induced the inflammation must be reached, and a destructive process in the nerve centers from chemic changes is too often beyond control.

Among painful states associated with too much engorgement of nerves or their centers are all the hyperemic, congested or inflammatory cerebro-spinal disorders, such as some headaches, toothaches, neuralgias, ataxic pains, overheating, hyperalgesias and hyperesthesias.

The opposite condition of relative bloodlessness occurs in cold, hunger, thirst, fatigue, pressure, anemic headaches and other painful states depending upon reduced blood volume.

Blood poisoning by alcohol, septic matter, gases, etc., while qualitatively altering the blood for the worse, reduce the quantity of pure blood to parts and act as anemic factors, while the foreign substances "irritate" the nerve centers. Uric acid crystals mechanically cause pain in the kidney tubules, ureters and bladder, and may reasonably be regarded as sensory disturbers elsewhere. Sodium urate deposits in the joints exert painful pressure.

In all these phases of suffering we observe an irritated part of the nervous system, bloodlessness or engorgement, associated with the pain, either as cause, effect or added factor.

A toxic substance circulating in the blood whether introduced from without or manufactured in the body, if denied proper elimination, as often takes place with uric-acidemia or other auto-intoxication, may irritate the vascular nervous control so as to produce contracted arterioles with increased arterial tension, a spastic condition observable in migraine and to an extreme in the frightful *raptus melancholicus*.

In these disorders, irritation primarily and relative anemia secondarily, are at the foundation of the suffering, while as a consequence engorgement of other organs or parts of organs complicates and adds pressure, or congestive pains.

Over-stimulation of nerves often produce over-stimulation of the circulation, or even its practical paralysis, with localized hyperemia and resulting pain.

In short all painful states may include the conditions of irritation, too much or too little nutrition, separately or combined, in various ways. These pain factors may be symbolically represented by the initials of irritation, hyperemia, anemia, to graphically illustrate pain, however induced:

Uric acid headache: I. A.; the irritation causing the anemia.

Chlorosis headache: A. I.; the anemia causing the irritation.

Cerebral congestion: H. I.; the congestion causing the irritation.

Over-stimulation: I. H.; the irritation causing the hyperemia.

These three conditions may be combined simultaneously or successively to produce very many apparently discordant pathologic states. Anemia in one part, however induced, may result in congestion in an adjacent part, and the pressure hyperemia may cut off nutrition from surrounding points so that both hyperemia and anemia may occur in closely related

parts, each condition adding its special irritative influence to the total pain; so the localized pain may have the formula I. A.; I. H.; I. H. A. within a narrow area, or either H. or A. may cause I., and, further, the combination I. H. A. may set up intensified irritation; the withdrawal of one factor serving to lower the pain intensity and paving the way to removal of the entire pain.

Let I. be induced by an exposed nerve, H. follows with may be A. in contiguous parts by pressure of blood; now while the removal of H. by blood evacuation may reduce the aggravating influence of blood pressure, which acts irritatively, the most sensible thing to do is to get at and remove the primary cause of the pain by protecting the nerve from exposure which sets up the hyperemia. If an abscess results from the phagocytic battle the septic advance adds further irritation, which must be disposed of in attempts to remove all causes of pain.

A general blood condition may favor the production of pain by having within it the elements of disturbance ready to centralize upon a weak point. Analogous sociologic states exist. Peter the Hermit and Walter the Penniless were foci of irritation in the eleventh century, leading up to the crusades in which two million Europeans were slain in two centuries. This blood letting finally carried off the disturbers and the disturbed, and, therapeutically, venesection has for ages been resorted to in pain relief, though derivation or the transfer of the disturbed circulation is nowadays preferred.

A point of irritation may be starved out by keeping nourishment reduced, it may be evacuated at the expense of the blood, or it may be held in check by removal of the elements that nourish its fury, or, best of all, the focus sometimes may be directly destroyed by medical or surgical means.

Far too often this latter process is impossible through inability to determine at the proper time just where or what the primary disturbing influences may be, or even if determined there is in most cases inability to get at and remove the origin of the pain. But the safest rule to adopt is to attempt to do so if within possibility, and where relief of pain is imperative with no practical means of removing the cause only such agents should be resorted to that do not entail other and often greater disadvantages to the economy, sooner or later.

Only such portions of the body as are supplied with sensory nerves relate consciousness to pain. Irritation of unsupplied parts may advance to various forms of destruction and until the sensory filaments are secondarily involved by extension, or through accompanying circulatory alterations, the warning which pain is supposed to afford is absent.

Several of the recently discovered synthetic compounds combine antipyretic with analgesic properties in different degrees. Acetanilid, formerly known as antifebrin, has been too recklessly used. It depresses the heart dangerously and requires careful watch of its physiological effects. "Antikamnia" (Helbing, Modern Materia Medica, page 3) has been found to contain acetanilid, sodium bicarbonate, caffeine and tartaric acid. In many such advertised preparations the possible introduction of acetanilid should be regarded. Even external application of acetanilid, as has been suggested for antiseptic purposes, is dangerous. Pseudo-scientific compounds, mainly with acetanilid mechanically mixed with other substances,

can be avoided by learning the status of their originators, manufacturers and clinical reporters.

Antipyrin is incompatible with too many materials to enable its administration in combination with ordinary remedies. Cesari's claim that it thickens and condenses the blood without coagulating it may account for its hemostatic properties and should be regarded in a study of its antineuralgic, antipyretic and other influences. Exalgin is too poisonous for analgesic use. Methyl chlorid as a spray produces local anesthesia through freezing the part to which it is applied. The visible whitening of the surface that occurs during its application indicates that bloodlessness is the cause of the sensory arrest. Paraldehyde is an unreliable sedative or hypnotic. Phenacetin or phenocoll have been successfully established as sedatives and are far safer than acetanilid or antipyrin. The salicylates and salol possess indirect slight analgesic properties, due to their antiseptic and anti-rheumatic tendencies, and dilute carbolic acid blanches animal surfaces and produces local anesthesia. Cocain hydrochlorate likewise reduces blood circulation at the point of local anesthesia. Its fascinating temporary euphoria and later excitation of nerve centers are worthy of study among psychologic effects of drugs.

Opium and its congeners are responsible for legions of debauched habitués, most of whom date their addiction from incautious prescribing. The benumbing influence of alcohol and opium upon the nervous system generally account for their exhilarant influence, on the principle of mental anesthesia inducing relative exaltation; the relief from care, concern and painful memories being subjectively interpreted as happiness. The debased sensory apparatus of the parietic dement causes him to insanely ascribe his buoyancy and general good feeling to greatness or good fortune realized.

Drugs that depress the motor apparatus mainly, such as conium maculatum, do not exalt the sensory field, rather the reverse, but many degrees of association between anesthesia, analgesia and exhilaration are observable in other neurotic medicines.

Opium primarily relieves pain, raises the spirits, then stupefies. Alcohol anesthetizes, exalts and ends in stupor. Chloral may numb the nervous system, mildly exhalt, then stupefy. Chloralamid, a much safer article, is mildly sedative, causes hypnosis, and the day following large doses a feeling of exhilaration is reported. Chloroform and ether excite, and finally obtund consciousness. Oxygen gas exhilarates. Nitrous oxid gas first exhilarates, and then affects consciousness. The bromids depress the circulation, are mildly analgesic, and in over-doses stupefy. Ergot by constringing overloaded blood vessels may secondarily act as an analgesic.

Phenacetin and phenocoll have greater analgesic properties, while being vastly safer in practice. Acetanilid and antipyrin possess varying degrees of pain relieving power.

Lactophenin is destined to largely supersede the entire array of analgesics proper, owing to its non-toxic peculiarities and the feeling of comfort described by many physicians as following its use. It is also antipyretic definitely, and being without the heart-depressing effect of the older antipyretics it will come into still more extended hospital and private practice administration.

It has occurred to me that the physiologic chemis-

try of materia medica could be appreciably advanced by tabulating the effect of graded doses, particularly of the recent synthetic compounds, as to when the sedative, antipyretic, antiseptic and hypnotic effects, if any, ensued, juxtaposed with their rational chemic formulæ, their relative looseness or closeness of molecular construction and affinities, with their relations to temperature, solubility, etc. The rapidity or slowness of compounds to enter into new combinations under the conditions afforded by the bodily organs has greatly to do with the therapeutic effects. Antipyretic influence can be exerted through action upon the blood vessel tonus or the blood corpuscles, and in some instances upon the thermal brain centers demonstrated by Ott.

Antisepsis can be conceived in such preparations as acting directly upon septic material or so modifying their products or the vital fluids as to lessen septic activity. Antagonism to fermentation is often practically antisepsis.

Analgesia can result from the direct influence of antiseptics upon irritative points susceptible to their influence; from allaying some consequence of irritation such as an accelerated circulation which aggravates pain, and if pain is due to circulatory faults mainly or wholly this effect upon the heart, arteries, or blood tends to relief. The visible change in the blood materials claimed by Cesari when antipyrin is given can readily be tentatively assumed as a cause of heat reduction, and incidentally pain alleviation.

The rush of phagocytes to an irritated point is accompanied with accumulation of red blood corpuscles. Pain can not continue without the material that enables molecular activity, and this material is afforded by the blood and lymph. Drive away congestion and though the cause of the irritation may remain, its influence is lessened greatly, and the warrior wandering cells have better opportunity to attack the foreign material unless they also are driven from the field of battle.

The pain of a "bone felon" is modified by holding the hand aloft; the Esmarch's bandage anesthetizes by blood deprivation; freezing anesthetizes similarly. Derivation may not be the means by which a disorder can be cured, but when blood accumulation in an organ is pathologic its distribution at least facilitates recovery.

The properties of lactophenin and its superior claims to the attention of physicians where a reliable and non-poisonous analgesic, antipyretic, and incidentally hypnotic, is needed, may thus be summed up from the vast number of favorable clinical reports.

It affords the best results with the least ill effects; it gradually reduces the temperature and for a longer time; occasionally the reduction is more rapid, but controllable.

The analgesic dose of 8 grains has no noticeable effect on the temperature.

Its range of incompatibility is less than other synthetic compounds such as antipyrin. It is combined with caffeine, quinin and salicylic acid by some practitioners. The minimum dose is 5 to 10 grains and during the day as high as 45 grains have been advantageously given in divided doses, according to the physiologic effects desired.

It is but slightly soluble in water, but as there is no disagreeable taste it can be given dry and be washed down with a drink of water. Notwithstanding its insolubility it acts promptly. A dose

of 15 grains usually acts as a gentle hypnotic. Cyanosis of lips and face attending occasional overdosing with acetanilid, antipyrin and sometimes phenacetin, does not occur when lactophenin is given, as it never produces heart or respiratory disturbances, dyspnea or collapse. The breathing and circulatory rate are unaffected except that the pulse becomes fuller and stronger, the reverse of the influence of the dangerous antipyretics. The nearest approximation to any unpleasant effect has been a slight faintness and moderate sweating, observed by a few physicians, while there is a general agreement among authors on the subject, that lactophenin not only relieves pain but adds a soothing, comforting feeling, sometimes ending in an agreeable slumber, without giddiness or uneasiness at any stage.

The unpleasant subsidiary effects of phenacetin are absent from lactophenin. Six grams daily have been used when indicated, though 3 grams *pro die* are mentioned as a maximum dose. Vomiting and exanthemata are not generally recorded as observed in using lactophenin. One writer says that it rarely induced vomiting and another mentions a rash in one or two cases. Children of 2 years of age require about one-eighth the adult dose and at the age of 14 about one-half that quantity.

The soothing influence, accompanying relief from pain, caused by lactophenin is described as "a calming effect in restlessness or delirium," "specially calmative of the nervous system in typhoid fever," "a pronounced soothing effect," "a calming hypnotic effect," "a feeling of comfort and ease." It also diminishes sensitiveness to painful impressions.

Experimental doses given to rabbits "annulled sensation and voluntary movements and lessened reflex excitability without respiratory or heart affection."

Von Jaksch mentions lactophenin as useful in typhus, others found it decidedly beneficial in articular rheumatism, insomnia, occipital neuralgia, frontal headache, the headache of typhoid fever, migraine, neuralgic pains generally, pneumonia, erysipelas, influenza, polyarthritis, scarlatina, sepsis, sciatica, headache attending round gastric ulcer, headache and sleeplessness in Bright's disease, bronchitis, acute gastritis, diphtheria, measles. It is reported to have relieved megrim and nervous headache in twenty minutes, and that in one to two hours after 15 grains were taken a quiet sleep began which lasted several hours. In croupous pneumonia the breathing improved, the cough of phthisis florida was lessened, an excited patient became calm and felt easier and better. It has been substituted for salicylic acid with advantage and reduced pain and swelling in twenty-four hours.

Personal observation enables me to corroborate the findings of other physicians as to the superior analgesic and antipyretic effects of lactophenin, its safety and promptness of action. The lancinating pains of locomotor ataxia and the suffering of syphilis of the spinal cord were not influenced by the remedy, nor could it be expected to avail much, if any, in cancer pains, but in all instances of pain attending acute disorders such as make up the generality of cases where analgesia is desirable, lactophenin has given better results than other synthetic compounds of the same group. Toothache from alveolar abscess was relieved long enough to secure a good night's sleep, and at the same time when the 15 grains of lactophenin was taken a fretful baby was being nursed, which

also slept unusually well the same night. Hoping that it might serve as a substitute for the bromids in the treatment of epilepsy, while my trials are not concluded, the results are negative. A hot bath or massage serving to distribute the circulation, catharsis that unloads the congested intestine and vascular system, even a hot foot bath, through derivation, has relieved headache, earache and even toothache. It is the withdrawal or minimizing of blood from the painful area that serves to allay if not remove the suffering.

When the professor referred to, set his cerebral machinery in motion so that his brain required blood and withdrew it from the optic that was being irritated by the cinder, the pain was absent until the lecture was concluded. Similarly, the seat of consciousness can be affected by hysteric, erratic blood-vessel action, so as to produce or terminate pain and paralysis through mental influence, and the pain suppression occasionally accomplished under hypnotic conditions is undoubtedly of this nature, and the seat of consciousness may, through derivation of blood by physical or mental action, be similarly affected. The operation of the nutrient reflexes in connection with every nerve impulse should have careful regard by physiologists, and many a mystery would be thus disposed of. The association of antiseptic properties with the analgesic and antipyretic in so many of the phenetidin compounds is also worthy of consideration. If such antiseptics are secured through a direct action of the medicament upon living plant and animal microorganisms, within the varying degrees of arresting or destroying their vitality, analgesia likewise could ensue from chemical lowering of nerve function, directly or through blood changes such as occur with antipyrin.

So it ceases to be remarkable that a substance hostile to minute organisms, an antiseptic, should also act as an antipyretic and analgesic by chemically exerting control over such vital operations as heat and pain production of higher organisms. These lessened molecular activities are exerted in different degrees by the different compounds; some are too strongly antiseptic to be safely used as analgesics or antipyretics; nevertheless the three properties are connected, notably in the case of carbolic acid, and to a safer therapeutic extent in the phenetidin derivatives. Both acetic and lactic acids are oxidized in the body to form carbonic acid, but isomerids of lactic acid exist in many tissues of the body and are products of muscle action. All acids lessen muscle irritability, and ethiden lactic acid has been found as a normal constituent of brain tissue in the proportion .05 to 100. The displacing from phenacetin of the acetic acid constituent by lactic acid, in the conversion of the phenacetin base into lactophenin, introduces an anti-ferment of a physiologic product, a recognized auto-antiseptic, elaborated in higher animal life in place of an acid such as acetic, which is more of a by-product in the economy. The lactic acid combination is more likely to meet physiologic needs than acetic acid when united with a phenetidin base.

70 State Street.

Ichthyol Administered Internally in Certain Gynecologic Troubles.—Günsburg has found ichthyol administered according to the following formula of the greatest service in chronic affections of the genitalia, with reflex disturbances of the digestive system: Ichthyol 4 grams, licorice extract and powder q. s. Mix and divide into forty pills; take two pills three times a day. He has them keratinised. Dyspepsia, constipation, abdominal pains and menorrhagia are rapidly improved or cured with it. —*Semaine Med.*, December 30.

SURGICAL DISEASES AND INJURIES OF THE NECK.

BY EDMOND SOUCHON, M.D.

PROFESSOR OF ANATOMY AND CLINICAL SURGERY, TULANE UNIVERSITY.
NEW ORLEANS, LA.

It is here assumed that the student of regional surgery is possessed of the knowledge of the general surgical diseases, *i. e.*, those diseases which may be observed in any other region, and the descriptions will be limited to the peculiarities only which those diseases present when they affect the neck or one of its regions, thus avoiding repetition as much as possible. If no peculiarity is mentioned in regard to diagnosis and treatment it is because they are the same as for the diseases in general.

This study is divided into that of the diseases and injuries of the neck as a whole and that of the diseases and injuries of its seven regions: The infra-hyoid (including the thyroid body, the supra-sternal fossa), the supra-hyoid, the lateral supra-hyoid (or digastric triangle or submaxillary region), the parotid, the lateral region (or region of the sterno-mastoid, or of the carotids), the supra-clavicular and finally the posterior region.

The following order will be followed in the descriptions: Malformations and swellings, injuries, neuroses, softenings, indurations, congestions, inflammations, gangrenes, ulcers, fistulæ, tumors.

SURGICAL DISEASES AND TUMORS OF THE NECK IN GENERAL.

Congenital fistulæ of the neck are due to arrest of development or lack of fusion of the branchial laminae or folds and clefts of the pharyngeal fissure; they are sometimes hereditary, but are sometimes discovered only a long time after birth; they may be due there to a cyst which has ruptured externally; they are usually very small, seldom admitting more than a case probe, exceptionally the end of the little finger. The external orifice is situated most commonly on the right side of the neck in front, and behind the sterno-mastoid, and between the thyroid cartilage and the sterno-clavicular articulation; sometimes, but rarely, at the angle of the jaw; it is sometimes on a projection, at other times in a fold of the skin; it occasionally presents cartilaginous or osseous particles; it may be found blocked by the dried secretions. These fistulæ resemble congenital tracheal fistulæ, but the latter open commonly on the middle line; they are more rarely found on the side and still more rarely on both sides. The internal orifice may open into the pharynx or larynx or trachea; it is observed almost always near the tonsil and base of the tongue, and is very small; it may become the starting point of serious inflammation and abscess. When they are complete an injection of milk penetrates the pharynx or the larynx. These fistulæ may be external blind or internal blind; the external blind are by far the most frequent. The course of the fistula is marked by a cord-like tract which corresponds to the track of the fistula; its direction is straight or tortuous, oftenest in the direction of the great horn of the hyoid bone; it is constituted by an external thick, fibrous coat, which forms the cord and is lined by a sort of mucous membrane which secretes a thin, viscid fluid containing epithelial cells, or is purulent. Internal blind fistulæ are very rare, but it is positively known that they exist. They present the variety called diverticula "by pulsion" of the pharynx and esophagus, due to the

dilatation and development of an originally small pouch under the influence of the accumulation of the food; they sometimes form very large tumors. The diagnosis of congenital fistula rests upon the secretion of the fluid, the presence of the cord, the penetration of the probe and the injection of colored fluid. Congenital fistulæ are almost always stationary; they are more a deformity than a disease.

Treatment is usually unnecessary, and fortunately so, because it usually fails when limited to stimulating injections; dilatation or curetting and excision is a laborious operation, not without danger and scarcely justified by the inconvenience experienced. Both orifices may close and leave an intermediate tract.

Congenital atrophy of the whole or more or less extensive parts of the neck is very rare without participation of the rest of the body.¹ The *congenital pigment atrophy* called *vitiligo* is rather common on the neck. Other skin atrophies are very rare. *Congenital atrophy of the sterno-mastoid* has been observed. *Congenital atrophy of the other structures of the neck* have not been observed.

Congenital hypertrophy of the whole neck has never been reported; neither has partial congenital hypertrophy apart from the congenital cysts and tumors. *Congenital hypertrophy of the constituents of the skin or of the tissues of the neck* has been reported; congenital hypertrophy of the thyroid body and of the thymus gland will be studied in their proper places. *Congenital deviations* have been observed, due to malformations or diseases of the vertebræ.

Acquired malformations of the neck.—Acquired *atrophic malformations* are observed here as the result of injuries, diseases, operations, cicatrices, as in cases of torticollis.

Acquired hypertrophic malformations of the whole region is noticed; a short neck is considered as a predisposing cause of apoplexy. Hypertrophy of the whole neck is observed in elephantiasis and myxedema. Acquired malformation of the skin and of the other structures of the neck present no specially interesting points.

Acquired deviations or asymmetries are seen, especially after burns and cicatrices and after torticollis or paralysis. Cicatrices are due to burns, wounds, abscesses, gangrene, ulcers, fistulæ; they are unsightly and often cause impairment of function; the skin may be bound down to the sternum; they excoriate easily from traction by the involuntary movements of the parts, and in that case they should be excised and sutured if small, but grafting or autoplasty should be resorted to, to prevent their reproduction if they be large.

Swellings of the neck.—Swellings of the whole neck are common; their causes are numerous; they may follow injuries, inflammations, tumors, operations. Their common feature is the great danger from the propagation to the aryteno-epiglottic folds, causing obstruction of the larynx and pressure symptoms, specially dyspnea, which it is often impossible to relieve because of the difficulty of reaching the trachea. If an attempt is deemed justifiable the operator should be provided with an extra long tracheal canula.

Softenings of the neck present nothing peculiar.

Indurations are represented by the peculiar indurations of the sterno-mastoid, which will be described with the diseases of the lateral regions of the face.

¹ We may recall here, however, the naturally long and slender neck of the unfortunate Anne Boleyn, who remarked that her neck would not give the executioner much trouble to sever.

Injuries of the neck.—Burns are here particularly serious on account of the swelling and the edema of the larynx, which may complicate them. Even when no deeper than the skin they result in cicatrices which are most deplorable because of the appearance of the parts and because of the deviations they cause, sometimes binding the chin down to the sternum; for this reason they should be grafted at the earliest possible time. Deep burns extending to the muscles and to the vessels are most serious, even when limited, for obvious reasons. The cicatrices pass into keloids oftener than in the other regions.

Contusions are not frequent, they are usually produced by falls, blows, hanging, garotting, throttling, passage of a wheel over the neck, or by the pressure of the dislocated clavicle. A blow on the side of the neck is a great aim with pugilists, because it is almost a sure knock-down or knock-out; it is often in its results grave, because of the importance of the organs of the neck, and may be accompanied by fractures of the hyoid bone, larynx and trachea; injuries to muscles, vessels, nerves, pharynx, esophagus; vertebral lesions, concussions and contusions of the spinal cord;² hematoma may form and become large and cause grave pressure symptoms on all the structures. Death may occur after a few days from edema of the lungs; also from embolism from one of the large vessels of the neck.

Wounds of the neck are comparatively rare in civil practice; sometimes they are accidental and due to a fall on a fragment of glass, a stem of iron or wood; they are most commonly due to attempts at murder or suicide; the suicidal are the most common and the most interesting.³ Superficial or extra-fascial wounds of the neck, *i.e.*, wounds not extending beyond the superficial cervical fascia, present nothing peculiar. However, a large incised wound of the external or anterior jugular, especially if these veins happen to be unusually large, may give entrance to air. In tracheotomy the anterior jugular is often wounded; also the inferior thyroid veins. If the parallelism of the lips of the wound has been disturbed, there may be much infiltration of blood; this requires enlargement of the incision and ligation in preference to pressure; cellulitis spreads rapidly. Gunshot wounds are rare, yet there are instances when a bullet has traveled under the skin and above the fascia without penetration of the fascia. Contused and lacerated wounds, if extensive, may be followed by cicatrices and their consequences.⁴ Gunshot wounds causing much destruction of skin present the same remarks as the lacerated wounds. Deep or sub-fascial wounds⁵ are almost all very serious because of the almost constant injury of some of the large vessels and nerves or of the special organs of the neck, larynx, trachea, pharynx, thyroid body, giving passage to air, food, blood, each of which call for special treatment. Complications of the wounds of the neck are the following: thrombus or extravasation of blood, due to the loss of parallelism of the lips of the wound through the various layers; entrance of air in the veins, more frequent and dangerous here than anywhere else; passage of food through the wound and

into the larynx or trachea; hemorrhage more or less profuse according to the vessels injured and its accessibility; emphysema, due to injury of some point of the respiratory tract with a gravity greater than in any other region on account of the involvement of the aryteno-epiglottic folds and the consequent obstruction of the larynx; aphonia from injury to the vocal cords or to the nerves; emphysema, edema, penetration of blood in larynx, or injury of the pneumogastric or laryngeal nerves; dyspnea due to the same cause plus injury to the phrenic; dysphagia, due to swelling or pain; erysipelas is a frequent complication; also pyemia or sepsis; edema of the glottis is very common; spasmodic croup due to pressure or to nerve injury, is not rare; concussion of the cervical column communicated to the spinal cord, to the pneumogastric, phrenic, cervical plexus, brachial plexus, have been observed in severe wounds.

The symptoms of entrance of air into the veins are a wind-sucking or gurgling sound, immediate pallor of the face, dilatation of the pupil, irregular or tumultuous action of the heart, embarrassed breathing and death. The wound should be plugged at once with the finger, and all the usual means of resuscitation vigorously and persistently applied. The amount of air introduced is a grave factor. If the wound be small, the operation may be continued by keeping it constantly filled with warm sterilized water.

The sequels of the wounds of the neck are: permanent aphonia or dyspnea or dysphagia, necrosis of the cartilages and of the hyoid bone, torticollis due to contraction of cicatrix, to inflammatory adhesions of the muscles or to nerve injury; fistulous tracts; granulations obstructing the respiratory tract.

Deep punctured wounds striking the large vessels are those which are most commonly followed by deep and extensive extravasation and traumatic aneurysms; they call for the ligation of the two ends of the wounded vessels; it is here that a proximal loop ligation of the main trunk, low down when practicable, will be of the greatest assistance in controlling the hemorrhage during the search for the bleeding ends. They are also more commonly followed by emphysema than the incised wounds. When they involve a nerve they may cause tetanus or spasmodic croup. Deep incised wounds are often rapidly fatal from the excessive hemorrhage, because it is rare that some artery or vein has not been opened; the same foregoing remarks apply here as to their treatment. Deep contused and lacerated wounds present here no special peculiarities not covered by the above descriptions and the description of these wounds in general. Gunshot wounds usually cause much hemorrhage; they sometimes recover most unexpectedly; of course their gravity varies with the injuries inflicted. When the ball is deeply seated, no dissection should be made to extract it until later if it produces disturbances. Foreign bodies in wounds of the neck are common, wadding, pieces of clothing, piece of the weapon or bullet.

Fractures of the neck are rare; their description belongs to another chapter.

Dislocations, also *sprains*, are the result of injuries in which the head is much stretched, most commonly and especially when violently striking an obstacle vertex first; they give rise to great pain, particularly when the head is thrown backward. The treatment consists in thorough rest of the part by lying on a bed or by applying a liquid glass bandage.

Poisoned wounds, i.e., bites, stings, are more fre-

² They are usually due to a fall, the passage of a cart wheel, the stroke of a stick, a fist blow; to the pressure of the dislocated clavicle.

³ The wounds are penetrating or non-penetrating according to whether or not they reach the trachea or the esophagus or the vessels.

⁴ Gunpowder stains should receive as especial attention as for those of the face, especially in the exposed parts of the neck.

⁵ That is wounds, extending beyond the cervical fascia and more or less deeply.

quent on the neck on account of its exposed condition; also more grave, because no clothing has protected the parts; also, because they are usually followed by great swelling, which reaching the aryteno-epiglottic folds, causes obstruction of the larynx. Bites of a rabid animal are more serious because they have a shorter distance to travel to reach the central organs of innervation and because no clothing has wiped the animal's teeth. In all injuries of the neck causing obstruction to the free circulation of the air, from whatever cause, there is great dyspnea, cyanosis, anxiety; the pulse is full, rapid; there is also aphonia, dysphagia, pain. Tracheotomy should be performed; it is often advisable not to wait for very urgent symptoms to have the operation performed, because death may come on rapidly or suddenly before the patient can be reached.

Surgical neuroses of the neck, i.e., paralysis, spasmodic affections, retractions, neuralgias are rare except those which affect the sterno-mastoid and the trapezius and which will be described in speaking of the various forms of torticollis.

Hyperemia or congestion of the neck often accompanies that of the face, but it seldom exists alone.

Inflammations present most important differences according as they are superaponeurotic or subaponeurotic. Inflammations of the skin proper present nothing peculiar except that erysipelas seldom originates there; it is usually an extension of erysipelas of the head; it is seldom that erysipelas affecting the head will not extend to the neck, and it is also rare that it extends beyond and reaches the trunk. Furuncles and carbuncles may be serious by their extent and by the swelling they cause, which may extend to the epiglottic folds and cause obstruction of the laryngeal opening. Malignant pustules are most common on the neck; the swelling which accompanies this affection is an added danger here if it extends to the aryteno-epiglottic folds. Superficial or superaponeurotic cellulitis is serious only when diffuse or extensive and for the same reasons as given above. When a superficial abscess forms and has to be opened, care should be taken to avoid the anterior and the external jugulars, because they are always pressed toward the surface close to the skin. Deep or subaponeurotic cellulitis is a very grave affection, because of the compression due to the swelling and because these symptoms are increased by the unyielding nature of the fascia. It may be primary, the result of cold, or secondary due to some injury or some lesion of the teeth, especially of the wisdom teeth, bones, lymphatics, thyroid body, scalp, ear, face, mouth, or to low fevers. It may come from neighboring organs; tonsillar abscess sometimes opens under the inferior maxilla, and deep axillary abscess in the supra-clavicular region, as does also anterior mediastinal abscess. Primary cellulitis and abscess may be due to wounds external or mucous, to fractures, to osteo-periostitis, to osteomyelitis of the inferior maxilla, to phosphorous necrosis of jaw, to submaxillary adenitis, to thyroiditis, or acute hygroma of the serous bursae of the neck. Most of these acute inflammations are really adeno-cellulitis, due itself to lesions of all kinds of the face and neck, superficial and deep. Sometimes the initial lesion is very small and insignificant; often the gland itself does not suppurate but the connective tissue around it does (peri-glandular connective tissue); this adenitis may involve the following ganglia: submental (or digastric, or supra-hyoid), infra-hyoid along the middle line (juxta-laryngeal, supra-hyoid,

laryngo-pharyngo-esophageal). In general diseases (diabetes, typhus, pyemia, typhoid fever, measles, variola, diphtheria, especially scarlatina) these inflammations appear most commonly toward the end of the disease or in the convalescence, and are more frequent here than anywhere else and call for special stress on some of the general features. The microorganisms met with vary much; beside the ordinary agents of inflammation we may meet with the micrococcus tetragonus, bacilli of typhoid fever, encapsulated diplococci from pneumonia; it is difficult to say which of these microbes are simply phlogogenous or also pyogenous. In abscess from dental caries spirilla of saliva have been met. Actinomycosis may cause cervical abscesses, although the organism lives specially in the mouth, in tonsillar depressions, in diseased teeth particularly; they may produce metastatic abscesses in the brain, thorax, abdomen; these abscesses are usually multiple and usually run an insidious and chronic course. Abscesses following injury or scarlet fever sometimes form a hard mass, slow in suppurating, causing great damage; sometimes they bleed alarmingly when opened, even after they have been opened several days, on account of sloughing of the vessels; they may be accompanied by thrombi in the large veins or sepsis. When the cellulitis suppurates the abscess may be circumscribed or diffuse; the pus may fuse in the chest, in front of the thyroid and sternum (previsceral route), behind the pharynx and esophagus (retrovisceral route), or along the carotid and jugular vessels in their sheath or in the sheath of the nerves of the brachial plexus behind the sterno-mastoid, reaching the supra-clavicular region and the axilla; it may open into the pharynx, esophagus, larynx or trachea, pleura, or mediastinum. Retro-pharyngeal abscesses may be limited; then they project on the sides of the neck in the maxillo-pharyngeal space; when they are median they can be reached through the mouth. In some subacute cases in the upper cervical region and at the root of the neck abscesses have a tendency to become encysted, and finally open on the skin; they may be chronic. When an abscess is near or over the cystoid, it pulsates, but then there is no expansion.

Chronic abscesses are oftenest due to a constitutional cause; sickly children with bad hygienic surroundings are the most common sufferers; they often start in the glands or bones or cartilages. A residual abscess is one due to the revival of an old cured inflammation. Chronic abscesses sometimes present multiple openings or sinuses; they sometimes ulcerate and perforate the arteries and veins. Scrofulous adenitis has the neck for a seat of predilection; the acute form is very rare; it is more special to adults; when the swellings are established the course is often slow. Simple chronic adenitis is very rare, it is very often scrofulous but not always inflammatory; they are due to repeated pharyngitis or carious teeth.

En résumé, the most common causes of cervical cellulitis are dental affections, lesions of the face and mucous membrane of mouth and pharynx; diphtheria and especially scarlatina; hence the great frequency in children and adolescents.

Diffuse abscesses are rare on the neck; they are sometimes gangrenous, they are often the result of a bad general condition, or of a badly treated circumscribed cellulitis. The peculiarities of cervical cellulitis are that sometimes they are very extensive and the general symptoms precede all the local signs of

deep cellulitis; usually they all suppurate; also they often cause cerebral anemia due to the compression of the carotids or to the coagulation of the blood in the compressed artery and vein.

The diagnosis of deep abscesses, especially of the acute abscesses, should be made at once by using the exploring needle and syringe, not a hypodermic needle, which may not give passage to thick pus, but a needle at least twice as large as the ordinary hypodermic needle. Exploration should be repeated every second day if necessary.

The treatment is evacuation and drainage, but in these dangerous regions fear of wounding important structures often holds the surgeon's hand when the abscess is one or two inches deep, until it becomes more superficial. By incising on the middle line and going around the trachea the knife can penetrate deeply with safety; also by incising behind the posterior border of the sterno-mastoid, or along the base of the jaw. It is recommended by some to cut down and ligate the vessels as they are divided, but when these are imbedded in indurated tissue this is almost impossible. Others leave the needle in place and cut down along it, but the divided vessels present the same dangers and difficulties. Hilton's method is to use the knife only to start, and as soon as deep parts are reached to tear with the director and use dressing forceps to dilate the small entrance gained into the abscess; it offers the same objections. The writer calls his method guided dilatation; it consists in the following steps: As above described, use a proper needle to locate the pus at the depth of one, two or three inches; unscrew the syringe and leave the needle in place; introduce through the needle a steel wire seven or eight inches long until it reaches the bottom of the abscess; remove the needle, leaving the wire in place; make a small incision through the skin to overcome the only serious resistance to the introduction of the dilators; take a trocar (with canula) of one-eighth of an inch in diameter, perforated from point to handle, and run it over the wire into the cavity of the abscess; it penetrates by dilating the tissues by the three blunt edges of its prismatic triangular point; then remove this trocar, leaving the wire still in place; take a trocar and canula of three-sixteenths of an inch and introduce it likewise along the wire; withdraw the second trocar and insert in a like manner one of a quarter of an inch, then one of five-eighths; finally withdraw the trocar and the wire and leave the canula in place; through the canula introduce a drainage tube of a quarter of an inch in diameter; remove the canula, leaving the drainage tube in place. A suitable probe can be introduced through the drainage tube and a counter-opening made at the proper place. After forty-eight hours the opening can be safely dilated to a half inch or more if it is found that the quarter-inch drainage tube is not sufficient.

By this method the tissues are not cut, but simply pushed aside all around, uniformly; there is no cutting at any time, since the edges of the triangular point are blunt; a round or conical point sometimes packs the tissues and does not penetrate; if a vessel or a nerve is encountered it is shoved gently aside out of the way; that is one reason why the dilatation should be gradual and why it is not advisable to pass at once from a one-eighth to a five-eighth trocar. There is no difficulty experienced, as far as the introduction is concerned, in passing from the smallest trocar to the largest.

Glanders is often accompanied by such swelling of the glands and peripheral tissues that life is much endangered thereby.

Inflammation of the tendons and of the muscles of the neck is very rare. The sterno-mastoid and the trapezius are sometimes inflamed more or less, acutely or chronically; but this will be described with the surgical diseases of the regions to which they belong.

Periostitis and osteitis of the region belong to another chapter. Arteritis presents nothing peculiar. *Phlebitis* of the external juglar is sometimes observed and is recognized by the usual dense cord; it often gives rise to intense pain of a neuralgic character. *Phlebitis* of the internal jugular is a most grave affection because of the propagation to the lateral sinuses of the brain; it will be described more fully when treating of the diseases of the region of the carotids. *Lymphangitis* is rare on the neck as a primary affection. *Adenitis* is most frequent, on the contrary, following the diseases of the various organs; they will be treated with the regions to which they belong. *Neuritis* is rare. The special organs of the region, the parotid and submaxillary glands, thyroid body and thymus, are liable to become inflamed, but very seldom, and they will be described further on.

Gangrene of the neck, in whole or in segments, is rare; grafting should be resorted to early to prevent the cicatrices and the consequences.

Ulcers of the neck resulting from inflammation are not common unless there has been sloughing. Strumous ulcers are common and often leave an indelible and much-dreaded tell-tale cicatrix. This can be removed when not too large by excision and stitching, leaving only a linear cicatrix instead of the irregular and striated strumous cicatrix. Tuberculous ulcers, secondary to the suppurated tuberculous glands, are also among the most frequent and present the same remarks. Syphilitic ulcers are the next in frequency. Cancerous ulcers are more rare; they are usually due to ulcerated cancerous glands, due themselves to secondary glandular infection; they have already been described. *Fistulae*, accidental, due to wounds are the most common. Aerial fistulae are those which communicate with the air passages; they may be laryngeal or tracheal; they are usually the result of wounds, accidental or surgical; they may be congenital, but it is rare; the tracheal are the most frequent, and are oftenest due to incomplete transverse wounds and to the retraction and stricture of the lower end; sometimes they result from the removal of parts of the tracheal cartilaginous rings in thyroidectomy, sometimes to tracheotomy. Alimentary fistulae communicate with the esophagus or the pharynx, and are called esophageal or pharyngeal; they are usually the result of accidental or surgical wounds or follow the opening of extensive abscesses. Glandular fistulae are the most common of all, being due to the suppuration of the glands of the neck. Cellulitis or abscess fistulae following these diseases are comparatively rare. Fistulae may remain after the complete removal of tumors; after the simple puncture or incision of cysts, of serous bursae. Dental fistulae follow the opening of abscesses due to diseased teeth, specially the wisdom teeth; they do not heal until the culprit tooth is extracted. Osseous fistulae are kept up by some carious or necrosed bone of the region which has to be treated. Fistulae complicated with erysipelas may be cured by it. *Fistulettes* may be cured by cauterization. In old fistulae the orifice is circumscribed by a cicatricial ring inti-

mately adherent to the edges of the loss of substance of the trachea; they demand an autoplasmic operation. Plastic operations are necessary to cure many of these fistulæ which remain after the removal of the original cause and after the dilatation and curetting of the tract.

(To be continued.)

THE DIAPHRAGM AND CENTRUM TENDINEUM.

WITH TEN ORIGINAL ILLUSTRATIONS BY THE AUTHOR.

BY BYRON ROBINSON, B.S., M.D.

PROFESSOR OF GYNECOLOGY IN POST-GRADUATE SCHOOL AND POLICLINIC.
CHICAGO.

The diaphragm is the chief characteristic of mammalian myology. The amphibia and animals below them in scale of structure have no diaphragm. The first distinct trace of it may be found in crocodile and bird, where the muscular fibers which are concerned in its formation arise from ribs. Even animals as high in the ascending scale as birds have an imperfect diaphragm; it does not separate the lungs and abdomen of aves completely. In fact several descriptions have appeared as to what is considered a diaphragm in birds. A complete diaphragm which arises from the vertebral column, ribs and sternum is a mammalian property only. The exact mode of the formation of the muscle is not fully known. The mammalian diaphragm is probably homologous to the so-called diaphragm of other vertebrates. The mammalian diaphragm is supplied by the phrenic nerves, which arise from the fourth, fifth and sixth cervical nerves and course along the lateral borders of the heart in contact with the pericardium to supply chiefly the anterior primitive portion of the diaphragm. In the human species it receives a sympathetic branch from the inferior cervical ganglion. Some of the lower intercostal nerves pass to the midriff. Besides, the diaphragm receives sympathetic branches from the abdominal brain along the phrenic arteries—the phrenic plexus. Originally the body cavity extended in the embryo from the visceral arches to the pelvic cavity; in the mammalian embryo the pericardio-thoracic cavity begins to be distinctly marked off from the future abdominal cavity by a transverse fold. This transverse fold begins at the vertebral and lateral wall, projects median-ward and dorsal-ward into the primitive pleuro-peritoneal cavity. This fold marks the course which the terminal part of the omphalo-mesenteric vein takes in order to reach the heart.

Oscar Hertwig says, "subsequently there is found imbedded in the transverse fold all of the venous trunks which empty into the arterial sinus of the heart, *i.e.*, the omphalo-mesenteric and umbilical vein with the ducts of Cuvier which collect the blood from the walls of the trunk." From this view it would result that the transverse fold—the incipient diaphragm—is intimately connected with the development of the veins. Similar folds are produced in the peritoneum by blood vessels as the plica-duodeno-jejunalis, the folds due to the arteriæ hypogastricæ and umbilical vein. It is known as the septum transversum or as Uskow named it, "massa transversum."

The primary diaphragm really belongs to the heart, as it consisted originally of projecting folds through which were conducted blood vessels to the great fluid or blood center—the heart. It may be noticed that the ventral part, *i.e.*, the primitive or original part, of the

diaphragm is the older and this explains why the two phrenic nerves chiefly supply the primitive or anterior portion. The muscular portion of the diaphragm gradually projects from the lateral and dorsal aspects toward the central portion of the body cavity between the growing liver and sinus venosus. A final fusion results between the primitive and secondary portion of the diaphragm. The hepatic and diaphragmatic development is inseparably connected early in embryonic life. But first the pericardial cavity is completely closed and then there remains two tubular cavities projecting from the peritoneal cavity bilaterally up to the visceral clefts. His called these cavities, thoracic prolongations of the abdominal cavity—a very suitable name. Into these original peritoneal prolongations jut out the lung structures, growing from the vertebral wall of the intestinal tube. Later in embryonic life the pericardial cavity is closed and occupies the chief ventral side of the embryo, the thoracic cavities now closed occupy the dorsal side, while the rapidly growing peritoneal cavity occupies the posterior portion of the embryo, all three cavities

Fig. 1.—Diagram to illustrate the lymphatic drainage of the centrum tendineum of the diaphragm into the two anterior and two posterior trunks. D, D, upper and lower end of the thoracic duct; 1, outer end of the diaphragm; 2, anterior lymph trunks passing on the posterior surface of the xiphoid appendix to accompany the mammary arteries; 3, 3', two posterior trunks of lymphatic vessels which drain the centrum tendineum and empty into the thoracic duct; 5, 5', valves of the trunks; 6, 7, 8, are dilated lymph spaces in the tendon. The black spot represents the point of the centrum tendineum where the heart rests on it, at which point there are no lymph spaces; 9 represents the mouths of the two anterior channels.

distinctly divided off by the characteristic mammalian muscle of the diaphragm. The pericardial sac first closes from above by the forward projection of the ducts of Cuvier, the primitive diaphragm forming the lower portion of the pericardial sac. Finally the edges of the projecting folds, due to the ducts of Cuvier, fuse and the pericardial sac is formed. The remains of Cuvier's ducts is the superior vena cava. From the dorsal and lateral walls of the trunk project folds, known as the pillars of Uskow, which fuse with the original septum transversum which was thrown into a fold by the veins which course to empty their contents into the heart. The diaphragm has an older ventral part supplied by the phrenic nerves and a younger dorsal part. The pericardial sac is of enormous size in the embryo while the two narrow, lateral tubular sacs hold the rudimentary lungs which are very small from non-use and slight blood supply. But with further ventral growth of the lungs they detach more and more the wall of the pericardium from the diaphragm and from the lateral walls of the thoracic cavity, thus increasing the pleural diaphragm-

matic surface. Again the liver is gradually separated from the primary or ventral portion of the diaphragm by the peritoneum growing over and becoming adherent to the upper surface of the liver, only leaving a small portion of the upper surface uncovered by peritoneum. This uncovered liver surface is bounded by the basal margins of the coronary ligaments. The characteristic mammalian muscle serves mechanically as, 1, a partition to divide the peritoneal cavity from the pleuro-pericardial cavity, 2, to fix the pericardial sac and 3, as a floor to support the pleuro-peritoneal endothelium. Anatomically it is so designed by origin and insertion as to aid respiration, allowing lung expansion and aiding contraction. It permits of much adjustability of pleura-peritoneal organs. It accommodates itself to the varying size of adjacent viscera. Physiologically the diaphragm is a vast and active absorbent. It is a filter, a sieve for peritoneal fluids (and also to some degree for pleural fluids). A considerable portion of the central part of the diaphragm of most animals is of a tendinous or aponeurotic nature. In some mammals there are several tendinous portions separated by muscular and connective tissue ridges. In cetacea the centrum tendineum is almost obsolete.

Fig. 2.—A diagrammatic profile view of the lymphatic duct with its visceral tributaries and nodules and two posterior lymph trunks from the diaphragm. 1, internal jugular vein; 2, innominate vein; 3, subclavian vein; 3, thoracic duct; 4, 4, small branches of the thoracic duct converging at a point where it empties into the subclavian vein; 5, 5, 5, the two anterior lymph trunks which drain the anterior portion of the diaphragm and accompany the internal mammary vessels, 6, 6, the two posterior lymph trunks which drain the posterior portion of the diaphragm emptying into the thoracic duct; 7, 7, a portion of intestine to illustrate the lymph capillary vessels; 9, 9, lymph capillaries; 10, 10, 10, the mesenteric lymph nodes; 11, receptaculum chyli; 12, lumbar lymph nodes or glands; 13, diaphragm. This figure represents the three great divisions of the lymph system: a, the non-valved variable lymph capillaries (9, 9), with sinuous endothelia and excavations emptying into the lymph trunks (10, 10) and nodes; b, the valved lymph trunks with the intervening lymph nodes emptying into the thoracic duct; and c, the thoracic duct (3) emptying into the subclavian vein.

In the study of the histology and physiology of the mammalian diaphragm the chief attention is nearly always confined to the centrum tendineum. My studies were mainly concerned with the diaphragm of man, the dog, rabbit and guinea-pig. The most convenient animals on which to study the central tendon of the diaphragm is the one which possesses a central tendon so thin and transparent that it will require no section for microscopic examination. The cheapest, most accessible or perhaps the most satisfactory animal on which to pursue histologic and physiologic study of the centrum tendineum is the rabbit. The centrum tendineum of this animal consists essentially of four layers, viz.: First, there is a layer of parallel radiating tendinous bundles, passing from the region of the vertebral column toward the costal arches. This tendinous layer lies on the posterior or abdominal side of the diaphragm. In the intertendinous spaces or

clefts of this layer, long irregular interstitial or lymph spaces exist; with the naked eye one can observe the radiating tendinous ridges, especially by stretching the tendon. In physiologic experiments it is in the intertendinous spaces that the chief accumulations of colored granules are deposited and really seen by the eye or tracing lens.

The second layer of the centrum tendineum is the circular or that lying on the pleural side of the diaphragm. It is quite uniformly developed, but at localized points there appears to be an excessive amount collected. These two tendinous layers, the radiating and circular, may be readily dissected from each other.

