To use this instrument, place a few drops of solution of cocain in the bowl, and if the patient can not lower the base of his tongue unaided, lower it with a smooth tongue depressor, place the instrument under the uvula and allow it (the uvula) to drop into the solution loosely. The moment the uvula comes in contact with the cocain solution the latter rises up the moist surface of the uvula to a considerable height above the level of the cocain by a sort of capillary attraction. Rarely will the touch be noticed, if the touch is gentle. After holding it there for a minute perhaps, and before the patient makes an effort to swallow (which he will do), withdraw the instrument, allowing the uvula to drag over the posterior lip of the bowl to dislodge any excess of the cocain that may adhere to it, thus preventing it from being deposited in the mouth. A better way is (having withdrawn the applicator) to touch the uvula with a pledget of absorbent cotton previously prepared. Repeat this application with a fresh solution once or twice at intervals of one or two minutes and you will find that in about eight minutes the anesthesia is complete and the operation may be proceeded with without pain.

For the last year or two I have used a roughly constructed instrument made by myself by inserting the handle of a pepsin dose spoon into a laryngeal mirror handle, which answered the purpose very well.

PHIMOSIS FORCEPS.

Salvatore, an Italian military surgeon, has invented a phimosis forceps which is described and illustrated in the *Gaz. d. Osp. e d. Clin.* of March 7. He claims that it totally prevents hemorrhage; the total anesthesia is so complete that the patient is merely an indifferent spectator of the operation, and there is no danger with it of injuring the organ, which afterward presents a normal appearance with no indications of having undergone surgical treatment. The instrument consists of two strips of metal fastened together at one end and in contact at the other, where there is a screw thread and thumb screw to graduate the space between them, as the two strips form an open ellipse, like a wagon spring. Each is pierced with a row of holes.

BOOK NOTICES.

Vita Medica; Chapters of Medical Life and Work. By Sir BENJAMIN WARD RICHARDSON, M.D., LL.D., F.R.S. New York and Bombay: Longmans, Green & Co. Pp. xvi and 496. 1897.

"These chapters of 'Vita Medica' were finished by my father on Wednesday, Nov. 18, 1896, just before 8 o'clock in the evening. At 10 he was seized with the illness which ended fatally on Saturday morning, November 21.

"The last proofs were not revised by my father, and, but for the few corrections that could be made without him, the book is published as it left his hands.

"BERTRAM RICHARDSON."

This book is, as its name imports, a history of the medical life of Richardson. The accounts of the early experiments with peroxid of hydrogen, antiseptics, studies on blood, sanitation, anesthesia, alcoholism, nervous centers, the germ theory, vital phosphorescence, are very interesting.

The charming manner in which the story is told, showing as it does the personality of the author, makes the book one to be sought after. The last twenty years have been rich in autobiographies of distinguished medical men, and among them all we must place this of Dr. Richardson as one of the very best of its class. It does not deal directly with the personal life of the author, yet his medical life has been so inseparable from it as to give us a glimpse of character at once admirable and worthy of imitation.

The many readers of Richardson's works in this country will be pleased with the perusal of this book.

The Retrospect of Practical Medicine and Surgery. Edited by JAMES BRAITHWAITE, M.D., Lond., assisted by E. F. TREVELYAN, M.D., Lond., B.Sc., M.R.C.P. Vol. cxiv., January, 1897. New York: G. P. Putnam's Sons. 8vo, pp. xv and 435. 1897.

Braithwaite, with its careful selections, conservative compilation and successful skimming of medical literature, has given us the clear crystal in this number.

Hypnotism and Its Application to Practical Medicine. By OTTO GEORG WETTERSTRAND, M.D. Translation from the German Edition by Henrik G. Peterson, M.D., together with "Medical Letters on Hypno-suggestion, etc.," by Henrik G. Peterson, M.D. Pp. xvii and 166. New York and London: G. P. Putnam's Sons. 1897.

This work has appeared in Swedish, German and Russian, and now, thanks to Dr. Peterson of Boston, it appears in English.

The therapeutic uses of hypnotism are becoming every day better known and its value more and more apparent.

Wetterstrand's work is a clinical report of great value, and his cases are commented upon with a profound knowledge of psychology, and evident sincerity. The book is timely and very instructive, as it teaches how to bring hypnotism within the control of the practitioner as a powerful addition to his armamentarium against suffering.

A Manual of Physiology with Practical Exercises. By G. N. STEWART, M.A., D.Sc., M.D., D.P.H., etc., with numerous illustrations including five colored plates. Pp. 796. Price \$3.50 net. Philadelphia: W. B. Saunders.

[From W. T. Keener, Agt., 95 Washington St., Chicago.]

A modern manual of physiology intended for the systematic study and as a guide for the laboratory.

The work is a thorough-going one, well illustrated, and modern in its method. We no longer have those smoothly flowing treatises on physiology that made the earlier works so popular; on the contrary, the modern physiology has come to be a mathematico-chemic statement concerning the functions of the body based on careful observation and accurate knowledge. While thus the romantic has disappeared, in its place has come science and the power that grows from it, and there is still enough of the marvelous in the study of the actual processes of nature to keep up a strong interest.

MISCELLANY.

A French Hospital at London.—The *Figaro* announce that the Baronne de Hirsch had followed up her gift of two million francs to the Pasteur Institute by a donation of one million francs for the foundation of a hospital in London, and several charitable institutions in Paris have just received large sums of money. It is estimated, says the *Figaro*, that in two months the Baronne de Hirsch has distributed in France, England and Austria eleven million francs.

The Bubonic Plague in Art.—The *Gaz. d. Osp. e d. Clin.*, of January, 31, has an engraving of a famous painting in a church at Verona, which represents St. Rocco, a holy philanthropist and pilgrim, who had the plague and recovered. He is showing the spot on his thigh where the characteristic lesion is seen through a slit in his garment; location and appearance are clinically correct. The cut is too blurred for reproduction. Raphael and others have portrayed the scenes of desolation during the plague, and the old masters were "realists" more than is supposed. Charcot recognized, centuries after, the clinical picture of glossolabial hemispasm in a certain well known painting at Venice.

The Plague Abroad.—The Sultan of Morocco has prohibited the annual pilgrimage of Moslems to Mecca on the ground that the prevalence of the plague along the usual route is a direct men-

ace to the public health. This is significant in the face of the fact that this is the first issue of any such general order. Somewhat antithetical to this handsome submission to popular demand is the printed dispatch from Bombay in the London *Daily Mail* of March 29. This recounts that on the preceding Saturday "a Mahometan, while living in the city with his wife, refused to allow her to submit herself to the prescribed inspection. The officials insisted, whereupon the Moslem drew his dagger and stabbed her to the heart. Then he stabbed the official physician and attempted to kill himself." The dispatch above alluded to likewise adds the information: "The plague is spreading rapidly in Bulsar and Gujerat, and its ravages are terrible."

The Nose and Menstruation.—The fact has been observed that the nasal mucosa undergoes certain modifications during the menstrual period, turgescence, exaggerated sensitiveness, tendency to hemorrhage and cyanotic discoloration. Fliess, of Berlin, has been studying this phenomenon and has found that a certain form of dysmenorrhea, in which the pains continue after the commencement of the menstrual discharge, is largely dependent upon the nose. He applies the term genital to those parts of the nose where these manifestations are most intense, namely the inferior turbinate bones and the tubercula septi. Lesions of these points produce this form of dysmenorrhea, while their cocainization arrests the dysmenorrhic pain as long as the effect of the cocain lasts. Cauterizing will also arrest the dysmenorrhea permanently, or at least for a long while. These nasal congestions occur during pregnancy at the time when the menses would otherwise occur.—*Reported at the Ges. f. Geb. und Gyn.*, December 11.