A third layer of the centrum tendineum is the pleura serosa lying on the circular tendinous layer. It is composed of an endothelia interrupted by stomata vera and spuria. It lies in contact with the lung.

A fourth layer enters into the centrum tendineum, the abdominal serosa. This is an endothelial membrane composed of flattened connective tissue cells, so placed edge to edge, as to produce a membrane which is interrupted only by stomata vera and spuria. The diaphragmatic abdominal endothelia rest on the basement membrane, the membrana limitans, which is perforated by groups of small openings. The histology and physiology of the above four layers of the centrum tendineum will engage our attention both experimentally and microscopically.

Fig. 3.—(After Ludwig and Schweigger-Seidel, 1866). This is a section of the centrum tendineum of a rabbit, 150 diameters; a, the peritoneum, d, in the pleura; b represents the four radiating tendon bundles; h, h shows the tendinous lymph spaces, one fully and the other partially distended; i illustrates the peritoneum, over a lymph space between the tendon bundles, depressions, i.e., the fluid lymph has disappeared from the channel; g is a blood vessel; c is the circular fibrous layer; e represents the peritoneum put on a stretch over the intertendinous lymph space.

Histologically the centrum tendineum has engaged the attention of original investigators for over thirty-five years. Von Recklinghausen began 1861 by showing that particles suspended in fluid and injected into the peritoneum passed through the serosa of the centrum tendineum and were liberally deposited in the lymphatics of the diaphragm. He used milk, oil, cinnabar, chinese tea, etc. His pupils Pia, Foa and Radjewsky continued his researches. Chzrozozinsky, and his pupil, Afannasiew (1867), did some excellent work on the diaphragmatic peritoneum. The most extensive and far-reaching labors on the centrum tendineum since the epoch-making experiments of Von Recklinghausen were the researches of Ludwig and his pupils, Schweigger-Seidel, Dogiol and Dyb-kowsky in the Leipsic Physiologic Institute in 1864-67. Those laborers asserted that the peritoneum is a lymph sac. The Russians, Lawdowsky and Kolosow did excellent work. The Italians, Bizozzero, Salvioli, Maffuci and Muscatello were progressive workers, and Bizozzero announced in 1874 that the membrana limitans of the centrum tendineum was perforated by groups of openings. The excellent labors of the Frenchmen are well known, as those of Ranvier, Dubar, Remey, Tourmeaux, Hermann. The Englishmen, Klein and Burden-Sanderson produced meritorious works. The combined labors of these investi-

gators point to the diaphragm or centrum tendineum as the significant locality of physiologic activity of the peritoneum.

The serosa of the peritoneal side of the centrum tendineum presents special features requiring careful attention. If a rabbit's diaphragm be stained *in situ* with .25 per cent solution of AgNO_3 and removed without trauma and mounted in glycerin we observe the endothelia and their corresponding dark network of interendothelial spaces; interendothelial substance is discarded. At the common junction of several endothelial cells may be seen structures which are designated stomata vera, while situated along the interendothelial spaces are structures known as stomata spuria. Again, another distinctive characteristic of the centrum tendineum is presented in the microscopic field which consists of parallel dark and light spaces. These dark and light strips radiate from the vertebral region toward the costal arches and correspond to the tendinous bundles and intertendinous spaces. The distinctive feature of the peritoneal serosa of the centrum tendineum is that directly over the radiating tendinous bundles the endothelia are large, regular and possess relatively few stomata vera, while the endothelia covering the light or intertendinous spaces are small, quite regular and possess very numerous stomata vera. Occasionally the large, regular endothelia may not only stretch as usual over the tendon bundles but in irregular distanced localities even bridge all the way across the lymphatic intertendinous channels, taking the place of the small irregular endothelial cells which cover the lymph spaces. In intertendinous spaces the stomata are arranged in rows chiefly occupying the central portion of the space. The light spaces are intertendinous lymph channels, while the dark spaces represent non-transparent tendinous bundles. The intertendinous lymph channels are irregular in shape and size, possess lateral bulgings or sinuses and run parallel with the bundles of tendons. The size of the intertendinous lymph channels vary according to the amount of fluid in them. They measure according to Schweigger-Seidel and Dogiel, from 0.06 mm. to 0.12 mm., *i. e.*, they vary one half in size.

The stomata vera of the peritoneal serosa of the central tendon, located chiefly in the intertendinous lymph spaces, are vertical canals connecting directly, the peritoneal cavity with the sub-peritoneal lymph channels. It must be admitted that there is an uncertainty in the examination of the peritoneum whether the stomata vera really correspond to holes in the serous membrane or not. Yet this uncertainty becomes less as one actually observes that, by injecting fluid holding in suspension solid particles into the abdominal cavity the solid particles will pass in vast numbers into the sub-peritoneal lymphatics of the central tendon of the diaphragm in a few minutes. The stomata vera are lined by granular, polyhedral, nucleated cells. The vertical canal has varying length. Sometimes it may only be as long as the thickness of the peritoneal layer, plus that of the sub-peritoneal lymph vessel wall, or the canal may pass down obliquely. Again, the vertical canal may pass down through a wide lymph capillary field to connect a deep subserous lymph space. In such a case the vertical lymph channel is really invaginated by the lymph space through which it passes.

It is true the stomata vera are irregular in distribution, share, size and number, but that can hardly be

considered sufficient proof against their existence. Schweigger-Seidel's theory that the stomata vera are surrounded merely by the nuclei of the adjacent endothelial cells must be abandoned as it does not correspond with the observed facts. One can see the usual nucleus in the endothelial plate, which surrounds the stomata vera in its accustomed locality. In examining specimens of the central tendineum the stomata may be observed open or closed, the mouth may represent a curved line as is easily observed on the lymphatica cisterna magna of the frog. Klein adds another kind of stomata, which are mere breaks or discontinuity in the endothelia leading into some lymph space which is only covered by a single layer of endothelium. Such stomata are not lined by granular, polyhedral, nucleated cells. The application of a solution of AgNO_3 to the stomata vera of the diaphragm produces in them a rich brown color, owing to the amount of precipitable albumin they contain. The stomata vera or vertical lymph channels are lined by a special layer of endothelial cells, more or less polyhedral in shape, consisting of granular protoplasm. The expansion and contraction of the granular nucleated cells which line the vertical lymph channels control the lumen of the stomata vera. They have a sort of sphincter so as to control the flow of peritoneal fluids. Ranvier called the stomata vera

Fig. 4.—A figure to represent a portion of the peritoneal serosa of the centrum tendineum of a rabbit after injecting fluid into the peritoneum for forty minutes while alive and again forty minutes while dead. The specimen was slightly silvered, then prepared by a solution of gold chlorid 1 part, acetic acid 5 parts, and water 994 parts, whence it presented a most beautiful and brilliant picture. 2, nuclei; 1, 1 shows the leucocytes emerging from sub-endothelial spaces, through stomata vera or stomata spuria—however, always through interendothelial space; 3 points to a leucocyte emerging from a stoma verum; 5 indicates a leucocyte emerging through a stoma spurium; 6 is a leucocyte entirely free. Note that the leucocytes become elongated as they emerge; 4 and 7 point to the leucocytes shimmering through the cover plate. Under the cover plate the leucocytes are round. Peritoneal irritation induces the leucocytes to come to the surface.

lymph wells and claimed that the so-called granular cells lining them were leucocytes. They are doubtless localities for reproduction of endothelial cells to replace worn-out or dying comrades. My experiments seem to show that the Berlin blue particles may be found passing through deposited in the vertical lymph channels.

On the interendothelial spaces of the centrum tendineum there exists after the application of silver nitrate solution dark spots, rings, ovals, thin rings with large light centers or thick rings with small light centers or very irregular masses. These structures are known as stomata spuria. Virchow called them lymphoid cells, Oedmansson, Von Recklinghausen and others called them connective tissue corpuscles projecting upward between the endothelial plates. I am quite well convinced by experiments that leucocytes wander from the lymph spaces below to gain entrance to the peritoneal cavity.

The interendothelial space in the centrum tendineum originally was called interendothelial substance, fluid, semifluid or cement substance. I have discarded all names for the word interendothelial space. By the use of osmic acid as a fixation agent, and silver

nitrate and tannin as reduction agents, we can dissolve the interendothelial space into two parallel lines with an intervening light space crossed transversely by anastomotic protoplasmic processes. The two parallel lines on the borders of the cover plate and the transverse anastomotic processes are the protoplasmic processes which bind the endothelial cells into colonies and groups. The anastomotic processes are thin and fine at the surface but increase in thickness and numbers as they descend from the surface. This interendothelial space gives ample room for contraction and expansion of endothelial cells, contraction of the cells elongate and thin the protoplasmic anastomotic process and the expansion causes the reverse condition. It thus can regulate peritoneal fluids currents.

The endothelium of the centrum tendineum consists of a cover plate (Kolossow, Ranvier), an indurated, hardened, metamorphized portion of protoplasm which is fixed by protoplasmic processes to the subja-

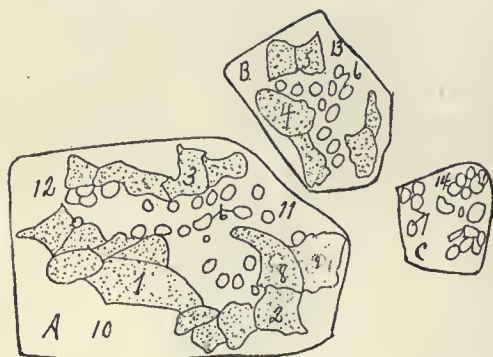

Fig. 5.—Drawn from the abdominal side of the diaphragm of a girl 13 years old to illustrate the pores in the membrana limitans. This diaphragm was removed seventy-two hours after death. It was stained with a 1 per cent. solution of nitrate of silver for ten minutes. It was then placed in carmin colored fluid for ten hours, where it absorbed considerable numbers of colored granules of carmin. It was then placed in Muller's fluid two days, sections prepared by snipping off small bits of the diaphragm were in general mostly desquamated and especially the cover plate and its edges were much dissolved. In this diaphragm the apertures of the membrana limitans appear mainly in groups. The groups are in general 10, 20, 30 and 40 in a group. Some groups of apertures in the membrana limitans appear to be 75 or 100, yet this may be where two or more groups coalesce. The size of the holes would appear large enough to admit from one to four red blood corpuscles abreast. Single holes may appear alone in the membrana. There is no doubt that some of the bright spots in the cover plate represent the apertures in the membrana limitans, as it is plain to see in this diagram. Some have interpreted the bright spots in the color plate as holes peculiar to it. The holes are round, oval, oblong, square, but chiefly round or oval. The maceration of the endothelia and their falling off by merely washing or rinsing is one of the best ways to observe the holes or pores. However, on vast areas of the diaphragm one can not see the pores. Hard brushing destroys distinct views of the pores. Nos. 1, 2, 3, 4, 5, endothelia isolated and connected; 6, 6 and 7 show the shape, size and relation of the apertures in the membrana limitans; 8, 9, nuclei of endothelia; 10, 11 and 12 in A and B and 14 in C show the membrana limitans with its pores. It resembles a soap bubble in fineness, but is visibly granular.

cent protoplasm, but the lateral edges have little or no connection with adjacent fellow endothelial cover plates. The best animal to study to observe the cover plates are the frog and turtle. The portion of the endothelial cell immediately beneath the cover plate is the real living protoplasmic essential part of the endothelial cell which contains the nucleus. It is contractile and expansive and connected to its fellows in colonies by anastomotic protoplasmic processes. The pleural serosa situated on the anterior or upper surface of the centrum tendineum is similar in structure to the peritoneal serosa situated on the under or posterior surface of the tendon.

We note then that the centrum tendineum has two layers of serosa and two tendinous layers. The elements of the serosa are the endothelial plates, stomata vera et spuria and interendothelial space, which we

have discussed sufficiently to expose the views of their structure and significance. We will now discuss the fine membrane on which the endothelia rests, the peculiarity of which is that it is perforated by groups of apertures in the serosa of the abdominal side of the centrum tendineum. It is known as the membrana limitans.

The membrana limitans is a transparent, glassy, fibrillar-like membrane situated beneath the peritoneal endothelia. The earliest amount of this membrane at command is a well-written article by Brinton, in Todd's Encyclopedia, 1847, under another name; "basement membrane." Todd and Bowman describe it as "a continuous transparent membrane of excessive tenuity and homogeneous or nearly so." Goodsir (1847) also described it, but he noted that it could be separated into its component cells, which were of a rhomboid and extremely flattened shape. Goodsir named it the "germinal membrane." Many examinations of this subject were made fifty years ago, with the result that vigorous denials of its existence were asserted. Brinton himself could not confirm Todd and Bowman's investigations. Arnold, in his "Hand-

Fig. 6.—Drawn from peritoneal side of a rabbit's centrum tendineum to illustrate a small capillary distinctly invaginated in the vast lymph spaces through which it courses. The diaphragm was silvered and the simple handling of the diaphragm during an experiment suffered to desquamate the free peritoneal endothelium so that one can readily see the blood vessel with its long spindle-shaped endothelia coursing through the vast lymph field recognized on each side by their sinuous endothelia. The lymph spaces pass over the blood vessels, but that is omitted to avoid confusion of endothelia; 1, 2, blood vessel; 3, 4, their nuclei; 5, stoma verum; 6, 7, 8, 9, sinuous endothelia of the lymph spaces; 10, 10, their nuclei; 11, 12, and 13, stomata vera of the lymph spaces.

buch der Anatomie," Freiburg, 1844, p. 216, calls it "a finely granular, fiberless ground substance." There can be no doubt that the basement membrane of Todd and Bowman and the granular fiberless substance of Arnold are one and the same membrane. In 1850 Kolliker, in his "Mikroskopische Anatomie," could not fully confirm the basement membrane, but acknowledged that beneath the endothelial layer there appeared a homogeneous element which was similar to a membrane. Henle, in 1840, "Ueber Serosen der Haute," in Froriep's "Notizen," demonstrated this membrane as intercellular substance of connective tissue, and again as formless germinating material. Luschka, in 1851, in "Die Structur der Serosen Haute des Menschen," calls it by various names, as structureless connective material, almost completely homogeneous, of glass-like transparency, smooth or very finely striped lamella. He says it is clear and shining and has the appearance of lightly ground glass. It may be noted that but little could be added to make Luschka's structureless material exactly the same as

the differently termed membrana limitans of today. He says this structureless material is found in all the serous membranes between its fibrous elements. The far-famed Reichart, who in 1845 first proposed the term connective substance, considered this material intercellular substance, which is finally transformed into a membrane possessing rudiments of the original cell elements. Luschka incidentally remarks that Todd and Bowman found occasion to call their structureless membrane the basement membrane.

In 1873 Bizzozero, who studied extensively the peritoneum, established the less distinctly seen object of older authors as a definite, recognized membrana limitans. However, it is the same identical membrane of Arnold, Henle, Todd and Bowman, Luschka, Reichart, Goodsir, Kölliker and others. What brought Bizzozero into prominence is not reaffirming the existence of the membrana limitans, but the announcement that the membrana limitans is perforated by apertures on the diaphragmatic serosa. This significant discovery is the only explanation so far offered which explains why the finely divided, colored granules are so rapidly carried into the lymph channels of the diaphragmatic serosa when injected into the peritoneal cavity. The diaphragm is the chief region of absorption of the material injected into the peritoneum, because the membrana limitans is perforated only over the diaphragm.

The membrana limitans has been described in animals by Wadd and others. Bizzozero asserted that it contained no cells, that it is simply finely striped. Acetic acid applied to it makes it swell and become invisible from transparency. I have made long search as to the location of the perforations and so far have never seen the membrana limitans perforated outside of the centrum tendineum. Almost all the perforations of the membrana limitans found have been situated toward the line of junction of the centrum tendineum and the muscular portion of the diaphragm, *i. e.*, toward the costal margin of the central tendon. My best specimens so far came from the human species and the dog. In these the membrane appeared as thin as that of a soap bubble with peculiar fine striations running parallel to each other, resembling glass ground in one direction only. The groups of perforations in the membrana limitans in the human species were apparently larger than in the dog and contained numbers of pores. In one case there appeared to be 80 to 100 pores in one group. In the dog I seldom saw groups containing more than 40 to 50 but oftener much less. The distribution of the groups of apertures were similar in man and dog. The group of pores resembled in distribution somewhat a vast herd of sheep in a wide pasture with larger and smaller groups here and there with but a few stragglers existing between. The distribution of the groups of pores might be compared to the groupings of the gonococcus in a specimen.

Irregularity of number, size and shape of groups characterize the distribution of pores on the peritoneal serosa of the centrum tendineum. The shapes of the pores are chiefly round and oval. The best specimens on which to find the pores are those preserved several days in Muller's fluid or preserved 12 to 24 hours in water, subsequently gently washing off the endothelia. In some specimens the pores could be observed through the serosa of the central tendon. So far in our work we have not found the pores in the center of the centrum tendineum, but always

toward the periphery. The outline of the perforation or pore is always sharp and distinct. The circumference of the pore seems to take on the silver stain actively, making it appear quite distinct. Where the pores are located as Muscatello notes, the membrana limitans appears to be quite adherent to the adjacent tissue. As regards the ease with which the pores in membrana limitans may be demonstrated, I must demur to the idea that it is certain or easy of execution, for one may attempt to find them on many specimens before success results. It is easy to observe that the membrana limitans is thicker and thinner in different localities of the peritoneum.

(To be continued.)

DISEASES OF THE RECTUM AS A CAUSE OF AUTO-INFECTION, WITH REPORT OF CASES.

BY J. R. PENNINGTON, M.D.

CHICAGO.

Auto-infection is not altogether a new subject, yet it has remained for modern bacteriology and chemistry to demonstrate its relation to, and importance in, the production of disease; and, today no subject commands greater interest or demands more serious thought and careful study, because when more thoroughly understood it will be found to be at the root and foundation of many of the so-called reflex and other obscure diseases. There are many sources of auto-intoxication, but this paper deals more especially with that variety of infection caused by the absorption of toxic substances generated within the alimentary canal by chemic, putrefactive or fermentative changes or bacterial development, aided and influenced by the existence of a pathologic condition of the rectum and contiguous structures.

That I may more clearly elucidate the subject, it will be necessary to call attention to the fact that the physiologic processes of the abdominal and pelvic organs, as well as those of many other organs and parts, depend in a great measure upon a healthy and non-toxic state of the sympathetic system of nerves. These organs, through this same system of nerves, are in profound and intimate relation with the rectum; and, therefore, any diseased condition of it, such as piles, fistula, ulceration, stricture, congestion, inflammation, etc., intoxicates and impairs the function of this system of nerves, and, according to that degree of intoxication and impairment, weakens the defense, modifies the nutrition and perverts the physiologic function of the kidneys, liver, intestines, etc., which in turn favors and invites infection.

It should also be remembered that because of the peculiarity of the nerve supply to the rectum, a patient may, and often does, consider a trivial affliction of this organ as one of great magnitude, while he regards and treats a truly serious and dangerous condition as if of no vital importance whatsoever; or, perhaps, the local manifestations may be so slight that the patient has not the least suspicion of its existence. In fact I have had patients doubt my diagnosis when they were actually suffering from self-poisoning caused by a pathologic rectum, saying it was impossible, as they suffered little or no pain and their bowels were regular. Future treatment, however, convinced them of the correctness of the diagnosis, that the rectal trouble was at the foundation of their affliction. Others again have questioned

my judgment when I have assured them that their rectal affliction was, comparatively, insignificant.

Boucharde tells us that "the organism in its normal, as in its pathologic, state is a receptacle and laboratory of poisons." This declaration is endorsed by our most eminent bacteriologists and chemists. And, further, recent investigations have established the fact that many of the morbid conditions from which the human race suffer have their origin or source of infection in the intestinal canal of their own systems.

The bacillus coli communis, the most prevalent bacterial germ developed in the intestinal tract, has been found in the brain, liver, lungs, kidneys and in fact in nearly every organ of the body. Its toxins are very virulent and under favorable conditions affect the vital tissues most insidiously. The watery extract of putrefying fecal matter within the intestinal canal has also been proven to be, under some circumstances, very poisonous.

Auto-infection is a very insidious disease and manifests itself in a multiplicity of ways. The following are a few of the commoner symptoms observed: headache, drowsiness, lassitude, "tired feeling," loss of ambition, palpitation, impaired appetite, flatulence, indigestion, nervousness, irritability, cold hands and feet, etc. Such patients are usually inclined to be melancholic. The skin has a pale, muddy, greenish-yellow or unhealthy color, and may have the odor of foul-smelling secretions. The breath is also frequently foul. In more severe cases the symptoms are those of impending dissolution. Many of these patients travel from doctor to doctor and are usually treated for grip, malaria, biliousness, nervousness and constipation. They tell you that as long as they continue to take medicine they feel better. This improvement is oftentimes chimeric and simply serves to aid the grim monster of death in more securely and insidiously fastening his venomous fangs into the very heart of their lives. When they stop taking drugs the trouble recurs and frequently in an aggravated form. To cure these individuals it is absolutely necessary to locate and remove the cause of the infection, otherwise it is simply a waste of time, energy, life, happiness and money. Constipation, it may be said, is probably accountable for more ills than any other condition to which human flesh is heir. It is one of the most frequent causes of self-infection, yet it should be regarded as a protection against intoxication, as it presupposes that all that is absorbable has been absorbed. But are constipated people healthy? They have headache, dizziness, lassitude, etc. Hypochondriacs are usually constipated and suffer from all manner of nervous phenomena, such as perverted sensibility, tingling and "creepy" sensations, and mental disturbances. The insane very commonly suffer from constipation. So do many epileptics. I do not say that all these troubles are caused by constipation, but I do say, regardless of the cause, that they are aggravated by it and that it impairs the function of the nervous system. Another point, and one which I wish to emphasize, is that a daily evacuation of the bowels does not necessarily mean that the individual is not constipated, neither does the absence of constipation exclude other ailments.

Were the esthetic young lady aware of the fact that in many instances her bad complexion and other ill feelings were due to the absorption into the blood of fecal matter and its deposit in her tissues and skin, we believe that she would pay more attention to the

physiology and hygiene of defecation and the diseases of the rectum and intestinal tract. And further, as we become more familiar with the various poisons generated within us and their great destructive powers, their power to disorder nerve centers and paralyze the action of the vital organs, we come to realize and are forced to admit, that we are constantly standing at the very threshold of self-destruction, that we are our own murderers. In another part of this paper I called attention to the close and intimate relation existing between the rectum, pelvic, abdominal and other organs, and shall now briefly append a few cases to illustrate what serious and dangerous constitutional diseases may be, and often are, caused by rectal affections and that the relief and cure of these afflictions depend upon the administration of proper and intelligent treatment of the rectal ailments.

Case 1.—Mrs. S., consulted in May, 1895, in regard to an external pile. She was emaciated, nervous, had a sallow complexion, palpitation, bronchial cough, pain in the left side and back, also ovarian and uterine symptoms, had no ambition and was inclined to be melancholic; her bowels were constipated and her appetite poor. Suspecting a more serious local trouble than that of an external hemorrhoid, I explored the rectum and found an ulceration the size of a silver quarter, located two inches above the anus. This cured, her symptoms vanished and she regained her usual health.

Case 2.—Miss B., age 25, hysteric, nervous, emaciated, suffering from palpitation and indigestion, bowels slightly constipated, breath foul, bronchial cough and cachectic. Removed four hemorrhoids July last. She now has a beautiful rosy complexion and has gained 20 per cent. in weight.

Case 3.—Bright's disease(?), examination of urine of patient, upon whom I operated for fistula, showed albumin in considerable quantity. He also had slight edema of feet and ankles, waxy complexion and other symptoms indicating Bright's disease, all of which including the albumin disappeared after the operation, when he became healthy and robust.

Case 4.—J. B., age 43, typical case of self-infection. Hypertrophied sphincter, greenish yellow complexion, palpitation, dyspepsia, headache, loss of appetite, nervousness, constipation, etc. Divulsion of the sphincter and a thorough course of the waters at West Baden and French Lick Springs completely restored his health. Will say in passing that I have found the waters of these springs most admirable agents for such cases. By their laxative, diuretic and diaphoretic properties they give the system a most thorough cleansing from all impurities. They are the most potent depuratives of which I have any knowledge.

Case 5.—Asthma(?). Patient afflicted with hemorrhoids and ulceration. Had a chronic cough, crouping rales, tenaceous expectoration and gave a history of asthmatic attacks and evidences of auto-infection. The hemorrhoids and ulceration cured; the lungs cleared up, the cough and *asthma* (?) disappeared.

Case 6.—Rheumatism(?). J. S., age 42, presented evidences of chronic muscular rheumatism, for which, to use his expression, he "had taken a barrel of medicine." The rheumatism disappeared simultaneously with the cure of his rectal affliction.

Case 7.—Salpingitis(?). Mrs. R., with soreness in left iliac region, pressure increasing the pain, emaciated, nervous and irritable, irregular as to bowels, leucorrhœic and passing large quantities of mucus. Her physician had been treating her for inflammation of left ovary and tube. I diagnosed her condition, catarrhal inflammation of the sigmoid flexure, and by treating her accordingly the *salpingitis* (?), pain, nervousness, discharge of mucus, etc., ceased.

Case 8.—A. R., 53 years old, emaciated, had diarrhea and cough, and was thought to be suffering from consumption of the bowels. By relieving him of an ulceration and stricture of the rectum his diarrhea and *consumption* (?) were cured. It is needless to say that his general health materially improved.

My friend, Dr. Mathews, in his most excellent "Treatise upon the Diseases of the Rectum," reports a number of very interesting and obscure cases, many of which no doubt were suffering also from auto-infection. I herewith submit a brief abstract of one of his cases taken from the chapter on "Reflexes."

Mr. H., a prominent banker, was afflicted with a fissure of the anus. Several eminent physicians thought him afflicted with a malignant disease, which they were unable to locate,

and that he was dying from its effect. Mathews also shared in this belief, saying that from his appearance and condition he thought he had a cancerous disease and that it never occurred to him that the ulceration in the rectum could bring him to such a deplorable condition; and he further says that after the fissure was cured "in a few weeks he resumed his business at his bank, having fully recovered from his *malignant(?)* disease."

Doubtless the reflexes played an important part in this case as well as in some of the others herein reported. Yet it was undoubtedly the auto-infection from which this patient was suffering that caused these able men to err in their diagnosis and opinion.

I could cite other illustrations, but these cases speak for themselves and serve to show that no diseases more secretly impair and undermine the constitution or cause a greater degree of personal distress, or are productive of more misery and suffering or serious consequences than those occurring around the rectum and anus; and yet, notwithstanding their great importance, no class of diseases is more grievously neglected. Granting that the above were cases of auto-infection originating from disease in the rectum (and if they were not what were they?) how many more sufferers might be relieved, or even cured, by properly studying and treating pathologic conditions existing in this region?

To permit this insidious and perpetual fire of infection and disease to gradually, though slowly and surely, burn out man's existence, either by ignoring, overlooking or treating with apathy the real cause of his trouble, and constantly filling him, empirically, with drugs, when by intelligent and proper treatment this destructive flame could be so easily and completely extinguished, thereby lifting him from a pit of misery and wretchedness to that high plane of sunshine and happiness, is but little short of criminal ignorance and negligence.

103 State Street.

HEREDITARY TREMOR.

BY WM. F. WEGGE, M.D.

PROFESSOR OF MENTAL AND NERVOUS DISEASES, MILWAUKEE MEDICAL COLLEGE; ATTENDING NEUROLOGIST, ST. MARY'S HOSPITAL, OSHKOSH, WIS.

Owing to the small number of cases of this disease reported thus far, the following history may be of interest:

C. S., aged 35 years, single, school-teacher, has always been in rather delicate health, but has never been seriously ill. At the age of 22 years, she for the first time observed a tremor of the hands which recurred at intervals, especially when excited or exhausted from work. One year after the first appearance of the symptom, it became worse after an illness of several weeks duration. About eighteen months ago, after an exciting experience in connection with her school-work the tremor became more general, and has continued to grow worse more rapidly, ever since; so that she was finally compelled to discontinue her work on account of the annoyance caused by this distressing symptom.

She states that the tremor becomes more marked in the presence of strangers, and for this reason she has avoided coming in contact with them for some time past. When alone it is very much less intense and disappears when she is at rest.

On examination the tremor is found to affect the upper extremities and the head more particularly. It is slow, rhythmic and affects speech somewhat, which

is slow and strained, apparently in the effort of suppressing the tremor. Nystagmus is absent. The hand writing is clear, firm and gives no evidence of tremor. An examination of the nervous system is productive of only negative results. The patient is somewhat depressed on account of her condition and presents some neurasthenic symptoms. Aside from this the psychic functions are normal.

On further inquiry the following family history is obtained. The parents are both living. There is no history of any irregularity of habits, etc., on either side. The father has always been nervous and has been afflicted with a tremor of the hands ever since some time previous to his marriage. His mother had a tremor of the head at the age of 35. The patient's mother's half-sister became insane at the age of 18 years, and died insane at the age of 60 years. The mother's father was periodically insane. One of the patient's sisters died during her confinement at the age of 35; was previously healthy as far as can be ascertained. Another sister, aged 25 years has had a tremor of the head for several years past. The third sister, aged 15 years, is afflicted with a tremor of the head and of the hands since childhood.

Hereditary tremor appears to be a rare disease. Brasch after a careful review of the literature on the subject has found reports of only thirty cases. He suggests the designation "Essential Hereditary Tremor" as the most appropriate one, since it is descriptive of the disease. The essential feature of the disease is the hereditary occurrence of tremor, without any other symptoms of nervous disease.

Clinically, hereditary tremor possesses no characteristics, being subject to many individual variations. In some cases the tremor is slow, rhythmic and with slight excursions. In others it is rapid and less regular. It may be confined to the upper extremities, which appear to be most frequently affected; or it may involve these together with the head, eyes, tongue and vocal cords. The lower extremities appear to be less frequently involved. In the majority of cases it is absent when the patient is at rest, but in some cases it continues even during sleep. Excitement and excesses of every kind tend to increase it. It may develop gradually and increase progressively, or it may develop suddenly and remain stationary thereafter. The age at which the disease begins varies much. In my case it began at the age of 22; in the case of one of her sisters at about the same age and in the younger sister during childhood. The age at which the disease first put in its appearance in the case of her father and in that of her paternal grandmother is indefinite, but it began rather early in life. Hereditary transmission is not always direct from parent to children, since one generation may be exempt, and the following generation inherit the disease.

More recently some authorities (Raymond and Serieux, Hamaide, Vantrin, Achard) have expressed the belief that a relationship exists between hereditary tremor and psychic degeneration.

That this relationship is a fact in all cases is certainly doubtful but in many cases one is almost forced to the conclusion that some such relationship does exist. My case is of little value in this connection. The patient's father has always been "nervous." It is evident that this may be interpreted in various ways. It certainly is very probable that the existence of a tremor would impress those about him as an evidence of nervousness. On the other hand the patient's ma-

ternal grandfather and aunt were insane. On first thought this fact may look like evidence supporting the above stated belief. A more careful analysis however will lead us to the conclusion that it is not. As far as I have been able to ascertain mental or nervous diseases have not occurred on the father's side. Neither have there been any peculiarities of character or disposition. The only evidence to be found is the tremor occurring in the father and in his mother. The maternal branch of the family can not be held responsible for the tremor occurring in these two cases. Then why should it be in the case of our patient? In two cases out of the three reported by Brasch no evidence of psychic degeneration could be obtained.

In the absence of reports of autopsies in such cases we are not informed of the pathologic changes, if any exist, upon which this peculiar disease is based.

The prognosis has been unfavorable with few exceptions. Haebler has reported a case in which recovery occurred after several applications of the faradic current for the relief of an intercurrent radial paralysis. It is doubtful if other cases that have been reported recovered were true cases of hereditary tremor. In my case the neurasthenic symptoms have disappeared under treatment but the tremor continues, though less severe.

NITRATE OF SILVER IN DISEASES OF THE SKIN.

Read before the Society for Medical Progress of the West Side German Dispensary, New York City, Jan. 9, 1897.

BY R. ABRAHAMS, M.D.

DISTRICT PHYSICIAN TO MT. SINAI HOSPITAL, NEW YORK.

At a time when the markets are flooded with new remedies, each one backed by innumerable clinical observations, it would indeed seem reckless presumption to speak about one laden with age. But, while in the wide range of applicability the drug for which I propose to take up the cudgels this evening falls far below many of the recent ones, yet in effectiveness, circumstances and conditions remaining the same, it outdoes all the latest rivals and arrivals.

My object here is to speak about nitrate of silver, its value in the local treatment of diseases of the skin.

The physiologic action of nitrate of silver as applied locally, depends upon the strength of the salt employed. It may be caustic, escharotic, astringent and alterative, each condition resulting from the use of the mitigated, pure, saturated or very weak solution. A quality of silver nitrate passed unmentioned by writers on materia medica, but one which is probably recognized by all physicians, is this, that the salt of silver, even in its weakest state of solution, is a good antiseptic. There is little doubt but that its excellent effects in gonorrhoea, ophthalmia neonatorum, etc., are due to its antimicrobial properties.

Wart.—Every variety of wart is amenable to nitrate of silver. Silver caustic has been used successfully in the removal and destruction of these papillary excrescences from time immemorial. The location of the verruca is no contraindication to the use of silver, but the size often is; for example in a case of condylomata acuminata, or venereal warts, in which the luxurious growth of the papillary buds covers a large surface, the use of silver, by reason of pain and hem-

orrhage, would be impracticable as well as objectionable. The technique in all cases is simple: Work the silver stick down to the bottom of the wart, make a few sweeps around, and the papillomata, by virtue of the chemic and mechanical action of the hard' lunar caustic, will be destroyed. Or, scrape off the lesion with spoon or finger nail and then apply the silver stick—here the salt acts as a caustic in destroying that which the spoon or nail failed to get away, and as a styptic in stopping the bleeding.

Corn.—I venture to recommend nitrate of silver in that form of epidermal callosity commonly called corn. Soak the corn in hot soapy water, then shave down the horny layers and then apply a 30 per cent. solution of silver nitrate. If personal experience is the best form of clinical evidence, then I could conscientiously testify to the effectiveness of this mode of treatment. The corn will never, or hardly ever, suffer resurrection after the silver has been applied to it.

Lupus Vulgaris.—Certain forms of lupus vulgaris are eminently adapted to the local application of nitrate of silver. The first indication is found in the small lupus papules which characterize the commencement of the destructive disease. It is evident that by effectively cauterizing the primary lesions the disease will be prevented from taking root. The second indication is suggested by the lupus nodules which are formed by the coalescence of the initial papules. Lupus in both these forms can be radically cured by and through the thorough application of silver caustic. The third indication is the serpiginous form of lupus. Here silver is used as a means only to stop the downward march of destruction. Kaposi² thus speaks of silver in the treatment of lupus vulgaris: "Apart from mechanical treatment, the use of caustic is important. The most practicable is solid nitrate of silver. It has sufficient resistance to penetrate the individual lupus nodules, thus uniting mechanical and caustic action. It also possesses the advantage that it does not enter healthy tissues. Large nodules of lupus tumidus, and particularly superficial infiltrations, may be burned out as thoroughly as with the sharp spoon. Since the solid stick not only destroys the vessels of the border and base mechanically, but also causes thrombosis, the cauterization furnishes all the requirements for effecting a cure." In the face of this eminently authoritative statement, it is hard to see why some writers of distinction fail to include this agent in the local therapeutics of lupus.

Epithelioma.—Lunar caustic finds a fitting place in suitable cases of epithelioma of the skin and mucous membranes. Generally speaking, the method of applying the caustic in cutaneous cancers is the same as in lupus or in the other growths above mentioned, but the indications are fewer. As in lupus, when the cancerous nodule or ulcer is small, nitrate of silver is an effective and curative remedy. It is also indicated in inoperable cases, in recurrent nodules and serpiginous forms of epithelioma.

The employment of the silver stick in various non-specific ulcers on the legs or other parts of the body, applied with the object to remove spurious granulation tissue, or to freshen up indurated edges, this use of silver is so universal that it needs mention only.

¹ The author, in every instance mentioned in this paper, refers to that form of lunar caustic the composition of which is: One part silver and three parts nitrate of potash.

² Kaposi: Pathology and Treatment of Diseases of the Skin. American translation, page 555. 1895. Wood & Co.

Of venereal ulcers, those most amenable to the treatment with silver are chancroids and the phagedenic type of either hard or soft ulcers. Specific ulcers pursuing, so to speak, a regular course of evolution and involution, should not be subjected to any cauterizing process whatever—silver or galvano-cautery; its treatment, however, is not the object of this paper. Chancroids, when properly treated from their very inception, rarely require the caustic action of silver or any other metal, salt or acid; it is only those soft ulcers whose treatment was unmethodical by the physician, or neglected by the patient, or abused by the quack, which become subjects of the silver treatment. In all those neglected ulcers the application of saturated solution of silver once or twice will materially change their looks and aspects, so that instead of the dirty-looking slough at the base and edges, healthy granulations will take its place in and around. There is one contraindication to the use of silver in chancroidal ulcer, and that is the locality or site of it. An ulcer situated at or in the meatus, or urethra, should not be cauterized, "since such cauterization is liable to produce edema and even result in stricture."³ In case of phagedenic ulcers, I believe that Ricord's nickname for potassio-tartrate of iron, is admirably adapted to silver nitrate, namely: It is the born enemy of phagedena." It is as good as the actual cautery. The result I have had and the results I have seen from the repeated applications of a saturated solution of silver nitrate to this class of intractable ulcers were indeed most gratifying. Ulcers which threatened to destroy the penis and some adjacent territory, were first checked and afterward cured by the timely and judicious use of this drug. This treatment should especially recommend itself to the man in general practice whose armamentarium may be lacking in a Paquelin cautery, or even to specialists who are well armed with instruments but whose patients stubbornly resist the application of "hell on earth," as one of my blasphemous victims specified the hot iron. It is true that annoying edema occasionally follows the application of the salt, but this drawback can be equally charged to the cautery. The application to the ulcer of a piece of absorbent cotton saturated with a 4 per cent. solution of cocain should always precede the silver treatment. This precaution will insure rest and quiet to the patient during the treatment, which should not last longer than a minute. Base and edges should be made the harbor of the solution. The mode of applying the silver is simple: Wind wadding around a stick or the uncharged end of a match, dip it in the solution and apply it. The frequency of the application is regulated by the resistance of the lesion to the treatment. Sometimes one application is enough and at other times two or more are necessary. The treatment after healthy granulations are set up, consists in the use of dermatol, boric acid or any other mild antiseptic.

Erysipelas.—As long ago as 1829 an English observer, Mr. Higginbottom,⁴ advocated the use of nitrate of silver in the treatment of erysipelas. He believed that with nitrate of silver, if properly applied, the spreading of the disease could be prevented. In 1869 the same observer reiterated his recommendation with renewed emphasis and additional conviction. He

attributed the neglect of adopting this method of treatment to an imperfect understanding of its correct application. The following are his directions: "The affected part should be well washed with soap and water, then with water alone to remove every particle of soap, then to be wiped dry with a soft towel. The concentrated solution of 4 scruples of nitrate of silver to 4 drams of distilled water is then to be applied with a small piece of clean linen attached to the end of a short stick, the linen to be removed at every subsequent application. As the solution of nitrate of silver is colorless, it is necessary to pass a little linen, just moistened, over every part where it has been used, in order to be equally diffused, so that no part may be left untouched. In about twelve hours it will be seen whether the solution has been well applied. If any inflamed part be unaffected, the solution must be immediately reapplied. Sometimes, even after the most decided application of the nitrate of silver, the inflammation may spread, but it is then generally less severe, and is eventually checked by repeated application." According to Wood, "this plan of treatment received a great deal of commendation from authorities." Wood also reports ulceration in two cases "apparently the result of the treatment." Personally, I have had no experience with this method of treating erysipelas; my lack of experience is not due, however, to hesitancy of adopting it, but rather to ignorance of the recommendation. It is reasonable enough to merit trial.

Eczema.—Most important of all diseases of the skin in which nitrate of silver does the most good is that form which is designated by the name of eczema intertrigo. This condition is always the result of friction and sweating occurring between two opposing surfaces of the skin. Therefore it is most commonly found in the axilla, bend of the arm, popliteal space, behind the ear, under large pendulous breasts especially in stout women, between fingers and toes, and last but not least, on and around the genital organs of male and female. This form of eczema is characterized by a destruction of the epidermis, weeping surface and intense itching. The first effect of the application of the nitrate of silver in any of these cases is a cessation of the terrible and agonizing itching; second, a discontinuance of the weeping; third, a stimulation of a growth of new epidermic cells and consequent restoration of normal tissue; in other words, the patient is cured. My experience in the treatment of eczema intertrigo in male or female genital organs is very considerable, and the almost uniformly excellent result obtained from the application of nitrate of silver renders me quite enthusiastic in my recommendation. It is no exaggeration to say that silver succeeded where other drugs eminently failed. It would certainly be a burden for you to listen, although a pleasure for me to recite, a long list of clinical histories of the patients thus treated. I must content myself with stating the fact that among the patients who were treated with nitrate of silver for eczema intertrigo could be found young and old—men, women, children and infants. The condition in some existed, prior to treatment, for weeks, in others months, and still in others, years.

Strength of the solution: The site of the eczema determines the strength of the solution to be used. The fluid is applied in the same manner as above described in the case of ulcer. It must be mentioned in passing that the silver stick is never applied in

³ Robert W. Taylor: A Clinical Atlas of Skin and Venereal Diseases, p. 103, 1889. Lea Bros.

⁴ Essay on the use of nitrate of silver, Ed. 2, London, 1829. Higginbottom's Practice, 1869, II, 34. Cooper's Surgical Dictionary, Vol II, p. 573, 1872. Therapeutics, its Principles and Practice, H. C. Wood, 1891, p. 480.

these cases. Now then, a 3 per cent. solution of silver is applicable to eczema intertrigo when located at the following places, namely: Behind the ears, on the penis, and between fingers and toes. Ten to 20 per cent. in the axilla, bend of the arm, under pendulous breasts and labia majora, in the latter event especially when the trouble is due to diabetes (pruritus). Twenty-five to 50 per cent. on the inner surface of the thighs and pubis. On several occasions a .5 to 1 per cent. solution was applied with benefit, in the form of a wet dressing, to a scrotum which was the seat of chronic eczema for months, if not years. The appearance of such a scrotum is quite characteristic; its tissue and size are increased in thickness and extent, and the indurated, rough skin is thrown into itching folds. The application in all these cases can be repeated three or four times during the week; the only time to stop is when an unduly marked hyperemia occurs, as it sometimes does, after the excessive use of the medicinal agent.

In acute and chronic eczema of the face and head, of infants and children, a 3 per cent. solution of silver nitrate is at times very serviceable. But the application need not and ought not to be kept up too long, as the above mentioned resulting hyperemia in some cases will interfere with its speedy and good effects. "Occupation eczema" sometimes can only be cured by the application of a 3 to 5 per cent. solution of silver nitrate. In all these instances the treatment in the interval consists of powdering the parts with bland powders and in keeping them well separated with wadding to prevent further friction.

Parasitic eczema.—Eczema marginatum is a disease which very frequently defies all sorts of applications, but will yield to a strong solution of nitrate of silver. I never began the treatment of marginal eczema with a solution of a strength less than 20 per cent., and very frequently applied a 50 per cent. solution. The raving itching can be successfully combated by this drug, while a complete cure is not a remote possibility.

Herpes tonsurans is the only other parasitic skin disease which can be practicably treated with silver. The application of silver to ring worm is, however, limited. The discoloration the salt produces would be a strong objection to its extensive use on the face, for example. Yet in suitable cases nitrate of silver is a clean and effective remedy. Not very long ago a friend, a young counsellor, visited one of the Turkish baths of the city. A week after, at least this was his affidavit, the right side of his gluteal region became the seat of a good baker's dozen of ring worms. After a few applications of nitrate of silver (30 per cent.) he was completely cured. The discoloration in this case was no ground for objection.

I now come to consider the last condition in which nitrate of silver is in the highest degree *the drug*. I refer to pruritus ani. The difficulty in managing this symptom can only be appreciated by the multiplicity of suggested therapeutics. It is evident that the proper treatment of a symptom is the removal of the disease. Such, however, is not always the case with itching of the anus. It frequently happens that after curing the hemorrhoids, the fistula, the constipation, the pin worms, etc., the itching will still continue unabated. Sometimes it seems as if it becomes a habit with the anus to itch and the patient to scratch. Besides, there is no denying the fact that the pruritus is often present to an excruciating degree while all

efforts to find its cause end in failure—we then take refuge in that mysterious term, neurosis. While eczema may occur, either localized at the anal region or as an extension and continuation of such a condition existing at the genital organs, yet in a great majority of cases the eczema in the case of pruritus ani is secondary, the result purely of that constant scratching in which all patients take a fiendish delight. In the treatment of this distressing ailment there is nothing in the pharmacopeia better, more effective, more gratifying to the patient and his medical attendant, than the vigorous application of a strong solution of nitrate of silver. In all cases the cause should be sought and when found removed, but if the pruritus still continues, apply a 30 or 40 or 50 per cent. solution, depending on the severity and intensity of the itching, and your reward will be worth the effort. In instances where the pruritus is apparently idiopathic, nitrate of silver in the strength alluded to is a veritable specific. Even where there is a palpable cause, silver will insure rest at night and quiet by day while the cause is being removed. The application should be made once or twice a week; in the interval, if necessary, use zinc salve plain, or with cocain (1 per cent.) in it. The preliminary use of cocain (4 per cent.) before painting the anal region with the solution of silver should never be forgotten, for while it does not obviate the subsequent transitory burning produced by the silver, it still mitigates it while the solution is being applied.

I am at an end of the discussion. I am aware that something is still missing in my paper, and that is an explanation of the *modus operandi* of the nitrate of silver in each and all of the diseases mentioned. But as the *rationale* is not far to seek, and as the physiologic action of the salt is so well understood, it is hardly worth while entering into it in a purely clinical paper such as this.

As a final remark I must state that many of the observations herein recorded were made and treated in private and dispensary practice, and that my entire experience with this valuable drug was rendered possible by my long, useful and grateful assistantship to that distinguished dermatologist, Dr. S. Lustgarten, in his skin clinic of the Mt. Sinai Hospital Dispensary.

156 Clinton Street.

THE PATHOGENESIS OF GOUT.

BY HANS FROELICH, A.M., M.D.

CHICAGO, ILL.

Garrod demonstrated in 1848 with his thread test the presence of uric acid in the blood in gout, and basing himself upon this fact, said that in gout there was reduced capacity of the kidneys to pass uric acid; and second, that the alkalescence of the humors in gout was decreased. Charcot believed in an increased production of uric acid, caused by a functional disturbance of the liver, and Cantani thinks that the uric acid originates in the cartilages themselves, and believes that the uric acid diathesis is the consequence of disturbance in the nutrition of the cartilages, the ligaments and the tendons near the bone. The scientific researches in gout and kindred diseases had for forty years been under the ban of Garrod's discovery; all the immense work done within this span of time has been in vain, of no practical value, because now we know that not only the methods which had been

employed for the discovery of uric acid were so inexact as to render the results almost valueless, but it has been proven that uric acid and the substance which generates it, is found in many other diseases without causing gouty symptoms. Von Jaksch found that in the blood of the normal muscle there is no uric acid, but that it is present in pathologic conditions, as in dyspnetic diseases like pneumonia, nephritis, and constantly in anemia. More and more evidence of this fact has accumulated. It was proven that diet had less influence upon the generation of uric acid than was supposed; it has been demonstrated that uric acid is constantly and considerably increased in leukemia, where it reaches the amount of 4 to 5 grams within twenty-four hours; even where the uric acid has been found not to be increased as such, it is always increased in its proportion to urea. Yet this increase of uric acid in leukemia never produces gout; there is in fact only one case known (Priebram's case) where gout complicated leukemia.

The first great step in discovery of the pathologic facts in this disease was taken by Ebstein, who proved (1882) that the precipitation of urates always is preceded by a necrosis of tissue, a purely local process, thus indorsing Cantani's views. Ebstein found characteristic changes in the kidneys, a shrinking caused by interstitial inflammation and accompanying deposits of urates, mostly biurate of sodium. Litten found that urates sometimes not only fill up the tubuli, but are interspersed within the interstitial tissue, and Dickinson joins him by declaring that precipitation of urates takes place solely within the intertubular fibrous tissue and that this part of the organ, thickened by a kind of inflammation, shrinks, compresses the tubuli, causing thereby the granulated kidneys. Wagner demonstrated that lead poisoning can be at the basis of this inflammation, and give rise to consecutive gout or deposition of urates. Cornil and Ranvier are convinced that in the gouty process of the cartilage the cells take part in the inflammation, and Rindfleisch calls them the very centers of the starlike crystals of urates. Ebstein found that the inflammation and precipitation of urates follow the cartilage fibrils, that is, their connective substance. The necrosis of tissue, according to his view, is secondary to the disturbance of the nutrition, which is the primary phenomenon of gout and must have reached the most advanced degree, must present the symptoms of complete decay before urates precipitate. Concerning the cause of this necrosis Ebstein clings to the view of all others, that it must have been caused by the gouty matter, the fluid uric acid, but he is not able to explain why the uric acid should cause tissue necrosis here and not in leukemia or other diseases which are accompanied by presence of uric acid. The question as it stands today is that we have a tissue necrosis in certain points of predilection, preceding precipitation of urates into these necrotic localities.

The questions we have to solve are:

1. What causes the pathologic appearance of uric acid in the tissue and blood?
2. What causes this necrosis?
3. What is the physiologic treatment of gout, after we have answered these questions?

The first question has been fully answered by Horbaczewsky (1892). His discovery brought us near the solution. He found that in maceration of nuclein-containing tissue outside of the body, which is pro-

duced by a certain degree of putrefaction or through boiling water, there are products split off, which produce uric acid. It is furthermore a fact, that nuclein-containing substances decay within the living body too; one is entitled, therefore, to suppose that the uric acid within the living organism originates from leucocytes.

The fact that in leukemia, where leucocytes decay *en masse*, the production of uric acid is constantly and considerably increased, confirms this supposition.

The further fact, that quinin and atropin, which arrest the formation and decay of leucocytes, reduce the production of uric acid, is another proof.

W. Weintrand (1895) in his investigations upon the influence of the nuclein contained in food upon the formation of uric acid, comes to the following conclusions:

The recent investigations with reliable methods concerning the secretion of uric acid, demonstrate that it is dependent in a high degree upon the metabolism of albumin. It has been found that animal or vegetable food had not the energetic influence which formerly it was supposed to have, even the quantity of the secreted uric acid did not vary according to the increased or decreased quantity of fed albumin.

It became evident that the absolute quantity of the secreted uric acid is individually somewhat varying, but represents a pretty constant quantity eagerly retained by each individual.

This agrees with Horbaczewsky's hypothesis, that uric acid originates from the metabolism, that is, from the decay of leucocytes, and that there is a constant proportion between the secretion of uric acid and the number of leucocytes. The increasing recognition of Horbaczewsky's theory removed the influence of food upon production of uric acid still more to the background. It was thought necessary to adopt this view only so far as the introduction of food produces digestive leucocytosis.

Weintrand demonstrated to a certainty that nuclein-containing food, thymus, brain, etc., is perfectly absorbed and causes a considerable increase of uric acid and its excretion.

The resorbed nuclein influences merely the formation and decay of leucocytes and by their increase indirectly the production of uric acid.

Horbaczewsky says that the number of leucocytes in fasting condition is small (hypoleucocytosis) and increases at once after introduction of food (leucocytosis). A similar parallelism exists if we compare the number of leucocytes of persons of various age, sex, nutrition, etc., with the secretion of uric acid of such persons. Children have more leucocytes than adults and secrete more uric acid. Women have less leucocytes in the blood than men and secrete less uric acid; also well nourished people have more leucocytes in the blood and secrete more uric acid than others do.

Not each rise of temperature causes increased secretion of uric acid, only the character of the fever is of influence (Bartel) as we see in the epicritic increase of uric acid after acute feverish diseases. This inflammatory leucocytosis takes place in croupous pneumonia, when the secretion of uric acid shows a hypernormal value during the fever, still increasing with falling temperature, and reaches its height when temperature is normal, and it increases in the same measure as the number of leucocytes decreases. T. F. Richter also says it is certainly true that this con-

nection between uric acid and leucocytes exists, but we do not yet know the degree of it; we know how much uric acid is secreted, but not how much has been formed in the organism.

According to F. Levison (*Zeitschrift für klin. Med.* 1894, p. 292) uric acid can not, like urea, be considered a metabolic product of albumin introduced through food. The secretion of uric acid in the body can not be considerably increased through introduction of large quantities of easily digested albuminates, neither decreased by hunger diet. It is generated through oxidation of the organized albumin in the body especially the nuclein, and its secretion is increased or decreased by all factors which produce a faster or slower destruction of the cellular elements of the body, especially the leucocytes, like disease, medicines, poisons, etc.

The production of uric acid in the body is in direct proportion to the number of leucocytes used up within that given time. So it is with the well known increase of uric acid of infants, it is directly proportional to the increase of leucocytes. Fleasburg found six hours after birth infarcts of uric acid in 14.3 per cent. of infants; twelve hours after birth in 56.2 per cent.; after twenty hours 94.7 per cent. These oscillations in uric acid are in direct proportion to the amount of leucocytes, which rises the first days after birth and then decreases until the fifth day, when it reaches the point where it has been the last month of fetal life.

Number of leucocytes in the last month of fetus 8,053; immediately after birth 19,600; twenty-four hours after birth 23,000; forty-eight hours after birth 17,500; fifth day after birth 8,500.

Gundoline examined the number of young, ripe (neutrophile) and over-ripe leucocytes and found:

	Leucocytes per sq. cm.	Young.	Ripe.	Over- ripe.
Last month of fetal life	8,053	1,013	556	6,458
Right after birth	19,600	4,000	2,352	12,348
Twenty-four hours after birth	23,000	5,520	1,840	15,640
Forty-eight hours after birth	17,500	3,695	1,575	12,250
Fifth day after birth	8,500	2,720	680	5,100
Nursing-age	12,908	7,598	833	4,477

This table shows the rapid transition of leucocytes into the over-ripe form. They can increase in pneumonia to 40-50,000 (Monti, Bergrun), though never in typhus.

Levison doubts the existence of leucocytosis in gout and ascribes the production of uric acid to retention by the kidneys (Garrod, Roberts).

The renewed activity in this whole question brought out a few publications about the metabolic changes in leucemia, which has so much in common with gout and which I report here only with the purpose to more fully exhaust the metabolic percentage of uric acid.

Kuehnau relates statistics of two cases. The leucocytosis in these cases was about constant at the beginning; the daily secretion of uric acid vacillated between 1.5 and 2 grams. This was succeeded by a period of increase of leucocytes which was followed by an increase of the daily secretion of uric acid. After this a rapid decrease of leucocytes set in, while uric acid even increased to 3.39 grams. This certainly gives basis to the apprehension that uric acid is formed through destruction of leucocytes.

The most exhaustive publication about leucemia appeared lately in the *Berl. klin. Woch.* by A. Fränkel. He found the marrow of the bone always diseased, the

spleen only sometimes enlarged. Fränkel's investigations of the blood of acute leucemia are the only ones thus far published. He found increase of the white and decrease of the red corpuscles, the leucemic character of the blood is based exclusively upon an increase of mono-nuclear cells of the character of lymphocytes, which had lost the ameboid motion, the multi-nucleated cells were present only in minimal quantity. The cartilages in some cases swell and are painful, the pain extends over the bone. Two cases which died from septic infection, showed with the appearance of the infection an immense decrease of leucocytes, which Fränkel attributes to leucolysis; with this leucolysis the general condition of the patient grew worse, which was partly due to this leucolysis, partly to sepsis. With the decrease of leucocytes the uric acid increased considerably, not only relatively to the present urea, but absolutely. The secretion of uric acid in leucemia can increase to five or six times the amount of the normal secretion. This publication again demonstrates conclusively that destruction of leucocytes is essential as regards the amount of uric acid secreted.

There are only a few micro-chemic investigations published, but those confirm the facts gained by experiment and investigation on pathologic specimens in regard to the origin of uric acid from leucocytes.

Neusser (*Wiener klin. Woch.*, 1894) found the number of leucocytes always decidedly increased, contradicting Levison, who denies any leucocytosis in uric diathesis. He observed the appearance of particular granules and formations of lumps within the protoplasmic zone, mostly in the immediate surroundings of the leucocyte nucleus which color black with the basic component of Ehrlich's triacid. They form perinuclear granulations roughly dentated, especially within the mononuclear large and small leucocytes, sometimes in polynuclear neutrophile and even in eosinophile cells, probably a forerunner of uric acid.

Neusser found these changes in gout, muscular rheumatism, asthma nervosum, chronic dermatitis, diabetes, neuralgias, migraine, vertigo and neurasthenia.

L. Heine (*Zeitsch. für phys. Chemie*, xxi, i) says nucleinic acid, unpaired, possesses very peculiar qualities, which disappear more or less in the paired combinations with albumin, and one is justified in thinking that formation and destruction of these combinations is a physiologically important process, which is connected with important functions of the nucleus. Liberfeld's experiments with Ehrlich's coloring demonstrates that in those conditions where a morphologic partition goes on, also a chemic dissolution of the nucleus constituents takes place, a splitting off of nucleic acid from albumin. Heine believes himself to have found that the essence of mitosis does not consist in a chemic dissociation of the nuclein bodies; these substances seem more to preserve their peculiarity as albumin combinations of the nucleic acid, only their physical grouping is modified in mitosis for the purpose of exact bisection.

In the above we have been able to demonstrate that the uric acid in the human body is generated by the decay of leucocytes, which have not reached their full physiologic development, that it is not a weaker oxidation of the albumin of the food, which latter always is oxidized, to urea. This destruction of leucocytes, for which Loewitt gave the name of leucolysis, is always preceded by a leucocytosis. Leu-

colysis is a chemic process which separates nucleinic acid from the albumin.

We proceed now to answer the second question.

What causes the necrosis in gout? The solution of the question as to the generation of uric acid has great practical importance, inasmuch as it tells us that without leucocytosis there is no leucolysis, without leucolysis there is no formation of uric acid, and that only food rich in nuclein increases uric acid. We know furthermore that in many other diseases formation of uric acid takes place within the blood without accompanying necrosis and gouty symptoms, and still the belief in uric acid as *causa peccans* is paramount; no discoveries, no reasoning is potent enough to unsaddle the uric-acid diathesis in the mind. Philosophy used to, and still, plays too big a rôle in our science, as long as it could not lay claim to be an exact science; but the practical results of our physiologic researches upon the recognition of morbid conditions and their treatment, have changed this also. There was so much we did not know that we had to make up for this apparent deficiency with some theory, which used to be labeled with a big name, sufficient to embrace a controlling part of the things which we do not know or know but little. This comprehension of a whole mass of vague ideas and fallacious conceptions, I might say a world of negatives within a seemingly positive name, for the time covered up this chasm in our knowledge, the habit to classify nothingness within something became second nature and we thought we were talking science when we generalized a whole lot of negatives in groups as hysteria, functional nervous diseases, etc. When I, a few years ago (*Med. Mirror*, January, 1893), demonstrated that these functional nervous diseases were built up on the same physiologic and pathologic basis as chronic rheumatism, a few called it ingenious, the great army of authorities and their blind followers shrugged at last their shoulders and ignored it. Yet I had the satisfaction to see that chorea was taken away from the functional nerve diseases and referred to the rheumatic diseases, and only lately Leyden declared that tabes was of peripheral origin, caused probably by the same influences which generate usually rheumatic disorders. The same conditions hold good with that devotion to the uric diathesis, it serves as a covering of the most incongruous morbid states and affiliated diseases which have a pathologic or physiologic relation whatever. Rheumatism and gout are—especially by the English school—thrown together in all possible modification of Greco-Latin nomenclature, rheumatic arthritis, rheumatoid arthritis, gouty rheumatism, goutic rheumatoid, meaning to say something which does not really exist. How grateful am I to Roentgen and his rays, which will establish in most of the cases the absolute absence of any urates! Rheumatism can be following gout as it follows any disintegration of tissue or necrosis through the disturbance of the lymph current (lymphostasis), but that is their whole affinity, with the sole exception of one etiologic fact, the want of exercise and indulgence, too much and too often, in all good palatable things. There the relationship stops. Rheumatism is essentially of delicate reaction upon atmospheric changes, vacillations in the humidity of the air; gout is not. In the long run of the disease we can have atrophy in rheumatism, in gout we have necrosis from the start. In rheumatism the destruction of leucocytes plays hardly any part, in gout it does

most conspicuously. In rheumatism we have agencies, probably ferments, of purely peripheral origin, like cold or auto-intoxication from lymphostasis with their tendency upon the connective tissue to produce fibrinous masses; in gout we have to deal with direct poisons, which destroy the leucocytes and liberate nucleinic acid. This is a fact proven by experience and experiment. Lead is demonstrated by experience to cause the same tissue necrosis with following precipitation of urates as gout. Ebstein produced the same phenomena by injection of chromic acid. We have only one pathologic process, which can rank with that of gout, I mean atheroma of the intima of the blood vessels. There we meet with the same tissue necrosis and following atrophy, only we find instead of urates calcium precipitated into the rough necrotic surface, probably caused by the surplus of calcium in the blood, which in the age when atheroma occurs is no more needed for the building up of the osseous skeleton of the body. Never did a scientist and prominent authority himself utter a more truthful word than Sternberg did when he said that nothing impeded the progress of science more than blind thoughtless following of so-called authorities. Bouchard injected 64 centigrams of uric acid per kilogram of living weight into rabbits, to investigate its toxicity and comes to the conclusion that we can never introduce into the veins of an animal more uric acid than in his first experiment (250 centigrams to 0.641 kilogram), since the doses of uric acid would saturate a quantity of water which of itself is toxic. Yet we meet with recent publications where the toxicity of uric acid in the uric diathesis is the cause of all kinds of auto-intoxications. If asked the cause of this intoxication we get again a big word for an answer, which is meant to say much, says nothing, the leucomains. We have harmless as well as noxious leucomains, but the main excrementitious poison of our intratissue respiration, the carbonic acid, which through strain in the parenchymatous lymph current stays too long in contact with the tissue cell, killing its ameboid function and provoking from the connective tissue in defense of the cell proliferations, never is alluded to.

We have seen in Fraenkel's exquisite observations that in acute leucemia the marrow of the bones is diseased, the epiphyses swollen and painful. The leucocytes do not reach their full ripe stage and fall to destruction without causing tissue necrosis. In gout we do not notice these changes in marrow and epiphyses. We have an acute feverish though a septic inflammation localized within certain places of predilection, cartilages, tendons, etc., where circulation is naturally slow. We must deduct from this phenomenon that in leukemia the undeveloped mononucleated leucocytes, which lost the ameboid motion, and with it their ability of development, decay in a place where the alkalescence of the tissue is so powerful as to neutralize the tissue-destroying ability of those agencies at once, which are liberated through the chemic act of decay. That is after they have passed their breeding places and reached the free current of the blood.

In gout it is quite different. There the destruction takes place in certain places, which show the effect of the chemic action of the destruction which has taken place there in tissue necrosis. As these places have a naturally slower circulation and the plasma there accumulated is limited, we have certainly to accept the consequences of the fact, that

the noxious agencies, which are liberated through the decay of leucocytes, remain in longer contact with the tissue, and as the alkalescence of the present plasma does not suffice to neutralize these agencies, they as a matter of course corrode the tissue, cause necrosis, and the uric acid, which originates at the same time, precipitates upon the rough necrotic surface. What is this noxious agent? It must be an acid, and as only one acid appears in this chemic process, the nuclein acid, it must be this acid. Nuclein acid dissolves living tissue if this is exposed to it. It remains to explain what causes the destruction of leucocytes in gout, why does this destruction take place in those places of predilection and cause that destruction and not within the blood, as it does in leukemia? In leukemia the destruction takes place owing to the innate weakness, the undevelopment of the leucocytes. In gout we meet the same mononucleated leucocytes, though not to the same amount. We can explain their presence through the etiologic fact that the habits of those persons, their irregular meals, taken too often and too much of it at the time, are bound to produce a more or less continuing leucocytosis, the hemopoetic organs are subject to permanent activity, the leucocytes are not given the time for full development and the organs of their production put them out in a decrepid, mononucleated condition. But nevertheless they would not decay before they reach the general current of circulation if they did not meet on their way there an agent which provokes their destruction already within the cartilage, etc. In lead poisoning they come into contact with this mineral poison; in those cases of gout, which are not due to lead poisoning, there must be another poison. What might that be? There is one powerful poison, produced through the intratissue respiration of our body. If the circulation is impeded and accordingly this poison instead of being rushed away is left in longer contact with the tissues and may and probably does cause destruction of leucocytes in gout on their way to the general circulation, that is probably carbonic acid.

Carbonic acid, produced in intratissue respiration, is ejected with certain leucomains from the parenchymatous cell to the surrounding lymph spaces and from there through diffusion or action of endothelium, or both, through the venous capillaries. A stasis within these lymph spaces of course impedes this action, the carbonic acid stays there longer and is allowed to exercise its toxic influence upon everything it comes into contact with, especially decrepid leucocytes. That in goutic patients we have lymphostasis owing to their want of exercise and overfeeding is certain, and can be demonstrated if the lymph current is accelerated through a laxative, which causes at once a mitigation of all symptoms of the gouty attack, and that the gouty attack takes place where there is already a natural disposition to lymphostasis is another affirming factor.

Intratissue respiration is without any doubt the most potent factor for preservation of the physiologic integrity of all our organs. A. Poehl (*Zeitschrift für klin. Med.*, 1894) of late made it the object of his investigations in connection with the effect of organic extracts, which he says, especially spermin, cause in dissolved condition, intratissue respiration, acting like a ferment. The products of regressive metabolism, the leucomains, he continues, are those nitrogen-holding products of regressive metamorphosis, which are oxidized into so-called intermediary products

instead of urea. The accumulation of these leucomains causes autointoxication; and the most common kind of autointoxication he declares is caused by reduced tissue breathing. Spermin, a nuclein found in testicles, ovaries, etc., has oxidizing power, but only in dissolved form; in presence of phosphates it turns insoluble, inactive. (Charcot-Leyden crystals.) In tissue which is passed by normal alkaline blood no insoluble phosphates can form, reduced alkalescence of blood is the essential moment of inactivity of spermin and its formation can be explained as follows:

Any nerve or muscle tissue if irritated decreases its alkalescence and can be brought to acid reaction, and as phosphates always are present the moments of spermin-phosphate formation with acid reaction are given. Under normal conditions no inactive spermin phosphates are found, because the passing normal alkaline blood prevents it. Reduction of the alkalescence of the blood favors its formation and continuing irritation of tissues can reduce the alkalinity of the passing blood, which again causes formation of inactive spermin. He thinks urea is a special product of aerobic tissue life and goes parallel with intra-organic oxidation and explains the vacillations of the production of uric acid, that it depends upon the circumstance whether the destruction of the nucleins proceeds in a more or less alkaline or acid medium. If this destruction takes place in alkaline medium the spermin will remain active and the oxidation to urea goes on normally, but if it takes place in an acid or reduced alkaline medium, then through splitting off of phosphoric acid insoluble spermin phosphate is found, which reduces the oxidation process and uric acid accumulates.

This is a very captivating and ingenious theory, only it does not hold good in gout. It may be the cause of neurasthenic troubles, but even then it would not explain the long duration of such chronic ailments, even if the formation of insoluble spermin were the cause the current of the blood would in less than no time remove it and replace alkaline reaction, and even if lymphostasis should be present enough alkaline plasma would pass through to reestablish the normal. Uric acid is not in gout increased through retention, but through hypoleucocytosis, which followed by leucocytosis produces first decrease, afterward excess of uric acid, not only relatively to the present urea, *but absolutely*. Uric acid, furthermore, is generated through decay of leucocytes and not a lower oxidation of food, which always is oxidized to urea. Another very important factor against Poehl's theory is the circumstance that the curative effect of spermin in those ailments, which he praises so highly because of intense and rapid effectiveness, fail to give other investigators the desired and promised results. We therefore sum up our answer to question No. 2 as follows:

The tissue necrosis in gout is caused by a poison, probably nuclein acid, sometimes lead; the uric acid in gout is generated by decay of leucocytes, which destruction is brought on probably through carbonic acid. The reduced amount of uric acid in the beginning of the gout attack is parallel with hypoleucocytosis, the following increase with leucocytosis.

Treatment.—If ever we succeed in establishing the true physiologico-pathologic basis of a disease, it will naturally be followed by the indications of a real physiologic treatment, and the adoption of the latter will culminate in its success in praxis. So it is here. The

treatment which I have built up upon the above facts has proved superior to any other and a success throughout.

Prevention.—We have to convince the patient of the absolute necessity to regulate his habits. Two light meals and one substantial one every day, almost to the minute, at the same hour. Never eat so much that you could not again sit down to the table and eat more. No cheese or eggs, no brains, sweetbreads, liver or kidneys; light wine, if any alcoholics. This will reestablish regularity in the periodic leucocytosis, and regularity in this act will again strengthen the hemoepoetic organs and enable them to turn out vital leucocytes. Passive and active exercise sufficient to agreeably fatigue the body, but never so much as to provoke exhaustion, this is especially to be avoided. Massage daily, not by a so-called professional masseur, but by a physician who makes this treatment a specialty. The professional masseur gives everybody the same general, more or less superficial, massage. This is good enough for a business man who substitutes this treatment for exercise, but it will never do where intratissue respiration has to be influenced. I do not mention this from personal motives, *pro domo*, because I limit my practice to this kind of work; I had to do it because I did not find satisfaction with the work of these masseurs. Especially the powerful muscle layers of the body have to be worked and emptied of their lymph down to the periosteum of the underlying skeleton, and in gout especially, those parts have to be well taken care of, which, on account of their retarded circulation are predisposed to localization of gout.

Alkaline mineral waters, if recommended, ought to be taken hot. The only effect of the lithia waters consists in their being substituted for alcoholic drinks, which still is a fact in their favor. I only mention here an experience I had with a patient whom I sent to Hot Springs, Ark. She suffered from rheumatic hemiplegia, but no one suspected her of being subject to lithiasis. Whenever she went there and drank the hot water, for the first few days she used to evacuate immense quantities of gravel. She drank for months lithia waters, *ut aliquid fiat*, without any effect. I ascribe this effect to the small proportion of alkali in those springs, which, especially if taken hot, approach more the real physiologic conditions. I recommend douches alternately with hot or cold water (Scotch douches).

Treatment of the attack.—We have to treat the attack locally, because gout is a local disturbance caused by poisons suspended in the blood, and generally to eliminate these poisons from the blood.

The general treatment has to be directed toward the change of the reduced alkalinescence of the blood and strengthening of the blood corpuscles. Adherents of the old school of course would forbid anything acid, fruits, salad, etc., on account of the alkalinescence of the blood. I am only glad in the interest of the welfare of these patients and of the promulgation of the principles of digestion, that they will never succeed in keeping the stomach from producing hydrochloric acid, they may envelop humanity in as much sweetness as the please. To strengthen the blood corpuscles we have in diluted hydrochloric acid a very good medium, it is an agreeable drink and can be taken oftener during the day. To remove the poison from the blood, we have only one way, that is a good old-fashioned bleeding, which may be repeated according

to the condition of the patient, especially if lead poisoning is apparent. Bloodletting should not be limited to the pocketbooks of our patients, it is a harmless remedy, as the removed blood is restored in a few days, and is the most powerful means of changing the condition and composition of the blood by its enormous influence upon the hematopoetic organs to more energetic and more extensive activity. The experience of our grandfathers, which praised this proceeding even in those persistent cases of chlorosis in apparently well nourished individuals, we know now to be based upon the fact that the bloodletting removes the numerous decrepid mononucleated cells and replaces them with more vigorous corpuscles. I can not make a plea strong enough for rehabilitation of this remedy, the interdiction against which I contemplate as one of those modern windmills, which have to be fought. Of course its use has to be left to the discretion of the physician.

To increase the alkalinescence of the blood we might apply the lymphagoga, which Heidenhain introduced. The extracts of crab-muscles and leech heads seem to be varying in their efficacy.

Of all the lymphagogas cinnamonic acid is the most reliable, the most rapid and the most harmless, but as the physiologic effect of all these medicines is connected with and based upon leucocytosis, I preferred to do without it, as just in gout too often repeated leucocytosis seems to be the main cause of the deficient development of leucocytes. Still, in cases where the kidneys or other organs are effected, which we can not reach by local treatment, lymphagoga could be the only way to increase the blood's alkalinescence at once.

The local treatment is the most important, and in its effects the most effective. We are accustomed to regard a surgical treatment of the local precipitation of urates, the tophi almost as sacrilege. They play the part of foreign bodies in our system, and each foreign body, if accessible, ought to be removed and we should thank Heaven in the interest of our patients, if there are any surgical means to treat their ailments. There is so much talked and written about dissolving these urates with lithium salts, piperazine and of late lysidri. They work very nicely in the reagent tube with water, but as soon as we take urine, the dissolving effect stops. How it works in plasma, I don't know; if these agencies are locally injected in a concentration strong enough to take effect, that the resulting chemico process causes a painful inflammation, which lasts almost two days. The only way to remove these tophi is curetting under asepsis, it ought certainly to be done in each case during the time no acute attack is apparent.

Another way to cut off an attack is the neutralization of the nuclein acid with a very diluted solution of bicarbonate of sodium. It is injected peripherally from the inflamed section hypodermically, and tenderly massaged over the whole part. It can be preceded by an injection of cocaine. My experience is that this local treatment is really abortive, it cuts off the attack within a day or two. Connected with these locally intended alkaline injections the same solution might be injected in larger quantities underneath the skin, certainly the best way to influence the alkalinescence of the blood.

As a matter of course the free action of the bowels is the first thing to be attended to in an acute attack of gout, it has a sudden effect upon the lymph motion

and through this accelerates the access of alkaline blood to the inflamed districts.

Our views of disease at present are in a stage of transition, the inherited slab bones are found to not fit anymore and if several diseases are discovered to present one identical pathologic phenomenon, they are thrown together heterogeneously as they might be. Loewitt observed what he calls leukopenia in rabbits with rapid sinking of temperature as soon as they were exposed to shock; another repeats the same experiment on turkeys, with the same results, finds leukopenia in neurasthenia (a totally arbitrary classification of morbid symptoms, which accompany many entirely different diseases) and says that leukopenia is the cause of neurasthenia, because we notice the same morbid fears there. Since excessive formation of uric acid has been discovered in many other diseases besides gout, Haig and others subject almost every chronic ailment to the uric diathesis, it has seemed to me therefore necessary to show that uric acid has no toxin effect and that its presence has directly nothing to do with the apparent disease. We have to go back to the generation of uric acid, to the poisonous noxes, which create uric acid, and there we find that gout is a disease *per se*, it has nothing to do with rheumatism or other diseases, we are able to distinguish it clearly from that whole mass of confused conception and substitute for its treatment a really physiologic basis.

THE USE OF THE CURETTE IN THE TREATMENT OF ENDOMETRITIS.

BY C. L. BONNIFIELD, M.D.

CINCINNATI, OHIO.

Endometritis, for the purpose of discussing the use of the curette in its treatment, is best divided into three varieties—catarrhal, septic and gonorrhoeal.

Catarrhal endometritis is the form of pelvic disease most frequently induced by improper habits of life, consequently the one most amenable to constitutional or medical treatment.

A large percentage of cases occur in unmarried women. In the society girl it is produced by the nightly exposure of the arms and a large portion of the chest, whereby the blood is driven into the interior of the body, congesting the uterus along with other organs; the tight corset, displacing the abdominal organs and interfering with the action of the heart and lungs; the numerous meals at irregular hours of stimulating and indigestible food, the position assumed in dancing and the exposure and lack of rest during menstruation.

In her less fortunate sisters, the school teacher and the shop girl, the constant standing serves as an efficient exciting cause.

Another cause, I deem of importance, is unsatisfied sexual desire. Genito-urinary surgeons tell us this is an important factor in the production of hypertrophy of the prostate, which is a condition in the male somewhat analogous to fibroid tumors of the uterus in the female. We all recognize the fact that this latter affection is a penalty frequently paid for celibacy. If it produce this graver result of persistent uterine hyperemia it is fair to suppose that it will also produce catarrhal endometritis.

The cause of the disease having been recognized, the proper treatment suggests itself. The faulty habits must be, as far as possible, corrected. If the patient

is anemic, iron, quinin and strychnin between, hydrastis and hyoscyamus or *cannabis indica* during the menstrual periods. An occasional mercurial purge is always indicated. While the symptoms are acute and exercise gives rise to pain, rest in bed should be enforced; later the patient's mind should be diverted from herself and her disease and healthful exercise in the open air, horseback riding, bicycling, etc., are of the greatest value. A change of climate, particularly a residence for some time at mineral springs, is beneficial. These measures faithfully used will cure many cases, and they should always be employed before resorting to any local treatment in the unmarried. I wish to protest against the growing tendency to curette every girl that has a little leucorrhoea and menstruates a day too long or with some pain.

If these measures fail the curette is indicated. It is much to be preferred to prolonged office treatment.

In married women the objection to local treatment does not exist, and in the majority of well-marked cases curettement is the appropriate measure.

It is true that a large number of this class of cases can be cured by office treatment. Drainage of the uterus secured by gauze, application of carbolic acid and iodine to the endometrium, bleeding the cervix, correction of mal-positions, etc., will in time effect cure, and there are cases where it is advisable to proceed in this way. Where existing disease of the heart or kidneys makes it unsafe to use an anesthetic, or where the patient will not readily submit to an operation, the gynecologist may prefer this method of treatment. To the general practitioner who desires to treat his own cases it will usually commend itself, for lack of operative experience makes an aseptic technique well nigh impossible for him to attain, and without there is some danger in the operation.

The severer forms of the disease can not be cured without curettement. Nor will curettement alone cure all of them, but curettement combined with such other local and constitutional measures as are indicated will.

It may be necessary to repair a lacerated cervix, or perform an anterior or posterior colporrhaphy, or both. Or an Alexander operation or suspension of the uterus may have to be done, for unless the circulation in the uterus can be restored to its normal condition, no relief of the symptoms will be permanent.

Septic endometritis usually follows abortion or labor at term, and this phase of the subject will be discussed by my friend, Dr. Mitchell; but it may follow the introduction of an unclean sound or operation upon the cervix; it may also develop during menstruation by infection from germs existing in the vagina. The curette with antiseptic irrigation should be used as soon as the diagnosis is made. Where there are stitches in the cervix they should be removed. If this treatment is instituted sufficiently early, it will generally give relief and obviate the necessity of later resorting to more dangerous surgery, that, even if successful, leaves the patient mutilated.

Gonorrhoeal endometritis when seen in its incipency can usually be cured by intrauterine irrigation and gauze packing, provided the disease be vigorously attacked at the same time, wherever else it may have found a lodging place, in the vagina, the urethra, the glands of Bartholin.

But if it has been in progress some time when it

comes under the physician's care, or if after a faithful trial of these measures it fails to yield, curetting is indicated, no matter whether the symptoms are acute and alarming or chronic, the only contraindication being a palpable accumulation of pus in or around the appendages. When this condition exists the pus should if possible be evacuated through Douglas' cul-de-sac; if this can not be done an abdominal section should be made for its removal, either operation being immediately followed by curetting.

Technique.—We are to have a special paper on this branch of the subject, so I touch very briefly on but one or two points. Before curetting, the uterus should always be thoroughly dilated. For this purpose I prefer the Goodell-Erlinger dilator and always work it with the hand, never with the screw, and make the pressure intermittently, as does Dame Nature when she dilates the cervix in parturition. Believing that in this way the cervix is less apt to tear, and if it should do so the force can be released before the tear progresses far. The sharp curette is the only instrument of any value in these cases. The sizes needed are the smaller to enter the horns of the uterus, the larger to more rapidly and with greater certainty go over the walls in their entirety. The curetting should be continued till at every point the operator can feel firm tissue and hear it grate under the instrument. The uterus should now be mopped out with a strong antiseptic, dried with absorbent cotton and packed with iodoform gauze tight enough to prevent any oozing of blood. In catarrhal endometritis this packing may be allowed to remain for from seven to ten days if there be no elevation of temperature. In septic or gonorrhoeal cases it is wiser to remove it in forty-eight to sixty hours, irrigate the uterus and loosely repack it. If the tight packing cause painful uterine contractions they can be relieved with codeia and hyoscyamus. Patients who have been curetted for endometritis should be examined a few weeks later, and if there is still some discharge issuing from the uterus, the endometrium should be treated with iodized-phenol twice a week. If this does not give entire relief, the curetting should be repeated. In some cases even the third operation is required. The accidents incident to the operation are laceration of the cervix, perforation of the uterus and rupture of an abscess adjacent to the uterus.

Laceration of the cervix can usually be avoided by following the method of dilatation indicated above. If a laceration of any extent take place it should be sutured at once.

Perforation of the uterus is an accident that has happened one or more times to almost every operator of experience. A soft cervix from which the vulsellum is inclined to tear, would put the operator on his guard. In two cases in which I have met with this accident I noticed afterward that the cervix was unusually friable. One of the cases had never been pregnant, the other had borne two children, the youngest of which was 16 months old. Both recovered without untoward symptoms. When the uterus has been perforated it will not be irrigated or swabbed out with strong antiseptics. It may be wiped dry with sterile absorbent cotton, and packed loosely with iodoform gauze. If the uterus was pretty thoroughly cleaned out before the perforation was made and the operator recognizes what he has done recovery is to be expected.

If one has good reason to suspect he has ruptured

a pelvic abscess into the peritoneal cavity, the proper procedure is an explorative abdominal section, and if his suspicions prove true he will flush and drain.

DISCUSSION.

Dr. PALMER—I do not know that I ought to speak upon this question, since I have designed two of the instruments referred to tonight, the dilator and the curette, and it might be too personal for me to speak upon the matter just now. I will, however, make a few remarks upon the propriety of using the curette.

There can be no doubt about the curette being an exceedingly valuable instrument. It is valuable in many cases of abortion, those cases, for instance, which we technically call "incomplete" abortions, in which some portion of the ovular tissue is retained, and these remnants give rise to trouble, sepsis and hemorrhage. Now, when the curette is used under such circumstances the instrument should be as large as can be put inside of the uterine cavity. The cervix is generally soft and relaxed and a larger sized instrument will usually go in than one would think. For an abortion which occurs at the most common time, some time along about the third month, the curette should be somewhat scoop-like in shape, smooth, blunt and not sharp. What we want to do is to remove any of the ovum that is retained, all the retained forming placenta and the decidual structures, but none of the genuine mucous membrane. In other words, we do not want to use any force but gently pass this kind of a curette from the fundus down, taking perhaps more care in going over the posterior wall and the horns of the uterus. But we never ought to use it with any degree of severity and never when it is sharp, as we ordinarily do employ the curette for certain gynecologic affections.

About twelve years ago the subject of the employment of the curette came up before this society at a meeting held at my house. I think I was the only one then who advocated the use of the sharp curette in gynecologic practice, and for this I was criticised pretty sharply. Now almost everybody employs the sharp curette. The dull curette, as a rule, is employed in obstetric and the sharp curette in gynecologic work. It is my practice ordinarily to dilate the uterus when the curette is employed for gynecologic purposes, but, as I have said, this is not necessary when the curette is employed for obstetric purposes. I am in the habit, usually, of washing out the uterus with the reflux tube before curetting. Before I stuff the uterus with some antiseptic gauze I generally again wash the cavity out with some hot antiseptic fluid.

Dr. STARK—In the first paper presented this evening a statement was made, that the further advanced in pregnancy the less is there a necessity for the use of the curette, and the essayist attributed the cause for this to the fact that the muscular structure of the uterus had become hypertrophied and its expulsive power had become thereby increased. I am inclined to take exception to this view. I believe the greater necessity for the curette early in pregnancy than late may be attributed to two reasons. During the first two months of pregnancy the ovum is covered over its entire surface with chorionic villi, and the attachment to the uterus is so extreme as to prevent the separation of the chorion in the expulsion of the ovum. I have seen ova expelled, and have no doubt others have, whose outer covering consisted only of the amnion. Another reason is that you do not have the same changes at this period which takes place later, namely, fatty degeneration of the sub-decidual stratum. In many instances also, the decidua vera is thrown off in large pieces, after seemingly the whole ovum has been cast off. That is, where the ovum is surrounded with the chorionic villi, you subsequently have clots expelled containing large pieces of the decidua vera, and this is due to its primary non-separation. And I believe, also, that we are able to cure many cases of true septic endometritis by the use of the curette. The reason for this is that we

remove the source of the lymphatic inflammation, in the same manner as we are able to cure a lymphangitis of the arm by disinfection and drainage of an infected hangnail or felon. In regard to the treatment of gonorrhœal endometritis by the use of the curette, I am thoroughly opposed to it. I do not believe it is scientific. I think the very fewest of such cases are cured. We all know that men who have had gonorrhœa come to us years afterward and complained of a slight gleet discharge in the morning, and if we examine the discharge it is free of gonococci; but, if we pass a sound and repeat the examination in a few days the discharge is very often purulent and full of gonococci. I remember when I was studying in Breslau I saw a case in which a woman gave birth to three children, each born with ophthalmia neonatorum. The lochial secretions examined were full of the gonococci. After the lochia had subsided, there were no gonococci. It has furthermore been shown that the discharges from the uterus just prior to and shortly after menstruation contain gonococci, while in the interim the secretion is free from the gonococcus. The mucous follicles of the uterus extend between the muscular bundles, and down there you will also find white corpuscle infiltrations which contain the gonococci, and make it impossible for the curette to remove the infection. All you can do with this procedure is to stimulate the germs and further their growth. And that has been my experience in practice, too. I would never think of curetting a case of acute gonorrhœa, and the chronic cases which I have curetted were worse afterward, and in one I know I induced a purulent salpingitis.

Dr. PALMER—In those cases, in which you did not think you got good results, was there any perimetritis?

Dr. STARK—Not evident, but perhaps there was some latent perimetritis. I believe there was some latent trouble there beforehand. But I am referring to cases of pure and simple gonorrhœal infection. After the curettage and other associated treatment the discharge is more profuse and the gonococcus is developed into activity and multiplies.

Dr. E. W. MITCHELL—Dr. Stark is correct in saying that the changes which take place in the decidua and in the development of the placenta are the chief factors in the more thorough separation of ovum and secundines as pregnancy advances. In speaking of the greater development of the *musculature* I had in mind the more prompt and thorough evacuation of the contents. I purposely said little about the technique, as Dr. Jones was to consider that subject especially.

I must confess that I have not been able to clear out the uterus with the fingers with the facility some of the gentlemen claim, although I have tried it many times.

SPECIFIC MEDICATION IN TUBERCULOSIS OF MAN AND BEAST.

Written for the Mississippi Valley Medical Association at St. Paul, Minn.

BY PAUL PAQUIN, M.D.

ST. LOUIS, MO.

Specific medication in specific maladies is now recognized as the objective point of medical research. Whatever the means employed, the course of events and the processes to that end, the object sought is the all-important question. The men who have, or do now, play a rôle in the endeavors of medical science, no matter how divergent their opinions may be, no matter how inharmonious their relations, results and manner of work, are only instruments for the accomplishment of a great task, and their personality and differences, as in all processes of evolution, are insignificant and inconsiderable as compared with the achievements sought for the benefit of mankind. Conflicts of intellects are as essential factors of medical evolution as are conflicts of intellects in other

spheres of civilization. As long as carried on in the broad, manly spirit that characterizes the man of truth, evidence and knowledge of cause and worth they will always receive attention from thinkers and honest delvers, and in the end must command respect, whatever may be the temporary influence of selfishness, greed, malice, commercialism and speculation, in the ranks of the original investigators or their followers and imitators, unfortunate conditions which of late are not wholly absent factors in the dissensions and retarding circumstances in medical science.

The study of the effect of antitoxin on the tuberculous phenomena in human beings, leads us back to the active principle underlying immunization, to-wit: the special agent which is itself curative to a degree, by virtue of its power to provoke the formation of a defensive force in the system. When Koch declared, publicly, for the first time, that the toxins produced in the culture of the bacilli of tuberculosis had a certain specific effect on the lesions of lupus, he did not explain what existed in tuberculin that could cause the modification. In fact, it seems that it was not then understood. We know now that it was because the tuberculin (or bacilli culture toxin) used by hypodermic injection in the patient suffering from lupus, provoked the formation of the antagonistic agent in the blood and tissues of the individual, which is now known as antitoxin, a name which is the general designation of nature's own remedy in the cure of microbial maladies. Tuberculin then is, to a degree, capable of modifying certain forms of tuberculosis, because it forces the affected organism to produce a certain amount of tubercle antitoxin. The inconvenience of it, from a practical standpoint, consists chiefly in the more or less severe reaction which follows the injection in the already seriously ill patients, and in the fact that in certain stages of certain forms of tuberculosis, particularly of the lungs, it seems to hasten the breaking down of tissue. It is claimed now that tuberculin, under other names, brought forth through the efforts of the Klebs school, may be so modified as to be free from the poisonous principle or principles. This theory seems supported by numerous animal experiments of Klebs, particularly in guinea pigs. Series of these have been published, and if we are to credit them as the reputation and scientific standing of the learned German in this country suggests, tuberculin, under its new name, deserves careful consideration. But if devoid of toxic principles, modified tuberculin (whether named tuberculocidin or antiphthisin) as curative or immunizing agent is not free from grounds of criticism involving the very structure upon which the modifiers of Koch's original discovery have sought to erect a school of therapeutics in the treatment of tuberculosis. In the first place, the only thing that science can possibly suggest as curative in tuberculin is its very power of provoking the formation of antitoxin in the affected and thereby a degree of immunity. Now what is the agent that forces nature to produce this defensive power? It is precisely the principle that *causes poisoning*, the principle that causes the fever and destruction, without which deleterious effects there would occur no demand on the injected body for the production of a defensive force. So it is that, notwithstanding the numerous animal experiments of Klebs (denied or not very well supported by other experimentalists) which seek to establish positively and definitely the therapeutic value of modified tuber-

culin, we find ourselves compelled to doubt their efficacy. In these days, when the ultra-progressive physicians clamor so loudly for experimental evidence in animals, of results obtained in man before accepting the latter, it would seem that the apparently brilliant results of Klebs in experimental tuberculosis would settle the fact that antiphthisin is indeed almost a perfect curative preparation. But unfortunately the results in man, except under the direction of the originators and controllers of the remedy, do not support the claims of the experiments in guinea pigs, as numerous and as thorough as they are pictured, and upon which I do not wish to reflect discredit.

On the other hand comes numerous reports by numerous physicians, abroad and on this continent, in which is proclaimed the value of sero-therapy in tuberculosis, but which fail to support their claim by animal experiments, fully, in all the physiologic and pathologic details that are demanded by the profession, and yet they bring forth proofs of unmistakable recoveries of tuberculous patients. Not one of the experimentalists and investigators abroad and in America has succeeded in proving, with all the delicate niceties of Klebs in his work, that antitubercle serum cures tuberculosis in man because it positively does so in guinea pigs or other small animals. Noting the definite and positive results in human beings, they have seemingly neglected the animal experiments which are today demanded as a crucial test that serum can cure tuberculosis in man. But if apparently neglected, let me say to you that the laboratories interested in the question have not been idle. From the humblest to the greatest, there has been conducted experiments for a long period on this very point, and if the workers in that field are few who have dared to publish results and pronounce them reliable, it is not because of dearth of them, but because they realize the exceeding delicacy of the work and the numerous fallacies and deceptions that follow apparently proven problems in laboratory investigations concerning tuberculosis. The unequal sensitiveness of guinea pigs and rabbits to tuberculosis and the tox-albumin of the germ structure, the excessively rapid development of the tuberculous phenomena in some of them when inoculated, have been factors which have made curative measures uncertain and the results often vague and valueless. It is not true that one can always interpret properly the results of any form of treatment in experimental tuberculosis in small animals, and apply them to man as a reliable guide in therapeutic expectations. This claim which the profession wants demonstrated before accepting sero-therapy in tuberculosis is made by the rash or inexperienced, not by the careful and conservative, who have delved the longest in the problems in question.

Experimental tuberculosis in the guinea pig and accidental tuberculosis in man, so far as the nature and effects, locally and generally on the system, and the rapidity and fatality of their development are concerned, offer very different conditions to deal with in treatment, which should not be forgotten by those who must have animal experiments today to confirm the assertion of a competent physician that a man who has been cured a year ago is really cured.

However, animal experiments are indeed a necessity in the prosecution of the task undertaken by several to demonstrate the value of serum in the treatment of tuberculosis. The results thus obtained, both

positive and negative, are scientific beacon lights of great importance—indeed indispensable, both with respect to the immunization processes, and in the domain of therapy.

My own very imperfect work in the study of tuberculosis dates back several years, and my first efforts in the line of therapy in experimental tuberculosis in small animals began during the period of the furore that followed Koch's famous pronouncement on the action of tuberculin in tuberculosis. With plenty of material, I carried on at the State University of Missouri, tuberculin treatment of several series of guinea pigs and rabbits for a long period, with indefinite, unreliable results, although fruitful in the varied information gained in so-called experimental medicine.

My experience with serum in experimental tuberculosis is much more recent, and was almost concomitant with tests of the same nature in man. Without facilities, the small animals inoculated with tuberculosis and afterward treated with serum were very few until this year, when several series have been used in different experiments, many of which are still in progress.¹ For the purpose of this occasion I shall mention, in figures only, the results obtained to date with serum in man and beast.