The Anti-Plague Serum.—Dr. Solomon of Louisville, in the *American Practitioner and News*, March 6, gives the most recent summary of the researches that are being made by Yersin and others upon the specific treatment of the plague. He says that Yersin, Calmette and Borrel are supplying us with an antitoxin which they obtain from the rabbit, the guinea pig or the horse, any one of which may be rendered immune by careful experimentation. This antitoxin has as yet seemed to do all that was claimed for it, namely, immunize animals which were about to receive injections of virulent bacilli, and cure others which had received an injection of virulent bacilli, yet were not too far gone to be saved. The theory which Behring applies to the workings of diphtheria antitoxin, and which is quoted in full in a letter addressed to the *Practitioner and News* from Berlin, last February, is applicable to all antitoxins and will bear brief repetition here. Behring says antitoxin prevents diphtheria by rendering cells immune before they have been poisoned by diphtheria toxin. A cell once poisoned is no longer capable of being rendered immune by antitoxin. Therefore give the antitoxin early and before the bulk of cells in the animal organism have been so changed by diphtheria toxin that they can no longer take up diphtheria antitoxin. A late issue of the *Progrès Médical* makes mention of the fact that Dr. Ortner and Prof. Albrecht, both of Vienna, have been sent by the Academy of Medicine to Bombay to make investigations relative to plague. The profession all over the world may congratulate themselves that these two men have been selected to do so important a work. Ortner, who is first assistant to Neusser, is one of the most painstaking and careful clinicians of Europe. Although scarcely 30 years of age, his position among the profession in Vienna, and the high esteem in which he is held are enviable. A Bohemian by birth, he combines with that keen far-sightedness characteristic of his people an indomitable energy. "Albrecht is equally as well equipped in his specialty and is too well known by Americans who study medicine (pathology) in Vienna to need any praise from me. His theme is microscopic pathology and he prances with Kolisko and Weichselbaum, who teach microscopic pathology. I repeat what I heard said of him by a colleague: 'I have never seen a pathologic slide placed before Albrecht that he could not immediately diagnose it.'"

All the Easy Questions in Science Have Been Solved.—President David S. Jordan of the Leland University, California, in a letter to the *Popular Science Monthly*, has stated that "Scientific investigators are not wizards;" their discoveries are not presaged by uncanny feelings nor green darkness, nor is there anything occult about their ways of working; they are simply men of unusual persistence and steady common sense. Everything easy was found out long ago, and additions to knowledge can only come from mastery of past achievements and mathematical accuracy in the registration of small details. The progress of science is not marked by surprises and contradictions. The result of scientific inquiry comes as a surprise only to those ignorant of the steps in investigation which leads up to it. The discovery that the peculiar rays, called "X" by Röntgen, could be made to cast shadows on a sensitized plate does not imply, as has been intimated by some, that thought can be photographed. One might sooner expect to photograph the songs of birds than "the cat's idea of man." The great power which exact knowledge gives adds nothing to the probability of the mythology of our own or other times. The "power of mind over matter" is not a form of hysterics. It depends on exact knowledge of the nature of material things. It is no occult influence showing itself in neurotic "adepts" by uncanny lights, under "astral" conditions. It is greatest by daylight, with sane men, among whom science is simply enlightened "common sense."

Colleges.

The annual commencement of the Atlanta Medical College, was held March 30. There were 38 graduates.—The fourth annual commencement of the Wisconsin College of Physicians and Surgeons, Milwaukee, was held April 6. Thirty students were graduated.—The annual commencement of the Barnes Medical College, St. Louis, was held April 6, and 116 were graduated.—The annual commencement of the Southern Medical College was held March 30. There were 30 graduates.—The tenth annual commencement of the Gross Medical College, Denver, Colo., was held April 8. There were 15 graduates.—The commencement exercises of the Baltimore Medical College, Md., were held April 8.

Hospitals.

The tenth anniversary of the opening of the St. Margaret's Hospital at Kansas City was celebrated April 5. The total number of patients treated has increased from 545 in the first year to 1,863 during the past year.—The Board of Health of Lambertville, N. J., has secured St. Andrew's Episcopal Church parish building to fit up a hospital for typhoid fever patients. There are said to be about twenty cases in the town.—A movement is on foot in Germantown, Pa., for the establishment of a non-sectarian hospital on the west side of that suburb. The institution is to be modeled after the Bellevue Hospital in New York and will not conflict with the German-town Hospital.

New York.

A HOUSE OF REFUGE QUARANTINED.—The New York Board of Health have ordered for Randall's Island a quarantine of the House of Refuge, an institution conducted by a private corporation known as the Society for the Reformation of Juvenile Delinquents. The resolution adopted asserts that the drainage is poor and that proper nurses have not been provided for the children, about 800 in all, some of whom are suffering from contagious as well as eye-diseases which may end in blindness. There is now no physician in charge, resignations and dissatisfaction being in order. To the allegations the President of the Society replies in effect that unless the State legislature votes an appropriation the institution can not be maintained, nothing being allowed for the improvement of the realty; that the property can not be turned over to the State, since the land was given to the managers with the proviso that it would revert to the city, when the society ceased to fulfil the conditions of its being; that except the lighting and the plumb-

ing, the buildings are in good condition; that the statistics are not awry, considering that children are sent from all the counties bordering on or near the Atlantic, including all of Long Island, New York, Albany and Rensselaer Counties, their particular House of Refuge admitting by order more children than the other two reformatories of the State; and further that there has not recently been a death in the institution, besides too contrary to statement that there has been no scarlet fever or diphtheria, while the sixty-eight cases of chronic diseases of the eye are not so bad an offset to the 200 cases of two years ago.