In guinea pigs 10 per cent. of the subjects inoculated with tuberculosis and then treated with serum from horses immunized by the use of only pure tuberculin were saved; rabbits, by the same treatment, 8 per cent. This was early in our experiments and indicated a meagre therapeutic value in serum—since, we have produced serum of much greater potency by using not only tuberculin in producing the immunity of the horse but also the tox-albumin of the dead virulent bacilli and even living cultures, as will be seen further. Experimental tuberculosis under various circumstances was arrested with this serum in from 25 to 55 per cent. of cases, according to stages and lesions. In man the results of sero-therapy in 226 cases of tuberculosis, reported with sufficient details to form a fairly accurate judgment, were as follows:

PULMONARY TUBERCULOSIS.		Number of cases.
Class 1.	Destructive Bronchopneumonia and cavities	37
Class 2.	Destructive Bronchopneumonia without recognizable cavities	66
Class 3.	With diffuse Febrile Pneumonia with or without a destructive process	19
Class 4.	With diffuse Non-Febrile Bronchopneumonia with or without destructive cavities	19
Class 5.	With circumscribed Febrile Bronchopneumonia	35
Class 6.	With circumscribed Apyretic Bronchopneumonia	13
	Diagnosis not reported clear enough for classification	32
	Hip Joint Tuberculosis	2
	Laryngeal Tuberculosis	1
	Ovarian Tuberculosis	1
		226

In every one of these cases the diagnosis was verified microscopically. During the treatment of these 226 cases the following results obtained:

	In-creased	Un-changed	De-creased	Not Recorded.
Effect of Serum on Fever, Subsided, 60; Reduced, 56; Stationary, 26				84
Effect of Serum on Night Sweats, Ceased, 69; Unchanged, 17				140
Result of Serum on Weight	125	15	27	59
Result of Serum on Strength	154	9	21	39
Result of Serum on Appetite	114	15	—	—
Effect of Serum on Local Signs, Disappeared, 46; Mitigated, 58; Unchanged, 29				94
Effect of Serum on Tubercle Bacilli, Disappeared, 40; Reduced, 103; Altered, 7				76
Effect of Serum on general well-being, Exclusive of 40 cures, Improved, 145; Unchanged, 9				32

¹ The report on these will form the basis of a paper which I shall have the honor to read before the Chicago Medical Society, within short period. In this paper scientific details shall be given.

Number of recoveries that seem complete and permanent	40
Number of apparent recoveries with existing lesions in statu quo	3
Number of improved, capable of performing usual duties.	41
Number of improved to a lesser degree	69
Number of deaths reported	32
Number of cases disappeared from observation or under various treatment	41
	226

As to pulmonary cases, the extent, stage and importance of the conditions at the beginning of treatment were as follows:

In class No. 1 there were 20 cases in advanced stage; 3 in early stage.
 In class No. 2 there were 33 cases in advanced stage; 6 in early stage.
 In class No. 3 there were 12 cases in advanced stage; 0 in early stage.
 In class No. 4 there were 9 cases in advanced stage; 0 in early stage.
 In class No. 5 there were 12 cases in advanced stage; 3 in early stage.
 In class No. 6 there were 7 cases in advanced stage; 1 in early stage.

⁹³ ¹³
 Unclassified accurately enough for satisfactory description, 115. These ranged between the first and third stage of a variety of classes.

Now as to the immunization process and the necessity of measuring the antitoxic value of serum in units, as for diphtheria antitoxin, as it is asserted Maragliano gauges the serum he uses.² I shall, only touch upon these points here. First: Immunization of the horse or other animal, is produced more or less completely by injections of tuberculin, and intensified by injections of tox-albumins and may be still exalted by injections of living cultures in the circulation; the whole period of daily or alternate daily injections covering three to six months, sometimes more. The less natural immunity an animal possesses, the greater the value of the antitoxin produced by artificial immunization. The antitoxic value may be measured by the physiologic neutralizing power of a given quantity of immunized serum on a toxic dose of tuberculin and tox-albumin in a given weight of guinea pig. Notwithstanding assertions to the contrary, among scientists considered authorities, and the very flattering comments of the American medical press thereon, the measuring of the value of therapeutic serums is not yet as reliable in practice as is that of diphtheria antitoxin. Among the causes which vitiate the application of Behring's law in tubercle antitoxin is the fact that healthy guinea pigs of the same weight respond differently to a given dose of tuberculin and tox-albumin of a given culture, and consequently the very basis of unit measurement is not absolutely uniform. On the other hand, the unit measurement has little practical value as a guide in dosage in therapeutics, because of the very numerous different forms of tuberculosis, the lesions present, the complications, the susceptibility of patients, and the more or less pronounced general effects on various important systems of organs in the affected, which are not subject to neutralization by tubercle antitoxin.³ The unit of measurement, however, is desirable and should be in vogue as far as it is practicable and no pains should be spared to render it more thoroughly reliable and useful, if for no other purpose than that to establish a standard of defensive power as uniform as possible. This year's series of animal experiments includes researches on that line and if I have been slow in using the facts accumulated and marking the bottles of our serum with a unit measurement, it is because no one realizes more fully than I do the uncertainty of experimental work in tuberculosis and that I must back my conclusions with a voluminous list of reliable results, which the critics of competence may duplicate and the pretenders in medical science can not

refute successfully by mere quibbling or disputing statements, malicious reflections, or meager and untrustworthy experiments.

Foreign investigators assert the reliability of their unit of measurement. As yet the assurances have not been confirmed by other than assistants of the originators of the systems, although our American medical press has with avidity accepted their statements on this point, as on all others, as being infallible, granting to investigators of our own country much less comfort, even though they present equally good results.

The earlier treatment is begun the better the chances of recovery. It is essential, therefore, that we leave nothing undone to advance our knowledge of the earliest diagnostic signs of tuberculosis, in order that we may begin treatment very early when most cases may be saved and that we leave no stone unturned to increase the power of serum.

Anti-tubercle serum is positively curative and has passed the experimental stage, but it is far from perfect. In our reports we respectfully submit the good, bad and indifferent results. The basis of the reports are on file in our office and subject to the scrutiny of any honest physician, just as we open to him every department of our laboratories. From the experience of others and my own, it will be observed that only a relative number of tuberculous patients can, with our present knowledge of tuberculosis and anti-tubercle serum, be treated successfully. The very fact that many cases of different kinds have been cured by the exclusive use of serum in bad climates proves its curative properties. If it does not succeed it is because of existing conditions such as intolerance to serum injections of any kind, which is very rare; general destruction of physiologic equilibrium beyond repair; incurable lesions; mixed infections, etc. As to mixed infection, I am glad to say that a serum specially adapted to arrest mixed germs is being prepared, and already we have flattering results.

SOCIETY PROCEEDINGS.

Chicago Pathological Society.

Regular meeting November 9, 1896.

Dr. JAMES B. HERRICK, President, in the Chair.

Dr. ARTHUR DEAN BEVAN read a paper on

CAUSES OF OBSTRUCTION OF THE COMMON BILE DUCT.

The following is a synopsis: The subject of gall bladder and gall duct surgery is of recent development. In 1867 Bobbs of Indiana first performed cholecystotomy; in 1882 Langenbuch made the first cholecystectomy; in the same year Gaston suggested cholecystenterostomy and demonstrated its feasibility by experimental operations on dogs, and in 1889 Terrier performed the first anastomosis between the gall bladder and the small intestine. In 1890 Courvoisier added the last of our present list of operations on the bile tracts, choledochotomy. In the last six years the pathology and surgery of the gall tracts have been carefully studied and worked up, and we are now in a position to draw conclusions approximating the truth.

In the development of this work many men have taken part. Among those who have done much for this new field of surgery should be mentioned Lawson Tait, Courvoisier, Riedel, Czerny, Murphy, Fenger, Merrmann, Terrier, Heddaeus, Kehr, Sandler, McGraw and Mayo Robson. The work of these men has gained for the surgery of the bile tract a recognition among standard surgical procedures. As in any line of surgical work, this work rests upon a careful study of the anatomy, the physi-

² These points are also part of the paper I am preparing for the Chicago Medical Society.

³ Serum produced by immunizing the horse with the complicating germs usually found in the lungs in pulmonary phthisis has proven very efficacious in mixed infections.

ology and pathology of the structures involved, and of a careful analysis of the clinical histories of cases. It is not my intention to weary you with a review of the anatomy and physiology of the bile tracts, but I would desire to emphasize the fact that in no field of surgery is this elementary knowledge of more value to the diagnostician and the operator than here; a knowledge of the pathology of the conditions which demand surgical interference is no less necessary; this knowledge has grown with the development of the surgery of the bile tracts; a thorough knowledge of the anatomy, physiology and pathology is requisite, therefore, to the correct interpretation of the clinical evidences submitted by an individual case; the pathologic conditions which may interfere with the normal functions of the bile tract are many, and it is to this point, and especially to the causes of obstruction of the common duct, that I desire to call your attention in this paper, and it is in this line that I would ask that your discussion be directed.

To no one does the practical surgeon turn more frequently for instruction than to the pathologist; the findings of the postmortem room are the proofs of the correctness or error of his diagnosis and practical work. It is usually an easy matter to make the sweeping diagnosis of obstruction of the common duct. It is, however, often difficult or impossible antemortem to diagnose correctly its exact cause. For instance, in one list of reported operations for cases diagnosed as obstruction of the common duct, more than one-half were shown by laparotomy to be due to other conditions. My own limited work has curiously emphasized this point, and has led me to search rather carefully the literature with the hope that a careful study of the pathologic conditions found postmortem and by laparotomy, together with the clinical histories of the cases, might lead to a better understanding of the subject, to more accurate diagnoses and to fewer unnecessary operations.

As a basis upon which to discuss the broad question of the causes of obstruction of the common duct, let me report briefly some cases of common duct obstruction, each one illustrating a different type, which have come under my own observation. These cases show the difficulty of making an accurate diagnosis of the cause of the obstruction.

Case 1.—An Italian of 65, referred to me by Dr. Coolidge. Intense jaundice of six months' standing, frequent attacks of colic, intermittent chills and fever, pain over epigastric region; on pressure some sense of resistance, but no distinct tumor. Diagnosis: Probable obstruction of common duct by stone. Operation at Presbyterian Hospital, assisted by Dr. Coolidge. Found carcinoma of head of pancreas, atrophied gall bladder, no stone. Abdomen closed, patient recovered from operation; died some months later from carcinoma.

Case 2.—A woman of 35. Intense jaundice of four months' duration; previous history of frequent attacks of colic, no history of having passed stone. Intermittent rigors and fever. Enlarged and easily palpated gall bladder. Operation at St. Elizabeth's Hospital; abdominal incision, exposed gall bladder, distended, aspirated it; contents clear, glycerin-like fluid, about half a pint; as the last of this fluid was drawn out a sudden rush of pure bile came out of the needle with some small fragments looking like ground coffee; bile tracts examined, no stone found. Several very large lymphatic glands in front of common duct larger than the end of my thumb; these were tightly bound down between the folds of the gastro-hepatic omentum and produced direct pressure of common duct. Gall bladder was stitched to abdominal wound and drained; bile flowed very freely from fistula, jaundice disappeared, temperature became normal and patient improved greatly; later a cholecystenterostomy with Murphy's button was made by my colleague successfully. The pathology of this case is uncertain, but I introduce it here to show the possibility of obstruction of the common duct by pressure of enlarged lymphatic nodes in the gastro-hepatic omentum.

Case 3.—A case at St. Luke's Hospital in which I was associated with Dr. L. L. McArthur. A woman of 35; repeated attacks of jaundice, no clear history of colic, last attack of jaundice has persisted for three months, slight temperature, general condition fair; physical examination negative. Operation by Dr. McArthur revealed no stone, normal gall bladder; a firm smooth mass in head of pancreas, which we believed to

be carcinoma, although it did not feel like one. Cholecystenterostomy with Murphy button, recovery and improvement, disappearance of jaundice, subsequent history makes diagnosis of carcinoma improbable. Dr. McArthur and I now both believe the case to be one of obstruction of the common duct by pancreatitis.

Case 4.—A woman of 23, referred to me by Dr. Frankenthal; history of repeated attacks of colic and jaundice; intermittent temperature, pain over epigastrium. Diagnosis: Obstruction of common duct probably due to stone. Physical examination negative. Operation at St. Luke's Hospital. Gall bladder normal; in front of common duct an atheromatous cyst three and a half inches long and one inch in diameter, between the layers of the gastro-hepatic omentum and winding over the right edge of same into the foramen of Winslow. With great difficulty the cyst wall was dissected out entire; wound packed with gauze and tube. Recovery normal; left hospital at end of four weeks; jaundice and pain disappeared. This is a most interesting and rare case; I find the only one on record of an atheromatous cyst producing obstruction of the common duct, although Wiedel reports a case of an atheromatous cyst in the gall bladder. There is some question as to the pathology of the condition, for the section of the cyst wall shows no epithelium, but the gross appearance of the cyst and its contents were typical of atheromatous cyst, and a careful examination excludes echinococcus and does not furnish positive proof of tuberculosis.

Case 5 is a postmortem made at Leipzig by Birch Hirschfeld, which I had the opportunity to examine; the patient had died of cholemia. The examination revealed obstruction of common duct due to syphilitic gumma.

Case 6.—A man of 60; repeated attacks of jaundice and colic, remittent slight elevations of temperature, pain over epigastrium; referred to me by Dr. Herrick, who made the diagnosis of obstructive jaundice, probably stone. Operation at Presbyterian Hospital. Gall bladder very small; stone in common duct, freely movable; common duct incised, stone removed, no other stones found; could not close duct with suture, so drained with rubber tube and gauze; recovery uninterrupted; bile flowed through tube for nine days, then ceased and evidently now flows into duodenum. Jaundice has disappeared. Pain has ceased and patient has apparently made a complete recovery.

Here we have in these six cases six different and distinct pathologic conditions of obstruction of the common duct. In reviewing the literature I find many others. Grouped together I find that obstruction of the common duct may be due to:

- 1, catarrhal jaundice; 2, gallstones in common duct; 3, carcinoma of the duct; 4, stricture; 5, sclerotic pancreatitis; 6, gumma; 7, hydatids in duct; 8, ascaris, seven cases reported; 9, pressure from stone in cystic duct; 10, enlarged lymphatic glands by pressure; 11, pressure from extramural tumors: benignant; atheroma, papilloma, papillomyxoma; and malignant; sarcoma and carcinoma; 12, pressure from inflammatory exudates; 13, adhesions producing flexures of the duct; 14, tuberculosis, one case reported.

I have grouped together all the causes of obstruction of the common duct reported in the literature to which I have access. Many of these causes are extremely rare, but the very number of possible causes shows how difficult it is to make a positive diagnosis before operating. The common causes of course are catarrhal obstruction, stone and carcinoma. In many cases it is not difficult to distinguish between these conditions and yet it has been impossible to make an absolute diagnosis in the majority even of the cases submitted to operation, as shown by the cases collected by Greig Smith, in which thirty-five laparotomies for suspected stone showed in eighteen cases obstruction due to other causes.

DISCUSSION.

Dr. D. W. GRAHAM—There is one cause of obstruction of the common duct mentioned by Dr. Bevan which has lost much of its importance, as we shall see if we compare the literature of today with that of twenty or thirty years ago. I refer to gastro-duodenitis. While no doubt a few of the milder cases of jaundice are still properly attributable to this cause, gastric disturbance accompanied with jaundice even though mild and transient, which were formerly ascribed to gastro-duoden-

itis, are today properly counted as due to the passing of gallstones through the common duct into the intestine.

Dr. HEKTOEN—Attention may be briefly directed to chronic biliary obstruction due to chronic cholangitis following acute cholangitis developing in close connection with typhoid fever. The gall bladder has been shown by Fütterer and Chiari to become a reservoir for typhoid bacilli in typhoid fever. The bacilli may remain in the bile long after subsidence of the fever. The routine bacteriologic examinations during postmortems made the last two years or so of typhoid fever patients have confirmed these statements. Cases of suppurative cholangitis and cholecystitis have also been described after typhoid fever. Not long ago I made a postmortem examination of a woman for Professor Henry M. Lyman. Some years previous to death she had an illness diagnosed by Professor Lyman as typhoid fever; toward the end of the attack there developed jaundice and pain in the region of the gall bladder. Since then she suffered from chronic jaundice, dying from hemorrhage from a gastric ulcer, after having presented for a time the bone symptoms of osteomalacia, which was verified by the autopsy. In this case there was a dense fibrous peri-cholangitis and -cystitis, the bile ducts being greatly narrowed and practically occluded. The liver contained biliary retention cysts and was quite green in color. General jaundice was present.

Dr. SAMUEL H. FRIEND read a paper on "Investigations upon an Umbilical Origin of Peritonitis."

Dr. LEMKE presented a paper for Dr. Dysart on
THE ACTION OF HUMAN SERUM UPON TYPHOID BACILLI; A CLINICAL STUDY.

Dr. Lewis R. Dysart, late resident physician of the Cook County Hospital, has made a clinical study of the action of human serum upon typhoid bacilli, the more important results of which I have the honor of communicating to the Society, in the absence of Dr. Dysart, who has gone to Mexico.

The majority of the tests were made by making an emulsion of typhoid bacilli in a drop of water upon a glass slide; three or four drops of blood were then obtained upon a glass slide, and by touching the blood with a loop of platinum wire the serum which collects on the outside of the drops was transferred to the emulsion of typhoid bacilli, with which it was thoroughly mixed. Care was taken that the bacilli were thoroughly emulsified, so that no clumps were present before the addition of the serum.

A cover glass was then placed over the emulsion and this examined with an oil immersion; hanging drops were also made in a like manner. Other tests were made according to the methods of Professor Pfeiffer, which consists in adding blood serum to an emulsion of typhoid bacilli in a test tube and noticing the formation of clumps, as seen by the microscope, and the precipitation of the bacteria to the bottom of the tube, as shown by the clearing up of the fluid and the appearance of a flocculent precipitate.

In eighty-nine cases of typhoid fever, where the clinical diagnosis seemed positive, and in some few of which the postmortem findings were those of typhoid, the bacilli rapidly gathered into the characteristic clumps; some of these were large and others of medium size, the bacilli becoming immotile. The clumping in many of the cases was marked as soon as the specimen could be gotten under the microscope, and in all at the end of from three to five minutes.

In fifty nine cases in which the clinical diagnosis was not typhoid fever, and in many instances verified by the postmortem, the reaction was not obtained. This list includes a great variety of different diseases, such as cirrhosis of the liver, chronic valvular heart disease, tertiary syphilis, pulmonary, intestinal and bone tuberculosis, malarial fever, lobar pneumonia, acute rheumatism, carcinoma of the stomach, tetanus, gonorrhoeal rheumatism, multiple neuritis, nephritis, hysteria, insanity, etc.

The reaction was obtained in three cases of diseases not typhoid fever; namely, in one case of acute articular rheumatism, in one of malaria (controlled by demonstration of the organisms in the blood) and in one of chronic rheumatism. In the last case only was there a history of typhoid fever previously, namely, thirty years ago. The reaction in these cases was prompt and the clumps were large. In two cases in which the diagnosis of typhoid fever seemed positive, clumping did not occur in five minutes, but when the Pfeiffer method was used marked clumping occurred within a short time, with considerable precipitation in the bottom of the tube. One of these patients has since died and the postmortem examination showed lobar pneumonia and the characteristic typhoid lesions.

In two cases in which the diagnosis of typhoid is not positive (patients still living) the reaction was not obtained by the simpler method but the Pfeiffer method gave a positive result. In one of these cases the diagnosis lies between an acute exacerbation of a chronic endocarditis and typhoid fever, in the second between typhoid and malaria, but the plasmodia were not found. In two other cases the reaction was also obtained but the diagnosis of typhoid did not seem absolutely positive but no other definite diagnosis could be made. In two cases in which the diagnosis lay between typhoid fever and miliary tuberculosis in one case and acute exacerbation of a chronic endocarditis in the other, the reactions were all negative. No opportunity has presented itself to verify the indications thus obtained by autopsies.

From a study of the cases, positive as well as negative, and also from a careful consideration of the doubtful cases referred to, Dr. Dysart reaches the following conclusions:

1. This reaction can be obtained from the great majority of, if not from all, patients suffering from typhoid fever.
2. That the reaction can not be obtained from the great majority of other diseases.
3. That in three cases, clearly not typhoid fever, a marked reaction was obtained repeatedly in the hanging drop.
4. That in some cases of typhoid fever, in which the reaction is not obtained within five minutes in the hanging drop preparation, the Pfeiffer test tube method may give positive results.
5. The absence of the reaction in typhoid fever has not yet been demonstrated to occur in cases verified by postmortem examination.
6. The presence of lobar pneumonia, and probably other complications and sequelæ of typhoid fever, does not prevent the occurrence of the reaction, as shown by two cases verified by postmortem examination.
7. In doubtful cases the serum should be diluted in accordance with the methods of Durham, Greenbaum and others, and in this manner the results might be found to be more definitely conclusive.

DISCUSSION.

Dr. PREBLE—I have followed Dr. Dysart's studies in the wards with a great deal of interest, because the subject is of far greater importance than the subjects which we ordinarily meet. Every one knows the extreme difficulty at times of making a positive diagnosis of typhoid fever. It is to be regretted that Dr. Dysart had so few opportunities to apply this test to cases in which the differential of typhoid fever from diagnosis of other diseases such as acute miliary tuberculosis is difficult. It is in these cases that we wish such aids as this. The method appeals to one as possibly being a rational one; I suppose the rationale of the test being, that the serum of typhoid patients contains antitoxins, which in some way impair the vitality of the typhoid bacilli, thus causing the motion to cease. It would be interesting to know in what way the serum of typhoid patients affects the bacterium coli commune, which resembles the typhoid bacillus in so many respects. Perhaps Dr. Lemke will be able to enlighten us upon this point. The

test has not been used to any great extent as yet. Dicalafoy reported one hundred cases of typhoid fever, each time with the same result, the serum causing agglutination of the typhoid bacilli. It is as important to know the negative side of a test as to know the positive side. We can know this only by further observation of cases of endocarditis, miliary tuberculosis, and cryptogenetic sepsis and the like, in which there is later opportunities of confirming the diagnosis by postmortem.

Dr. BABCOCK—I would like to ask at how early stages in typhoid fever the serum works on this culture.

Dr. WEAVER—There was a question raised in regard to the action of the serum in the case of the bacillus coli communis. It has been shown that the bacillus coli communis thrives in typhoid serum and that there is no clumping or death produced. This work which Dr. Dysart has done has added considerably to our knowledge of a subject which we know comparatively little about so far. The work of Dr. Dysart seems to me to be one of the most valuable things in a scientific line that has been carried out by any of the house men in the County Hospital, so far as I know anything of their work, for a number of years. It seems to me he deserves particular credit for this work which he has accomplished.

Dr. HEKTOEN—It will be remembered that when Pfeiffer and Kelle published their first article concerning the action of serum of immune animals on typhoid bacilli they asked particularly that the profession repeat these experiments and verify them, and it seems to me that in Dr. Dysart's work this request has been carried out well. The practical importance of this reaction, the apparent rationale of which we all understand, is being appreciated everywhere, and this is shown by the fact that already the boards of health have arranged for carrying out this reaction quite generally.

Dr. HERRICK—Dr. Hektoen has called attention to the fact that boards of health have already offered to make examinations in the same way that examinations are made for the profession in suspected diphtheria. That has been rendered possible by the fact that this same reaction has been found to occur when a drop of dried blood, even though it be several days old, is moistened with water and added to the emulsion of typhoid bacilli. The reaction with the dried blood has been proven by Vidal, and independently, I believe, by Wyatt Johnston of Montreal, who, about a week ago, reported that fact and made the announcement that the Montreal Board of Health would make examinations for the profession.

Still, we must not be premature in our conclusions. If Dr. Dysart's results are true, it shows that perhaps 3 per cent. of failures will be met with. He found in three cases, one of acute articular rheumatism, one of chronic rheumatism and one of malaria, a distinct reaction, and found it repeatedly, so that the test may be, after all, rather of negative than of positive value, that is to say, the failure to get the reaction may be all that we can rely upon and it may tend to exclude typhoid fever.

Dr. HEKTOEN—That is a very proper objection taken by Dr. Herrick just now; it may be said, however, that the test as carried out by Dr. Dysart is not altogether correct, because the serum must be diluted to a certain percentage, and in his last conclusion Dr. Dysart referred to that fact and says, that in continuing such tests, if the serum be properly diluted according to the recommendation of certain authors, the reaction may become more conclusive; and herein lies opportunity for still more work in the future.

Dr. LEMKE—With reference to Dr. Babcock's question, I can only say that Dr. Dysart was able to get positive reaction in all cases entered at the hospital; in many cases it was at the end of the first week.

EXHIBITION OF SPECIMENS.

Dr. L. HEKTOEN showed a carcinoma of the pylorus with extensive growth of tumor into the veins about the stomach

removed from a greatly emaciated colored man, 56 years of age, upon whom, as a last resort, an operation for gastro-enterostomy had been made by Prof. John B. Hamilton, shortly before death. The tumor is situated around the pylorus, which is practically occluded, and it presents a large ulcerated surface with raised margins. The particular feature to which attention is called is the extensive growth of tumor tissue into the wall of the stomach and behind it (Fig. 1). The gastric veins are all distended and nodular, as though they were the seat of an extensive thrombosis. This tumor-thrombosis, so-called, extends into the portal vein and fills the entire main trunk, and from this vein the thrombosis extends backward against the blood current into the veins that go to make up the portal vein, the splenic vein and the superior mesenteric vein for some distance, but just how far can not be said, because in the removal of the growth these veins were cut off while still containing tumor masses in the gastro duodenal vein. There is also extensive secondary carcinoma of the lymphatic glands in the gastrohepatic omentum and the pressure of these upon the bile ducts produced biliary obstruction and some jaundice, and this is still shown in the specimen by the greatly extended gall bladder.

In order to explain the intravenous extension of the tumor it is assumed that in some way the carcinoma grew into the venous or capillary network of the wall of the stomach and

Fig. 1.—Growth of carcinoma into gastric and portal veins and the radicles of the latter, secondary to carcinoma of the pylorus. The posterior surface of the stomach, which is turned so that the pylorus is to the left, is exposed. A, cut end of gastro-duodenal vein, from which the microscopic section drawn in figure 2 was taken.

from there rapidly extended in many directions, finding but little obstruction to its growth in the blood channels. It is quite remarkable that the growth should continue against the current instead of into the liver, as would be expected. There were no metastases in the liver. Contrary to expectations there was no ascites. The absence of ascites is hard to explain. The extreme emaciation and the consequent small amount of blood in the body may have allowed collateral circulation to be established without any evident changes in the caliber of the collateral channels.

The microscopic examination (Fig. 2) shows the lumen of the gastro-duodenal vein, at a point about three inches from its end, to be filled with a typical carcinomatous growth, the islands of epithelial cells being enclosed in distinct and often broad bands of connective tissue which seem to be more an integral part of the tumor than a new production from the vein wall. Here and there are spaces filled with blood, and it may be that the portal circulation was maintained in sufficient degree to obviate passive congestion through such spaces in the "carcinomatous thrombus."

Dr. KING presented some specimens of *tuberculosis testis* and related the history of the case from which they were obtained.

Dr. HERRICK presented specimens of heart, showing *mitral and tricuspid stenosis*.

He said: I will take a few minutes to show a heart that shows mitral and tricuspid stenosis, the third case that has come to the autopsy at the County Hospital recently. It concerns a middle-aged woman with a previous history of rheumatism, subjective symptoms of heart disease and physical findings that indicated pericarditis. Tricuspid stenosis was not recognized during life. The heart shows a mildly enlarged left ventricle, the walls thickened, the mitral valve with the cusps thickened and drawn together, the orifice admitting perhaps one and one-half finger tips; the left auricle is also enlarged, as it is in any case of mitral stenosis. In the left heart I should also say the aortic valves are slightly thickened and it was thought at the autopsy, which was made by Dr. Hektoen, there was possibly a slight incompetency. The

Fig. 2.—Growth of carcinoma in gastro-duodenal vein, multiplied 175 times; a, blood; b, cell nest; c, connective tissue trabeculae.

right heart shows a dilated and hypertrophied right ventricle, the tricuspid orifice admitting three finger tips, the free margins of the valve being thickened and deformed. The right auricle is hypertrophied and dilated. At the last meeting I reported two cases of tricuspid stenosis and it is certainly very strange that a third case should have come to autopsy within so short a time. This case corresponds to the common findings in cases of tricuspid stenosis. The patient was a woman; the tricuspid obstruction is combined with lesions of the left heart and most commonly with an obstruction at the mitral valve. This is further a case of acquired tricuspid stenosis, not congenital, that being proved by the absence of symptoms of cyanosis in earlier life, proven also by the absence of defects in the ventricular and auricular septum and of a history of rheumatism.

PRACTICAL NOTES.

More "Brutal Figures" in Favor of Serum Treatment of Diphtheria.—Cuno describes in the *Deutsche Med. Woch.* of December 24 the results of two years' treatment of diphtheria with Behring's serum at a hospital in Frankfurt a.-M. There were 483 cases received in all and the mortality fell from never less than 37 per cent. in previous years to 10.5 per cent. of the total number, or to 7.03 per cent. excluding the moribund cases. The noticeable feature of the report is that no local treatment was used. It was found that with sufficient doses of the No. 3 serum the false membranes rolled up at the edges, seemed to dry up and were finally expelled without bothering the already sufficiently tormented little patients with local applications. Heart weakness was combated with injections of alcohol and camphor, and abundant nourishment was given through a sound if necessary.

Erythromelalgia.—Dr. Schenk has described a case of erythromelalgia in an article published in the *Medicinische Presse*, on the subject of his clinical investigations of the nervous sys-

tem. This disease was first described by Graves and afterward by S. Weir Mitchell, according to whom it is a disturbance of the circulatory system, whereas Vulpian named it *paralyse vasomotrice des membres*. At present it is supposed to be the result of a disturbance of the nervous system. The symptoms include sleeplessness, urinary and rectal troubles, spinal ataxy, atrophy of the skin and the muscles of the upper arms, increase of the knee-jerks, analgesia alternating with hyperalgesia, and decrease of the sexual impulse. The urinary and sexual disturbances are due to a lesion of the vesico-spinal and genito-spinal centers which are to be found in the region of the fourth lumbar vertebra; the ataxy points to a disease of the posterior column, the increase of the knee-jerks to an irritation which may be caused by an inflammation. The disease is no doubt due to vaso-motor disturbance consequent on an ascending degeneration in the posterior column of the cord. Woodnut has also described a case of erythromelalgia due to myelitis.—*London Lancet*.

The Treatment of Piles and Pruritis Ani with Collodion.—Dr. D. W. Samways says he has found that the itching in cases of pruritis ani disappears at once on the application of simple collodion. After a few moments of somewhat intense smarting (which can be prevented by cocain if necessary) no further itching is felt ordinarily for twelve or twenty-four hours, if at all. He supposes that the ether or alcohol in which the gun-cotton is dissolved stops the irritation and the collodion film, by protecting from the air, prevents its reappearance. In cases of external piles he has observed that the application stimulates the pile to contract, that the hardening film of collodion supports the pile thus contracted, and that the contracting collodion (not collodion flexile) further reduces it. It is the principle of the elastic stocking applied to the hemorrhoidal instead of the saphenous veins, he says, and with a like result. The collodion is best applied by dropping it on a few fibers of cotton wool, which are spread over the pile each morning after defecation.—*British Medical Journal*, November 21.

Effect of the Influenza Bacillus on the Central Nervous System.—Cantani first ascertained that rabbits supported easily intracerebral injections of sterilized water, and intraperitoneal injections of non-fatal doses of Fraenkel's diplococcus. He then experimented with living cultures of the influenza bacillus (Pfeiffer's), injecting them into the dura mater and even into the brain matter. The results showed that the brain is a particularly favorable medium for the development of the influenza bacillus. A series of passages through rabbits' brains produced a culture which killed others in small doses injected into the peritoneum. The same results were obtained by inoculating with cultures first sterilized by being heated to 57 degrees C., only larger quantities were required. The animals that died from the injection of the virulent cultures, showed all the signs of a profound infection. The congested peritoneum frequently contained extravasated fluids; the spleen, kidneys and capsules were gorged with blood; the bladder contained bloody urine. The lungs were congested, the pericardium contained exudations. But in none of these organs, nor in the blood, was the influenza bacillus discovered. The brain had every indication of a subacute meningo-encephalitis, and the bacilli were found in the cerebral and also in the medullary substance.—From the *Ztschr. f. Hyg. u. Infectiouskr.*, No. 2.

Trional.—The superiority of this hypnotic over all others is proclaimed anew by Von Mering in the *Presse Medicale* of December 9. He has administered it to over a thousand patients without a single accident. His dose is 1 to 1.20 gram before retiring each night, and it can be kept up for a long while. It is especially serviceable in neurasthenic insomnia, psychosis with excitement, etc. In insomnia due to some painful affection he gives 5 milligrams of morphin with the gram of trional. Not content with his own experience, he wrote to

seventeen eminent authorities, including Krafft-Ebing, Norden, Jastrowitz, Binswanger, Rabour, etc., for their opinion of trional. Fifteen expressed their preference for trional; one used sulfonal or trional indifferently, and the seventeenth failed to reply. Dr. Vogt recommends that a certain quantity of some warm liquid be taken at the same time (about 200 grams). If the trional is continued a long while it is well to have a bottle of some alkaline water taken during the day (Vals, seltzer), and to suspend the medication for a day or so every five or six days. The one drawback to trional is the hemato-porphyrinuria occasionally caused by it to a slight extent ("infinitely less frequent than with sulfonal"). Von Mering's experiences and experiments incline him to believe that it is not due directly to the trional, but to a sort of idiosyncrasy, a less than normal resisting power to the effect of the medication. (See the JOURNAL, page 765, Vol. xxvii.)

Alexandroff's Sign for Early Diagnosis of Coxaigia.—Beside the usual symptoms of incipient coxaigia, Alexandroff insists on the importance of two additional signs, the atrophy and fatty degeneration of the muscles and bones, and especially the hypertrophy of the subcutaneous cellulo-adipose layer, which exists in every stage of the disease from the first and increases with the gravity of the case. In advanced stages the hypertrophy extends throughout the whole member. This is the cause of the effacement of the fold between the thigh and buttocks (*pli fessier*) and the difference in this respect between the sound and the affected thigh is very evident, as much as $1\frac{1}{2}$ to 4 mm. in some cases. Alexandroff has invented a special instrument, the adipometer, resembling Weber's compass, to measure the thickness of this subcutaneous layer. The movable portion of the apparatus slides on a graduated plate and a spring near the handle allows a pressure of 5 to 10 grams. He has been using it for six years and states that atrophy of the member coinciding with hypertrophy of the fold, is one of the most important signs by which to recognize tuberculous osteo arthritis before any other symptoms have appeared, while the absence of these trophic troubles is conclusive evidence of the non-existence of a tuberculous lesion of the coxo-femoral articulation, even when it is indicated by other symptoms.—*Presse Médicale*, December 9.

Surgery of the Pancreas.—A successful operation for tumor of the head of the pancreas which has showed no relapse in the two years since, inspired the surgeon D. Biondi, to study the literature on the subject and experiment for himself further. He found that his was the only successful case of the kind on record. He ascribes the infrequency of such operations to the difficulty of diagnosing, as neighboring organs may be the seat of trouble, and also to the difficulty of operating in such friable tissue and the dangers of hemorrhage. He states that it is necessary to leave a portion of the head of the organ, as total extirpation is fatal, while animals and his patient bore partial extirpation without inconvenience. His method was the extra-peritoneal treatment of the pedicle. His patient recovered rapidly and gained twenty-four pounds in six months. He finds that small wounds of the wall of the common bile duct heal without closing the lumen. Also that the secretions of the pancreas are liable to cause peritonitis indirectly, and therefore it must not be allowed to penetrate into the peritoneal cavity. It is impossible to prevent this if the entire head of the pancreas is removed, although as stated above, a portion of the head can be removed with impunity if one of the ducts is left intact. The indications for surgical intervention he considers to be cysts, hemorrhage, suppurations, local fatty degeneration, calculi and benign neoplasms. In malignant neoplasms an operation may ensure six to eight months of comparative health. He recommends an exploratory laparotomy to confirm the diagnosis (*Cbl. f. Chir.*, December 19). We note in connection with the difficulty of diagnosis in these

cases a recent case described in the *Wien. klin. Woch.*, No. 45, which presented every symptom of intestinal occlusion, although no obstruction was found at the laparotomy to account for it. Death soon followed and the necropsy disclosed apoplexy of the pancreas with gangrene of the peritoneum and purulent peritonitis.

Ulcus Ventriculi Treated by Rectal Alimentation Alone.—Boas and others have recommended this method of treating ulcer ventriculi when all others have failed, but E. Ratjen writes to the *Deutsche Med. Woch.* of December 24 describing the brilliant results he has obtained with it, used exclusively. Treatment commenced at once as soon as the diagnosis is established. He combines it with the strictest repose in bed and absolutely nothing taken into the stomach except clear water, peppermint tea, or pieces of ice dipped in brandy and water if there is heart weakness. The absolute rest for the stomach thus induced (even the secretion of hydrochloric acid ceases comparatively) allows the healing process to continue undisturbed, and the relief from pains reconciles the patient to the treatment. He uses Boas' clysm (250 grams milk, two yolks of eggs, a pinch of salt, one tablespoon red wine, one tablespoon starch flour) three times a day for ten days, after a natural or artificial evacuation of the bowels each morning. A special apartment is set apart for the use of these patients in his hospital or at their homes, where they never see or smell the food of others. Local hot compresses are used to relieve pain. As aids to diagnosis he mentions the following symptoms: 1, the subjective symptoms make their appearance soon after eating and depend upon the variety of food; 2, the freedom from pain after vomiting and when the stomach is entirely empty; 3, the points painful to pressure in the epigastrium and in the back near the vertebra. The pains are worse during the ectasia of the organ from stenosis of the pylorus after eating and are relieved by acid vomiting; 4, the hemorrhages. The diagnosis can never be absolutely certain at the best, but this exclusive rectal alimentation benefits other gastric troubles and also serves to differentiate ulcer from carcinoma ventriculi. It has also been successful in one case of nervous vomiting from hyperesthesia of the stomach. He has found in each case that the stomach was not entirely normal in its position, and has explained to the patients the importance of having all their clothing suspended from the shoulder, etc. With three exceptions who did not complete the cure, the patients have all been able to eat solid food since without pain, and have increased in weight. His report includes fifty-five cases.

Hay Fever and Uric Acid.—Dr. N. L. Wilson of Elizabeth, New Jersey, writes the *New York Medical Journal* for December 26, as follows: "I do not mean to say that every case of uric acid diathesis is a hay fever subject, any more than I would say every such case had eczema, but I do mean to say that there is a close relationship between uric acid and hay fever, and I do say that every patient having a neurasthenic tendency, if you please, and a pathologic mucous membrane of the respiratory tract, is irritated by uric acid, and thus far my observations have led me to suspect it in every case of periodic hyperesthetic rhinitis. In the treatment of these cases the greatest care must be exercised. You must ever keep in mind that alkalies, salicylates, etc., produce a uric acidemia so long as there is an increase of uric acid within the system. During the attack they must be used with care and in small doses. I have certainly increased the severity of an attack by giving ten grains of salicylate of sodium three times a day. During the attack it is better to free the blood from uric acid by the administration of an acid. Aromatic sulphuric acid acts very well. After freeing the blood gradually extract the uric acid from the tissues by 2 or 3 grain doses of salicylate of sodium (given three times a day), cut off the acid-producing foods, such as meat, beer, wine, cider, lemonade, etc. Keep your patient's

nervous system in the best possible condition by proper feeding, hygienic measures, and nerve tonics if necessary. See that no polypi, spurs, or hypertrophies exist in the nostrils. Begin a crusade against uric acid six weeks or even two months before the time of the attack. For the local relief I have found menthol and camphor in liquid alcohol, very gently sprayed into the nostrils, effectual in some cases. There are cases, however, which are apparently irritated by this solution, and for these I have found, if I would contract the tissue with a 6 or 10 per cent. solution of cocain, and then gently coat the turbinate with a thin film of flexible collodion, they would experience relief. For the itching and irritation of the conjunctiva, hot water or yellow ointment rubbed into the conjunctiva will afford relief.

Disinfection of the Urethra by the Internal Administration of Enterol.—Enterol is a watery, colorless, sometimes slightly brown liquid, with a specific gravity of 1.036, and with the taste and smell of kresol. It is slightly soluble in one hundred parts of water, and has about six times the antiseptic strength of carbolic acid. Properly diluted—that is, one part of enterol to five hundred of water, it can be given in the dose of from half a dram to a dram daily for months at a time without producing any untoward symptoms. It is given in pill, capsule, and mixture with equal parts of olive oil. Fass, in *Centralblatt f. die Krankheit. der Harn*, etc., states that thirty of the capsules can be taken at a dose without harm. After entering the stomach about 80 per cent. remains in the alimentary canal and 20 per cent. is excreted by means of the urine. If employed in weak dilution and with abundance of liquid, the probability is that much more is absorbed. In the treatment of bacterial inflammations of the genito-urinary tract, the patient is gently purged, the lower gut washed out with clysters of water or neutral oil, and a milk or liquid diet given, enterol being administered with each repast. After large doses and prolonged use of enterol the urine sometimes turns green. The author states, however, that he has given the drug in doses of one-half to one dram daily for weeks, the urine exhibiting the characteristic gray-green color, without producing any systemic complications. Indeed, the drug does not produce the slightest irritation in the kidneys or genito-urinary tract, and even in chronic nephritis the albumin contained in the urine is not increased. Nevertheless, we are cautioned against the use of the drug in cases of acute nephritis, congestion of the kidney, or feebleness of the heart. The drug possesses the merit of being safer and more efficient than any of the non-internal antiseptics. Nervous women, after taking the capsules, complain of an unpleasant taste in the mouth and burning in the stomach. When there is marked inflammation of the stomach the drug should be greatly diluted. In the case of gastric ulcer the drug should not be exhibited. The indications for the use of the drug are for the cure of cystitis, pyelitis, and before and after operative interference with the urinary passages in cases of acute gonorrhoea. In the latter affection the enterol is particularly efficacious, eight capsules being given each day.

Guaiacol and Creosote in Pulmonary Phthisis.—Dr. F. R. Walters joins with some other contributors to the *Lancet* in drawing attention to the value of this group of remedies in the treatment of phthisis, which many in England are disposed to doubt. He says: I am well acquainted with the advantageous properties of the carbonates of creosote and guaiacol and have myself prescribed the former with apparent benefit. But at present the price of the drugs is prohibitive except for wealthy patients. A lady under my care who had been taking creosotal for a few weeks plaintively asked me one day whether it was absolutely necessary to continue paying a guinea a bottle for her medicine. In some recent wholesale price lists the carbonates are listed at prices from fifty cents to a dollar, or more, per ounce. These high prices are prohibitory for hospi-

tal patients, and are strongly objected to by ordinary middle-class patients when the course of treatment is (as it must be in phthisis) a long one. Under these circumstances one is driven to use the cheaper remedies in most cases and to overcome their drawbacks in other ways. The causticity of creosote and guaiacol has in my opinion been somewhat overrated, as I find them clinically well borne if suitably prescribed, in most cases in doses up to 45 minims per diem by the mouth, and occasionally in much larger doses. Every medical man is in the habit of prescribing without any ill effects such caustic drugs as phenol, liquor potassæ, and nitric and sulphuric acids, merely by suitably diluting them, and the same can be done with creosote and guaiacol. The latter should always be given on a full stomach, and their solution in alcohol or glycerin further diluted by mixing with some bland fluid such as milk. Possibly in this way an albuminate is formed; but at all events, this is effective and in most patients causes no disturbance. Pille and capsules I regard with suspicion, as they might liberate their undiluted contents on the surface of the stomach and are much less readily tolerated by most patients. As regards the relative toxicity of creosote and guaiacol and their carbonates, one would not expect to find much difference after absorption, since the carbonic acid is liberated in the bowel. Poggi's experiments refer to guaiacol and not its carbonate. I hope very shortly to test their correctness. It will be a boon to the public if the profession can induce the manufacturers of creosotal to dispose of it at considerably reduced prices, and thereby themselves obtain for it a much larger market.—*London Lancet*, December 12.

Cause and Prevention of Suppuration of Stitches.—Some recent writers explain the occasional suppurations of the stitches in carefully performed operations to the presence normally of certain pathogenic microorganisms in the underlying layers of the derma which causes suppuration when exposed to the air by the wound. Remlinger even asserts that most of the microorganisms found in the blood drawn from the finger are derived from the lower layers of the skin. His statements are revolutionary in regard to the conclusions we have been drawing from inspection of a single drop of blood in infective disease. We know that the flora of the superficial layers is extensive, but he announces that he found the staphylococcus albus (twenty-three times); aureus (eleven times), and citreus (fourteen times); the streptococcus pyogenes (eight times) and the coli bacillus (five times), in his experiments on fifty perfectly healthy men, taken with a sterilized needle from the deeper layers of the derma. The only means to avoid error in examining the blood is to draw it from the deeper tissues with a needle not only sterilized, but inserted while still red hot. The logical inference is that surgeons should make their incisions with the thermocautery in order to destroy these intracutaneous germs, but the same effect is secured by a much simpler method, the disinfection of each stitch with alcohol, as E. Blondel announces in the *Journal de Méd. de Paris* in an able review of the subject and the latest theories. He has revived the Hippocratic practice of bathing wounds with wine as taught by Theodoric and Mondeville, and applies it with invariable success. Especially in total perineorrhaphy, which is so difficult to perform with perfect antiseptis, he has secured results far surpassing any previous achievements. He makes as few stitches as possible in the lower layers, and before drawing them tight he wets them and the edges of the wound with 90 per cent. alcohol, and sponges the tissues with a cotton pad dipped in it. Each suture is treated in the same way, and the final suture is sponged with strong alcohol and then dusted with iodoform or equal parts of dermatol and aristol, repeated every second day afterward. Alcohol dries the surfaces better than any other substance. Its effect on grease is also a factor in the result. It has a coagulating effect on the serum and thus favors cicatrization.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the Association living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, JANUARY 30, 1897.

THE HYPOTHETICAL CASE IN MEDICAL EXPERT TESTIMONY.

The value of the hypothetical case in obtaining medical expert opinion is one of the questions in regard to which both lawyers and doctors appear to disagree. A recent editorial in one of our contemporaries quotes a prominent lawyer as saying that it serves a purpose in showing the utter worthlessness of the opposing testimony, presumably seeing in it no other use or value. It was admitted by him that in this it was a weapon that cuts both ways and he considered that its influence in one direction was counteracted by that in the other, so that its real effect is practically zero.

If this notion is correct, no self-respecting expert would really care to go on the stand and answer a hypothetical question, and it would seem that no sensible lawyer would see any necessity for asking one, if the opinion obtained could be really at once counteracted by another equally well based. In fact, the lawyer's statement seems a little odd, since it practically assumes that the testimony on both sides must be equally worthless, and leaves a chance for anyone to suppose that he considers all testimony of witnesses as to facts, as well as of experts altogether, without value.

Theoretically, it would seem to an average, fair-minded individual that the hypothetical case offers an ideal method of obtaining expert opinion. A carefully drawn up question, embodying all the essential particulars fairly stated, is certainly a rational means

of obtaining the correct judgment as to the assumed facts, and it has the advantage to the expert of saving him the trouble of delving into details and of making him more or less a witness as to facts instead of opinion. The possibility that the hypothetical case does not represent the facts, does not alter the case; the fault is then with the advocate, not with the expert. If it is so used it ought to be a dangerous weapon to its employer, provided the opposing counsel knows how to avail himself of his opportunities, and ought to indicate a recognized weakness of his case by him who employs it.

The hypothetical case has also the advantage that it is not so liable to make the expert an advocate, as is so often the tendency when one is testifying as to the result of opinions obtained by personal examination. Physicians on the stand, of course, need not be unduly interested on the side of their employers, and as experts should not be, but they have the common human weaknesses, and it is believed that perfectly honest men feel some sense of obligation to render a *quid pro quo* when they have received large fees, and this, in itself honorable, feeling may lead them into awkward situations on the witness stand. If they only expect to receive large fees for their testimony they are liable like other men to be led into temptation, which is the stronger if they have given time and trouble to the personal examinations than if they have merely read over and formed an opinion on a stated case. It is only by assuming that physicians do sometimes, probably unconsciously, yield to such temptations that we can account for some medical testimony. Of course one who can not free himself from all prejudices, that of interest as well as others, is not fitted to give an expert opinion, but all persons are not always aware of their disqualifications. While physicians are condemned for this occasionally, it is only fair to say that they are no more liable to be faulty in this regard than are judges or jurymen, who should of all men be the most impartial.

One great trouble with the hypothetical case is that there are so many lawyers who do not know how to properly construct it. In cases involving medical questions, such as insanity, etc., they should as a rule employ a competent expert to help them draw it up from the facts that are to be brought out by their witnesses. It need not include all the facts but only enough, simply and clearly stated, to enable their experts to express a positive opinion, as it will be a great advantage to their cause if still others are in reserve to be presented before the jury to strengthen the case after the opinions have been obtained. The value of such a method has been repeatedly demonstrated, notably in one rather recent case in one of the large cities where this policy actually made the experts for the prosecution the most effective witnesses before the jury for the defence.

There will be, without question, many physicians who will prefer in certain cases, to testify only after personal examination and study, but for general purposes and purely for the obtaining of expert opinion, it is probable nothing better than the hypothetical case has been or can be devised. An honestly drawn up hypothetical case can not hurt a good cause and may damage seriously a bad one; one that misrepresents the facts should not deceive a jury, with a competent opposing counsel, and in either case the position of the impartial expert is the same; he has only to give his opinion on the case as put before him.

SINUS-PLEURITIS.

That attacks of pleurisy often pass unnoticed during life appears perfectly evident from the frequency with which adhesions and other signs of that condition are found postmortem in cases in which death has resulted from some independent disorder. There also come under clinical observation a very considerable number of cases in which fever of varying type, intensity and duration is the most conspicuous manifestation and for which no adequate primary cause can be discovered. That in many of these cases the febrile manifestations are dependent upon some obscure inflammatory disorder there can be no reasonable doubt and it can scarcely be considered hypercritical to question the actual existence of such a state as simple continued fever. It is possible that local elevation of temperature may result from purely local influences, but the cause for general elevation of temperature must be sought in some disturbance of the thermotaxic mechanism, resulting in a derangement of the adjustment between heat-production and heat-dissipation. This disturbing influence may be chemic (nutritive, toxic) or physical (traumatic, inflammatory).

For a number of cases in which inflammation of the pleura pursues an insidious and latent course, as well as for another number in which apparently inexplicable fever exists, an explanation is offered by the account given by KOLL (*Deutsches Archiv für klinische Medizin*, B. lvii, H. 5, 6, p. 597) of a group of upward of 30 cases observed in the medical clinic of the Julius Hospital at Würzburg and which he characterizes by the designation sinus-pleuritis. The symptoms of the affection are suggestive of some disorder of the heart or stomach, so that its true nature may escape detection unless it be specially looked for. The lesion of the disease consists in an inflammation of the lowermost portion of the pleura anteriorly and laterally and sometimes posteriorly, unattended with demonstrable effusion. In the large majority of cases the disease sets in suddenly, like an infectious disease, with usually slight fever and other symptoms of constitutional disturbance, generally without appreciable cause. Only in a small number was a previous

history of exposure to cold or of excessive physical effort, and the like, ascertainable. In isolated cases a relation appeared to exist between the attack and acute and muscular rheumatism. The disorder did not follow other affections predisposing to inflammatory complications of the serous membranes (diabetes, nephritis). In individual cases the onset was not acute, so that definite information as to the beginning of the attack could not be obtained. In one case it was related that the patient had had a similar attack some five years before.

The subjective manifestations in most cases pointed to acute or chronic gastric disease, the most conspicuous symptom consisting in diffuse or circumscribed tenderness in the gastric region, setting in suddenly during a state of health. A point directly below the apex of the ensiform cartilage was noted as painful with especial frequency. In about half the cases the pain was induced, or when already present, was increased by the ingestion of food, and almost always by pressure. Some patients further volunteered the information that forced inspiration was particularly painful. In a considerable proportion of the cases there was also frequent eructation and vomiting. One patient, in fact the first in whom the disease was recognized, presented symptoms of gastric ulceration, and she was accordingly nourished with food administered through a tube for a period of four or five days. In most cases the gastric symptoms disappeared in the course of several days almost completely. Almost all of the patients complained of pain behind and on either side of the sternum, radiating thence in the course of the inferior margin of the lungs. These pains, which were of burning character, were usually increased by deep inspiration, physical effort and inclination of the body forward. Some patients complained of palpitation of the heart, and in some the frequency of the pulse was found to be increased (to 140) without, however, physical evidence of cardiac disease. One patient suffered for eight or ten days from severe dysphagia.

In most cases the constitutional symptoms were mild—headache, fatigue, general malaise, impairment of appetite. In several the attack set in with a chill. Usually there was slight continued fever (101.5 degrees). As a rule the temperature declined on the second or third day. Then there was slight irregular elevation of temperature, usually in the evening, in some cases continuing for weeks and months.

In all cases there was found constantly a soft, fine, rhythmic friction-sound corresponding and restricted in distribution to the pleural sinus in the region of the heart and along the lower lateral borders of the lungs. It was most marked at the left border of the sternum on a level with the fourth and fifth ribs and was noted with especial constancy somewhat within and generally below the apex-beat of the heart at the

level of the small bridge formed by the tongue-shaped process of the upper lobe of the left lung between the pericardiac-costal sinus and the phrenico-costal sinus. This sound could be heard faintly at mid-sternum at a point corresponding to the slight marginal sinus of the right lung, and from midsternum at the level of the sixth rib it radiated with increasing intensity along the lower sinus upon the right and left sides almost to the vertebral column; or it ended gradually in the lateral portions of the reserve spaces. The sound was principally to be heard only during the second half, viz., at the height of a deep inspiration and at the beginning of expiration and disappeared usually after protracted vigorous breathing, to return in the course of two or three hours. In a few cases the sound could be heard during the respiratory pause, isochronous with or following the action of the heart. The pleural character of this "precordial" sound was established by the fact that it was heard only over the pericardiac-costal sinus and never over any portion of the anterior surface of the pericardium not covered by pleura. That it is not physiologic and dependent upon the movement on one another of healthy pleural surfaces was shown by comparative observation. In patients in whom spontaneous pain or pain induced by pressure below the apex of the ensiform cartilage was present, a distant friction-sound was audible. This might have been due to inflammation of the diaphragmatic pleura or of adjacent peritoneum.

Of complications there was noted in two patients, in conjunction with acute exacerbations, acute intestinal catarrh. In a case consequent upon acute rheumatism mitral endocarditis was observed. Another case also presented acute endocarditis.

The disorder was characterized by its obstinacy of course and its tendency to relapse. Even in cases in which the objective manifestations were mild from the outset the friction-sound was most persistent. In general, aggravation and improvement alternated, little influenced by medication. The most marked of the subjective disturbances subsided after eight or ten days' rest in bed, while the objective phenomena underwent but little change. Salicylates, phenacetin and the like appeared to exert no influence. Calomel in doses of $2\frac{1}{2}$ grains three times a day seemed to do good in some cases, as did also hot poultices.

In only about a quarter of the cases was recovery complete on dismissal from the hospital. The remainder, while in general free from subjective discomfort, except perhaps pain on deep inspiration or a sense of pressure or burning in the affected region, still presented objective manifestations. When the attack proper was over the patients displayed a tendency to lack for a long time the feeling of perfect health.

The condition is to be differentiated from acute or chronic gastric catarrh, gastric ulceration, pericardial

disorders, intercostal neuralgia and, in the absence of fever, from simulation.

THE CONTAGIOUSNESS OF PNEUMONIA.

In the London *Lancet* (An epidemic of pneumonia occurring at Peshowar, *Lancet*, 1896, p. 1630), Dr. JOHN STEPHENSON of H. M. Indian Medical Service, reports an epidemic form of lobar pneumonia occurring in the men of the First Bengal Infantry. The epidemic lasted for two months in the coldest part of the year, and was most intense at the middle of this period, while it was more fatal in the the earlier part.

After giving details as to age, death rate, etc., the writer continues: "With regard to the etiology of the disease there were appearances at one time of its spread by contagion. Thus, the suddenness and severeness of the epidemic, and especially the so frequent development of the disease a few days after admission, led us to consider whether infection might not be a factor of the etiology. It appeared almost as if the hospital wards themselves might be harboring and diffusing the causal microorganism. Many men were taken from the lines to act as sick attendants, and several of these men were taken into hospital suffering in the same way. Thus, a Christian bandsman was being nursed by another Christian, who contracted pneumonia and was also given a Christian attendant; the latter also became ill with pneumonia. This appeared to be a passing on of the infection from the first to the second and from the second to the third. However, on examining the statistics it was found that in reality the sick-attendants were no more frequently afflicted than the regiment generally."

Many years ago this question of contagion had attracted attention, for in the memoirs of the United States Sanitary Commission, Dr. RUSSELL reports: "The surgeons on duty with the regiments in the barracks (at Benton, Mo.) report that men occupying the same bunks with those affected were very much more liable to be attacked than those more remote. Some of the most intelligent surgeons believed that it was actually contagious."

Quite recently, Dr. J. B. AYER has alluded to this phase in a paper on "Senile Pneumonia" (*Boston M. and S. J.*, 1896, p. 305). In referring to the contagiousness of the disease in old persons he says: "I have in mind the cases of a matron aged 79 and a nurse of 45, both nursing a woman 57 years of age, who died on the fourth day following an attack of pneumonia. The matron died four days later with typical senile pneumonia; the nurse also died of pneumonia, surviving the patient eleven days. I can not recall another case where the disease was so plainly transmitted." Dr. W. H. THAYER, in a letter (*Boston M. and S. J.*, 1896, p. 379) commenting on Dr. AYER's paper, throws some light on the subject by his statement that: "The increase of pneumonia has been in

the last thirty years, or since diphtheria became established in this country. Before the advent of diphtheria in 1858 contagious pneumonia was unknown, and single, uncomplicated pneumonia was rarely fatal. It was not recognized as a constitutional disease, but only as a local inflammation produced by exposure to cold."

More than twenty years ago Dr. WM. P. SEYMOUR of Troy, N. Y., began to recognize a pneumonia of diphtheritic character without any membranous exudation in the throat—he verified his observations by occasional cases from year to year—in which there was evident contagion, the fauces presenting a stringy secretion but no membrane.

It would seem that we have cases in which the diphtheria bacillus produces a typical lobar pneumonia, without involving the throat. If such be the case we can understand the so-called contagiousness. Probably researches to determine this point could be undertaken very profitably.

"CANCER HOUSES" AND CANCER AREAS.

Among other interesting topics connected with the alleged contagion of cancer is the one of "cancer houses" and cancer areas. By the former is meant houses which in a series of years will have several deaths from cancer among their tenants. The term cancer areas refers to large tracts of country where this disease is more than usually prevalent. The Old World offers a better field for observing these phenomena, as might be expected from the less migratory nature of its population.

Mr. LAW WEBB, known for his investigations into the immunity of colliers from cancer, has brought forward some interesting data on the subject of cancer houses (*Birmingham Medical Review*, 1892, p. 342). He states that in a certain village of Shropshire, of twenty houses, occupying not over an acre of ground, nine cases of cancer were treated in fifteen years. None of the patients were blood relations, but all the inhabitants used water from a pump by the roadside. One of the cottages which furnished three of the cases was preëminent for filth. Near this hamlet are three more houses which have furnished six cases of cancer in the last quarter century. Dr. ACKERLY relates an equally remarkable series at Ashburton, Devonshire. The town has a small stream running through it; near this stream (twenty yards), is a large house, with the cellars below its level, and where four cases have occurred in fourteen years: *A*, a lady occupying the house for many years; *B*, the next occupant, a lady; *C*, husband of *B*; *D*, the second wife of *C*. Again, four deaths have been reported in the last four years in persons living within 100 yards of the same house.

Mr. D'ARCY POWER narrates some striking examples in his paper on "Cancer Houses" (*British Medical*

Journal, 1894, i, 1240): Miss B., aged 45, lived in a certain house in the suburbs of London for thirteen years, and died of cancer of the stomach in 1884. Miss T., aged 47, succeeded to her place and occupied her bedroom. She had lived in the house for twenty years, and died of cancer of the liver in 1885. Mrs. J., aged 67, who had lived in the house for twenty-eight years, succeeded to the place and to the bedroom occupied successively by Misses B. and T., died of cancer of the breast and uterus in 1893. Each of these patients appeared to be in perfect health until they took one another's place; there was no blood relationship. BLYTH mentions three successive tenants of a house, who died of cancer. The last one was visited by a Mrs. V., who subsequently was affected. Mrs. V.'s niece of 14 years, who nursed her and slept with her, contracted cancer of the breast. SCOTT (*British Medical Journal*, 1894, i, 1302) reports three cases in a damp house, and CHAPMAN (loc. cit.) three in a fine house standing in large grounds.

Nor are cancer houses confined to Great Britain, for at the Surgical Congress at Lyons in 1894, GUELLOT mentioned fifteen examples which yielded fifty victims. FABRE, in his work "De la Contagion du Cancer" reports a case of MOLIERE'S. In a well built-house at Lyons on the banks of the Saone four deaths from cancer occurred in a decade; there were no deaths from any other cause.

In regard to cancer areas it is well known that the frequency of cancer varies widely in different countries, and that in each country there are equally wide variations in the frequency of its occurrence in different districts. ARNAUDET claimed some years ago that cancer is much more frequent in certain districts of Normandy than in Paris. A committee of thirty-five physicians was formed in Normandy to investigate these figures of ARNAUDET, and they assert that while cancer is undoubtedly unduly prevalent in certain remote hamlets (due in their opinion to heredity), yet taking the whole of Normandy, it is no more frequent than elsewhere in France.

Mr. HAVILAND (*Allbutt's System of Medicine*, i, 52), who is distinguished for his researches into the medical geography of Great Britain, has shown that in England and Wales the areas where the highest mortality from cancer obtains are found to be about the lower parts of rivers flowing through low lying valleys, and which seasonally overflow their banks. The areas with the lowest mortality occupy the more elevated regions in the old rock formations, as the Cambrian, Silurian and mountain limestone; the last has the lowest mortality.

These facts by no means prove that cancer is contagious; they seem to afford some comfort, however, to the adherents of its parasitic origin. If the disease be due to an organism, there may be some com-

mon condition of soil and water in the cases quoted by which the organism is enabled to pass part of its life outside its host.

SANITARY TRIVIALITIES.

"And it shall be unlawful for any person or persons to use or to engage in the sale of any bottle, mechanism or other device for the artificial feeding or nursing of infants or children under three years of age, that has connected therewith a rubber tube, hose or such contrivance."

The passage of an ordinance in the above terms, by the Board of Aldermen of the city of Buffalo, signals another victory for the Commissioner of Health, Dr. ERNEST WENDE, over popular incredulity and ridicule. One astute city father declared that "this is drawing it pretty fine. There are many healthy specimens of manhood here today that sucked at the end of the long tube, and it is used for the young of animals, too," and it was gravely argued that being good for the raising of pigs it ought to serve equally well for babies. Another asked: "Can't you blow in the thing and clean it?" "The trouble with the Doctor," said a third lawmaker, "is he thinks he has a patent on the health of the city. His circulars are not panaceas." Nevertheless, the Health Commissioner showed that the circular which he had first issued on this subject, and which was antagonized by the very aldermen opposing the ordinance, had resulted in the falling off in deaths of infants from between four and five hundred to about two hundred and forty. After a last shot in the sneering question: "Why don't you go further and declare in favor of a certain kind of nipple?" the amendment was adopted and druggists can no longer sell nursing bottles with rubber tubes in the city of Buffalo.

The city fathers do not suck milk through a rubber tube, whatever else they may absorb by suction through straws or paper tubes and probably very few are interested in drug stores that sell them, but the city father does cough and expectorate and chew tobacco and spit, and so the anti-spitting ordinance has not yet been added to the municipal code, and perhaps it had better not be, if like the analogous regulation of the New York City Board of Health it is only to be printed in scarcely legible type and displayed where it can not be read, or if read is never enforced.

Buffalo has already accomplished a great deal in municipal sanitation. The regulation of the milk supply and the identification and isolation of diseased cattle in herds are all-sufficient. A register is kept in the health office of the location of every fatal case of diphtheria, scarlet fever and typhoid fever, and if these are found to occur along any special milk delivery route, all the milk supplied on that route is carefully traced to the dairy and thence to the herd.

Municipalities are only the aggregate expression of individual education and individual perceptions. Nine out of ten in the community doubtless thought with the Board of Aldermen that the commissioner of health was engaged in a petty business interdicting the rubber tube of the nursing bottle, and many of them will probably send elsewhere for them and surreptitiously use them in defiance of the ordinance. Let any one attempt to call attention in a New York street car to a violation of the spitting regulation and he will be insulted by the offender, told by the conductor that it is none of his business, and recognize unmistakable disfavor among the passengers. The well-meant suggestion to a mother that her daughter was incurring danger by holding an especially dirty bank-note between her lips while looking for change was rewarded by an angry scowl from both. There has lately been a favorite toy on sale in the large cities by licensed street vendors, consisting of a pair of painted rubber mustachios, inflated to the length of several inches by blowing through a tube held in the mouth, a huge papier maché nose adding to the attractive grotesqueness of the thing, for children. The vendors, who are of the lowest order of unclean Greeks, Armenians and Russian Jews, attract crowds by suddenly distending the mustachios, holding the tubes in their mouths until a purchaser is found, and respectable, well dressed, intelligent people may be seen handing the toy over to their little children. How many house-keepers ever give a thought to the refrigerator in the butcher's shop, loaded day after day with often questionable meat, to the fish-box in which layer after layer of stale fish is buried in the ice, to the musty receptacle in which the grocer stores his goods, or to the cellar in which the dealer in fruit and vegetables keeps his perishable stock? Does any inspector examine the storage boxes beneath the dining-car, when they are refilled at a station, to see that they are thoroughly emptied and cleansed before refilled? One is confronted everywhere by apparently trivial sanitary neglects, each of which in its possibilities for evil will be found anything but trifling. Dr. WENDE deserves to be congratulated on his success in suppressing the rubber tube of the nursing bottle, and the city of Buffalo for having a commissioner of health who is not deterred by ridicule from attacking so-called sanitary trivialities.

CORRESPONDENCE.

Section Dinners.

PHILADELPHIA, Jan. 25, 1897.

To the Editor:—Some of us who are most familiar with the Annual Dinners of the Section on Ophthalmology, hope that the setting aside of the first evening of the coming meeting of the AMERICAN MEDICAL ASSOCIATION for section dinners is a step in the development of what will be in future, a very important feature of our annual gatherings.

These originated in the Section on Ophthalmology from a

suggestion by Dr. Leartus Connor, in his address as Chairman of the Section at the meeting in Washington in 1891. The suggestion meeting the approval of the Section, the first dinner was arranged for the Detroit meeting in 1892, and since then it has been a most enjoyable feature of our annual meeting.

For the sound development of the ASSOCIATION it is of the highest importance that the members of each Section have opportunities for becoming personally acquainted with one another. Personal acquaintance and friendship constitute the strongest basis for organization and add immensely to the pleasure of the meeting; and to the certainty that year after year the members who have experienced such pleasure will be found in regular attendance. I believe that it is to this, more than to any other one thing, that the exceptional and steady growth of the Section on Ophthalmology of late years has been due.

In arranging for such a dinner, certain points seem to be well settled by the experience of those Sections that have adopted the custom. Some of these I would commend to the attention of Section officers:

1. The greatest economy of time is secured by having the Section dinner about the usual dinner hour, say, between 6 and 8 o'clock P. M.

2. The price fixed should be low, that it may not prove exclusive or burdensome to the younger and poorer members. The price fixed for the Ophthalmic Section is \$2. This is quite sufficient to get a good dinner in any city that we meet in, but excludes wines, so that no difficulty is had from the scruples of the temperance members. At the same time those who wish wine are free to order for themselves.

3. No large number is necessary to make the dinner a success. Such an occasion may be quite as enjoyable where a dozen members with similar tastes and interests meet after the separation of a year as any larger gathering can be.

4. Speeches, if formal speeches are to be indulged in, should be *very* short. No one who can not recognize this requirement of the situation should be asked to speak. Indeed, it seems to me that a transgression against the rights of hearers, in the way of a tedious after-dinner speech, should be met by a polite, if possible, but firm refusal to listen, which might be expressed by the resumption of general conversation or by calling for someone else to speak. This sounds desperate, but desperate diseases demand desperate remedies.

To arrange for a Section dinner, the President of the Section, or, if the Section has an incompetent President who will not attend to the duties of his office, the Executive Committee should enter into correspondence with the proprietors of one of the hotels that are willing to grant concessions to the members of the ASSOCIATION. Or, what is perhaps better, the Section officer should enlist the service of some active and competent member of the Section residing at place of meeting. Having fixed the price to be paid per plate, the hotel manager can be asked to furnish a bill of fare, such as he would be willing to supply at such a price. When the arrangement has been made, and it should be made early, it should be announced through the JOURNAL and upon the program of the meeting, if this is sent to members of the Section. The announcement should state time, place and price of the dinner, and the name and address of the member to whom the names of those expecting to attend should be sent two or three days before the meeting.

If the President of each Section will this year take fifteen minutes and write to the proper member of his Section, resident in Philadelphia, a letter urging him to move promptly in the matter, and stating what is desired as to price and the probable number to be provided for, every Section can at the coming meeting have a successful dinner, to which those who participate will in future years look back with pleasure.

Some of the Section officers have, I know, already taken the necessary steps, and it is to be hoped that the others will immediately follow their example.

EDWARD JACKSON, M.D.

PUBLIC HEALTH.

The New Fluid Vaccin.—The New York City Board of Health has recently undertaken the preparation of bovine vaccin in capillary tubes and in vials, at a cost of 10 cents for a capillary tube suitable for a single case, vials for ten vaccinations and for fifty, at 75 cents and \$3, respectively. The ivory points are sold as formerly at 10 cents each. The pulp virus is examined bacteriologically and clinically before it is allowed to be used or sold. The tubes and vials should be kept in a cool, dark place and should not be opened till the time of using the virus. The virus is usually reliable for twelve weeks from date of collection, which is marked on containing box, but should not be used for a longer period than three days from the date of opening the vial. The virus may be removed from the vial by dipping into it the accompanying slip of wood, and from the capillary tube by blowing it out with a rubber bulb. The virus should be smeared on the scarified area and thoroughly rubbed in. Merely smearing it in is not sufficient. The area should be left bare until the virus has entirely dried.

Over 5,000 Cattle Condemned for Tuberculosis.—The Cattle Commissioners of Massachusetts have made their annual report for the year 1896. A large showing of work is made as to the quarantining of animals regarded as infectious and suspicious, the examination of animals coming from without the State to the cattle markets without certificates, and upon special permits, examination of stables with a view to their sanitary improvement, and laboratory and stable experiments to determine various problems connected with the work of the board. A table is given showing the number of animals quarantined in each city and town, the number condemned and the amounts paid. There are 550 animals which have been condemned, but the warrants for killing are in process of settlement. The totals of this table are: Meat cattle assessed in the towns 212,601; number tested 8,969; number condemned 4,694; amount awarded \$153,733. Thirteen towns made no returns as to herd inspections. During the year the board has had at its disposal \$30,000. It has paid for 5,198 head of cattle condemned as tuberculous, the sum of \$173,206. There are in hand 550 warrants for cattle to be killed, the value amounting to \$16,040. There has been paid for quarantine expense \$28,223, making a total of \$217,470 returned to cattle owners.

The Great Convention of the "Antis"—There is proposed to be held a great convention of the anti-vaccinators and other enemies of disease prevention, at or near Gloucester, England, in the year 1898. It is expected that Bacillus will preside, but there will be even older and better known names among the guests of honor. An English writer suggests that some good aristocratic names might be had to lead off with as, for example: "The Duke of Anasarca, Marquis Sarcoma, Earl R theln, Viscount Rubeola, Lord Pertussis. Legal luminaries, who have just as much to do with the subject, could be represented by Lord Justice Chlorids and Sir Albuminoid Ammonia, Q. C. The names of microbes might be borrowed and slightly modified to give dignity to the list: Sir Staphylococcus Aureus (suggestive of an eminent financier), the Rev. Bacillus Prodigiosus, D.D., Dean of Albumoses, etc. The names would sound well to foreign ears and really it seems a pity that we should have to put up with second-rate titled people when we have got such a good choice and such a wide range of professions to select from, whose members have just as much to do with public health work."

Leprosy in Iceland.—Dr. Edward Ehlers of Copenhagen, is the author of a prize essay on that subject. It is especially devoted to the study of the conditions under which leprosy has declined in Iceland and the extent of its former and present prevalence. Dr. Ehlers from his researches believes that leprosy was introduced into Iceland, after the crusades, from Norway. In the seventeenth century the disease was very prevalent, little being done in the way of isolation or otherwise to limit its spread. A great epidemic of smallpox in 1707, and of measles in 1846, did more than all other measures to lessen the number of lepers, as they were the first to succumb to any epidemic influence. At the present time it is computed that there are about 200 lepers in Iceland. As there is a considerable number of Icelanders in Manitoba, it is important that a strict watch should be kept on all emigrants coming from Iceland. The London *Lancet* has the following item which places the number of cases much higher than has been reported by Ehlers:

"Iceland, although larger than Ireland, is so sparsely inhabited that altogether the population does not exceed 75,000 or about one person to the square mile. Amongst the number, however, there are no fewer than 400 lepers, and yet no attempt has so far been made either to alleviate the condition of the sufferers or to prevent the spread of the disease. There is not a single refuge or hospital for lepers in the whole island. In the other parts of Europe where the disease is prevalent, to wit, Spain, Portugal, Italy, Turkey, and the Scandinavian peninsula, lazaret-houses were long since established, to the great advantage of the healthy as well as of the afflicted. In Norway especially, where of recent years segregation has been rigidly enforced, a great improvement has taken place and, according to M. Hallopeau, there are not now more than 800 lepers in a population numbering upward of 1,700,000 souls. Iceland, of course, belongs to Denmark, but its shores are largely frequented by the French for fishing purposes, while many English tourists visit the island every summer for sport or relaxation. It is certainly little creditable to international hygiene that no steps have been taken to ameliorate the miserable condition of Icelandic lepers."

Deficient Supplies of Water for the Cities of Eastern New York.—

An interesting report relating to the water supply of New York and Brooklyn and the Hudson valley cities has been made by Dr. Smelzer, the Secretary of the New York State Board of Health. It is held by him, and others whom he has conferred with, that this whole question should come under State control and in no way better than in connection with the work of the State board of health. For the past ten years the State of Massachusetts had maintained as a part of its State Board of Health an engineering department at an expenditure of \$30,000 a year, and, to use the language of that board: "It is difficult to estimate the extent of the useful results accomplished under the provision of the act establishing it." All sections of the country were indebted to Massachusetts for researches in connection with the purifying of water supplies. A comprehensive system of water supply, which should apply to the Greater New York and most of the Hudson valley cities, ought to be investigated and worked out by State authority, as was so satisfactorily accomplished for Boston and suburbs by the State of Massachusetts. An abundant supply of water could be obtained from the southern and eastern slopes of the Adirondacks for New York and Brooklyn, as well as for the Hudson valley cities. This was an enterprise, the report said, vitally affecting the health of a large population and it would more properly come within the scope of the State Board than under any other department. As an illustration of the very good work that could be done in that way the Croton watershed investigation was referred to, which the State Board of Health made in 1886. It was very much to be desired that an appropriation be secured to inaugurate and carry on this important work.

Egypt's Need for a Quarantine against the Plague.—Circumstances alter cases. The recent history of Bombay in respect of

the plague is exciting solicitude in Egypt, for that country was once its habitat. It is true that there has been no plague there since 1845, but if it were to be accidentally re-introduced it might be even more difficult than was the case with cholera to eradicate it from its former haunts. No one knows quite why plague suddenly left Egypt, for it can hardly have been due entirely to the sanitary precautions of that day. Perhaps it was merely an extension of the eastward recession of the disease, which began in the latter half of the seventeenth century and helped, with other causes, to free Europe from its ravages. Quarantine may be quite unnecessary in England, protected by its insular position and by the millions spent upon the country's sanitation, but one can not help feeling that Egypt is still somewhat like a powder magazine from which the tiniest spark has very jealously to be excluded. The quarantine regulations of 1878 against plague have just been revised by the International Board in Alexandria. In accordance with modern notions ships are divided into three classes—clean, suspected, and infected. In the case of clean ships coming from a plague stricken port seven days must have elapsed, linen and bedding must be disinfected, and drinking-water must be renewed. Suspected ships are defined as those on which there has been plague, but not for the last nine days. Ships carrying a medical officer and a disinfecting stove will be allowed to traverse the Suez Canal in strict quarantine, while other ships will be kept long enough to disinfect clothes and personal effects and to satisfy the sanitary officer that there are no fresh cases on board. Passengers destined for Egypt will be kept under observation for two days while their effects are disinfected. Lastly, there are the infected ships, meaning those which have had a case of plague on board during the last nine days. Passengers suffering from plague must be isolated in a hospital on shore. Healthy passengers are to be divided into small groups and kept in quarantine long enough to allow eleven days to have elapsed since contact with the last case. The whole ship and its contents are to be disinfected, and as in all other cases, the drinking water is to be renewed and the bilge water disinfected and discharged.—London *Lancet*, January 9.

Action Regarding the Prevention of Tuberculosis.—Important action was taken by the Health Department of New York city on January 19, including pulmonary tuberculosis among the communicable diseases that must be reported by physicians to the sanitary bureau. The sanitary code was amended by the adoption of a new section, as follows: "Pulmonary tuberculosis is hereby declared to be an infectious and communicable disease, dangerous to the public health. It shall be the duty of every physician in this city to report to the sanitary bureau in writing the name, age, sex, occupation and address of every person having such disease who has been attended or who has come under the observation of such physician for the first time within one week of such time. It shall also be the duty of the commissioners or managers, or the principal, superintendent or physician of each and every public or private institution or dispensary in this city to report to the sanitary bureau in writing, or to cause such report to be made by some proper and competent person, the name, age, sex, occupation and last address of every person afflicted with this disease who is in their care or who has come under their observation within one week of such time. It shall be the duty of every person sick with this disease and of every person in attendance upon any one sick with this disease, and of the authorities of public and private institutions or dispensaries to observe and enforce all the sanitary rules and regulations of the Board of Health for preventing the spread of pulmonary tuberculosis." The medical members of that department, Commissioner George B. Fowler, M. D., and Drs. Hermann M. Biggs and T. Mitchell Prudden of the pathologic service have made a very close study of the prevalence of tuberculosis and of the best measures applicable

to a large city for its prevention. An estimate has been made that 20,000 sick exist in that city, and that the ravages by tuberculosis have increased 30 per cent. in the last fifteen years. A recent report by these gentlemen contains four leading recommendations that can be acted upon at the present time: "1, that such action be taken by the health board as seems necessary and proper to at once secure the provision of hospital accommodations, under its charge, for the care of the poor suffering from pulmonary tuberculosis, who, as active sources of danger to the community, may properly come under its supervision; 2, that an amendment be made to the sanitary code declaring that tuberculosis be officially considered a communicable disease, and formulating regulations under which its sanitary surveillance shall be exercised; 3, that all institutions in this city which admit and treat pulmonary tuberculosis be subjected to regular and systematic inspection by officials of this board, and that specific regulations be established for the conduct of such institutions in accord with the proposed amendment to the sanitary code; 4, that the scope of the measures designed for the education of the people in regard to the nature of pulmonary tuberculosis and the methods to be taken for its prevention be enlarged, and a closer sanitary supervision be maintained over individuals suffering from this disease in the densely populated tenement districts and in the crowded workshops and public buildings of the city." Their report also states further their convictions that the action proposed is timely and feasible: "We fully believe that with proper regulations tuberculosis may be restricted within the few narrowest bounds and eventually, perhaps, almost exterminated. This is not the idle dream of sanitary enthusiasts or theorists, but is a conviction founded upon the most thorough and conclusive experimental investigations, which have been amply confirmed by practical experience." In order to make possible such restriction in the prevalence of this disease, it is necessary that the health department shall assume a more complete and comprehensive control. This requires: 1, the adoption of such measures as shall make possible the general sanitary supervision of pulmonary tuberculosis under well defined conditions and regulations, differing in many respects from those applied to other more readily communicable diseases; 2, the possession of such facilities for the care of the poor suffering from it as shall make possible the removal, when necessary, of those who are dangerous sources of infection. "From the beginning of this work the officials of this department have encountered, in the utter lack of proper facilities for the care of consumptives, an obstacle to practical success so great and so disheartening that we feel impelled to urge our conviction that the grave responsibility which rests upon the health department in this matter can not longer be adequately sustained without the immediate establishment under its direct control of a hospital for the sole benefit of the tuberculous sick."

NECROLOGY.

EDWARD PEARSON ELLIOT, M.D., first assistant in the Danvers Insane Hospital, died January 10. He was a native of Boston and was a graduate from Harvard College in 1875, and from the Harvard Medical School in 1882. He served as house-officer in the City Hospital two years, and studied abroad two years. He had held his position in Danvers during the past twelve years.

ASA J. WHITE, M.D. (University of Buffalo, 1863), of Cortland, N. Y., died from apoplexy, January 12. He was assistant surgeon of the 109th Regiment, N. Y. Vol. Infantry from Sept. 4, 1864 to June 4, 1865.

LUIGI CALORI, professor of anatomy at the University of Bologna, Italy, for fifty-three years, and subsequently presi-

dent. So many prominent members of the profession have died abroad within the past few months in the early prime of life, that we note with satisfaction that the career of this popular writer and instructor was rounded out to a more natural completion; he was in his 90th year.

JOSEPH A. LIVINGSTON, M.D., of Brooklyn died Dec. 31, 1896, in his 28th year, by typhoid fever, with intestinal perforation. He was a native of that city and a graduate at the Long Island College Hospital, of the class of 1890. He was for a time in practice at West Cornwall, Conn.

BYRON W. MUNSON, M.D., of Sharon, Conn., died January 3 of asthma and heart trouble. He was 53 years old. Dr. Munson was a graduate of the Yale Medical School of the class of 1869. He served through the late war with the medical corps. From 1881 until 1890 Dr. Munson was superintendent of the State Soldier's Home at Noroton, Conn.

ANDREW J. FULLER, M.D., one of the best-known physicians of Bath, Me., and the first vice-president of the AMERICAN MEDICAL ASSOCIATION, died there, January 10, aged 74 years. Among the offices he had held was that of president of the Bath Board of Trade for eighteen years, and of the Lincoln fire insurance company for five years. He was graduated in medicine from the Bowdoin School of Medicine in 1841, and Jefferson Medical College in the year following. In 1871, he was president of his State Medical Society. During the war he was surgeon to the Second Maine Infantry. He was connected in a prominent way with life insurance interests. His first place of settlement was Searsmont, but in a 1847 he became permanently domiciled at Bath. An essay by him on the treatment of cholera infantum was presented as a report to our ASSOCIATION in 1856.

LOUIS J. SASS, M.D., of New York City, November 19, at the age of 76 years. He was a native of Havana, and was graduated from the New York Medical College in 1858. He was one of the pioneers in the modern treatment of diseases of the nose and throat, a specialty in which he won considerable distinction. He had a great deal of mechanical ingenuity, and was perhaps, the first to make use of compressed air for the application of medicated sprays to the larynx and nasal passages.

DANIEL MARCH, Jr., M.D., of Winchester, Mass., died in Woburn, January 1, aged 52 years, of angina pectoris. Dr. March was born in New Haven, Conn., but came to Woburn with his parents when a boy. He graduated from the medical school of the University of Pennsylvania in 1868. After serving as house physician of the Episcopal Hospital in Philadelphia for over a year, he removed to Pittsburg, where he practiced for a time. He removed to Winchester in 1879, and had a large practice in that town and vicinity. He joined the Massachusetts State Medical Society and his professional life is the subject of the following note in the *Boston Journal*: "He succeeded Dr. Winsor of Winchester, as medical examiner of the fourth Middlesex District about ten years ago and held that office ever since. He fell over a wire fence a few days ago while crossing a lot and received a severe shock, from which he had suffered considerably, and he had thought of going away for a while to recuperate."

MISCELLANY.

Notice to Physicians and Librarians of Public Medical Libraries.

[Medical journals are requested to copy this notice.]

1. Correspondence in relation to the enterprise should be addressed to Dr. Geo. M. Gould, 119 S. 17th St., Philadelphia.
2. Librarians of public medical libraries are requested to notice these exchange lists and to correspond direct with the advertised donors and recipients; and are also urged to for-

ward to Dr. Gould: 1. Accurate lists of periodicals, books or pamphlets needed to complete their files. 2. Lists of duplicates which they will give other libraries or exchange for numbers desired. Give both volume numbers and dates of periodicals.

3. Every physician is to inspect these lists and to give the books and periodicals for which he has no further use to public libraries, and having no particular choice, to correspond with Dr. Gould in reference to their disposal, in order to secure the greatest usefulness by the profession.

4. Owing to the additional labor it would involve, queries concerning the supply of desired items to private libraries can not be answered.

5. The conditions of all gifts are that the recipients shall be reputable organizations, composed of the regular medical profession; that the library shall be a public one—i. e., open for consultation during stated times to physicians generally; and that, if unbound, the periodicals and books received shall be bound and catalogued.

6. Send nothing before corresponding, in order that the gifts may go direct from the donors to their proper destination.

7. In order to secure the best success, physicians and librarians of other countries are invited to cooperate.

8. Notify Dr. Gould of any gifts or exchanges effected.

Previous list: November 21, 1896.

W. U. REBER, M.D., LEHIGHTON, PA., WILL DONATE:

American Journal of Medical Sciences, 1866 to 1882, complete; 1866 and first half of 1867 bound in three volumes.

American Journal of Obstetrics, all of 1882, including quarterly supplements; also the supplement of October, 1881.

Obstetrical Journal of Great Britain and Ireland, American supplement, all of 1874.

Quarterly Compendium of Medical Science, 1883, Jan., April, July; 1884, Jan., April, July, Oct.; 1885, Jan. only; 4 series, April, July, Oct.; 5 series, April, July, Oct.

Medical Abstract of Medical Science, vols. 2-7 (1875-1880).

Half Yearly Abstract of Medical Science, 1867 to 1871, in full; 1873 in full; 1874, Jan. only.

London Lancet, vols. 1 and 2 of 1893.

Annals of Surgery, vols. 15 to 18, 1892, 1893; extra numbers, 6, of vol. 15, and 5, of vol. 20.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, vols. 25 and 26, 1895; vol. 27 up to No. 20, 1896.

Medical News, vols. 27 to 29, 1869 to 1871, March No. of vol. 27 missing; vols. 31-37, 1873-1879; vols. 38-39, 1880-1881; also the supplement of July, Aug., Sept., Oct. and Nov. of 1874.

Half Yearly Compendium of Medical Science, 1874, part 14, July only; 1875-1882, parts 15-30, complete.

University Medical Magazine, vol. 1, complete; vol. 2, Nos. 1-10, only; vols. 6 and 7, 1894-5, complete; also extra No. 1 of vol. 1.

Annals of Hygiene, vol. 2, Nos. 6-12, 1887, an extra copy No. 7; vol. 3, Nos. 1-4 and 6-11, 1888.

New York Medical Record, vol. 20, Nos. 14-27, 1881; vols. 21 and 22, 1882, complete; vol. 34, Nos. 12-16, 18 and 19, 1888; vol. 46, 1894, complete; vols. 47 and 48, 1895, complete; vol. 49, 1896.

New York Medical Journal, vols. 21 and 22, 1875, complete; vol. 42, 1885, Nos. 5-13 only.

Medical and Surgical Reporter, vols. 32-43, 1875-1880, complete; vols. 44 and 45, 1881, No. 23 of vol. 45 missing; vols. 46-49, 1882 and 1883, complete; vol. 50, 1884, No. 19 missing; vol. 51, 1884, No. 24 missing; vols. 52 to 59, 1885-1888, complete; also odd numbers, Jan. and Dec., 1894, Oct., 1888, and July, 1887.

Ephemeris of Materia Medica, Pharmacy, Therapeutics, etc., vol. 1, No. 1 missing; vol. 2.

American Journal of Pharmacy, vol. 3, 1873, Nos. 4-12; vol. 46, 1874, complete.

Therapeutic Gazette, 3d series, vol. 1, 1885, complete; vol. 2, 1886, Nos. 1-8 only; vol. 4, 1888, No. 3 only.

Philadelphia Medical Times, vol. 18, new series, vol. 1, Oct., 1887 only; vol. 19, new series, vol. 2, Oct., 1888 only.

International Journal of Surgery, vols. 6-8, 1893-1895.

Railway Surgeon, vols. 1 and 2, 1895 and 1896.

New Remedies, vols. 6-9, 1877-1880; vol. xi, 1882.

Homeopathic Recorder, vol. 1, 1886, Nos. 4, 5 and 6; vol. 2, 1887, complete; vol. 3, 1888, Nos. 1, 2, 3 and 6.

North American Journal of Homeopathy, vols. 13 and 14, 1865 and 1866, bound; vol. 1, No. 2, Nov., 1886, unbound.

The Bucknell University Library, Lewisburg, Pa., has:

Braithwaite's Retrospect, vols. 57, 58, 59 and 60.

Obstetrical Journal, supplements, vols. 1, 2, 3, 4, 5 and 6.

FOR SALE.

The following volumes may be had at exceptionally low rates. Prices made upon application. These sets were bought remarkably cheap and will be sold at cost, but only to public medical libraries. Private buyers need not apply.

American Journal of the Medical Sciences, unbound, complete from November 1827 to December 1895.

London Medico Chirurgical Transactions, complete, in cloth, from Vol. 1 to 77, with catalogue and index.

British and Foreign Medical Review, Vols. 5 to 24 (1836-47), and an index volume. In half-calf.

Johnson's Medico-Chirurgical Review, Vols. 1 to 42, including the years 1820-1843 in the old series and a continuation of six volumes in the new series, 1843-47. Cloth.

American Journal of Obstetrics and Diseases of Women and Children from the commencement in 1868 to 1895. Unbound.

PERIODICALS AND PUBLICATIONS NEEDED TO COMPLETE SETS.

THE BUCKNELL UNIVERSITY LIBRARY, LEWISBURG, PA., NEEDS:

American Journal of the Medical Sciences, vols. 1-38, inclusive; 44, 47-66, inclusive, 77, 83 to date.

London Lancet, all before 1866, and 1879 and 1880, and all after 1881.

Medical and Surgical Reporter, vols. 1-4, inclusive; 6-13, inclusive; and all after vol. 27.

THE DETROIT PUBLIC LIBRARY

needs numbers to complete volumes as follows:

American Journal of Insanity, vol. 35, July and Oct., 1879; vol. 36, Oct., 1879 and Jan., 1880; vol. 41, Jan. and April, 1885; vol. 46, Oct. 1889, Jan. and April, 1890; vol. 47, July and Oct., 1890; vol. 49, July and Oct., 1892.

American Journal of Ophthalmology, vol. 1, 1884, Oct. and Dec.

American Journal of the Medical Sciences, vol. 5, n. s., April, 1843; vol. 11, n. s., April, 1846.

Pasteur's Remains have been removed to the chapel built to receive them in the Institut Pasteur.

Frequency of Death from Pulmonary Tuberculosis after Amputations.

—Marie has found so many cases of death from this cause that he is inclined to consider it more than a coincidence, and asks whether it can be due to the diminished resistance of the vitality after the amputation. He suggests that this possibility be borne in mind and statistics collected to decide the question.—*Presse Méd.*, December 12.

A Joy to its Friends and a Terror to its Foes.—A journal that gladdens the heart and delights the understanding every month is the *Texas Medical Journal*, Austin, Texas, otherwise known as the "*Red Back*." As Chimmie Fadden would say, "it is up to de limit." Standing for the ethical in both medicine and journalism, it is the uncompromising foe to the medical pretender and adventurer. It is a joy to its friends and a terror to its enemies; *suaviter in modo, fortiter in re*. There is but

one *Texas Medical Journal*, and Brother Daniel is the editor thereof. May its vigor never perish, nor its complexion fade.—*Atlanta Medical and Surgical Journal*, January, 1897.

Roosevelt Hospital, New York City.—The trustees have recently opened for private patients a new pavilion, which has been erected west of the main building of the institution. It is designed for the treatment of surgical, gynecologic and medical cases under the most approved conditions, and care has been taken to fit up the rooms in such a manner as to render them homelike, cheerful and attractive. The first two floors of the pavilion are arranged to accommodate patients in single rooms or *en suite*, and the third and fourth floors have been set apart and furnished as a home for nurses, thus providing accommodations for the training school just opened.

The New York College of Physicians and Surgeons.—The College of Physicians and Surgeons will profit by the proposed new gymnasium for Columbia University. That institution will soon begin building one of the largest and best gymnasiums in the country. It is to be included in what will be known as the University Building, which will stand near the center of the new grounds on Morningside Heights. This structure, which is to be three stories in height, will be 260 feet long and 180 feet wide. In the basement there will be a magnificent swimming pool, said to be the largest of its kind in the world, and around it will be ranged all kinds of baths. On the main floor will be the gymnasium proper, with rooms on either side for boxing, fencing and other exercises, and with a running track extending all around it. The latter will be one-tenth of a mile long and twelve feet in width. The estimated cost of the building is \$500,000.

The Economic of Pasteur's Discoveries.—One aspect of Pasteur's work is generally overlooked—his immense additions to the wealth of Europe, through the prevention of deaths among animals. Huxley said that the saving of animals in France alone was enough to pay the enormous indemnity demanded by Germany. Last spring a paper was presented to the French Académie de Médecine, by M. Hutrya of Budapest, describing some of the epidemics that have destroyed legions of cattle and sheep by anthrax, and myriads of hogs by swine disease in Hungary. Recently vaccinations against these diseases have been introduced. In 1894, 110,789 cattle were vaccinated, and the death rate among them, which had previously been 5 per cent., went down to 0.0024. Also, 224,684 sheep were treated. The death rate among these had been 10 per cent., and it went down to 0.32. We have read lately of great losses at the West from some disease among hogs; whether it is identical with what is known as swine disease in Hungary is not known; but in the latter country in 1894, 681,118 hogs were vaccinated, and the death rate went down from the 20 per cent. of relatively good years to 0.28.

State Care of the Insane in New York.—It is claimed by the State Commission in Lunacy that a saving of more than \$1,000,000 annually will result under the operation of the law providing for the State care of the insane. Under this law about \$5,000,000 is expended each year through the supervision of the commission for the operation and maintenance of the ten State hospitals and their 19,000 inmates. All the State hospitals are now completed with the exception of those in New York and Brooklyn. A contract aggregating \$350,000 for a group of buildings in connection with the Long Island State Hospital in Brooklyn has just been awarded. There are 2,500 dependent insane in Kings County. The commission has under way plans for the expenditure of \$750,000 for new buildings for the Manhattan State Hospital, in New York city. The legislature, however, has not yet made a good portion of this amount available. There are 7,000 insane in New York city, a large number being taken care of in the old structures on Hart's Island. New buildings are to be erected for these insane as

soon as possible. The system of caring for the insane wholly by the State has been in operation since March 1, 1896, when the County of New York transferred its insane and its property to the State. The year previous the County of Kings surrendered the control of its insane, with its property, to the State. In 1890 the transfer of the insane from the county poorhouse began. At this time there were 2,200 out of about eight thousand registered insane in the poorhouses, exclusive of those in the counties of New York and Kings. All of the insane are now receiving the beneficent care provided by the State. The private asylums in the State take care of more than one thousand insane persons. The number of private institutions is not increasing under the new law.