A DISPENSARY BILL PASSED.—The New York State Legislature has passed a bill for the protection of the public dispensaries against "the alleged" indigent, making wilful, false representation a misdemeanor punishable by a fine not less than \$50 nor more than \$250. Dispensaries are to be licensed by the State Board of Charities and are not to be established in any drug store or tenement house. A secular paper in a brief comment says, "it practically abolishes fake or quack dispensaries where poor people are badly treated." This is unjust since the profession at large never even insinuated to that effect. The fight has been against the undue multiplication and bootless competition. The treatment in the main has been beyond criticism.

DIVISION OF A HOSPITAL FUND.—The Hospital Saturday and Sunday Association, whose receipts for this year amounted to \$61,500 have distributed of this sum \$50,000 among thirty-five institutions. Of this former sum, \$8,200 was designated for special purposes and \$3,300 was reserved for expenses. The collections were \$2,500 more than last year and the number of "Free Hospital Days" was 690,841.

A BROAD AND LIBERAL DISPENSARY.—The New York Hospital proposes to erect a mammoth out-patient department on its property at Sixteenth Street, with facilities for treating hundreds daily. The plan is to gather in the rich and poor alike at the low price of one dollar per month. Bargain days all the year around! "Young man, go West," was Horace Greeley's answer to every solicitor for bread or work.

THE PUBLIC SCHOOL MEDICAL EXAMINERS.—The corps of Medical Examiners, recently appointed by the Health Board to examine children as a prophylactic measure against the spread of contagious diseases began their work on March 29 last. At present the system is to apply to the primary schools and the primary departments of grammar schools. The 150 examiners who are to make written reports are assigned to duty as near as possible to the schools in their immediate district. In the suburbs where the schools are small, one medical examiner is assigned to two schools, while in instances where the attendance is large two examiners are assigned to one school. As the whole matter is still experimental President Wilson states that until the official reports are presented it will be difficult to ascertain the true number of cases, but that the Board as in the past is bound to protect the public against the most insidious beginnings of any epidemic.

UNDER THE WILL OF LOUISE A. HONDAYER, the French Hospital will receive a reversionary bequest of \$3,500; the St. Francis' Hospital of Trenton, \$10,000; the Eye and Ear Hospital, same city, \$1,000; while certain orphan asylums and homes for aged persons will obtain upward of \$40,000.

NASSAU HOSPITAL OF LONG ISLAND.—Land for a hospital at Garden City, Long Island, has been secured by the board of trustees of the newly chartered Nassau Hospital Association. The officers are the following: President, L. N. Lanehart, M.D., of Hempstead; Secretary, James S. Cooley, M.D., of Glen Cove; Treasurer, J. H. Bogart, M.D., of Roslyn. The following medical men were also elected members of the staff of the hospital: William H. Hoag, Manhasset; J. H. Bogart, Roslyn; John Mann, Jericho; E. D. Skinner, Mineola; James S. Cooley, Glen Cove; William H. Zabriskey, Glen Cove; George H. Fuller, Oyster Bay; Charles H. Ludlam, Hempstead; L. N. Lanehart, Hempstead; John Hutcheson, Rockville Center; F. T. DeLous, Rockville Center; John H. B. Denton, Freeport; G. H. Hammond, Freeport; Dr. Peishing, Far Rockaway; G. A. Finsterer, Floral Park. The incorporators named in the certificate of incorporation are as follows: Drs. L. N. Lanehart, C. H. Ludham, E. D. Skinner, John Mann, G. A. Finsterer, J. H. Bogart and James S. Cooley.

BELLEVUE HOSPITAL.—Work has been begun upon three

new buildings at Bellevue Hospital. They will include an erysipelas pavilion, an isolated pavilion for cases of contagious diseases and a new boiler and laundry house. The buildings will be placed on the open ground near the river. The morgue is to be moved temporarily to the center of the lawn to make way for the isolated pavilion. The structures will be of blue stone and red brick, and will be sufficiently attractive in design to relieve the bleakness of the old hospital buildings.