Cincinnati.

THE MORTALITY REPORT for the week ending January 22 shows: Deaths from all causes, 132; stillbirths, 3; annual rate per thousand population, 16.94; zymotic, 13; phthisis pulmonalis, 22; other constitutional, 13; local, 63; developmental, 13; violence, 8; preceding week, 145; corresponding week 1895, 125; 1894, 108.

THE ONSTETRICAL SOCIETY held its annual meeting January 21 and elected the following officers: President, Dr. Charles L. Bonifield; vice-president, Dr. C. B. Schoolfield; secretary, Dr. E. S. McKee; treasurer, Dr. Geo. E. Jones.

THE CONNER SURGICAL SOCIETY of the Medical College of Ohio held their first smoker and banquet January 23 at Lancet Hall and the affair was in every way a success. The membership of the society consists of the faculty and students of the Medical Department of the Cincinnati University.

THE WALNUT HILLS MEDICAL SOCIETY held its annual meeting at the Cincinnati Club January 21. The following officers were elected: President, Dr. Edward Ricketts; vice-president, Dr. Edward Shields; secretary and treasurer, Dr. O. W. Stark.

Philadelphia.

THE COLLEGE OF PHYSICIANS at its annual meeting, held January 6, re-elected Prof. J. M. DaCosta president and Dr. Thos. R. Neilson secretary. The president reported the clinical history of a case of hemiplegia from acute lead poisoning, in a woman 35 years of age, caused by exposure to the effluvia of fresh paint. Lead was detected in the urine, which was free from albumin and from sugar. Recovery followed treatment by iodid of potassium and massage with faradism of the muscles. Strychnia was substituted for the iodid, when improvement was marked. Dr. D. D. Stewart exhibited a specimen of large innominate aneurysm cured by the use of gold wire and galvanism, and claimed special advantage from combining the use of a weak galvanic current with the use of the wire for treating otherwise inoperable cases. The patient's condition, for months, had been rendered more comfortable, so that he could walk about the streets, and there was complete relief from former pain. The aneurysm was filled with a firm clot. Death was due to intercurrent disease (apoplexy) which was not connected with the aneurysm nor the operation. Dr. J. M. Anders read a "Memoir of the late Dr. Earnest Goodman." Dr. H. A. Hare read a brief communication on the effect of chloroform on the circulation, in which he especially spoke of the prompt fall in blood-pressure shown in experiments upon dogs, after beginning the inhalation of chloroform, which he had formerly attributed to heart failure. It was found, however, that by compressing the abdominal vessels so as to raise the arterial tension, the heart would resume its contractions. He now explains the cause of sudden death during chloroform narcosis as a vaso-motor phenomenon; the chloroform, acting upon the vaso-motor centers in the medulla, causes dilatation of the veins and fall of arterial tension, all the blood in the body being emptied into the veins. Therefore remedies to increase arterial tension should be resorted to, with compression of the abdominal aorta in cases of sudden asphyxia. Fatal results from the use of chloroform do not occur in parturient women, because the pains stimulate the vaso-motor

center and counteract the depressing influence of the anesthetic. It is also a comparatively safe agent to use in the case of children, as young hearts bear it better than old ones. The last paper was one by Dr. Stengel on "Auscultatory Percussion."

THE PHILADELPHIA PEDIATRIC SOCIETY held its first meeting after organization, January 12, Dr. J. P. Crozer Griffith, President, in the Chair. A case of neuritis occurring in a boy during the treatment of chorea with Fowler's solution, was exhibited by Dr. Stengel. A case of progressive neural atrophy beginning in the calf muscles (the peroneal form described by Charcot) was shown by Dr. C. S. Potts. Three cases of cretinism in patients under 12 years of age were shown by Dr. H. B. Carpenter and Dr. M. H. Fussell. All of them were said to be improving under the effects of extract of thyroid gland.

Dr. JAMES TYSON was elected president of the Philadelphia County Medical Society at its last meeting.

AT THE ANNUAL meeting of the Alumni Association of Jefferson Medical College, held January 9, Dr. H. G. McCormick of Williamsport, Pa., was elected president for the ensuing year. Resolutions were adopted relating to the deaths of Prof. Wm. H. Pancoast and Dr. James Graham. An appropriation of \$200 was made toward equipping the pathologic laboratories.

Washington.

HEALTH OF THE DISTRICT.—Dr. J. E. Walsh, medical sanitary inspector of the health department, who has had charge of the contagious disease branch of the service, is himself a victim of diphtheria.

TO REGULATE THE SALE OF POISONS.—A bill to prevent the sale of poisons in the District of Columbia was introduced in the House on the 18th inst. by Mr. McCormick of New York. This declares it shall be unlawful for any but a regular pharmacist, or some one under his direct supervision, to sell certain poisons, enumerated in two separate schedules. When sold by pharmacists these articles must be in triangular bottles and labeled "poison." The purchaser must also be informed of the nature of the poison, and must show that he wants it for legitimate purposes. A book, in which these sales are recorded, must always be kept open for inspection. The penalty provided is a fine of not less than \$5 nor more than \$50.

MEDICAL SUPERVISORS' FIRST MEETING.—On the 14th inst. the first meeting of the Board of Medical Supervisors was held for the examination of persons who want to practice medicine and surgery in the District. Dr. Kleinschmidt, president; Dr. Woodward, secretary, and the other members of the board were present. Three candidates were examined. Under the law establishing the board all graduates who desire to practice medicine have to undergo an examination. This applies to all persons who had not registered previous to June 6.

TO RESTRICT VIVISECTION.—Senator Gallinger has by request submitted to the Senate letters from various distinguished men throughout the country in favor of the bill for restricting vivisection in the District of Columbia.

INTERNATIONAL ANIMAL QUARANTINE.—The agreement between the Secretary of Agriculture and the Canadian Minister of Agriculture relative to the quarantine of animals passing from one country to another, provides that each country shall accept the veterinary certificate of the other as final, and that they shall keep each other informed of any outbreaks of contagious disease; that a quarantine of from ninety to fifteen days shall be imposed upon cattle or ruminants, or swine coming from European countries in which pleuro pneumonia or foot-and-mouth disease exist; that breeding cattle shall have certificates of freedom from tuberculosis, or submit to a week's quarantine, and cattle from feeding or stock ranches must have certificates of freedom from diseases of all kinds. Sheep may be admitted subject to inspection and slaughter if disease appears. They are also accorded privileges of passage in bond through ports without inspection. Swine for slaughter may pass without inspection to bonded slaughter houses, or when properly certified as part of a settler's effects. Liberal rules are laid down for the entry of horses into either country, and particularly for those belonging to Indian tribes and travelers.

ANTHROPOLOGICAL SOCIETY'S OFFICERS.—At the annual election of the Anthropological Society, recently held, the following officers were elected for the year; President, Dr. Frank Baker; vice-presidents, Prof. W. J. McGee, Mr. George R. Stetson, Gen. George M. Sternberg and Dr. Cyrus Adler; general secretary, Dr. J. H. McCormick.

THE OLEOMARGARIN BILL PASSES THE HOUSE.—The oleomargarin bill passed the House on the 14th inst. The full text of the bill is as follows: "That all articles known as oleomargarin, butterin, imitation butter or imitation cheese, or

any substance in the semblance of butter or cheese not the usual product of the dairy and not made exclusively of pure and unadulterated milk or cream, transported into any State or Territory, or remaining therein for use, consumption, sale or storage therein, shall, upon arrival in such State or Territory, be subject to the operation and effect of the laws of such State or Territory enacted in the exercise of its police powers to the same extent and in the same manner as though such articles or substances had been produced in such State or Territory, and shall not be exempt therefrom by reason of being introduced therein in original packages or otherwise: Provided, that nothing in this act shall be construed to permit any State to forbid the sale of oleomargarin except in such a manner as will advise the customer of its real character."

MEDICAL SOCIETY.—At the regular meeting of the Medical Society held on the 20th inst. Dr. Bishop read a paper entitled "Some Physical and Therapeutic Facts on Static Electricity." Dr. L. W. Richardson reported a case of laryngectomy, and presented the specimen. Dr. Burnett presented pathologic specimens of gumma of the ciliary region and a phlebolith of the conjunctival veins.

THIRD TRI-ANNUAL MEETING OF THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.—Dr. S. S. Adams, chairman of the Committee of Arrangements of the Third Tri-annual Congress, called a meeting of the committee on the 21st inst. The congress will meet on May 4, 5 and 6 next at the Columbia Theater, Washington, D. C. Important business matters for the coming event were transacted. The members of the committee present were Drs. S. S. Adams, W. N. Johnston, S. O. Richey, G. M. Sternberg, Shands and Frank Baker from Washington and Drs. Meak, Tiffany, Atchison and Theobald of Baltimore, Md.

THE PUBLIC SERVICE.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending Jan. 23, 1897.

Asst. Surgeon H. LaMotte, detached from treatment at naval hospital, Philadelphia, and ordered before retiring board at Washington Jan. 26, then home and placed on waiting orders.

Change of Address.

Beach, S. C. from Chicago, Ill., to McCook, Neb.; Bazan, F., from 415 Sutter St. to 776 Geary St., San Francisco, Cal.; Berg, O. H., from Carpenter and Milwaukee Ave. to 547 N. California Ave., Chicago, Ill.

Dal. J. W., from 860 to 482 Milwaukee Ave., Chicago, Ill.

Lincoln, D. T., from Geneva, N. Y., to 73 Pinckney St., Boston, Mass.;

Lan. O. H., from 1356 Woodward Ave. to 25 Piquette Ave., Detroit, Mich.

Stover, G. H., from Eaton to Fort Collins, Colo.

Westervelt, J. D., Jr., from Alice to Dallas, Texas, care Jeff House's Drug Store; Wilmarth, A. W., from State Hospital for the Insane, Norristown, Pa., to State Home for the Feeble Minded, Chippewa Falls, Wis.

ORIGINAL ARTICLES.

A CONTRIBUTION TO THE STUDY OF THE DIAGNOSIS OF TYPHOID FEVER BY MEANS OF THE BLOOD.

Read before the New York State Medical Society, Albany, Jan. 26, 1897.

BY A. HIRST APPEL, A. B., M. D.

CAPTAIN MEDICAL DEPARTMENT U. S. ARMY, AND

FRANK J. THORNBURY, M. D.

LECTURER ON BACTERIOLOGY, UNIVERSITY OF BUFFALO.

In a recent article upon the subject of continued fevers,¹ its distinguished author commenting upon anomalous typhoid, writes "it will lurk and hide its features completely, where it is unsuspected the difficulties attending its clear discernment from certain continued fevers of considerable duration not typhoid, may baffle even the most sagacious physician."

Among the febrile conditions the diagnosis of which may offer at times extreme difficulties of differentiation, he enumerates remittent and relapsing fevers; influenza; the the "ardent fever" of the tropics; "thermic" fever (Guitéras); "asthenic" simple fever (Murchison); "starvation" fever (DaCosta); "Malta" or "rock" fever (Milner); atypical continued fever" (Cain), from a supposed septic agency in the soil; "cypress" fever (probably relapsing fever); the "simple continued fever" described by Baumgarten (doubtful as to its being anomalous typhoid); the prolonged fevers arising in connection with local conditions, as from miliary tubercle, the fever of fecal accumulations, at times closely resembling typhoid; anemic fever; the fever of purpura, especially hemorrhagic; "hysterical" fever, in which the disturbance of heat function may last weeks, months, or even years; the "innominate" fever, described by Goddheart; fevers arising from organic changes—as rapidly advancing arterio-sclerosis; the fever of lithemics; of organic disease, as the endocardium, lung, pleura, duodenum, in which the lesion is slight, masking the etiology; of catarrhal pneumonia; of local plastic pleuritis; and the cases of "inexplicable pyrexia" described by Hale White.

Outlining the distinguishing clinical features of these various conditions, and the bacteriologic, microscopic, and chemic examinations of the blood upon which reliance is placed for making the differential diagnosis, no mention is made of the reaction obtained, in cases of true typhoid, with the blood when applied to active cultures of the Eberth bacillus; a test which since 1894, when Pfeiffer first called attention to the subject, has been confirmed in value, and bids fair to become pathognomonic, if this expression can be applied to a test, in the differentiation of these obscure febrile conditions from true typhoid.

The antagonism existing between the typhoid bacillus and blood in which an antitoxin has been devel-

oped by the presence of its products, has been known since 1888, when Chantemesse and Widal demonstrated that certain animals could be rendered immune against the typhoid bacillus, by the subcutaneous injection of sterilized cultures of this organism.

In 1892, Bitter concluded that immunity, which he induced in rabbits in the same manner, was due to the presence in the animal of "antitoxin."

Bruschettini in the same year, following the same line of research, noted that the blood serum of animals immunized by cultures sterilized at 60 degrees C., possessed antitoxic properties, and had far greater germicidal potency over the typhoid bacillus than the blood of the normal rabbit. Stern (1892) observed that the blood of a man who had suffered an attack of typhoid fever 17½ years previously, showed unusual bactericidal power over the bacillus of Eberth; and Chantemesse and Widal arrived at the conclusion that "in general the guinea pig is immunized against the action of virulent typhoid cultures by the subcutaneous injection of a small quantity of the serum of persons who have suffered an attack of typhoid fever, no matter how remote." The fact of the existence of antitoxin in the blood of patients who are or have been victims of typhoid, and of its presence also in the blood of immunized animals has been utilized successfully, experimentally, in animal therapy and more recently to some extent in man.² The serum of the blood from a fatal case of typhoid was found by Stern to be still more potent in animal as a therapeutic agent, than that of recent convalescents.

In 1894 the discovery was made by Richard Pfeiffer of Berlin that the specific poison of the bacillus of Eberth is not present in the filtered culture but is closely associated and remains with the bacterial cells. The bacilli may be killed by a temperature of 56 C. without injury to this toxic substance. By the latter, then, animals may be immunized and their blood be found to contain an antitoxin which has a specific bactericidal action upon the typhoid bacillus. Pfeiffer also clearly established the presence of this antitoxin

² Pfeiffer and Kolle, (Deutsche Medicinische Wochenschrift, Nov. 16 p. 6), publish results obtained upon the human subject by injection, into the subcutaneous tissue of the back, of bouillon cultures of typhoid bacilli, sterilized at 56 degrees C.

Healthy persons having no previous history of typhoid fever, experienced malaise, chills, giddiness and pain at sight of puncture, usually two or three hours after injection, with evening temperature upon the first day of about 101.3 F. which soon fell to the normal. They find that one injection of culture brings about the specific change in the blood which causes agglutination and immobility of the typhoid bacilli in pure cultures, recognizable in about six days, and exercised in as great a degree as they have ever been able to observe in convalescents from typhoid.

By mixing serum thus obtained with unsterilized bouillon cultures and injecting the mixture intraperitoneally, they find that guinea-pigs, although succumbing to the unsterilized cultures alone, will survive inoculation with the mixture, and tabulated the quantities of dead culture thus required to secure immunity.

Injection of dead cultures in man resulting in the production of substances in the blood serum inhibiting the specific bacteria, they hope thus to secure immunity by prophylactic inoculations, analogous to the results of Haffkine's protective inoculations against cholera, now substantiated by many thousands of cases. Should further observations confirm that they can confer the same immunity as exists in persons having had the disease, the procedure will become one of the greatest practical value, especially "in the face of epidemics or in war, since whole armies having been at times decimated by this scourge."

in the blood of patients who had recently suffered an attack of typhoid, and in the same year demonstrated its peculiar action upon the Eberth bacillus. Undoubtedly however, to Widal of Paris is due the credit of first utilizing this knowledge in every-day practical clinical work. Instead of obtaining the serum from the vein of a patient's arm, by means of a sterilized syringe, decanting after separation, the technique originally employed, he found that the dried blood or serum would give the result as published by him in the *Bulletin Médical* of August 12, 1896.

On Sept. 17, 1896, Wyatt Johnston of Montreal, observing the same fact, read a paper before the American Public Health Association, advocating the use of dried blood, as better adapted for bringing this test within the range of ordinary public-health laboratory work, and "enabling it to be dealt with in a wholesale manner." The latter method makes the discovery easy of application, and gives it the practical importance it now possesses. A drop or two of blood dried upon a slip of paper or cover glass (absolute sterilization is not essential), can be transmitted long distances with ease and safety, and is sufficient, in most cases, to determine the presence or absence of the disease.

To obtain the reaction it is simply necessary to dissolve the drop in sterile water and transferring it to a cover slip, inoculate with the pure culture and examine. If the case is one of typhoid fever, the reaction becomes manifest within a few minutes.

The following scale, formulated by Widal, enables the stating in terms of more or less exactness the measure of agglutinating power of any given specimen, indicating the strength of the antitoxin in the serum examined, and may be useful in doubtful cases.

Taking a series of sterile tubes containing respectively 1, 2, 3, 4, and 5 c.c. of bouillon, he added to each a drop of the serum to be examined; inoculates with a trace of culture, and examines in from twelve to twenty-four hours. If, for example, the tube containing 3 c.c. of bouillon, gives a typical reaction, while that which contains 4 c.c. does not, the agglutinating power of the fluid studied is exercised between 1 to 60 and 1 to 80; in a typhoid case the agglutinating power of the serum varies generally between 1 to 60 and 1 to 80; it could reach 1 to 100, rarely passing this limit; where it reaches 1 to 80 or 1 to 100 we find the reaction always takes place immediately. Let the specimen be prepared ever so quickly and examined as soon as it can be placed under the microscope, beginning of the clumping process of the bacilli will have already taken place. In the very early stages of the disease we found the reaction less pronounced at first, but gradually increasing in intensity, although even late a few bacilli may still retain some motion. These evidently were not acted upon by the agglutinating substance, which apparently had exhausted its energy upon the organisms already aggregated into clumps. Its action here presents some similarity to the chemic process of disinfection, which results in the production of a third substance through *contact* of the bactericidal agent with the cells. But that the process of agglutination is probably not a chemic change in the composition of the bacteria, but rather a sort of catalytic action, is proven by inoculating suitable media with the bacteria which had been agglutinated and rendered immotile by typhoid serum. Strangely enough, they grew with apparently the same vigor as the original cultures, their progeny

recover their independence and active motion and the new growths again respond to the typhoid reaction.³

The blood retains its agglutinating power with great tenacity. In dried specimens reexamined after two or three months we found it undiminished, although no particular care was taken to guard against contamination. A number of specimens sent us for examination from a distance, were collected without aseptic precaution upon ordinary writing paper and transmitted by mail. The method employed did not appear to affect the result, typhoid cases promptly giving the reaction, thus indicating that unusual precaution in the collection of specimens to be examined may be quite unnecessary. Dried blood is slow to undergo putrefactive changes, the saphrophytes responsible for such changes needing moisture for their proliferation.

That the agglutinating property be exhibited it is not necessary that the culture be living and active; dead bacilli are likewise massed into clumps by the serum. After exposing a pure culture of Eberth's bacillus to 60 C. for half an hour (the thermal death point being 56 degrees) they were still found to agglutinate. Further illustrating the tenacity with which the antitoxic power is retained in Stern's case, cited above, showing unusual bactericidal power in the blood of a man who had suffered an attack of typhoid fever seventeen and a half years previously, and Widal's reported case, which gave the reaction after seven years, we were successful in obtaining a decided reaction in a case thirty-one years after recovery,⁴ and other cases examined after one, two, eight and ten years, gave the reaction with virulent cultures. We have also found, as stated by Dieulafoy, that the agglutinative power is by no means confined to blood serum, but is found in other fluids of the economy. The reaction appears, exceptionally, in the *urine* of typhoid cases. It is constantly found in the serum of *vesication*. Widal and Sicard found it in the pericardial, peritoneal and pleural serum in three cases, post-mortem. A marked reaction can be obtained from the *milk* of nursing women affected with typhoid; likewise from the milk or the colostrum of rabbits and the milk of goats inoculated with Eberth's bacillus.⁵

The serum of *edematous infiltration* in typhoid cases agglutinates powerfully. In a case of grave typhoid recently reported (Etienne), which provoked abortion in a pregnant woman, the blood of the patient agglutinated typically, but that of the fetus was negative. In rabbits, however, inoculated by Widal and Sicard six hours before, the fetal blood agglutinated from birth, although less powerfully than in the mother, proving that the agglutinating substance passed into the fetal circulation. The reaction can be obtained from the human biliary secretion. Negative results were obtained from the cerebro-spinal fluid and that of the vesiculæ seminales. Negative results were obtained from the saliva, but Achard and Bensaude have demonstrated the reaction where the submaxillary or parotid secretions were collected within the gland ducts. The *aqueous humor* and the secretion from the *lacrimal gland* will also in typhoid

³ It may be possible, however, that these cultures result from a few cells which, enclosed in the mass, escaped the action of the agglutinating agent. [We found also that the bacilli, after agglutination, stain readily with the anilin colors. Where doubt exists, fibrin particles may thus be easily differentiated from masses of bacilli.]

⁴ In a physician who happened into the laboratory while we were examining blood specimens.

⁵ Journal Académie de Médecine, Sept. 26, 1896.

cases give the reaction of agglutination. The tears constitute a secretion always easy to obtain. The fact that they give the reaction is important. From the internal angle of the eye, with a fine pipette, a drop sufficient for an extemporaneous examination can always be aspirated. A distinction is made by the French observers between the secretion naturally present and that provoked artificially, as by ammonia or menthol. They find in the latter case the reaction often fails. Examining in both ways cases giving the blood reaction typically, our results confirm the observations of Widal and Sicard, who found the reaction in the tears of ten out of fourteen cases examined with the natural secretion, but when provoked artificially it persisted to a slight degree in but three. In two immunized rabbits the reaction appeared typically in a mixture of two drops of secretion to ten of culture. The lachrymal secretion of persons never having had typhoid, and of normal rabbits, was negative. In immunized rabbits the aqueous humor gave the reaction in seven out of nine cases. In normal rabbits the aqueous was negative.⁶

From these results, showing the agglutinating property in the tears, the aqueous and the serum of edema the conclusion is reached that the leucocytes play no part in the secretion of the agglutinating substance. Duclaux has shown that the greater part of the casein of milk is separated from the filtrate, after passing through a Chamberland filter. Achard and Bensaude demonstrated that milk thus filtered, in parting with this albuminoid, loses its power of agglutination previously possessed. In blood serum thus filtered the power is also greatly diminished. In fluids poor in albuminoids (as the cerebro-spinal and saliva) the reaction fails. The inference is therefore logical that for the production of the agglutinating reaction the albuminoids are essential.

The albuminoids existing in the blood include serum-albumin, serum-globulin and fibrinogen, the latter existing in the circulating serum, but in the act of coagulation under the influence of the fibrin-ferment, separating into fibrin (which forms the clot), a globulin and probably other substances. To separate the serum-albumin from the serum-globulin, they add magnesium sulphate to saturation to a tube of typhoid serum. The globulin is precipitated and separated by filtration. Mixing now two or three drops of the filtrate deprived of globulin to ten drops of culture, it is found that the bacilli retain their independence and motility. The serum deprived of its globulin seems to have lost its agglutinating property. The globulin remaining upon the filter, from which possible remaining traces of serum-albumin is removed by again washing the precipitate with a concentrated solution of magnesium sulphate until the filtrate will no longer coagulate by heat, mixed with an equal part of distilled water is found to possess the agglutinating property in a high degree. The phenomenon is still further intensified if less water is added, showing thus that the agglutinating property is definitely associated with the globulin.

Arthus and Pagès, in order to study the fibrinogen as it exists in the blood, prevented coagulation by adding potassium oxalate, about 1.5 to 1,000, to the blood as it issued from the vessels. In the plasma thus obtained the fibrinogen is retained. To precipitate this they add 15 parts to 100 by weight of sodium

chlorid, dissolving the precipitate in distilled water. The solution of fibrinogen thus derived from typhoid blood agglutinated the bacilli. Treating now the plasma, deprived of its fibrinogen, with a saturated solution of magnesium sulphate and filtering they obtained the same result as in the serum of coagulated blood; the filtrate containing the albumin had lost its agglutinating power which was retained by the globulin remaining upon the filter.

The other body fluids experimented upon, the serum of blisters, of the peritoneum, of the pericardium and of edema in typhoid cases, react in the same manner as the blood plasma. Fibrinogen and globulin apparently possess the agglutinating property.

Dieulafoy, Widal and Sicard have made an analysis also of the milk, which contains an albuminoid not found in solution in the blood. A goat inoculated with typhoid furnished, seven days afterward, milk possessed of a high degree of agglutinating power. By adding an excess of magnesia sulphate, the casein and lacto-globulin are precipitated together with the fat globules. The filtrate containing but the albuminoid lactalbumin, shows but slight agglutinating capacity. Adding a solution of sodium chlorid to saturation, the casein is precipitated with the fat globules, while the lacto-globulin remains in solution in the liquid with the lactalbumin. The filtrate gives the reaction typically, even though the whole milk is but feebly agglutinative. The phenomenon could not be due but to the presence of the lacto-globulin, for, on now adding magnesium sulphate to saturation the power of agglutination in the filtrate disappeared entirely. By coagulating the milk with rennet, the lacto-serum obtained was powerfully agglutinative, which property again disappeared upon precipitation with magnesium sulphate to saturation. To determine the presence of this property in the casein they now add to the milk acetic acid in the proportion of 1 to 2 parts per 1,000, to precipitate the casein, washing with water to get rid of the acid and of traces of lacto-globulin. Dissolving the precipitate, after filtration, in sodium hydrate, 1 to 100, they found that the solution, containing no other albuminoid but the casein, strongly agglutinated the bacilli. It is thus shown that the albuminoids contained in the *blood* of typhoids do not alone possess the power of agglutination, but that casein and without doubt other albuminoids can also acquire it, imparting this power to their solutions and regaining it upon precipitation.

The practical bearing of these experiments lies in the fact that the whole blood, containing *all* the albuminoid elements, instead of being less sensitive to the typhoid reactions, as Widal and others first supposed, is in fact *more* so than the serum alone; we therefore obtain incomplete or pseudo-reactions from typhoids years after recovery and perhaps other conditions from solutions of the whole blood, fluid or dried, which are not observed when the serum alone is used, and which may be misleading; the agglutination observed being at times equal to that of true typhoid fever in the active stage of the disease. In these cases, however, there is not observed the same progressive loss of motion that is found in true typhoid, and herein lies the differentiation; more stress must be laid upon the *loss of motility* of the bacilli than upon their clumping. In fact, in pseudo cases the latter is sometimes more complete and often more quickly exhibited than in true typhoid. Where doubt still exists, the differentiation is more readily accomplished after

⁶ Ibid. The chemie analyses and experiments upon the fluids of the body are translated from Widal and Sicard's paper quoted.

twenty-four hours, the specimen being meanwhile kept at blood temperature.

While the clumping for the most part persists there are at the same time numbers of individual bacilli in the clear spaces that retain their active motion, this activity being much greater than we find in true typhoid cases. Their number also increases upon longer exposure, thus definitely making the distinction from typhoid blood. Clumps once formed we have never seen break up again in true typhoid; the reverse often happens in pseudo-reactions. There still remains, however, a number of cases, especially where the history shows previous typhoid, in which the agglutination and loss of motion is so marked and so closely resembles the reaction of typhoid in its active febrile stage, that errors in diagnosis might still readily be made when dried blood is tested with virulent cultures of the bacilli.

As already stated, pseudo-reactions are rare with the serum alone separated from the clot. But when *all* the albuminoids are present, as in the dried blood, the agglutinative property, intensified, is readily excited when brought in contact with a very virulent culture, even where there are no present symptoms of the disease.

The "quantitative" test, under such circumstances, affords a valuable means of guarding against error. By diluting, with sterile water, the specimen to be examined, a point is reached where the reaction becomes negative; but where a control specimen from an undoubted typhoid case, with equal dilution, still gives a typical reaction.⁷

Still more reliable conclusions may be obtained by discarding entirely the very virulent culture, using instead one the virulence of which has not been increased by successive seedings, but instead is transplanted from a month-old growth upon agar into bouillon and incubated twelve to twenty-four hours before use.⁸ Thus grown, the bacilli are still measurably active, but their rapid, darting motion is absent; they exhibit but gliding, serpentine movements across the field.

Reexamining with the culture thus obtained blood specimens in which agglutination occurred with virulent cultures, we were able to completely eliminate the troublesome pseudo-reactions, and by this technic therefore obviate much of the confusion and error resulting from the examination by the dried blood method. The conclusion seems indicated, that given a case of acute pyrexia of some duration, in which the blood gives the reaction of agglutination with a culture thus prepared, and where there is corresponding loss of motility in addition to the clumping, we may safely decide that we are dealing with a case of typhoid fever.

Where active motion persists with clumping, the specimen must be kept at blood temperature for twenty-four hours. In typhoid cases the reaction is *progressive*, clumps once formed do not again separate; immotility becomes more complete and the clear spaces between the clumps of bacilli more defined. The reverse obtains in pseudo-reactions, when, after twenty-four or forty-eight hours, the hanging drop may perhaps be swarming with active bacilli.

In dried blood specimens from fifty cases examined, in nearly all of which the clinical symptoms were more or less typical and sufficient to make the diag-

nosis of typhoid fever, we were able to obtain the reaction upon cultures thus attenuated, even when the blood was diluted until the color was scarcely discernible; while in cases, as above noted, in which we had obtained the reaction with *virulent* cultures from blood in health a number of years after recovery, the reaction, under the same conditions, was constantly negative.

Another point of distinction may often be found in the *time* required for agglutination to take place, it often occurring in pseudo-reactions *more quickly* than in typhoid. The rapidly formed, oscillating, swaying masses of bacilli are not, as a rule, the effect of typhoid blood. With the latter, more often, especially with largely diluted blood, the *motion* is first arrested, clumps not forming until later.

To determine the differential *character* of the reaction we made a large number of comparative examinations of the action of typhoid blood upon other motile organisms, especially of those closely allied to Eberth's bacillus in morphologic and biologic characteristics. Of these the "colon" bacillus is the most important, closely resembling Eberth's bacillus, always associated with the latter in typhoid discharges, and believed by many observers to be one and the same organism, an evolution from saprophytic existence to pathogenic potency taking place in cases of typhoid fever. In the operative procedures recently successfully undertaken for suture of perforations of ulcerated intestine in this disease, it is remarkable that the "colon" and not Eberth's bacillus was found upon bacteriologic examinations of the scrapings of the ulcerated surfaces.

Both the typhoid and the colon bacillus vary considerably as a result of conditions relating to their environment, and it is difficult to determine whether certain bacilli of this group, sometimes found in river water, etc., are to be regarded as varieties of one or the other species mentioned, or as distinct species. Cesaris-Demel and Orlandi concluded (1894) that animals immunized against the "colon" bacillus furnish a serum which has protective and therapeutic value against infection by the typhoid bacillus, and the reverse.⁹

But in regard to their response, in artificial cultures at least, to typhoid serum, they differ widely. No matter how powerfully and quickly the serum used agglutinated the bacillus of Eberth, we were never able to observe the least effect upon the "colon."

Among other motile organisms tested in pure culture, the behavior of the *B. pyocyaneus* with typhoid serum is also of interest. It is but recently that the use of sterilized cultures of this bacillus was tested in the treatment of typhoid fever—it having been shown by experiments upon animals that sterilized cultures of *pyocyaneus* exercised an immunizing influence against typhoid infection, similar to its known antagonism to the bacillus of anthrax. The results we obtained in a measure confirmed these observations, although Kraus and Buswell concluded from their observations in twelve cases treated with sterilized *pyocyaneus* cultures, that this method of treatment "has no specific curative value." By inoculating guinea-pigs with *pyocyaneus* we secured a serum from the abdominal cavity containing the bacilli in large numbers. Active typhoid serum had a slight agglutinating effect upon these bacilli, rather more in the serum thus obtained than in artificial culture. When,

however, the blood serum from the same guinea-pig (a control containing no bacilli), or the diluted dried blood, was inoculated with a virulent bouillon culture of Eberth's bacillus, the latter were quickly agglutinated and immobilized as by typhoid blood serum; showing, as well as by their immunizing influence, that an undoubted antagonism exists between these organisms. The normal blood serum of the guinea-pig gave negative results.

The effect of the typhoid serum upon a number of other motile bacteria found in water, the *B. fluorescens*, *Indicus*, *subtilis*, *violaceus*, etc., in each case was negative. They continued their motion as freely and independently in the serum as in their normal habitat.

Little or no antitoxic effect could be observed upon the pathogenic organisms causing, like typhoid, notable intestinal lesions, as the spirilla of Asiatic cholera (which are agglutinated promptly by cholera serum), or of Metchnikoff or of Finkler-Prior, or upon the bacillus of hog cholera, closely resembling the "colon" bacillus morphologically.

The essential etiologic organisms of malignant edema and tetanus also retained their separate existence and motility in the serum.

Excepting, then, the reaction with virulent culture of the *B. pyocyaneus*, we were unable to find that other motile organisms, saprophytic or pathogenic, were at all affected by typhoid blood.

Regarding the action of blood from pathologic conditions other than typhoid upon the Eberth bacillus, it has not been possible for us to compare the result of blood examination in many of the obscure forms of continued fevers above described, which often offer such great difficulty in diagnosis. From such affections, however, as we have been able to examine, fairly definite conclusions were obtained.

In addition to the fifty cases of more or less typical typhoid, our conclusions are based upon the study of about twenty-five cases in which the clinical symptoms were more or less doubtful and suggestive of typhoid, of miscellaneous affections, and of many specimens of normal blood of man and the lower animals.

The examinations made included blood from acute and chronic rheumatism, gout, aseptic (surgical) fever, mumps, malarial fevers (intermittent and remittent), influenza, cystitis, acute bronchitis, acute enteritis, catarrhal pneumonia, appendicitis, acute pericarditis, syphilis, etc.

At times we obtained from apparently normal blood, and from that of miscellaneous affections in which there was no suspicion of typhoid fever, an unmistakable reaction, resembling that of typhoid blood; confirming the experience of Stern (1894), who concluded therefrom that a protective influence was exercised, in some cases, upon animals, with blood from individuals who had never suffered from typhoid fever, although larger doses were required. He suggested that this antitoxic power is possibly due to mild or unrecognized previous infection.

The agglutinating effect has been found in diabetes. The normal placental serum is said to possess marked destructive power for the *B. typhosus*.¹⁰

The presence of the reaction in such cases may occasion errors in the diagnosis, which must be guarded against. In a case of influenza, with nervous symptoms, headache, prostration, fever, bronchitis, we found

a decided reaction with a virulent culture. It was learned that the patient had had an attack of "typho-malarial" fever some eight years before. We established the diagnosis of influenza in this case by culture test, isolating the influenza bacillus from the blood, cultivating it in nutrient agar and examining in stained preparation.

Such difficulty is not confined to the blood of the human subject. In testing the blood of an apparently normal rabbit, not immunized, we were astonished to find that it possessed a high degree of agglutinating power upon the bacilli of virulent cultures, resembling in every respect that of typhoid serum. To determine whether this property was a normal attribute of rabbit's blood generally, we tested in ten other rabbits, but with negative results.

The blood of the horse, as stated by Bordet, often produces a clumping and granular appearance in typhoid culture, not distinguishable from typhoid blood except that it produces a similar agglutinative effect upon the "colon" bacilli, which typhoid does not.¹¹

We observed also, in testing hen's blood, that one specimen (of a number examined) produced marked effect upon the typhoid bacilli, agglutinating them in the same manner as typhoid serum.

We could not find it in the blood of other animals, that of the ox, sheep, calf, deer, dog, cat, pig, guinea-pig, mouse, pigeon, all acting in the manner of normal blood. Rabbit No. 1 was repeatedly examined, a number of specimens taken upon several different days, with a like result.

What causes the phenomenon in these particular animals? Although the numerous attempts to communicate typhoid fever to the lower animals have given a negative result in every instance, so far as producing the characteristic lesions as found in man, the fact is well established that Eberth's bacillus will multiply abundantly in many of them, and can be obtained from the spleen exactly as in the human subject, and that although infection is often fatal, a large proportion survive artificial inoculation.

A reasonable hypothesis might thus be drawn to account for the occurrence of typhoid fever in previously uninhabited districts, upon the prairies or in the depths of the woods, where the source of the infection can not be traced to human importation.

Descazals¹² reports an epidemic of "psittacose," a disease which Peter characterized as "typhus of parrots," recording the cases of forty-seven persons affected, with fifteen deaths. The disease is traced to the importation of parrots. An infected individual seems capable of transmitting the infection to others. The infection closely resembles typhoid, but the onset is often marked by local manifestations about the mouth.

But from whatever other cause this agglutinating substance may be present in the albuminoids of the blood, whether in lower animals or in man, the effect upon the typhoid bacilli may be distinguished from that obtained from typhoid fever blood. Upon dilution of the specimen examined, discarding the virulent for attenuated cultures, the bacilli in the latter will still become typically agglutinated with typhoid fever blood when diluted to a degree in which the pseudo-reactions entirely disappear.

Regarding the possibility of obtaining the diagnos-

tic reaction in the early stages of typhoid, Case No. 16 of our series warrants especial attention from the fact that it was elicited upon the third day of the fever. A copy of the temperature chart, in this case received by mail from the neighboring city of Rochester, with the specimen of blood, we pass around for your inspection. The subsequent clinical history of this case confirmed the diagnosis. If further experience proves the practicability of recognizing the disease thus early, the value of the test, especially in justifying prompt adoption of precautions for the prevention of future infection, will be very great.

Five of the specimens of blood examined elicited from us a report contradictory to the clinical diagnosis. To these cases great interest also attaches—as their subsequent histories all tended to confirm the bacteriologic rather than the clinical diagnosis.

In Case No. 22 of our series the blood examination was made upon the fifth day after admission to the hospital.

The temperature record in this case; the significant clinical symptoms: Enlarged spleen (common, however, in many conditions in children), diarrhea, semi-stupor for several days; some doubtful rose-colored spots upon the abdomen, and finally, the fact that the child was taken from a typhoid-fever infected house (a sister occupying the adjoining bed in the hospital with a typical attack); certainly strongly suggested the clinical diagnosis of typhoid fever, which in fact had been made.

But note the result of the blood examination: The reaction was entirely negative, while that of the sister was prompt and decided. An opinion in accordance with this examination was therefore given. Naturally, the further progress of these two cases was watched with the greatest interest, and the hospital records, which we here also present, can be fairly assumed to be confirmatory evidence of the reliability of the test; the temperature of the boy falling to 99 degrees two days afterward, and not going above this again during the remainder of his stay in the hospital—some ten days.

In Case No. 34 of our series, the "typhoid state," was especially marked; dry fissured tongue covered with a brownish-black fur, sordes-covered lips and teeth; temperature ranging between 102 and 104; diarrhea; no rose spots; hebetude; early epistaxis. Repeated examinations failed to reveal any agglutinating property of the blood. The subsequent history of this case was not that of typhoid, the grave fever symptoms disappearing two or three days after the examination. This patient, it may be interesting to note, developed instead a mild form of insanity, which persisting, he has since been committed to the State Asylum in this city.

In case No. 41, in which the typhoid condition and symptoms were also very suggestive; examined on the fifth day of the disease, the reaction was negative and our opinion, rendered in accordance, elicited the counter-opinion from the attending physician, a gentleman of wide experience, that he *knew* his patient had typhoid fever, notwithstanding. The subsequent clinical history of the case, however, did not justify his diagnosis, the joint lesions of rheumatic fever developing a few days later, typically. While many, especially of the etiologically obscure continued fevers, remain still to be submitted to the test, such work as has thus far been done seems in a remarkable degree to confirm its great value in diagnosis.

Widal concludes, as the result of his admirable work upon this subject, that: "A negative result obtained with the serum of a case of suspected typhoid, affords a presumption against the diagnosis of typhoid fever; but it is only a probability, especially if the examination has been made in the first few days of the disease. The examination should then be repeated in the next few days. The presumption that a case in which a negative result has been obtained is not typhoid becomes correspondingly stronger as the disease becomes more advanced."

As supplementing investigations regarding the diagnosis of typhoid fever by means of the typhoid organism in the blood, we have made experimental observation upon the reverse problem, to wit: The detection, by means of the serum, of the typhoid bacillus in water, an important problem usually attended with much practical difficulty and often of doubtful result. The bacteriologic examination of drinking water resolves itself, ordinarily, into a search for the bacillus of Eberth and its differentiation when presumably found from the bacilli *coli communis* and other allied motile water organisms.

Miquel's scale for the classification of the purity of water, ascending from the "exceptionally pure," containing from 0 to 10 bacteria per c.c., to the "very impure," containing 100,000 and upward per c.c. while affording an excellent standard limit of comparison, is practically valueless from the standpoint of pathogenesis; water classed as "very pure," containing but 100 bacteria per c.c., may be more dangerous than the very highest of this scale.

We demonstrate under the microscopes upon the table, the results obtained from an analyses of a specimen of ordinary hydrant water, infected with the bacilli of Eberth from a pure culture, and at the same time with "colon" bacilli and a number of other motile water bacteria.

Mixing in sterile tubes each containing 10 c.c. of beef tea, a few drops of this water, adding Parrietti's solution (ac. carboli., 5 grams; ac. hydrochlor., aq. dest., grams 100) and incubating at 40 degrees C. to eliminate most of the ordinary water bacteria. The tubes were plated (using agar) and these were maintained at 40 degrees C. for twenty-four hours, when we could distinguish with dry lenses, colonies suggestive of the typhoid bacillus by their landscape appearance.

With the sterilized needle these colonies were fished and after proper dilution active typhoid serum inoculated with the organisms. The specimens upon the table are hanging drops of the serum thus prepared. The colon and other motile organisms in the same serum are seen independently and moving in the field. The typhoid bacilli, proved to be such by animal inoculations and other tests, in striking contrast are agglutinated and motionless.

These results indicate that typhoid serum affords a simple and apparently certain means of differentiating the typhoid from similar organisms found in water, or at least, of corroborating results obtained from other methods of analysis.

Tincture of Moringa as Remedy for Icterus.—Dhargalker of Bombay, has secured remarkable results with the bark of the root of the *Moringa pterygosperma* in eight cases of catarrhal icterus, administered in a tincture prepared from the bark of the root, 2 to 4 grams, three times a day for adults, and 15 drops for children.—*Semaine Médicale*, December 23.

FAILURES OF MIDWIVES IN ASEPSIS.

Read at the Meeting of the Obstetric Staff, Chicago Health Department, November 21, 1896.

BY C. S. BACON, M.D.

PRESIDENT OBSTETRIC STAFF, CHICAGO HEALTH DEPARTMENT; PROFESSOR OF OBSTETRICS, CHICAGO POLICLINIC.

The need of this movement, that we now assist in inaugurating, which contemplates the control of the practice of midwives, is generally acknowledged. The credit for its origination belongs wholly to our experienced Assistant Health Commissioner, Dr. Reilly. It is the first practical and promising attempt in America to regulate midwife practice. I believe that we, the members of the staff, have an unusual opportunity to do a valuable service to the community.

Our work is humanitarian and based upon humanitarian motives. I believe that the chief consideration that induced each of us to enter into this work was that of benefiting the community. No doubt the legitimate desire to enlarge our experience through the observation of unusual and interesting cases had its influence on all of us; also the advantage to be gained through association with others interested in the same specialty. Yet back of all was the fact which our observation and experience have shown to exist, that the health and lives of many helpless and innocent people are jeopardized through the illegitimate practice of midwives. Just as the medical profession is always ready to unite in any well-digested effort to stamp out or prevent an epidemic of disease, so, when once a chance was given us, we were all ready to engage in the effort to reduce the well-recognized dangers to which thousands of poor women were exposed through the unrestrained ignorance of their attendants during childbearing, as well as through their unlawful practices to interfere with pregnancy.

These remarks do not imply that our attitude is one of hostility toward the midwives. On the contrary, it is our aim to assist them in their legitimate work. There are about 900 midwives in Chicago, and they attend from 20,000 to 25,000 cases of labor annually. Moreover, a large share of our population is composed of immigrants from Europe who are accustomed to employ midwives. If it were desirable to do away with midwife practice it would be absurd to attempt a thing so impracticable. But it is not desirable. A well-trained midwife can care for a poor woman and her child in a case where the employment of a nurse is an impossibility, better and much more cheaply than a physician. If she confine herself to her proper duties, and if she be trained to perform them and to recognize when she should call for assistance, she is a valuable member of the community.

The objections to midwives are that they are ignorant, especially of the principles and practice of asepsis, that they are prone to usurp functions not belonging to them, and that they often advise and produce abortions. It is the especial object of this movement to correct the abuses in their practice. In the June Report of the Health Department Dr. Reilly calls attention to the criminal practice of midwives, and mentions the fact that the recent records of the coroner's office show thirty-four cases of deaths of unfortunate women and girls from this cause. If in so many cases the responsibility is fixed, how many cases are there where the responsibility is unknown? A recent investigation of the puerperal mortality statistics of Chicago¹ shows that during the last ten years abor-

tion has been assigned as the cause of death 161 times. This does not include cases of death assigned to uterine hemorrhage, septicemia, etc., which, as we know, often result from abortion. It is probable that a great many of these deaths were due to criminal practice. How many were performed by midwives we have no means of knowing, since the physicians called in and in attendance at the death issue the certificates. The common observation of all of us and the facts just cited from the coroner's report, show to what an extent the mortality depends upon criminal midwife practice. We must also remember that not only the great mortality is due to this cause, but a vast amount of sickness likewise results. It is one of the most important objects of this movement to stamp out this criminal practice. In none of the thirty-four coroner's cases was any punishment inflicted on the perpetrators of the crime. Our criminal laws can therefore have little or no effect in preventing the continuance of these crimes. The rules and regulations which will control midwife practice in the future provide that under no circumstances shall any midwife have in her possession . . . any drug or instrument or other article which may be used to procure an abortion. In the enforcement of this provision, as well as in those regulating the scope of their practice, we hope to see these crimes abolished.

Midwives usurp the functions of physicians not only by performing obstetric operations, but also by trying to treat and manage medical and surgical cases. The law-makers of all the States are gradually coming to recognize the importance to the community of a well educated and well trained medical profession, and are insisting upon a four years' special training based upon a thorough preliminary general education, as a requisite to a license to practice. We all know the necessity for a thorough training in anatomy, physiology and bacteriology to a comprehension of the principles of surgery. How then can a woman of limited education in four to six months learn to appreciate the indications for operative interference, to say nothing of the technic of difficult and dangerous operations. The most she can learn is to know the progress of normal labor and to recognize such deviations therefrom as to require her to call for assistance, and to ground herself thoroughly in the details of antisepsis and asepsis. Therefore our rules, following those of all countries whose experience has formulated these restrictions, specify when a physician must be called. Any violation of these specifications shall be considered as proof that the midwife practices medicine, and makes her subject to the penalties prescribed by the medical practice act.