COUNTY MEDICAL SOCIETY.—Since April, 1895, when the law providing for the criminal prosecution of quacks was restored, the New York County Medical Society has caused the arrest of eighty-three persons for practicing illegally, and it has obtained convictions in fifty-one cases. These persons have paid \$3,690 in fines, and a number of them have been sent to jail beside. The legal department of the society has a large number of cases pending. This fact alone is deterrent of much illegal practice, and not only tends to prevent the pretenders from trying to establish themselves in New York city, but also drives some of them to other localities where the duty of prosecuting offenders is not undertaken by the profession.

MEDICAL DEPARTMENT OF NEW YORK UNIVERSITY.—The trustees of the New York University have accepted the deed of the Loomis Laboratory, and at the same time the Medical School, which, since its establishment in 1841 has been under the management of a separate board of trustees, now passes under the control of the trustees of the University, together with its endowment of \$100,000 and its property valued at about \$300,000.

Washington.

BOARD OF HEALTH REGULATIONS.—Senator McMillan has introduced in the Senate, at the request of the Commissioners, a resolution providing that the commissioners be authorized, in making regulations under the authority conferred by Congress, to alter, amend or repeal any of the ordinances of the late board of health, which were legalized by joint resolution approved April 24, 1880, whenever in their judgment the public interest requires it.

MEDICAL ASSOCIATION OF THE DISTRICT.—At the meeting of the standing committee of the Association for organization, held on the 16th inst., the following officers were elected: Dr. Geo. N. Acker, president; Dr. R. T. Holden, secretary. The committee adjourned to meet in ten days to consider matter connected with the meeting of the AMERICAN MEDICAL ASSOCIATION in June next.

THE FOURTH TRIENNIAL MEETING OF THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.—The Congress will meet in Washington, D. C., on Tuesday, May 4, and under the direction of the Executive Committee, consisting of Drs. Samuel S. Adams, chairman, Washington; Louis McLane Tiffany, Baltimore; W. W. Johnston, Washington; Irving C. Rosse, Washington; S. O. Richey, Washington; J. Taber Johnson, Washington; Charles F. Bevan, Baltimore; I. E. Atkinson, Baltimore; T. Morris Murray, Washington; George M. Sternberg, surgeon-general, U. S. army; Samuel Theobald, Baltimore; William H. Howell, Baltimore; A. R. Shands, Washington; Frank Baker, Washington. The following places of meeting have been arranged for:

American Ophthalmological Society, ladies' parlor, No. 2, the Arlington.

American Otolological Society, ladies' parlor, No. 1, the Arlington.

American Neurological Association, St. John's Parish Hall, 16th Street.

American Gynecological Society, lecture hall, Columbian University, corner 15th and 8th Streets.

American Dermatological Association, new reception room, the Arlington.

American Laryngological Association, Cosmos Club.

American Surgical Association, chemical laboratory, Columbian University.

American Climatological Association, post-graduate room, Columbian University.

Association of American Physicians, museum, Columbian University.

American Association of Genito-urinary Surgeons, the Shoreham.

American Orthopedic Association, examination room, Columbian University.

American Physiological Society, Prof. Lodge's room, Columbian University.

Association of American Anatomists, physical laboratory, Columbian University.

American Pediatric Society, Prof. Huntington's room, Columbian University.

The officers of the congress are: President, William H. Welch, M.D.; vice-presidents, ex-officio presidents of constituent societies; chairman of executive committee, Landon Carter Gray, M.D., New York city; treasurer, Newton M. Shaffer, M.D., New York city; secretary, William H. Carmalt, M.D., New Haven, Conn. The president of the congress, Prof. Wm. H. Welch, M.D., of Johns Hopkins University, will deliver an address Wednesday evening, May 5, at 8:15 o'clock, in the Columbia Theater. The exercises attending the unveiling of the statue of Prof. Gross, under the auspices of the Surgical Association, will be held on Wednesday, May 5, at 5 o'clock.

WASHINGTON OBSTETRICAL AND GYNECOLOGICAL SOCIETY.—At the meeting of the society held on the 2d inst., Dr. John Van Rensselaer read the paper of the evening entitled "The Need of Care in Instrumental Dilatation of the Cervix Uteri." The paper brought forth a full and instructive discussion. Dr. H. L. E. Johnson presented a number of polypi, which he had removed from the female urethra. Four with long pedicles were removed from one case. At the meeting held on the 13th inst., Dr. W. M. Sprigg read the paper of the evening entitled, "Puerperal Infection and its Prevention."