So far the State goes in defining the functions of midwives and in controlling them. It does not directly propose to educate them. However, we must admit that their ignorance of asepsis and antisepsis is practically a very great objection to them. There is much danger from this source, which is forcibly illustrated by the study of the mortality from puerperal infection in Chicago. In the tables already referred to I have obtained the average annual mortality rate from puerperal infection for the decennial periods 1866 to 1875, 1876 to 1885, and 1886 to 1895. In the first period there were 127 deaths from puerperal infection for every 1,000 deaths from all causes of women of childbearing age, namely, women from 15 to 45 years old. In the second decennial period there were ninety-seven deaths, and in the last period seventy-three

¹ See "The Mortality from Puerperal Infection in Chicago," by C. S. Bacon, *Amer. Gyn. and Obst. Journal*, April, 1896.

deaths. The rate based on the number of confinements shows about the same rate of decline. In the three periods, for every 1,000 confinements the rate was 7.6, 5.5, and 4.1 respectively. These figures show indeed a decline, and so far are encouraging. The decline corresponds in time to the spread of the teachings of Lister, and is no doubt due to the excellent teaching of asepsis and antisepsis in our medical schools. The fact remains, however, that the mortality rate from puerperal infection is still very much too high, and indeed has increased during the last four years. In 1891 it was 62 per 1,000 deaths of women of childbearing age, in 1892 it was 60 per cent., in 1893 65 per cent., in 1894 71 per cent., and in 1895, 69 per cent. In other words, puerperal infection still kills more women in the prime of life, women of the greatest worth to their families and to the State, than any other cause except consumption.

Who is responsible for this large continuing mortality, physicians or midwives? While it is impossible to answer this question from the imperfect records of the registrar's office, it seems very certain that the improvement for the last decades is due to the better training of medical students, and that the bad results of the last few years are largely due to midwife practice, which has not made corresponding advance.

Hence I claim justification in presenting to this staff the subject announced on the program. The scope of our duties is yet to a certain extent indefinite and will be left to natural development. We are called on by midwives to treat childbed fever. Is it not reasonable that we should try to prevent its development? I look forward to the growth of our organization in such a way that each member of the staff shall have practical charge of the midwives in his district. Like the commander of a company in an army, he shall inspect the records and outfits of the members of his division, and he shall come to feel so far responsible for the practice in his district that he will try to keep the mortality and morbidity records as low as possible. This is the condition in some of the German provinces where the best obstetric results are obtained. It is impossible for us at present to exercise such control. As Dr. Reilly pointed out at the last meeting, it is important that we go slowly at first in order not to wreck the movement at the start by over-zeal. The first thing to do is to secure a complete registration of midwives. So long as a certain number defy the authority of the City Board and the State Board of Health they would defy us and we would accomplish nothing. It will probably take some weeks or months longer to bring the defiant midwives to terms or to revoke their licenses to practice, and until then we must confine our efforts to advice to those who call on us. Yet in this way we can, if we will, accomplish very much of value, and for this reason it seems to me timely that we begin to study the mistakes and failures of midwives and consider the means to correct and prevent them.

The gravest mistakes midwives make in their legitimate practice are in the aseptic management of labor. Their most important mistakes in this direction are the following: failure to secure cleanliness of person and surroundings of patient, failure in subjective cleanliness, use of improper lubricants, making unnecessary internal examinations.

Concerning cleanliness of patient.—Many patients who employ midwives regard the hemorrhage accompanying labor and the amniotic fluid as a kind of filth,

and consequently find it proper to collect these discharges in filthy cloths. To them it would be absurd to put on clean bedding before labor, and one finds dirty rags and dress-skirts used for pads. They have, moreover, a great fear of cold, and use feather beds and keep the windows carefully closed. The same fear leads them to avoid the use of water about their bodies. To manage a labor properly under such conditions requires a thorough belief in cleanliness and considerable energy to exert the necessary authority to overcome ignorant prejudice. A midwife, even if she have an idea of the importance of cleanliness, finds it much easier to put up with the surroundings than to improve them. Any one of us who has had any practical acquaintance with the conditions present in such cases will not condemn a midwife too severely for not securing a state of surgical cleanliness. We will also allow for the fact that she can not exert the same authority as a physician. For her assistance it is well that she have very definite and detailed directions to aid her, and to fall back upon in case of opposition on the part of the patient. Such I would formulate as follows:

Have the patient prepare beforehand a piece of white oil-cloth $1\frac{1}{2}$ yards square and at least six clean sheets, and plenty of old pieces of sheets or cloths thoroughly boiled and washed. All should be put together with the baby-clothes in a clean drawer and not handled with dirty hands. At the beginning of labor remove all bedding from the bed, cover the mattress with the oil-cloth and put over it only the clean sheets and the cloths for pads. Under no circumstances use old blankets or cotton comforters, or dirty skirts as pads. Have the patient take a tub or sponge bath with soap and water, put on a clean night-shirt and give her an enema. Do not let her touch the clean bed with dirty or everyday clothes.

Before each internal examination wash the outside genitals thoroughly with soap and the antiseptic solution which is used for disinfecting the hands, but do not give a vaginal douche either before or after labor. If there be a purulent discharge or if the vulva look sore, call in a physician, for these conditions are dangerous and apt to cause fever in the mother or sickness of the child. When the afterbirth comes away remove the sheet and pads, wash the patient with the antiseptic solution, wash and wipe off the oilcloth, and spread over it a clean sheet and clean cloths for pads as before. For a napkin for the patient use only absolutely clean cloths and do not fasten them tightly against her. Afterward change the sheets and pads as often as necessary, and wash the patient every time with clean soap and warm water.

Concerning subjective cleanliness.—Keep the clothes and hands clean. A midwife would better wear light-colored wash-dresses. Under any circumstances she should have a number of large white aprons with sleeves which cover the entire dress to protect the patient and her bed from contamination by the street dress. In cases of emergency she should cover her dress with a sheet.

Great care should be taken to keep the hands free from cracks and from sores about the roots and sides of the nails. If a midwife have any ulcer or running sore on her body she must not attend any labor until the sore is healed. In short, she must avoid all infection of the hands, for it is very difficult and takes much time to clean them again. Before making an internal examination she must disinfect the hands

and arms. This process consists in the following steps:

1. Washing with soap and water as hot as can be borne for ten minutes, using the brush and paying especial attention to the folds of the nails. All finger rings must be removed. A midwife should not wear rings.

2. Cleaning around the nails with a steel nail-cleaner or with a knife until no dirty particle can be seen.

3. Washing another minute with soap and hot water.

4. Scrubbing the hands and arms three minutes in a disinfecting solution. A midwife may use a sublimate solution (1 to 1,000), creolin or lysol 1 per cent. or carbolic acid 3 per cent. The sublimate is the most efficient, but chaps the skin of some people, who may find lysol the best to use.

After disinfection the hands must not be contaminated again by touching anything before making the examination. Hence the patient must uncover herself and flex the thighs so that the midwife need not touch the sheet. Then, with the thumb and fingers of one hand, she should separate the lips of the vulva so that the examining fingers do not carry into the vagina any impurities from the outside.

Concerning a lubricant for the examining hand.—Vaseline and oil, which are generally used as lubricants, are dangerous, for they are good collectors of germs. Even carbolized vaselin, if contained in boxes or jars into which the fingers are dipped or which are exposed to dust and dirt, may contain living germs, for the oily substance protects them from the action of the germicide. The importance of a proper lubricant was well illustrated by a recent report of Dr. Weichardt, the medical officer in charge of midwifery practice in a district in the Duchy of Sachsen-Altenburg in Germany (see *Monatschrift für Geburtshülfe und Gynäkologie*, June, 1896). During the year 1895 there were in his district 1331 labors attended by the thirty-five midwives, with no deaths. The mortality in previous years had been 5 to 6 per cent. Dr. Weichardt suspected the cause of this mortality to be the boxes of carbolized vaselin used by the midwives for lubrication, so he had them provide themselves with collapsible tubes filled with carbolized vaselin. This change alone brought about the ideal result shown in the report. I have ordered from Sharp & Smith such tubes, which will probably be the most practical and safe lubricant for midwife use. Such tubes are also put up by Johnson & Johnson. In a woman who has borne children and also in a primipara, after rupture of the membranes, when the vaginal canal is bathed in the amniotic fluid, there is generally no need of any lubricant. Ordinarily I use soap when any is needed. The collapsible tubes of soft soap are well adapted to this purpose. To use either soap or vaselin in tubes, a little should be squeezed out on to a clean plate or saucer, and with the tips of the sterilized fingers a little is taken up and rubbed over the fingers mixed with the disinfecting solution. Otherwise a piece of hard soap whose surface has been well cleaned can be thoroughly washed in the sublimate solution and then serves very well to lubricate the fingers.

Concerning unnecessary internal examinations.—Professor Leopold has shown in hundreds and even thousands of cases in the hospital in Dresden, that it is possible to conduct labor without any internal

examinations. With very little practice it is much easier for any one to determine the position of the child by external than by internal examination. The progress of labor can also be determined by the rate of the descent of the head. Internal examinations are always somewhat dangerous. Germs are almost inevitably carried into the vagina, where they may infect the tears in the cervix or vaginal walls made by the head of the child. The danger increases with the frequency of examination. It is well proven that the chance of fever increases proportionately with the number of internal examinations. Any ordinary case of labor lasting only six to ten hours rarely requires more than one examination to be made. Patients sometimes think that a midwife or doctor assists them by making long or frequent internal examinations. This foolish idea should be dispelled. Let the rule be, examine only when there is a good indication, such as uncertainty as to the position, fear of prolapse of the cord, delay in the labor, or when it may be advisable to learn the degree of dilatation of the cervix. In making the examination do not introduce the fingers into the uterus, and be careful not to rupture the bag of waters.

In this hasty summary of the chief mistakes of midwives in asepsis I have aimed to indicate where they fail by insisting with considerable attention to detail upon the rules of practice which should govern them. While I have not aimed at a complete discussion of aseptic midwifery, I believe that a careful inspection will show that no important detail has been omitted and no unimportant direction included.

426 Center Street.

CLEANLINESS THE FIRST PRINCIPLE OF HYGIENE.

BY WILHELM HOTZ, M.D.

CHICAGO.

Hygiene, the science of health, is undoubtedly the first foundation of therapeutics, the science of restoring lost health, because without knowing the laws which maintain health, no physician can tell his patient the right way that leads him to health and give him the proper advice how to regain it. Hence disease, as we call lost health, must be in one or the other way the consequence of departure from the natural path of life, or, in other words, disease is the indication of the loss of the vital equilibrium; its symptoms are the manifestation of the vital force to regain the normal state.

By studying such abnormal conditions and the way by which nature is seeking to lead the organism back to the prior state of health, we will find out not only the proper way of cure, but learn also how to keep up our health, *i. e.*, the principles of hygiene.

Hygiene is as old as the history of mankind. Its highest development has always been found in the most civilized countries, today as well as several thousand years ago, not because they have the highest civilization—nothing in the world develops without necessity, its motive power—but because the more a people has advanced in so-called civilization the more are the natural laws of life usually neglected, so that it may be doubted whether the high development of science, technics and industries of the modern world is really the result of mental progression, or is not rather the necessary effect of reduced vitality and lessened resistance to morbid influences, accord-

ing to the law of self-preservation. Such *facts* induced man to find means to preserve his species and to study the laws of health to that end.

Hygiene is therefore as old as the history of mankind, but wherever we find sanitary measures, in ancient or modern times, they always relate directly or indirectly to cleanliness. Today we admire the magnificent structures that have been built many thousand years ago by the old Egyptians only for the purpose of securing a pure and abundant water supply. Greeks and Romans built luxurious bathing houses for public use, knowing already that proper care of the body is a potent factor in preventing disease. Had not Hippocrates already taught that prophylaxis is the best part of the science of medicine?

The first hygienic measures in regard to personal health which man recognized are physical cleanliness and abundant exercise. Soon after followed the acknowledgment of moderation in eating, drinking and general manner of living. From the individual experience in relation to personal health resulted, in larger communities, the public health, viz.: general sanitary measures, as, for instance, the regulation of water supply and the securing of pure food by the erection and supervision of public slaughter houses and bakeries, the disposal of the dead and of the excreta, etc. Hence the more the human family developed their faculties in the direction of modern civilization, the more new measures and precautions have been found necessary to protect the public health, till finally the whole affair became a matter of governmental supervision. In brief: All hygienists, from the ancient Egyptians down to the modern scientists, recognized cleanliness as the first principle of health and believed in realizing it by endeavoring to secure pure air, pure water and pure food for the people at large.

The notion, however, of what cleanliness means, its correct definition, was never perfectly clear the same to every body, because the effect of the contrary condition is also not always alike. The man of a good constitution who can stand great extremes, for instance, offers a stronger resistance to injurious surroundings and stands in less need to take care for his physical welfare than a man of more delicate constitution; his idea about cleanliness in regard to his body, food and surroundings, will therefore be not as clear and exact; consequently the conception of *pure* or *impure* is a matter of individual agreement, so long as no certain scientific definition can be given of it. Such a definition can not yet be given in every respect, but it can be very evidently and without doubt in regard to septic materials.

Pasteur, the late French scientist, discovered that all putrefaction is caused by microbes. Other scientists found that in almost all diseases microbes are present, that disease is consequently a process of putrefaction started by certain microorganisms which found their way into our system. But the action (or better), the existence of said microorganisms is fortunately limited, as well as of other living organisms and depends on suitable food; without the proper nutritive elements they are not able to exist beyond a certain length of time, or at least not to propagate themselves. Since Pasteur's discovery we know that no putrefaction of organic matter can take place without the presence of microbes; we know further that all microbes need organic material as a first condition

of their existence and that dead organic substance is a more suitable soil for them than living organisms, because the latter offer a natural resistance to all noxious influences. So we find microbes most numerous wherever dead organic matter exists—the primary enemy of health. Hence the quick and complete destroying of all dead organic matter, which is and can not be well protected from putrefaction, would be the best method of preventing the spreading of pathogenic microbes, those species which we have chiefly to deal with in health and disease. If microbes were necessary in nature's economy to decompose all dead organic matter in order to set free the latent energy which is stored up in all the higher compounds the organic world represents, it would be different; such seems not to be the case, however, since there are other much more efficacious factors by which dead organic matter can be reduced into single inorganic elements, than by the mediation of organisms, and which force would be better to that end than fire? Why do we not make use of the same wherever it is advisable, instead of allowing the ground on which we live to be soiled by waste and refuse of organic nature of every kind? Why is it that, in contradiction to our modern progress and our knowledge about the origin of disease, we still let the ground get infected by following the old method of burying corpses of men and animals and letting nature take care of them by the way of the most slow and unwholesome process we know of, the action of putrefaction, the same one which we know to be the starting point of almost all diseases? I consider the microorganisms, apart from their fermentive power, as ideal watchmen of health, because their presence and action is quite often the first indication that something must be wrong, or that our body is in an abnormal state of health. Without the prompt action of microbes on diseased tissue it would be extremely difficult to discover the lesion and its origin soon enough to prevent further injury to the system. I can not believe that the pathogenic microbes are the direct cause of disease, but rather think that about in the same way as pure chemical poisons affect the system, disease is originated either by toxic materials, as the products of our *own* metabolism, poisoned air, impure food and bad surroundings, or as in cases of inoculation of specific microbes by *their* products of metabolism. If this view, as given above, should prove to be correct the hygienist has only to deal with poisonous or non-poisonous substances man is liable to come in connection with; while he should consider all the pathogenic, saprophytic and fermentive microorganisms as useful agents and as our natural guardians which protect us from disease. So the deductions from the bacteriologic propositions point again to cleanliness as the first factor to maintain our health.

But not bacteriologic researches alone and their practical demonstrations, show the truth of cleanliness as the first principle in hygiene; still more is this assertion proven by the study and observations made on the human body under circumstances of great sensitiveness to all unfavorable influences.

In cases of direct injuries and wounds, for instance, where the natural protective organs are entirely excluded from action, we notice the influence of any infectious matter first of all and in the most marked way. Thereupon is based, as you know, the aseptic method in surgery. The least carelessness in this respect may be followed by ill effects and shows evi-

dently how careful we ought to be in introducing foreign substances into our system.

Next to the effect of direct infections by wounds, we notice a high sensitiveness of the system to all kinds of impure influences in case of disease. The first thing nature tries to do in case of disease usually is to clean the system from foreign substances and to prevent further supply. Such symptoms as loss of appetite, nausea, vomiting, diarrhea, profuse sweat, etc., tell us very distinctly in what way the body will regain its normal state, and also where the origin of the abnormal condition lies. In nine out of ten cases I am sure that the cause can be traced to carelessness in regard to cleanliness, that there is a lack somewhere, either in reference to cleansing, dressing and general surroundings of the body, or that the internal system has been neglected, the secretory and excretory organs are out of order; so that the poisonous products of metabolism cause a kind of auto-intoxication; but as I said, the practice of cleanliness alone may prevent at least nine out of ten cases of disease.

The first and most important advice, therefore, the physician gives to the sick refers to general hygienic measures based upon good ventilation of the sick room, pure and easily digestible food and proper care of the body.

What the physician *does* and the only thing he *can* do for the sick is certainly to assist nature in its efforts to restore health, and, as far as the symptoms indicate the need of the system, the physician has to be only a true student of nature in order to be also a successful physician. Is the surgeon who uses the scalpel to remove, or to reach the diseased part, doing more than assisting nature in its endeavor to get the pus and impure matter out of the system? No; both medical practitioner and surgeon correspond in so doing to the first principle of hygiene.

Cleanliness in every respect is a vital question in infancy. Nothing, I believe, is more fatal for the new-born than neglected nursing, insufficient cleansing and impure food. The immensely high death rate, especially among the lower class of people, is certainly due to the carelessness with which children are nursed and left to themselves, growing up in filth and fed on impure food, more like animals than like human beings. Indeed, there is still a great field of action for the physician, where he can realize the simplest hygienic measures without having to fear that the health of the people will reach such a high state, and the people itself will become so well educated that every one may be able to be his or her own physician while the practitioner will have to starve! No matter how far off that time may be, it would certainly be better and more honorable for the profession, than is our age of progressive physical degeneration, where almost every one believes himself to be able to act as his own adviser in illness, but in his ignorance swallows drugs and so-called patent medicines in astonishing quantities, according to his fallible judgment, instead of following the natural laws of hygiene, or in case of disease calling for a competent physician.

I think the more man progresses in regard to general civilization and special culture of the mind, the more stress he must lay on general health, if he does not want to endanger all that he has gained through pain and difficulties of every kind for centuries past. And if experience and science clearly teach us that cleanliness in its fullest extent is the first principle in hygiene, as I have tried to prove, then we should

strive not only to acknowledge, but still more to apply this axiom of health in all respects. The deeper we go into this matter the more we realize the great truth there is in the well known quotation: "Cleanliness is next to godliness."

THE ADVANTAGES IN THE TREATMENT OF SYPHILIS AT THE HOT SPRINGS OF ARKANSAS.

Read before Arkansas Medical Society in May, 1896, at Fort Smith, Ark.

BY EUGENE CARSON HAY, M.D.

PRESIDENT OF HOT SPRINGS MEDICAL SOCIETY; MEMBER ARKANSAS MEDICAL SOCIETY, MISSISSIPPI VALLEY MEDICAL SOCIETY AND AMERICAN MEDICAL ASSOCIATION.

My object in selecting this subject for my paper to be presented for your discussion today was for a two-fold purpose: First, to endeavor to correct many of the fallacies and erroneous ideas in regard to the Springs that exist in the minds of our profession who have never visited the valley. And, secondly: To outline the methods we use in the treatment of syphilis and endeavor to give valid reasons why the Hot Springs of Arkansas enjoys the reputation of being such a Mecca to all syphilitic subjects.

Physicians abroad (at least a preponderating majority) claim that the only virtue the Springs possess lies in the change of climate and removal from business cares, the devotion of the patient to his treatment and care of his health while there. These they claim are the sole reasons why we have such excellent success in the treatment of these cases. And should the same régime be adopted at home, with the institution of ordinary warm baths, equally as good results would be attained.

I will admit that these are very important factors in the handling of these cases, and I will speak of them later. But they are not the primary ones. The true secret of the good results attained at the Springs in the treatment of syphilis lies mainly in the positive clinic fact that *these waters exert a pronounced tonic effect on all syphilitic subjects*, and one that is a daily clinical observation of every active practitioner residing at the Springs. Whether it is because the waters possess more solvent and eliminative powers than ordinary hot water, or that there is some unknown element in allotropic form possessing superior healing virtues, can not be positively stated. Their use is eminently empirical and our reasons for the clinic facts we daily observe are theoretical.

Some of our physicians think that the heat is the sole property, others electricity, others the method in which it is heated beneath the earth's surface, as they think the heat is generated by chemic reaction. And others believe the water contains elements in allotropic form, as I previously referred to. Again others attribute the benefit to the silica held in solution. The heat is of course important, because as soon as the water is cold all its therapeutic value is lost. As to the mineral constituents, to my mind, they are of no significance, averaging about eight grains to the gallon, consisting mostly of silica, sodium, potassium and chalybeate salts.

My own ideas are that the solvent and eliminative powers of the waters are so far superior to all others that it enables the patient to tolerate larger administrations of mercury and iodid potassium with less constitutional distress than can be borne at home, and that the water by its great eliminative powers relieves,

through the pores, the blood of all effete material more rapidly than could be done by any other water.

Before proceeding further I will speak of some of its physical properties. The water comes from the earth through fifty-eight different springs, at a temperature varying from 140 to 158 degrees F., as clear as a crystal, free of all odor and pleasant to the taste, as it is carbonated. If stood in the cold, by ordinary water of the same temperature, it retains its heat from two to three hours longer. This experiment I have tried repeatedly and verified. When cold it makes a pure and most delightful drinking water, but slightly constipating to some people on account, I presume, of the iron it contains.

The bath can not be tolerated at anything like as high temperature as when bathing in ordinary hot water; 100 degrees F. is generally the highest temperature prescribed, 110 degrees F. absolute maximum, and only permitted exceptionally when the subject has a very strong heart and blood vessels free of all signs of degeneration.

In Europe the "Roman bath" is given as high as 150 to 170 degrees F. from 20 to 30 minutes. And I likewise will insert here that tubercular patients grow progressively worse while bathing in these waters.

With these remarks I will pass on to the other advantages I spoke of above, which the profession abroad claim is our sole stock in trade and I concede of great importance. Because, in the first place, when a patient comes here he or she comes for treatment alone and has nothing to attend to but follow the doctor's instructions. When a patient realizes he has acquired a syphilis I do not know anything more pathetic than to witness this poor creature's mental anguish, especially if he is a gentleman. He feels that he is afflicted with a loathsome disease and ruined for life. Hence he must conceal it from even his most intimate friends and, like a criminal at large, using every subterfuge to escape detection, he watches every little blemish that appears upon his body, feeling convinced that should they be noticed his friends or relatives will immediately suspect or recognize his curse, the result of which would be disgrace. This anxiety, combined with his own secret remorse, precipitates him into a most deplorable mental condition and interferes to a large degree with his physician's efforts to effect a cure. Now, gentlemen, what is the result if you send him to Hot Springs? The first is immediate and magical. This mental anxiety is immediately dispelled and his mind is at last at rest, because upon his arrival he finds so many fellow sufferers, and a number whose condition is so much worse than his own, that he consoles himself with the thought that it could have been worse. His unfortunate associates give him their moral support, resulting from a bond of brotherhood and sympathy that exists between them all. He has come to a "haven of rest," where his trouble is treated as an accident instead of disgrace. He sees that it is a disease that is not confined to any certain class. The rich enjoy its "ear marks" as well as the poor; and he starts in upon his treatment with a heart relieved of its burden. As he is there for treatment, and treatment alone, being relieved from all business cares, he becomes a very plastic patient in his physician's hands. He is first instructed as to his diet, which is to stop eating all sweets and acids; his mode of living, which is to keep regular hours; stop smoking and chewing if addicted to the use of tobacco, and abstain abso-

lutely from the use of all intoxicating liquors. The next step is prescribing his medicines and baths. The inunction method is used almost exclusively by the physicians at the Springs, taking the official 50 per cent. ointment and usually dividing an ounce into eight, six or four papers, and rubbing in the contents of one paper each day, according to the exigencies of the case.

The bath is then prescribed, and the general routine for the day is as follows: The patient arising at 7 A.M., breakfasts at 8, then allowing from two and one-half to three hours to elapse so that digestion is thoroughly established, goes at 11 A.M. to his bath, which consists of immersion in the hot water contained in porcelain lined tubs from six to twelve minutes at a temperature from 94 degrees to 96 degrees F.; at the completion of which he is thoroughly rubbed down by his attendant until the skin glows from the stimulation of the peripheral circulation. He is then wrapped in his bath robe and passes into a lounging room that is kept at a temperature of 90 degrees F. He remains there from thirty to sixty minutes; and it is while in this room that the inunction of mercury is applied while the skin is active and the pores open, in the following manner: The patient sits astride of a straight back chair with arms folded over chest and back exposed; the attendant with his hand encased with rubber mitten spreads the ointment over the entire surface of the back, and standing by the patient's side commences with a long sweeping motion exerting an equable pressure distributes the ointment evenly, and continues until the back seems to become quite dry, which takes generally ten to twenty minutes depending on size of inunction. The patient then puts on a light gauze shirt called the "mercury shirt" which is worn constantly under his other garments and is never washed or discarded until he has finished his course. This naturally in course of a week or so becomes quite well saturated with the ointment and is the source of constant absorption. The patient then passes into another cooling room kept at a temperature of 80 degrees F., and after remaining thirty to forty minutes returns to his room and lies down before luncheon for about one hour, and he has finished for the day. If iodid of potassium is administered it is generally given in the saturated solution or 50 per cent with some adjuvant like essence of pepsin. I myself prefer the 50 per cent. solution, and use Fairchild's essence of pepsin as it protects the stomach, aids digestion and you do not witness any of the disagreeable gastric symptoms like these produced by the saturated solution alone. Diaphoresis is not encouraged in the bath during the inunction course, because as the emunctories are filled with mercury any excessive sweating would expel what we want absorbed. After saturation is produced the mercury of course is discontinued, at least until the symptoms all subside. About five or six days before the patient takes his departure for home he is instructed to take about as many vapors in addition to the plain baths, which I will detail briefly as follows: Plain bath ten minutes at 100 degrees F., then placed in vapor closet for five minutes standing in a vapor arising from water about 150 degrees F. He is then released and passes into the hot room kept at 120 degrees F. and remains from five to ten minutes. While in the bath and hot room he is instructed to drink the hot water freely. After passing through this you can well imagine the perspiration must be flowing quite freely. He is then removed to the first

cooling room I above referred to, kept at 90 degrees F., wrapped up thoroughly in his bath robe and allowed to cool off. The day before departure, especially if the patient lives in a cooler climate, a plain warm bath is administered and followed by an alcohol sponging to close the pores.

This is a complete synopsis, as briefly as I can state, of our methods.

Before closing I wish to say a few words in regard to the administration of mercury and iodid of potassium. There is no place on this continent where such enormous doses of either of these drugs can be given and produce such slight and mild constitutional disturbances as at the Springs. Patients frequently come here who can not take specific treatment at home and tolerate both mercury and potassium while taking the baths without suffering any inconvenience. When I make the statement that as high as 1000 grains of iodid of potassium has been given in a day at the Springs possibly some of my hearers will be incredulous; but to verify this assertion I will refer you to the remarks about Hot Springs in Dr. Keys' excellent book on syphilis and genito-urinary diseases, page 553, edition of 1890. I recently had a case of cerebral syphilis in which I administered 600 grs. a day. The patient's appetite remaining good, bowels regular, and the drug producing only the ordinary weeping of the mucus surfaces.

That these waters do possess superior solvent and eliminative properties I contend. It is a common experience to have patients present themselves suffering from the baneful effects of mercury, gums tumified, eroded and bleeding upon slightest pressure, when by the administration of a few vapor baths, the inunction course can be instituted and continued without any distress. But a great many of these cases are not due to saturation, but to their former physician's neglect of observing the condition of the teeth before starting them on a course of mercury, and the stomatitis is of local origin caused by the accumulation of tartar or a decayed tooth. Their system is not under the influence of mercury at all, and can instantly be relieved by sending them to a dentist. The reason why such large doses of mercury and potassium can be tolerated at Hot Springs is due to the important part the skin takes in the elimination of these drugs. This is a fact discredited by a great many physicians and ridiculed by not a few; but I believe is equally as important as the kidneys.

Ronovitch,¹ in 1895, made a series of experiments upon a number of patients to whom mercury was being administered in some form. "A Roman hot bath was used for twenty minutes to induce perspiration and equal quantities of sweat and urine were used for examination. He concluded that the elimination of the drug through the perspiration is much greater than has hitherto been supposed. A relatively larger quantity was excreted by the sweat than by the urine, but this only in cases in which mercury was introduced into the system by friction. This the author explains by the retention of the drug in the sudoriparous glands, friction causing it to be pushed into the glands before it had time to enter the circulation; but the quantity was the same in the sweat and urine of patients treated by injection."

In conclusion I wish to be understood that I do not even insinuate there has ever been a case of syphilis cured by these waters alone. But I do claim emphat-

ically that they act as a tonic when bathed in by syphilitics as no other water will in this country. The mercury and iodid of potassium is received more kindly into the system and all the physical accidents will disappear more rapidly than by any system of treatment that could have been instituted at the patient's home.

CONGENITAL TEETH.

BY E. S. MCKEE, M.D.

CINCINNATI, OHIO.

The following case was presented by the writer to the Cincinnati Obstetrical Society at its April meeting Feb. 22, 1896. Mrs. L. 2-para, bore at eighth month gestation, twins. Both were male and were soon delivered, the first presenting a vertex and the second a shoulder necessitating turning. One was immediately observed to have two inferior incisor teeth presenting. The children were small and poorly developed. The mother was a very small woman. The teeth were both very loose and in continual danger of dropping out. One disappeared at the tenth week, probably being swallowed; the other remained *in situ* until the death of the child, which occurred at the twelfth week; it died in convulsions away from home and the physician who was sent for ascribed the cause of death to meningitis. Premature labor in this case, as that of Crausius, occurred at the eighth month. Helwig at the seventh, and also that of Lann, which is reported as occurring prematurely. The extraction of teeth in the mother during pregnancy was reported by Flesh. In the writer's case two teeth were extracted during the third month. The tooth remaining at the time of the child's death was removed and was exhibited by the writer to the Cincinnati Academy of Medicine. None of the gentlemen present at either of these societies had ever seen a case of this kind. The child was shown soon after birth to about 100 students of the Medical College of Ohio and a number of medical men.

These cases serve as a curiosity for doctors and students and are a sight many do not behold in a lifetime. Some writers claim the possibility of no milk teeth appearing to fill the vacancy left by exfoliation or removal.

The important writers on this subject are Jacobi, Forcheimer, Pliny, Bartholin, Magitot, Schuerig, Ballyntyne, Pierce, Vargas, Buist and Mackenzie.

Congenital teeth are very rare. Paris maternity reports from 1856 to 1863 out of 17,573 births there were only three cases of congenital teeth, or about one in 6,000. Ballantyne in the *Edinburgh Med. Journal*, May 1876, reports 70 cases gleaned from the literature.

Dr. C. C. Surber of Independence, Kansas, writes me that six years ago he delivered a lady of a fine boy, who had two central inferior incisor teeth $\frac{1}{2}$ inch long, very sharp but loose. He removed them at four weeks because of the cutting of the upper gums. He has not seen the child since it was 4 years old but the incisors had not then made their appearance.

Dr. Geo. W. McCoy, Columbus, Ind., reports to me by letter that Dec. 27, 1874 he delivered Mrs. M. of a male child, natural in every respect except two teeth in the upper gums; one full length and size of temporary teeth, the other small and about half through the gums. Both teeth were exfoliated about the fifth week. The child is a hearty and strong man.

This freak of nature has been noticed at wide inter-

¹ Journal Universal Medical Science, November, 1895.

vals and with great rarity for a long time. Shakespeare has frequent references to it. In Richard III the Duchess of York says: "Marry, my uncle grew so fast that he could gnaw a crust at two hours old. 'Twas full two years ere I could get a tooth."

Queen Margaret: "That dog had his teeth before his eyes."

King Henry VI: "Teeth hadst thou in thy head when thou wast born to signify that thou camest to bite the world."

Richard: "For I have often heard my mother say: I came into the world with my legs forward. The midwife wondered and the women cried: O, Jesus save us, he is born with teeth; and so I was, which plainly signified that I should snarl and bite and play the dog."

In English and French history we have mention of Richard III, Louis XIV, Richelieu, Mirabau and Mazarin. Inheritance is shown in some cases. In the instance of Mattei, the infant's mother had been born with a tooth, and in Limerick's the mother had two congenital teeth, as did also her second child and a child of her sister.

The etiology of the premature eruption of the teeth is considered due to some abnormal development of the bone; probably most cases have some connection with rickets. In some children who cut their teeth young, the fontanelles close early, but not so in those cases where the teeth are congenital. The enamel is usually very thin or absent. The etiology of congenital teeth is in some instances described as the premature occurrence of the processes which normally lead to the cutting of the milk teeth, in a few cases it is probably due to a true ectopia of the dental follicles and its tooth. Such premature eruptions are usually found in children suffering from improper nutrition or other abnormal systemic conditions.

Treatment: A tooth dangling uselessly and aimlessly in the mouth should unquestionably be removed; otherwise inaction is preferable. The teeth are sometimes so situated as to prevent closure of the mouth, or to make nursing painful and futile, and endanger the nourishment or life of the child. The danger of hemorrhage is probably magnified by Magitot, having lost one child in which the hemorrhage recurred on four separate occasions and proved fatal despite all treatment. He lays down the rule to never extract the teeth. If the child is puny and delicate perhaps syphilitic, hemorrhages are possible.

MOVEMENTS OF THE MANDIBULAR CONDYLES AND DENTAL ARTICULATION.

Read in the Section on Dental and Oral Surgery, at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY W. E. WALKER, D.D.S.

PROFESSOR OF PROSTHETIC DENTISTRY, DENTAL DEPARTMENT SOUTHERN MEDICAL COLLEGE, ATLANTA, GA.
PASS CHRISTIAN, MISS.

This paper is a continuation of the line of thought and investigation indicated in my paper entitled "The Glenoid Fossa; the Movements of the Mandible; the Cusps of the Teeth," read before the Southern Dental Association in November, 1895.¹

Up to that time I had not been able to find mention of the facts that, in the movements of mastication, the mandibular condyle moves "not only forward but also downward, causing the ramus to drop, in the anterior and lateral movements of the mandible"

and that the condyle on the side toward which the jaw is advancing, in the lateral movements, does not merely "rotate on its axis," otherwise "remaining stationary" as we are taught, but that it also moves both upward and backward, very slightly in many subjects, and not at all in some, but considerably in others.

I enlisted the services of men who have access to libraries not within my reach, but even with their assistance, I had been unable to learn of any description of the temporo-mandibular articulation and the movements of the mandible corresponding with my observations. I had therefore concluded that the observations were original.

My paper having been placed in the hands of Dr. E. C. Kirk, as editor of the *Dental Cosmos*, with the request that he would refer me to anything bearing upon these points, he later directed my attention to the report published in the *Boston Medical and Surgical Journal*, July 4, 1889, by Dr. Chas. E. Luce, of the Harvard Dental School, of certain original investigations in the movements of the lower jaw, conducted in the physiologic laboratory of the Harvard Medical School.

It was very gratifying to me to learn that these distinguished investigators, working by widely different methods from my own, had reached the similar conclusion that "certain errors exist in all descriptions of this articulation given by eminent anatomists and physiologists;" a partial explanation of some of the inaccuracies being assigned by Dr. Luce to "the fact that they have made too much use of the cadaver to demonstrate the actions of the articulations, whereas it may be that the contraction of the various muscles cooperating with and antagonizing each other, is the important factor in determining the exact movements of the jaw."

Another cause is in the failure, in studying the temporo-mandibular articulation, to make due allowance for the fact that "in the dried skull the glenoid fossa is emptied of its intra-articular fibrocartilage, double synovial sacs and membranes, forming altogether a thickness of two or three millimeters, which space will be found, in the dried skull, between the upper surface of the condyle and the roof of the glenoid fossa" making it impossible to reproduce the normal play of the condyle in its socket, and consequently the true movement of the mandible. The published report of the Harvard investigations antedates my own studies by several years, but does not appear to have attracted the attention of the dental world.

Dr. Kirk at the same time directed my attention to the Transactions of the International Medical Congress (Berlin), in which appears an illustrated paper by Dr. Schwarze (of Leipzig), giving an account of his attempts to improve upon Dr. Bonwill's anatomical articulator based upon the study of these Harvard investigations.

Dr. Schwarze failed, however, to grasp the idea of the relations existing between the line traced by the condyle movement and the planes of occlusion and articulation, and the plane of the alveolar process, and therefore missed the essential point, viz., that to secure normal articulation in each individual case, it is necessary to reproduce in the articulator the exact angle formed by the intersection of these lines in the subject.

While, in his experimental modifications of the Bonwill articulator, Dr. Schwarze used a movable

joint, it was all haphazard work. Not having recognized the existence of a definite angle, varying widely in different individuals,¹ he naturally made no effort to secure any definite angle in the articulator, and finally abandoned his attempted improvements with the remark that the nearer he approached nature the further he found himself from practical results.

In the words of Dr. Luce "the first requisite in the study of jaw movements is to move the jaw," and the second "to get a permanent record of the movement."

light, a profile view was photographed, the bright spot reflected from the bead during the motion of the jaw in opening and closing the mouth being continuously photographed, and recorded on the negative as a line, giving the actual movement of the place upon the jaw to which the bead was opposed.

As recorded by this device, the mouth being opened to its greatest extent, the movement of the condyle is traced "as a curved line with the concavity upward," the beginning of which, or that portion traced in the

TABLE OF CONDYLE MOVEMENTS.

In the Harvard school investigation the photographic method of recording the movement of the jaw, was employed. A light frame-work was constructed, reaching around the face from the lower incisor teeth (to which it was securely fastened) nearly to the ear. By adjustable devices bright beads were placed directly opposite the condyle, gonion and symphysis. The subject being placed in strong sun-

"short openings" of the movements of mastication being in the "forward and downward" direction, and—as shown by a study of its illustrations—at about the same incline to the facial line that I had noted as the average in normal articulation.

After the reception of the report of Dr. Luce, in order to more thoroughly study the subject, and to confirm the results of these different methods of observation, I constructed an apparatus somewhat

¹ See Dental Cosmos, Jan. 1, 1896, p. 88.

similar to the one used in the Harvard laboratory, and obtained the photographs which I present for your inspection. The white spots show the location of the "beads" and the lines made by this change of position in the movements of the mandible.

No. 1 shows the right side, with extreme mouth opening, showing the distance traversed by the head at the symphysis, one at the region of the first molar and one over the condyle.

No. 2 is the left side, showing the same points.

No. 3 is the right side, showing the distance traversed by the three beads in moving the mandible from right cusp contact to occlusion and over to left cusp contact. The ink mark which was placed on the side of the face before photographing, shows where the bead rested in occlusion, the trace forward being the left lateral movement and back of it the tracing of the right.

No. 4 is the left side, showing the tracing of the beads in moving from occlusion to incisive contact.

No. 5 is a front view, showing the movement of the bead from right cusp contact to occlusion.

No. 1 shows the right side with extreme mouth-opening, showing the distance traversed by the head at the symphysis, one at the region of the first molar and one over the condyle.

To further verify these observations, in another series of experiments I replaced the "bright beads" by a small point of pencil, which traced the movement of the condyle on a sheet of stiff paper, held against the side of the face with the edge parallel with the facial line.

By this method the movements in a large number of cases can be traced in the time required to photograph and develop the negative of a single case.

In edentulous cases I fastened the appliance to the handle of an "impression tray," in which I used Teague's impression compound, additionally securing it by clamping to the mandible when necessary.

By this method I obtained tracings from a large number of individuals, but failed in a single instance to obtain so great a curve, or proportionately to the size of the illustration, so long a line as shown in the Luce report. However, his curve was apparently derived from the movement of the condyle when the mouth was opened to a very extreme degree.

The Luce illustrations are given as a correct reproduction of the photographs, with the relative propor-

tion observed between the width of the face and the extent of mouth-opening.

Assuming this to be the case, the subjects opened the mouth much wider than I have been able to obtain. I have measured the mouth-opening compared with the width of the head sighted from the front and find that the mouth-opening is less than one-third of the width of the head, while in the illustration showing a front view it is more than one-half as great.

These tracings are spoken of by Dr. Luce as being "interesting to dentists, as they show what has to be contended against in taking the bite preparatory to the insertion of an artificial substitute."

But a far greater interest attaches to the correlation of the line traced by the condyle in the movements of the mandible and the facial line.

There is a certain definite correlation between the morphology of the morsal surfaces of the teeth and the angles made by the intersection of the functional portion of the condyle path² with the facial line, which I call the condylo-facial angle; also the angle

No. 2 shows the left side with extreme mouth-opening, showing the distance traversed by the head at the symphysis, one at the region of the first molar and one over the condyle.

made by the intersection of the condyle-path with the plane of occlusion (or the alveolar plane in edentulous subjects), the condylo-occlusal, or the condylo-alveolar angle, as the case may be.

I show the tracings in two cases, taken:

1. With the mouth opened to its fullest extent.
2. With the mouth half-opened as in admitting food to the mouth.
3. Short openings as in biting and grinding the food.
4. Right lateral, and
5. Left lateral movements of the mandible.
6. Anterior protrusion.

Only the first of these were recorded by Luce, and that seemingly exaggerated.

The cusps and incisive edges of the teeth come in contact only in the short openings represented by the straight portion of the upper end of the line traced in the lateral and protruding movements, and it is that portion of the tracing only that bears any relation

² I mean that short straight portion of the condyle tracing forward and downward made in the movements of mastication, extended till it intersects the facial line.

to the cusps of natural or artificial teeth, the angles formed by the intersection of the extension of this portion of the line with the facial line and the oral planes mentioned being the angles in which we are interested in our studies of the movements of the mandible in connection with dental articulation.

In the paper before referred to³ I gave the conclusions which I had deduced from my experiments in the articulation of the models of natural teeth, and the great variations found in the condylo-occlusal angle of different subjects—ranging as I there stated from 22.5 degrees in one case to 45 degrees in another, those being the greatest extremes noted up to that time. More extended observation, however, has shown an even greater range.

Having proven to my own satisfaction the fact of this variation in the condylo-occlusal or condylo-alveolar angle, I constructed an articulator with an adjustable angle to reproduce these variations—with degree gauges to record the measurement of the angle, which varies not only in different subjects but also very considerably in the movements of the two condyles of many individuals.

No. 3 is the right side, showing the distance traversed by the three beads in moving the mandible from right cusp contact to occlusion and over to left cusp contact. The ink mark, which was placed on the side of the face before photographing, shows where the bead rested in occlusion, the trace forward being the left lateral movement and back of it the tracing of the right lateral movement.

I have also constructed an apparatus which I have called a facial clinometer.

This device registers the direction of the condyle path, and of the plane of occlusion (or the alveolar plane of edentulous subjects) as compared with the facial line, and measures in degrees the angles formed by the intersection of these lines, also the "classic facial angle," the mandibulo-facial angle, etc.

It also measures in millimeters the distance that one condyle moves forward with the synchronous backward movement of the other condyle, in the function of mastication.

I quote from Holden's Human Osteology: "In masticating we can readily feel that one condyle advances toward the anterior margin of the glenoid cavity, while the other recedes to the posterior."

The authorities are not in accord on this point, but

the clinometer shows it very plainly; it is true that in some subjects the condyle does not move back at all, while in others it recedes considerably, and often one condyle recedes more than the other.

The ratio between the forward movement of one condyle and the synchronous backward movement of the other varies greatly in different individuals, and even in the same individual the ratio often varies in the left lateral movement as compared with the right.

This distance-measurement is registered in millimeters by the clinometer and also on the articulator, where it serves to correspondingly regulate the distance at which to place the bite-correcting fulcrum-screws from the condyles of the articulator.

The importance of being able to recognize the extent to which, in any given case, one condyle recedes as the other advances, and of being able to utilize the observation is shown by the following diagram:

The mandible, as we know, is based on the equilateral triangle, the sides measuring four inches.

In the diagram, A and B represent the condyles, C the point between the central incisors.

If we imagine that the mandible is thrown to the left, and that the left condyle A does not recede, B,

No. 4 is the left side, showing the tracing of the beads in moving from occlusion to incisive contact.

the condyle of the right side takes the position of B', while C, the median line of the incisors, travels to C'. In the molar region F travels to F' on the left and H to H' on the right.

But in a case in which the right condyle, B, advances the same distance as before, while the left condyle, A, recedes one-third of that distance, moving to A', we will find that the entire triangle acts as though turning on the fulcrum D.

C instead of moving to C', will reach C'', while F will have moved to F'', and H to H''.

In constructing a set of teeth for a subject in whom, by reason of the condyle receding on the grinding side, the fulcrum is at D, as shown, instead of at A, if, by reason of the construction of the articulator the fulcrum is immovably fixed at A, instead of being movable to suit the case, we would find the articulation at fault to the extent of the difference between the points F' and F'', H' and H'', C' and C'' respectively, causing inevitable interference of the cusps, necessitating

³ See Dental Cosmos, January, 1896.

either the sacrifice of the cusps or the reconstruction of the set.

There are two reasons why teeth mounted upon plates should have cusps.

Dr. Bonwill points out that it is necessary in order that there may be a reciprocating or balancing articulation; that is, that when the incisors are brought in contact the molars will also touch to balance, and that when the buccal cusps of one side are brought in contact for the purpose of grinding food, we may have a balancing contact on the opposite side, the upper lingual cusps resting upon the lower buccal.

This "balancing articulation" I have illustrated on pages 39 and 40 of the January, 1896, *Cosmos*.

Dr. G. V. Black, in his recent experiments with the dynamometer, has shown that the subject wearing plates can not exert nearly so much force as those having the natural teeth.

He also found, in studying the physical characteristics of foods, that it requires very much less force to comminute food with a cusped crusher than when placed between plane surfaces.

This is the second reason why cusps are necessary to artificial teeth, and in fact, even more essential to teeth inserted upon plates than to the natural teeth.

It is much to be regretted therefore, that so many of the unfortunate people who have to wear plates which deprive them of a portion of the crushing power, should also, from lack of an adjustable articulator, be deprived of cusps upon the artificial teeth, thus still further diminishing their masticating force.

In my work thus far I have used only a heavy, clumsy working-model of the clinometer, made of brass in order that it might be altered as found necessary in the test of actual use. I hoped to have it here in its perfected form, made of aluminum, but have been disappointed.

Photograph No. 6, however, represents the head-piece of the clinometer in position (the jaw-piece, which is secured to the lower jaw to indicate the movement of the condyle, being here omitted).

An adjustable frame surrounds the head, resting upon it at the points A and B. A slender, dependant piece C, not very clearly shown in the photograph except on the forehead and just at the base of the nose, indicates the facial line. The piece D set par-

allel with C by the set-screw E, and held rigidly in position by the brace G, carries the adjustable transverse piece H, the degree gauge I registering the angle formed at the intersection of D and H.

In this position it serves to register the condylo-facial angle when H is placed parallel with the condylo-path indicated by the jaw-piece when the latter is in position and the jaw moved as heretofore described, a point over the condyle traveling freely in the slot of the loosely adjusted transverse piece H, the latter being fixed by a set-screw when its direction has been determined by the movement of the condyle pointer. The position of the transverse piece H can also be changed so that it will register the "classic facial angle," the maxillo-facial angle, etc.

The same dependant piece D, when placed in front of the face supported by the projection J and the brace K, and placed parallel with the facial line indicator C, and using the same transverse H and degree gauge I, serves to register various other angles.

Photo. No. 7 shows a modification of the transverse H, which enters the mouth and indicates the plane of

No. 5 is a front view, showing the movement of the bead from right cusp-contact to occlusion.

occlusion—not from the incisive edges and cusps of the upper teeth with the mouth open, but the morsal edge of the lower incisors and the summit of the cusps of the lower first molar when in complete closure.

To obtain this plane, points are affixed to the device which enter the sulcus of the upper molars to exactly the depth of the overlap of the incisors when the incisors are in occlusion. This function of the transverse H is also seen in the photograph No. 8, where it serves by other slight modifications to measure the plane of occlusion as described, also the plane of articulation, the alveolar plane, etc.

The angles and measurements thus recorded by the facial clinometer not only fully confirm the deductions from my experiments with models of the natural teeth, but show an even greater range of variation in the angles in question, not only between different individuals, but in the movements of the two condyles of the same person.

It has been said: "In the domain of organic life

there is rarely perfect symmetric correspondence in the two halves."

This condition was therefore anticipated, but not to the remarkable extent demonstrated by actual measurement.

I will cite two remarkable illustrations of this great variation:

One, a gentleman of 60 years, for whom I made full upper and lower sets. He had never worn plates before. The clinometer recorded the condylo-alveolar angle as 1 degree on one side and 10 degrees on the other, with which angles in the articulator a reciprocating articulation was obtained. This case was the lowest angle I have ever encountered, but it is largely due to the fact that his molars were lost some years ago, while a pair of bicusps and the incisors have only been removed a few months. Thus the alveolar process is greatly absorbed at the rear but scarcely any at the anterior portion. When absorption takes place in front the angles will undoubtedly become greater.

No. 6. The facial clinometer in position.

The second case is that of a lady 70 years of age. She has natural teeth below but has worn an artificial set above for over twenty years, having had different sets made but not with satisfaction, not having been able to bite.

The condylo-alveolar angle in this case was 22 degrees on one side and 44 degrees on the other. The variation was so great that I doubted the correctness of the record. Not wishing to trouble the patient with a repetition of the measurements, in placing the case in the articulator I made a compromise, taking 5 degrees from one side and adding 5 degrees to the other.

But I found it impossible to get a reciprocating articulation until I had restored the angles to the clinometer record. This was a peculiarly difficult case, not only because of the extreme angles but because the lower molars were worn by contact with porcelain teeth above, and the lower incisors having been relieved of all work were long, and the patient was unwilling to have them shortened.

The articulators devised by Drs. W. G. Bonwill, E.

T. Starr, W. W. Westmoreland and more recently by R. H. Antes, have both a lateral and a protrusive movement, but inasmuch as they fail to reproduce the drop of the ramus due to this hitherto unrecognized combined forward and downward movement of the condyle, they do not reproduce the true movement of the mandible, and therefore do not permit the normal articulation of the cusps of models of the natural teeth. Consequently they can not be relied upon to produce a correct articulation of artificial substitutes.

The physiologic articulator, with its adjustable angle, its degree and millimeter gauges for recording the measurements taken by its adjunct, the facial clinometer, will probably appear too complex for some, especially as compared with the dental articulators heretofore in use, which, with few exceptions, have been mere occluders.

But to those who desire to give their patients the best results possible, and who are not satisfied with anything short of scientific accuracy, the study of the

No. 7. The plan of occlusion.

mandibular movements as measured and recorded by the clinometer, and reproduced by the adjustable articulator, will be found not only instructive and interesting, but also of great practical value in their application.

As I have said in the article before referred to: "The movement of the condyles constitutes an important factor in many departments of our work, as in its bearings upon the articulation of the teeth, in the study of the cusps of the natural teeth with a view to bettering the articulation, either in orthodontia or in the treatment of the disease commonly known as pyorrhea alveolaris, in the shaping of artificial cusps, whether in fillings, crown, bridge or plate work; in the treatment of diseases of the facial muscles, of the glenoid fossæ, or of plastic adhesions, etc."

The Vogt Prize.—The pupils of Professor Vogt of Moscow collected 2,000 roubles on the occasion of his recent twenty-fifth "jubilee," the income of which is to be awarded each year to the last work on general pathology by a former student of the university.—*St. Petersb. Med. Woch.*

DEFORMITIES OF THE NASAL SEPTUM.

BY J. H. McCASSY, M.A., M.D.
DAYTON, OHIO.

But little success in the treatment of diseases of the upper respiratory passages and the ear can be attained while occlusion or partial occlusion of one or both nostrils exists. It is essential, therefore, that deflections of the septum nasi and other intranasal abnormalities be removed at the outset, so that the ingoing current of air may pass through the nasal chambers and be properly warmed and moistened therein. Physicians will not question the soundness of these conclusions, yet they too frequently let patients thus afflicted go the "rounds" without offering them advice and suggestions as to the necessity of primarily removing intranasal abnormalities for these cases. Mouth breathing, headache, epistaxis, sneezing, frontal neuralgic pains, insomnia and total or partial deafness are common symptoms of nasal obstruction. Chronic nasal catarrh and septal deformities go hand in hand.

Classification—1, osseous; 2, cartilaginous; 3, osseo-cartilaginous (Jarvis). This is the best and most natural classification. The seat of the deformity is found in the cartilaginous septum in two-thirds of the cases.

Causation—Civilization seems to be a factor of nasal deformity, for the American and European races are prone to them. Collier says about 80 per cent. of the savages are exempt from them. During early life falls or blows on the nose or rough wiping of it, sets up a low grade of inflammation—the perichondrium is over-nourished, new cells are deposited and the cartilage within its unyielding framework bulges to one side from excessive growth. Usually considerable thickening occurs at the eminence forming enchondroma and at the junction of the cartilage with the bone, bony deposits occur forming exostosis.

Case 1.—Deflection of the cartilaginous septum with enchondroma. Mr. M., aged 30 years suffered for many years with chronic nasal catarrh, pharyngitis and deafness. He complained of fullness in his head, sneezing, frontal neuralgic pain and insomnia. Examination revealed deviation to the left and great thickening of the cartilaginous septum. The enchondroma was situated about half an inch back from the nasal outlet. This exerted considerable pressure against the outer wall of the left nostril, giving rise to such reflex symptoms as sneezing, headache, frontal neuralgic pain and lachrymation.

An 8 per cent. solution of cocain was applied for eight minutes, which produced anesthesia and shrunk the spongy tissue enabling the writer to view the contour of the parts. A scalpel with a narrow blade was used to excise the redundant tissue. Commencing at the floor of the nostril, the incision was carried inward three-sixteenths of an inch, then curved upward about half an inch. An assistant kept a close watch in the other nostril to warn against cutting through the septum. This precaution precludes the possibility of such a mishap. This operation was completed in a few seconds. A full view of the parts being cut is the safeguard in this operation. Delay will result in obscuration of the parts from hemorrhage. A sharp, narrow-bladed knife will remove cartilaginous outgrowths readily. It being impossible to determine beforehand the presence or absence of bony tissue the writer usually begins the operation with the knife, only using the saw and alligator forceps when absolutely necessary. A 12 per cent. solution of the nitrate of silver was brushed on the cut surface to aid in arresting hemorrhage. In a few minutes bleeding ceased. The nostril was then washed out with Dobell's solution. The patient was directed to blow the clots out. The nostril was then packed with cotton saturated with carbolic vaselin. This dressing was used for two weeks, being changed once or twice daily for the purpose of cleansing. As a result of this operation a good patulous nostril was secured

and septum straightened considerably. The naso-pharyngeal catarrh yielded kindly to astringents of nitrate of silver and chlorid of zinc and alkaline and albolene sprays. The reflex symptoms complained of soon disappeared.

Case 2.—Exostosis and enchondroma with deflection of the septum. Mr. S., aged 45 years, a bookkeeper, was referred to the writer by Dr. Ensey in July, 1896, for naso-pharyngitis, and on-coming deafness. Examination showed that the septum was but slightly deviated to the right, but a large exostosis and enchondroma, located about half an inch back from the nasal outlet, occupied the floor and septal side of right nostril, shutting off the passage of air. This precluded the possibility of using the Eustachian catheter in the right ear.

Under cocain anesthesia, with the scalpel an elliptical portion of the mucous membrane was removed from the eminence of the outgrowth. A mastoid curette was used to separate and push back about a quarter of an inch the mucous membrane toward the base of the tumor. The knife failing to cut the exostosis the saw was used for a while, but owing to the shape of the tumor the saw could only be used to outline the cut both above and below. Then the alligator cutting forceps was used and the growth cut or twisted off in five pieces. Hemorrhage was pretty free for a few minutes. The parts were cleansed with Dobell's solution and the mucous membrane was coapted as nearly as possible without stitches. The nostril was packed with cotton saturated with carbolic vaselin. The after-treatment was the same as in Case 1. Healing was uneventful; a good patulous nostril was secured and the catarrhal symptoms soon diminished.

Case 3.—Deflection of the nasal septum without exostosis or enchondroma. Mr. T., aged 35 years, was referred to the writer by his family physician in March, 1893. He was a mouth-breather and had copious secretions from his naso-pharynx and from his right nostril. As long as he can remember he has suffered with headache, sneezing and frontal neuralgic pains. He said he had taken a barrel of medicine without getting any relief from his trouble. Examination revealed an enormous hypertrophy of his right inferior turbinate and the cartilaginous septum was curved to the left nostril so as to press against the outer wall of the left nostril, completely occluding it.

The hypertrophy was removed by two linear incisions to the bone drawn from the back to the front with the cautery knife heated to a white heat. This was done under cocain anesthesia at two sittings.

Then under cocain anesthesia an operation was made in the septum with an old cataract knife. An incision an inch long was made horizontally from before backward; another incision one-eighth of an inch in the middle was made below the first one, which tapered to nothing at either end. This permitted an elliptical portion of the cartilage and mucous membrane to be removed. By means of two vertical incisions a similar but shorter elliptical portion of the septum was removed. This made a stellate opening in the cartilaginous septum. (Max Wocher of Cincinnati had made to the writer's order a clamp with the blades over an inch long by three-fourths of an inch wide. When the blades were clasped firmly they were held in place by a set of screws, each blade had a hole in the center of it one line in diameter for the purpose of drainage.) After the hemorrhage had ceased the parts were cleaned and the clamp applied firmly by a pair of long forceps. The firm pressure straightened the septum and coapted the cut edges nearly. The clamp was worn for three days, being removed daily and the parts cleansed. A few doses of morphin were given to allay the pain and uncomfortable feeling arising from the pressure of the clamp. At the end of the third day the clamp was displaced by a perforated hollow rubber splint which was worn for two weeks, being removed daily for cleansing purposes. Healing occurred without interruption. The case remained under treatment for three months, during which time the naso-pharynx was brushed every second day with a 2 to an 8 per cent. solution of nitrate of silver and sprayed with Dobell's solution, each treatment being concluded with a spray of albolene containing a grain to the ounce of both carbolic acid and menthol. At the end of this time the naso-pharyngeal catarrh was practically cured and the headache and neuralgia had disappeared.

These cases are not reported here for uniqueness but because they represent fairly well the prevailing types of deformities of the cartilaginous nasal septum, not including spurs. The line of treatment adopted is simple, but successful. No clamp or reasonable amount of pressure will straighten simple deflection

of the septum while too much tissue remains in it. The redundant cartilage or bone must be removed. Fortunately simple deflection of the septum is rare. Not many cases will require the operation described in Case 3. In the great bulk of cases if the redundant cartilage or bone is pared off and the septum thinned thereby, the tissue in healing contracts and helps to straighten the septum and a good breathing space will be secured. The writer usually adopts the simpler operation first, leaving the clamp operation as a last resort. Indeed it is difficult to get patients to undergo the clamp operation. In cases having no manifestation of syphilis or scrofula little fear need be entertained for perforation or ulceration; delayed healing may occur but not the former. It is not necessary to be too penurious about the loss of a little mucous membrane. It will readily reform and produce a healthy secreting surface.

32 West Fifth Street.

FOLLICULAR OR CROUPOUS TONSILLITIS.

Abstract of a paper read before the Falls City Medical Society,
December, 1896.

BY P. RICHARD TAYLOR, M.D.

Professor Materia Medica and Therapeutics, Clinical Lecturer on Diseases of the Eye, Ear, Nose and Throat, and Dean of the Faculty of the Hospital College of Medicine; Member of Kentucky Medical Society, etc.

LOUISVILLE, KY.

Follicular tonsillitis usually begins with a temperature of 102 to 104 degrees, accompanied by chills and rigors, a full bounding pulse, throbbing headache, aching of the bones of the extremities and loss of appetite. The tonsillar symptoms do not become prominent until six to twelve hours later. Fulness is felt on deglutition, and a sensation as though a jagged foreign body was projecting from the tonsil; the anterior and posterior pillars and tonsil will be swollen, the follicles will be larger than normal and filled with a gray exudate and coagulated lymph.

At the end of twenty-four hours, the throat symptoms will be markedly exaggerated; the inflammation will have extended to the pharynx, and probably to the larynx; the soft palate will be edematous, the uvula elongated, and the feeling of fulness and stiffness of the muscles of the throat will be increased. There is dryness of the pharynx and greater swelling and edema of the pillars. The deposits in the follicles have become profuse and may be continuous over the surface of the tonsil. The pain has greatly increased and is continuous, being extreme in deglutition; the lymphatics about the neck are usually involved. The attack lasts from seven to ten days, but may be prolonged by the infection attacking first only one tonsil and later the other.

Cause.—The predisposing cause is enlarged tonsils with open crypts and follicles with ragged edges. That it is due to a specific organism is unquestioned. A number of organisms have been found in the exudate, but just which one produces the disease has not been determined.

Treatment.—The temperature, throbbing pain in the head and aching of the limbs can best be controlled with quinin and some of the coal tar derivatives, preferably phenacetin. I get the best results from 2½ grains each administered every two hours until distressing symptoms are relieved. Gargles of very hot water will increase the patient's comfort and lessen edema.

The tonsils, being the seat of the disease as well as

the point of infection, demand the greatest attention. The exudate upon the surface of the tonsil can be easily wiped away with a probe armed with dry cotton. Usually, any attempt to dislodge it with the probe from the follicles results in its being pushed deeper into them.

For the last eighteen months, I have adopted a method which renders it easy to thoroughly cleanse the tonsil and which shortens the duration of the attack, and in many cases, seen early, completely aborts it. I use a blow pipe made of soft silver about seven inches long, curved at the smaller end, resembling a long, curved Eustachian catheter; in fact, the catheter can be used very nicely as a substitute. After wiping away with the probe and cotton all exudate from the surface of the tonsil, I then attach this blow pipe to the cut-off from my air receiver, just as I would a spray tube. The curved end should be placed about one inch from the tonsil, the air turned on at about twenty pounds pressure, and the current of air passed rapidly from follicle to follicle, which will completely remove all accumulations.

The follicles are then washed with a solution of bichlorid, 1 to 3,000, with an angular Saas spray tube held very close to the follicles, after which the tonsil and sometimes the surrounding mucous membrane is painted with a solution of nitrate of silver, 40 to 60 grains to the ounce. The application of the silver solution will have a decided anesthetic effect and your patient will experience great relief. Other applications may be substituted for the silver solution, but I have found it serves the purpose best. This treatment should be repeated twice or thrice daily according to the severity of the attack. Iodin should be avoided in all acute stages.

To abort this disease the case must be seen during the first twenty-four hours of the attack, the earlier the better. Even when seen too late to abort the attack, this treatment materially lessens the severity.

Incidentally, I have successfully used the same blow pipe to remove soft accumulations and small foreign bodies from the ear.

THE DIAPHRAGM AND CENTRUM TENDINEUM.

WITH TEN ORIGINAL ILLUSTRATIONS BY THE AUTHOR.

BY BYRON ROBINSON, B.S., M.D.

PROFESSOR OF GYNECOLOGY IN POST-GRADUATE SCHOOL AND POLICLINIC.
CHICAGO.

(Concluded from page 207.)

The membrana limitans is a very fine, thin connective tissue layer on which the endothelia rest. It is finely granular, or better, a finely fibrillar or striped membrane. It contains no cells. It has a watery or glass-like transparency, which is plainly observed when the endothelia are fallen off or very lightly brushed off. As Bizzozero and Salvioli have shown, the membrane is not exactly alike over all the parts of the peritoneum, but is perforated over the diaphragm. They say that the perforations of the membrana limitans are situated on the zona tendinea, and the zona peritendinea of the diaphragm. Bizzozero and Salvioli assert that the pores of the membrana limitans have a diameter from four to sixteen mm. and

a round or oval circumference. They occur in groups of fifty to sixty, of irregular egg-shaped form; the pores correspond to the meshes of the fibrous connective tissue. I have examined this glass-like membrane, the membrana limitans, in various parts of the peritoneum, as the diaphragm, omenta, mesenterium ligamentum latum, and there is no doubt about one's ability to see the membrane when the endothelial layers have been carefully brushed off, but we can not always be sure to find it, and it is not easy to isolate. Again, to find the pores of the membrana limitans which Bizzozero and Salvioli say exist only on the zona tendinea and the zona peridendinea of the diaphragm is not at all easy, at least so far as my researches are concerned. It is rather to be said that it is an uncertain process to find the pores. Muscatello made examinations of the membrana limitans on the ligamentum latum of the serous covering of bowel, stomach, liver, spleen, pancreas, uterus and anterior abdominal wall and the diaphragm. He found that the membrana limitans, as Bizzozero and Salvioli has asserted, is perforated on the diaphragm. In no other place could he find pores in it. The method Bizzozero recommends to isolate the membrana limitans is to place large pieces of serous membrane several days in Muller's fluid and then 12 to 24 hours in equal parts

Fig. 9.—Lymph vessels of a man about 30 years old, twenty-four hours after death, pleural side of diaphragm. Oc. 4 ob. 3 R. The diaphragm was penciled. Silver nitr. applied one hour $\frac{1}{4}$ per cent. Ground substance, 1, not drawn. The larger vessels show quite elongated spindle-shaped endothelia but many of the smaller show very sinuous shaped endothelia indicating that they are capillaries; 2 indicates the confluence of six lymph vessels; 1 shows the ground work of the lymphatic net work. Δ Note the irregular bulging of lymph vessels.

of water and alcohol. Now the endothelia are brushed off with a pencil or washed off with a stream of water. One then tries to seize the membrane with a forceps so it may be isolated. The membrane is then spread out and colored with eosin or acid fuchsin, when one can examine it in glycerin and water. Muscatello notes as all others who have examined the membrane that it is a fine fibrillar structure. It is a membrane of a continuous uninterrupted surface with no pores except on the diaphragm. In my examinations of the membrana limitans I will here record a phenomenon, which few authors note, and that is if the endothelia are brushed off very lightly, or better, washed off, one can occasionally observe small pits or depression in the membrana limitans. These pits or depressions are simply the places where the endothelial cells once were.

The only other author known to me as mentioning the fact, is Muscatello. The membrana limitans is generally thicker over solid organs, such as the liver and uterus. However, one generally finds the membrane on the diaphragm with as much certainty as anywhere. Still, I agree with Muscatello, that one can often find it on the bowel as well. By careful observation one can often see endothelial cells, con-

nective cells of fiber clinging to the membrana limitans at points where it was forcibly torn away. Again, in places it is so intimately associated with the underlying connective tissue that it can scarcely be separated, and a little too strong penciling ruptures it in various directions.

The membrana limitans is a thin sheet of tissue, a continuous membrane on which rests the protoplasmic portions of the endothelial cells. According to Bizzozero, Salvioli, Muscatello and my own researches it is perforated only on the diaphragmatic serosa, and hence arose the explanation of the fact that the diaphragm is the chief point of absorption of the peritoneum. The reason that the mesenterium will remain distended with air when blown up, as Bichat recorded it, is because the membrana limitans is not perforated on the mesenterium.

From considerable research and quite a number of experiments on the peritoneum of rabbits (and other animals) it appears that there is a current directed toward the diaphragm.

So far it appears the diaphragmatic membrana limitans alone possesses pores and is the chief locality of the peritoneum which possess the power to absorb and deposit the colored granules into the subjacent lymph channels. Dubar, Remy and Maffucci assert that there are other localities of the peritoneum for rapid absorption, but this has not been extensively confirmed. I have noted absorption of colored granules in the centrum tendineum, gastro-splenic omentum and about the omentum of the pylorus. The strange reason for the diaphragmatic membrana limitans being the only portion perforated has received no adequate explanation so far. But the diaphragm is an organ of motion and a bed of lymphatics and perhaps the pores are a remnant of the original aperture between the pleuro-peritoneal cavity.

The significance of the perforation of the diaphragmatic membrana limitans and the stream of fluid in the abdominal cavity directed toward it is a practical matter in peritonitis, for it is very suggestive of drainage.

1. In my experiments on animals it was distinctly evident that the region of the diaphragm (including to some extent the omentum minus and root of the omentum majus), was the chief region of physiologic (and ultimate pathologic) activity. The swarm of leucocytes told the story. The particles of Berlin blue almost entirely passed into the vast lymph bed of the diaphragm. With time the particles pass into mesenteric glands and viscera, but this is entirely secondary to the passage into the lymph channels of the diaphragm.

2. It has been found that in puerperal peritonitis the serosa and lymph channels of the diaphragm are intensely inflamed as first demonstrated many years ago by Recklinghausen.

The centrum tendineum is a vast system of lymphatic channels. The credit of making the foregoing views known is due to Dr. Daniel Von Recklinghausen, now professor of pathologic anatomy at Strasbourg. He demonstrated this fact by vast personal labors and many experiments, aided by his introduction of the use of silver salts. Ludwig, Schweigger-Seidel, Dybkovski, Klein and others perfected his labors. The very reason that the centrum tendineum has had so much attention is because it is a bed of lymphatics and through it peritoneal fluids will pass carrying with them various kinds of solid particles.

The following are the methods to demonstrate the diaphragmatic lymphatics:

1. By placing a very thin piece of the centrum tendineum of a small rabbit stained with silver nitrate and mounted in glycerin under the microscope we may be able to observe the valvate trunks and the non-valved capillary lymphatics. The serosa is sufficiently transparent to allow the lymphatics to be noted beneath it.

2. By brushing or penciling the abdominal serosa, but especially the pleural serosa of the centrum tendineum with a piece of cotton on a tooth-pick or a camel's hair brush and then subsequently pouring on the brushed surface .25 per cent. solution of silver nitrate for a few minutes one can observe in specimens mounted in glycerin well defined lymphatic vessels and capillaries.

3. To inject into the abdominal cavity of a living animal (rabbit) fluid holding in suspension solid colored granules, subsequently (from 10 minutes to 24 hours) killing the animal, carefully cutting out the diaphragm, brushing its surface and silvering it. Mount small pieces in glycerin when the valvate lymph trunks and capillaries are plainly visible containing the colored granules.

Fig. 10.—From guinea-pig's pleural surface of diaphragm, penciled, stained with silver nitr. and drawn to oc. 4 ob. 3 and reduced $\frac{1}{2}$. The object of the cut is to show how the juice canals in the ground substance flows into the lymph capillaries, *i. e.*, the lymph canalicular system and the lymph vessels are directly connected with each other; 1, 2, 3, lymph vessels; 4, 5, 6, denote juice canals in the ground substance which is marked 7, 8, 9, 10. At 11 and 12 observe the juice canals in the ground substance blend with the lymph vessels; 13 and 14, valves of the lymph vessels; 15, 16, endothelial cell and nucleus in the ground substance. This guinea-pig had been injected with a solution of Berlin blue, fifteen hours before death; 17 shows lymphoid corpuscles in the vessel; 20, endothelium of lymph vessels. One can observe the particles of Berlin blue free in the lymph vessels as noted by +. One can see the leucocytes in the lymph vessels and some have enclosed in the bodies particles of Berlin blue. One can occasionally observe particles of Berlin blue scattered in the juice canals. By fifteen hours of peritoneal irrigation are more prominent, and at 11 and 12 is seen the most typical transition of the cells of the lymph canalicular system, into the lymph capillary vessels. With 1-15 oil immersion lens one can discover vast numbers of colored granules overlooked by low power. At 18, 19 and 20 may be seen lymphoid canalicular systems which do not nearly fill the space.

4. The lymphatics may be demonstrated by carefully cutting out a diaphragm of an animal dead as long as twenty-four hours, silvering it and allowing it to remain one-half to several hours in a solution containing colored granules of Berlin blue. Mounted in glycerin it shows the lymphatics containing the colored granules.

5. Inject into a recently dead animal (rabbit) a fluid containing Berlin blue, in half an hour cut out the diaphragm, silver, mount in glycerin, whence one may observe the lymphatics, capillaries and valvate trunks.

6. The lymphatics of the centrum tendineum fill better if artificial respiration be kept up for ten to fifteen minutes. The peritoneum of the just killed dog and rabbit absorb fluid and solid particles about as rapidly as that of the living animal.

In every method one may expect frequent failures

from trauma, *i. e.*, dragging or too much brushing and occasionally too little brushing. After very many trials and experiments to demonstrate the lymphatics of the centrum tendineum, we would give the following simple directions. Kill a rabbit, open the chest and abdomen with as little trauma as possible. Wind a little cotton on a tooth pick and brush the abdominal side of the centrum tendineum with the cotton, wet in the animal's serum or distilled water, gently two to three times. Then pour over the tendon *in situ* .25 per cent. solution of silver nitrate for three to five minutes. Serve the pleural surface of the tendon exactly similar. Now, with the most exquisite gentleness, cut out the diaphragm and place it in distilled water in the sunlight for a few hours. Snip off small bits with sharp scissors and mount them in glycerin. Preserve the whole specimen in Müller's fluid, or 10 per cent of formalin. For preservation the specimen should be desiccated with alcohol, however, a very short time—one minute—or it will dissolve out the silver lines, a half minute in oil of cloves and mount in zylol balsam. If one desires to have a clear nucleus, the specimen should be colored with hematoxin for one or two minutes, and if a beautiful color is desired for the ground substance, the sub-endothelial tissue, a very dilute alcoholic solution of eosin for about a minute will perhaps be sufficient.

Fig. 7.—Lymph vessels of pleura serosa of diaphragm of rabbit. Ob. 4 oc. 3 R. The surface was well penciled and then stained with a $\frac{1}{2}$ per cent. solution of silver nitr.; v. v. valves. Note the irregularity of outline of the vessels. Ground substance dark. The lymph vessels are dilated.

A curious but significant feature of the centrum tendineum is that where the pericardial sac lies on the tendon, lymphatics fail. There would be no particular physiologic object in having the centrum tendineum sieve-like immediately under the pericardium where it is adherent to the tendon, for the peritoneal fluids would then only pour into the pericardial sac.

The recognition of the lymphatics in the centrum tendineum after the application is easy and perfectly certain. We notice two kinds, 1, lymphatic trunks with distinctly visible valves, and 2, various kinds of capillaries and lymph spaces. By far the most typical location is on the pleural serosa of the tendon. It does not appear that the dog's lymphatic system is so well developed as that of a rabbit or guinea pig, hence, for the purpose of demonstrating, the lymphatics of the latter animals should be chosen. Under the microscope the lymphatic trunk consists of a distinct wall, composed of sinuous or spindle-shaped, nucleated endothelium, which is beautifully brought out by the silver stain. The individual endothelial cell forming the lymph vessel wall may be enormously long, perhaps its major diameter may exceed its minor diameter by ten-fold, showing a very narrow and long spindle-shape, or the endothelia may be very

irregular in shape and possess a sinuous outline similar to the cranial suture. The vigorous emptying and filling of the lymph vessels give elongated shape to the endothelia, as it does in blood vessels. It appears that the endothelia of the lymph vessels possess stomata vera and spuria similar to the peritoneal serosa; however, this is denied by some investigators. The interendothelial space is just the same as that of the peritoneum, *i. e.*, consists of two dark parallel lines crossed transversely by anastomotic protoplasmic processes. But the most significant and characteristic feature of the lymph trunks are the valves which appear on the vessels at very short intervals. The valves are a fold of the vessel wall and pass generally entirely across the wall. Frequently at the valves the endothelia change their course from a longitudinal to a transverse direction. Behind the valve the lymphatic trunk bulges out and one can observe a succession of such dilatations and constrictions of the vessels. In fact, on the pleural surface of the centrum tendineum the lymph vessels have so many valves that they resemble a succession of flasks placed one after the other. Sometimes the valves have a beautiful curve and where the valve exists the vessel is enormously dilated. Vast numbers of lymphatic trunks exist in the centrum tendineum. The lymph trunks are very much wider than blood vessels and if

Fig. 8.—Lymph vessels of pleural surface of diaphragm of rabbit. Pencil and silver nitr. $\frac{1}{2}$ per cent. applied; 1, valves; 2, 2, 2, 2, lymph capillaries with endothelia delineated; 8, lymph vessel trunks whose endothelium is not marked. Note the irregular bulging of the walls; 4, 4, 4, ground substance not drawn. Oc. 4 ob. 3 R. 7 and 7, valves of capillaries opening into the main trunks.

one is puzzled to decide whether the vessels be for blood or lymph, all that is necessary is to trace the vessels to a valve which will decide in favor of a lymph trunk. Again, in blood vessels as large as an ordinary lymph trunk one is able to observe longitudinal or circular muscular fibres; beside the contour of a blood vessel is even while that of the lymph trunk is usually irregular.

The lymphatic spaces or capillaries of the centrum tendineum cover vast areas; in fact, in some specimens which happen to be well silvered and quite transparent, it appears that the whole of the centrum tendineum except where the heart rests and the periphery of the tendon or peritendinea is simply a bed or space of lymphatics. The lymph capillaries or spaces in the central tendon are characterized by sinuous spindle-shaped, or irregular nucleated endothelia. The word sinuous generally best expresses the shape of the endothelia. The capillary lymphatic system of the central tendon is vast and one may frequently note the lymphatic capillaries by looking through the transparent endothelia of the pleural or peritoneal serosa. The lymphatic capillaries and trunks are seen to be connected and all stand in open communication with the peritoneal cavity. Several layers of lymphatic vessels lie in the centrum tendineum, such

as the capillaries immediately under the pleural or peritoneal serosa, the vast intertendinous lymph spaces, the straight lymphatics, the deep lymphatics and those straight lymphatics which pass between the tendon bundles to connect the systems of lymphatics of the pleural and peritoneal side of the central tendon.

The distribution of the lymphatics in the centrum tendineum requires some time to determine experimentally and microscopically. The latter method I practiced extensively and found the trunks of lymphatics to pass, 1, toward the costal periphery of the tendon, 2, toward the mammary vessels ventrally, and, 3, toward the dorsal part of the tendon to reach the thoracic duct. The chief field for the lymph capillaries is toward the central portion of the tendon and the vessels gradually widen toward the periphery, finally terminating in four large lymphatic trunks, two dorsal-ward to the thoracic duct, and two ventral-ward to the mammary vessels.

In the physiologic method of demonstrating the lymphatics of the centrum tendineum we injected into the peritoneum of rabbits especially (sometimes employing dogs and guinea pigs) a solution holding in suspension particles of Berlin blue, killing them from a few minutes to fifteen hours later. Shortly after such an injection into a rabbit's peritoneum, say ten to fifteen minutes, the centrum tendineum presents a brilliant display of radiating blue lines passing from the dorsal region of the tendon toward its periphery in the intertendinous spaces. If the tendon is placed between the eye and strong sunlight the blue lines are very apparent. With a strong lens the lines are still more visible. It must be remembered that in some experiments unaccountable failures arise, as we have to do with factors of peritoneal absorption not yet understood. For example, I took a dog of about seven pounds weight and injected 100 cubic centimeters of fluid (composed of NaCl, 2 per cent.; 2 cubic centimeters of a 5 per cent. solution of ferrocyanid and H_2O) into the peritoneal cavity. Killing the dog in fifteen minutes, I found 130 cubic centimeters in the peritoneal cavity, while the same dog dead a few minutes absorbed 25 cubic centimeters in fifteen minutes. I found that dogs and rabbits just dead absorbed fluid almost as fast as they did while living, and also quite a similar standard prevailed in the same dog, dead or alive. It may be noted that the anterior efferent system of lymphatic vessels pass toward the posterior surface of the xiphoid cartilage and eventually along the mammary vessels to the retro-sternal glands, while the two posterior trunks of the central tendon empty into the thoracic duct just anterior to, or above, the point where it emerges from the diaphragm. The lymphatic vessels of each half of the diaphragm can communicate with each other. The lymph trunks of both systems are characterized by possessing spindle-shaped endothelia, many valves and by lying chiefly between the two tendineous layers and the pleural serosa. The lymphatic capillaries emptying into these lymph trunks are characterized by sinuous endothelial walls which possess no valves and have very irregular excavations in different localities and directions. Now, since we have a circular layer and a radiating layer of tendon bundles in the centrum tendineum, we will have straight or radiating lymph capillaries in the intertendinous space of the radiating bundles of tendons. Also straight or circular lymphatic capillaries between the circular ten-

don bundles. We may call them together, intertendinous lymphatic spaces or capillaries. These have quite a uniform breadth with lateral sinuses or bulgings at various intervals. We also have another kind of lymphatic capillaries which lie chiefly under the pleural serosa and are of irregular and variable breadth. Hence we have two kinds of lymph capillaries. 1. The intertendinous, which run straight in a radiating direction and in a circular direction corresponding to the directions of the tendinous bundles of the centrum tendineum. These two systems of deep and superficial lymphatic capillaries communicate generally where they cross each other by short straight vessels; sometimes a large lymph vessel will suddenly become narrowed and pass between two tendon bundles to gain the other side of the tendinous layer. 2. The lymph capillaries which lie mainly under the pleural serosa, of variable breadth, with sinuous endothelia and provided with excavations.

Peritoneal injections holding coloring matter will demonstrate the various kinds of lymph capillaries in the centrum tendineum. The mechanism of the diaphragm is wonderfully constructed for the purpose of acting like a sieve, as a great and rapid absorbent. The chief aid to this absorptive capacity is the motion given to the centrum tendineum by respiration. The narrowing and widening of the tendinous bundles, due to contraction and expansion of the diaphragmatic muscle in respiration urges onward the lymph current. The motion of respiration acts on the centrum tendineum like a pump. The deep and superficial straight lymphatic capillaries aid especially in forcing onward the lymph stream through the spreading and closing of the intertendinous bundles. Again, as persistent anatomic exactness is not characteristic of the lymphatic system, we find peculiar deviations, spiral lymphatics, outside of the various systems mentioned.

Whatever may be the functions of the superficial straight lymphatics of the centrum tendineum, they absorb a wonderfully large amount of coloring matter from the peritoneal cavity in a very short time, both in the living and dead animal. So far as my experiments are concerned, no place in the centrum tendineum is so active in absorption as are the superficial, straight or radiating lymphatics. It appears that respiration dilates and contracts the radiating intertendinous spaces to a very marked degree. The straight, deep and superficial lymphatics seem to me to be the very important lymph channels of the centrum tendineum. In respiration the straight lymphatics are widely dilated, while in expiration they are narrowly contracted, thus allowing them to fill and empty during the motion of inspiration and expiration. The straight, deep and superficial lymphatics connect the anterior and posterior systems of lymph vessels of the centrum tendineum, becoming in this manner an important factor in the onward progress of the lymph through the sieve-like tendon. Perhaps in this respiratory motion lies its evolutionary process, its gradual steps toward its present condition in mammalian life. With the acquisition of more and more lung tissue the diaphragm assumed a wider range of activity. The wider range of diaphragmatic activity brought with it a necessity of considerable separation of musculo-tendinous bundles at the maximum point of diaphragmatic expansion, because the origin and insertion of the diaphragmatic muscles, musculo-tendinous bands are very various and arranged in an

irregular circle, *i. e.*, on the irregular costo-vertebral internal circumference. As all tissue spaces are the recipients of variable quantities of lymph the intertendinous spaces of the centrum tendineum from their periodic narrowing and widening, not only become lymph receptacles but important channels for lymph currents, whose extent and rapidity of flow rests on the regularity of diaphragmatic activity. Ages on ages of mammalian life with increasing pulmonary tissue and power only tend to fix and increase this peculiar but significant function of the centrum tendineum. Again, during expiration the large liver presses upward on the musculo-tendinous bundles of the diaphragm, tending to increase the intertendinous spaces and enhancing the lymph flow. An examination of a rabbit or other animal's diaphragm will quickly reveal the vast intertendinous spaces and the enormous amount of fluid they may contain when the tendon bundles are widely separated from each other and how very much fluid would necessarily be forced out by their tendon bundles approaching each other and closing up the vast spaces. One can not assert, perhaps, that all the tendinous bundles are sep-

Fig. 11.—Lymphatics of the peritoneal serosa of a rabbit drawn under Oc. 4 ob. 3 R: 1, 1, 1, 1, 1, valves. Note how the endothelia of the lymph vessels becomes directed transversely to the vessels at the valves. The ground substance is simply drawn black to show the vessels plainer. Silver nitrate 2 per cent. is applied for fifteen minutes after penciling; 2 shows the endothelium passing into capillaries by its sinuous outline. In the lymph channels it is elongated and spindle-shaped; 3, lymph channels and trunks. The lymph vessels are dilated.

arated during expiration, now that all approach each other during inspiration, but that in all probability the musculo-tendinous bundles separate and approach each other once during one respiration, *i. e.*, a complete act of inspiration and expiration. Therefore, we may assert that the chief absorptive power of the centrum tendineum is due to its straight, deep and superficial lymphatic spaces and the rapidity of the absorption is due to respiratory movements. It must not be overlooked, however, that the quiet diaphragm of a just killed animal will absorb almost as fast as the living one. Death (in non-septic cases) probably does not alter the diaphragmatic structure for four to six hours. In one case I found Berlin blue particles absorbed in the human diaphragm seventy-two hours after death. The experimental physiology of the centrum tendineum will be reported in detail in another place, but in some thirty carefully planned and executed experiments we learned some salient physiologic features of the tendon, which may be summarized with the conclusions of research on the centrum tendineum.

1. The diaphragm is the characteristic muscle of

mammalian life, beginning imperfectly in crocodiles and birds.

2. The centrum tendineum consists of four layers, two of serosa, abdominal and pleural, and two layers of tendinous bundles, the radiating and circular.

3. The characteristics of the serosa are stomata vera and spuria and the interendothelial space. The interendothelial space is divisible into two parallel lines and crossed by anastomotic protoplasmic processes, resembling a railway with its ties. The endothelial cells are held together in colonies by transverse protoplasmic processes.

4. The characteristic of the tendinous layers is that they possess the deep and superficial straight lymphatics between the bundles, and that these straight lymphatics connect the anterior and posterior lymph system of the diaphragm.

5. The intertendinous lymph spaces between the radiating bundles of the centrum tendineum are covered by a sinuous endothelia of smaller dimensions and more irregular than covers the adjacent bundles of tendons, and possess numerous stomata vera arranged quite regularly in rows.

6. The centrum tendineum is a bed of lymphatics consisting of valved trunks and capillaries of variable width possessing sinuous and spindle-shaped endothelia, lateral excavations and no valves.

7. The rapidity and extent of absorption of the central tendon is due to the widening and narrowing of the intertendinous lymph spaces depending on the motion of respiration. In expiration the radiating intertendinous spaces widen and thus span the lymph space between the tendinous bundles. In inspiration the intertendinous spaces narrow and this forces the fluid onward.

8. The lymphatics of the centrum tendineum stand in open connection with the peritoneum through vertical canals lined by granular, polyhedral cells, whose dilations and contractions regulate peritoneal currents.

9. There is a fluid current existing in the peritoneum directed toward the centrum tendineum.

10. The diaphragm or central tendon is the chief place of peritoneal absorption for colored granules. (I formerly thought it the only place of absorption, but experiments showed a slight absorption in the gastro-splenic omentum of colored granules in the region of the pylorus, and perhaps others will be found by search.)

11. The membrana limitans, so far as my researches extended, is perforated only on the centrum tendineum, which gives a physical explanation of rapid absorption of colored granules through the centrum tendineum.

12. The colored granules wander through the central tendon mainly in a free state and to a less extent enclosed in leucocytes.

13. I can not observe any macroscopic, microscopic or physiologic differences between the centrum tendineum of man and other animals.

14. Lymphatics almost fail when the pericardium and central tendon coalesce. Blood vessels are not constant in location in the centrum tendineum; they are mostly found on the pleural, and sometimes on the peritoneal side, often in the intertendinous spaces.

15. The peritoneal serosa absorbs more rapidly than the pleural serosa.

16. The respiratory movements of the diaphragm act like a pump on its lymphatics.

17. Since the dead centrum tendineum absorbs sim-

ilar to the living, the so-called "vital" process of the endothelial cells must be questioned.

18. It is the lymphatics that play the rôle of absorptive in the central tendon, and not the blood vessel.

19. The best coloring matter to place in the injected peritoneal fluid to test the physiologic action of the centrum tendineum is Berlin blue.

20. The particles of Berlin blue may be traced in the centrum tendineum in two directions: *a*, toward the posterior surface of the xiphoid appendix to accompany the many arteries; and *b*, toward the vertebral column to empty into the thoracic duct just above where it emerges from the diaphragm into the thorax. This places the non-valved lymphatic capillaries of variable breadth and possessing excavations in the middle portion of the centrum tendineum, with the valvate lymphatic trunks toward the costal periphery.

21. The vast absorptive capacity of the centrum tendineum depends on its direct connection by means of stomata vera with the peritoneal cavity, on its great extent of lymphatic vessels and spaces on the perforations of the membrana limitans, and on the respiratory motion of the diaphragm.

22. The force of gravity, intra-abdominal pressure and contact of fluids against the centrum tendineum enhances the rapidity of the absorption of colored granules. For if an animal is hung up by the hind legs the absorption is more rapid than if he be made to sit up. Also movements, manipulation, massage, kneading of the abdomen, etc., hasten the deposit of colored granules into the lymph spaces of the centrum tendineum. So far experiments do not indicate to me that starving the animal hastens absorption to any considerable extent.

23. I can not observe in the experiments that tying one or both thoracic ducts (*i. e.*, the two innominate veins), retards absorption of the colored granules into the centrum tendineum. But the experiments have shown that if the thoracic duct (*i. e.*, the left innominate vein) be tied, the injected peritoneal fluids appear in the bladder about twenty minutes later than if the duct be left untied. The test is made by injecting fluids into the peritoneum containing 2 to 6 per cent. of potassium ferrocyanid subsequently every five minutes, squeezing the urine out of the bladder and adding ferric chlorid, producing a beautiful blue reaction if any potassium ferrocyanid be present. The test is so delicate that the blue reaction will occur at about 1 to 30,000.

24. The vast and active absorptive capacity of the centrum tendineum with the consequent fluid stream directed toward it is a strong argument against peritoneal irrigation, as any fluid in the peritoneal cavity will quickly stream with its contained germs toward the diaphragmatic tendon, the dangerous grounds of peritonitis. I have frequently observed inflammatory products on the peritoneal serosa in pleuritis and pneumonia. Recklinghausen found violent inflammation on the peritoneal serosa of the centrum tendineum in septic puerperal sores.

Cause of Accidents from Tincture of Iodin.—The hydroiodic acid which develops spontaneously in old tincture of iodine, and is found in the impure article, is the cause of the nausea, vomiting, tympanism, pain, etc., that have been known to follow uterine injections. If present no precipitate forms when water is added to the alcoholic solution of iodine.—*Gaz. méd. de Liege*, December 31.

PECULIARITIES OF THE SURGICAL
DISEASES AND INJURIES OF
THE NECK.

BY EDMOND SOUCHON, M.D.

PROFESSOR OF ANATOMY AND CLINICAL SURGERY, TULANE UNIVERSITY,
NEW ORLEANS, LA.

(Continued from page 203.)

Tumors of the neck.—The gaseous tumors of the neck are represented by emphysema resulting from some wound of the air passages or of the lungs in the supra-clavicular fossa; it may be due to fracture of the base of the skull extending to the mastoid cells; it may include all the layers and spread over the whole body; the crepitation of emphysema is characteristic.

Aeroceles (laryngoceles, tracheoceles) are tumors formed by air filling an adventitious pouch; this excludes pneumatocele. The predisposing causes are weakening of the tract and emphysema. The occasional causes are strains (cough, labor). Some are congenital dilatation of the laryngeal ventricles, abnormal prolongations; some are traumatic and due to wounds of the trachea, rupture of the intercartilaginous spaces; some are pathologic, due to dilatation of the glands of the mucous membrane, to ulcerations, syphilitic or due to former disease of the cartilages, or to abscesses; they may consist in a single hernia of the mucous membrane through a rent in the walls, or to rupture; they may consist of all the coats with the penetration of the air in a cavity preëxisting, such as an abscess, or of air into the tissue condensed all around. The symptoms are changes in the voice and resonance upon percussion. The course varies; they are usually persistent. The palliative treatment consists in compression. In some cases extirpation is possible. They present the following forms, varieties and complications: aerocele with brusque development, which may cure of itself; aerocele stationary; aerocele with slow development; aerocele with an irregular course, alternately slow and fast; aerocele simple, due to the rupture of all the coats of the walls, except the mucous membrane; aerocele due to the opening into an abscess; reducible aerocele, which refills by straining; irreducible aerocele, when the orifice of communication has become obliterated; aerocele with alterations of the voice; aerocele due to previous or still existing disease; aerocele with suffocation and dyspnea, calling for tracheotomy. Pneumatocele is due to hernia or great protrusion of the lung into the supraclavicular region; it is recognized by percussion and by its disappearance upon pressure and quick reproduction by forced respiration; pneumatocele follows the respiratory movements.

The liquid tumors of the neck are the following: Liquid hematoma following blows or contusions, or punctured wounds, or incised wounds, when the lips have lost their parallelism; they may result also from a cured aneurysm. Angioma is not very rare; it should be left alone if it does not grow; if otherwise, the removal is indicated, but with all sorts of precautions against the bleeding, which is so profuse here especially; provisional or permanent ligatures of the large vessels above and below should be placed as soon as possible after the skin and fascia are traversed. The tissues are to be divided only between the two artery forceps or two ligatures; injuries to the common carotid or internal carotid necessitating their ligation are grave lesions, also those of the jugular

vein especially when divided high up. Aneurysms are frequent on the neck, but their location so influences the diagnosis, prognosis and treatment, that they will be more profitably studied with the regions where they specially belong.

Cysts of the neck are of several kinds and are known under the following names: mucoid cysts (Lanne-longue), branchial cysts, deep dermoid, deep atheromatous tumors, congenital hydrocele of the neck, hygromata, atheromatous cysts of lymph nodes. They are almost all rare and congenital, but they are not all branchial; their size varies; they are situated along the course of persistent obsolete tracts lined with epithelium, in the neighborhood of the pharynx and larynx and along the larger vessels; they often have prolongations adherent to the muscles, the vessels, the thyroid cartilage and hyoid bone, and even the vertebral column; they are single, or multiple resembling a bunch of grapes. Their walls are sometimes thick or sometimes thin, or sometimes absent altogether. The walls and their contents vary according to their forms or varieties; their shape is globular or oval; sometimes they present independent masses; they are lobulated, which is due to fibrous or muscular bands crossing them and binding them down; their consistence is more or less soft and fluctuating. They may take a sudden and unexplained rapid course and become very large; they may remain stationary; sometimes they become inflamed and hardened or present intracystic hemorrhage, or undergo spontaneous cure; they may burst externally or in the pharynx; sometimes after having become inflamed and bursted they leave fistulous openings; this may occur also when they have been opened. Their forms and varieties are as follows: Branchial cysts are those which possess a dermoid or a mucoid lining membrane, which form presents two varieties. The mucous or mucoid cysts are lined with ciliated epithelium; they are usually median cysts.