THE PUBLIC SERVICE.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for week ending April 17, 1897.

Surgeon J. W. Baker, detached from the "Bennington" on relief and placed on waiting orders.

Surgeon M. H. Simons, orders to the "Columbia" revoked and placed on waiting orders.

Surgeon E. Z. Derr, orders detaching him from the "Columbia" revoked.

P. A. Surgeon E. S. Rogers, detached from New York navy yard and ordered to the marine rendezvous, New York.

Change of Address.

Auld, J. Maxwell, from 705 Jackson Boul. to 714 Monroe St., Chicago.

Barr, G. W., from 615 Hampshire St. to 1240 Park Pl., Quincy, Ill.

Blech, Gustavus, from Washington, D. C., to 119 Miami Av., Detroit, Mich.

Billmeyer, G. M., from 846 S. Wood St. to 714 W. Polk St., Chicago, Ill.

Clark, M. A., Barnesville, to 175 Cotton Av., Macon, Ga.

Ferguson, A. H., from 2950 Indiana Av. to 548 51st Boul., Chicago, Ill.

Forrester, Joseph, from W. 4th to 904 Peach St., Erie, Pa.

Fitzpatrick, G. W., from 409 Garfield Av. to Room 215 Temple Bldg., Kansas City, Mo.

Judd, C. E., from 18 Campbell Park to 93 Flournoy St., Chicago, Ill.

Montzambert F., from Toronto, Ont., to Quebec, Que.

Owsley, W. T., from Glasgow, Ky., to 206 F. St., N. W., Washington, D. C.

LETTERS RECEIVED.

ADDRESS.

THE MEDICAL NEEDS OF SYRIA.

An address delivered before the graduating class of the Marlon Sims College of Medicine, St. Louis, Mo. April 10, 1897.

BY LABIB B. JUREIDINI, A.M., B.D.

CLARKSVILLE, TENN.

The attention of the civilized world has lately been awakened to a certain corner of it where crime and massacre have become rife, and where fanaticism and tyranny have been maturing their most horrible results. Information about the lands in which these scenes have been, and are being enacted, and about the nations that are groaning under the iron hand of the unspeakable Turk, now assumes a new aspect of interest to all, especially to the sympathetic hearts of the American people. To physicians and all others interested in their noble profession, all that pertains to the medical conditions and needs of these countries will be among the first topics of interest. It shall be my effort tonight to present before you the medical needs of Syria, my native country, which, though not undergoing the same convulsions that are now tearing up other sections of the Ottoman Empire, may yet be taken as a fair representative of the rest, inasmuch as the same general conditions prevail in it as in the others, and as it breathes the same religious and political atmosphere.

But allow me to say at the start that I shall not be able to present the subject before you from a professional point of view. I can bring no resources of medical knowledge to bear, for I have none. And when in my country I never tried to make a particular study of its medical conditions. Nevertheless, there are certain phases of its medical needs that do not require a specialist to discover. And I shall attempt to exhibit them in a popular, rather than a technical way—to give the facts as they are suggested to my mind.

And first of all a few words about the climatic conditions of Syria may be appropriate. There are certain peculiarities of the Syrian climate which may have a tendency to help the rise and spread of disease. One is the continued drought of the summer season. For over four or five months, no rain falls at all. The soil becomes parched up and in frequently beaten places it is pulverized into dust, the particles of which flying about in the air, enter the system in various ways, sometimes carrying with them organic germs, and they give rise to several diseases. Then in some localities, especially in low lands, the heat of the summer is intense, and favors those diseases that are fostered by a hot climate. A very few localities besides are marshy, and hence malarial. But these are all the natural disadvantages, as far as I know, from which Syria suffers. In all other respects, its climatic conditions are favorable. The climate is mild and even. There are not those sudden changes in the tempera-

ture which prevail in large portions of this country. Our climate, like our music, is rather monotonous, and indeed the balmy breezes of the Mediterranean sea which sweep along the slopes of the Lebanons, and the thousands of clear, crystal springs that gush forth from the mountain side, and the numberless delights that reside in its glens and valleys, render that region one of the garden spots and health resorts of the world. And as far as the climate is concerned, there is no reason why the people of Syria should die of any other complaint than accident or old age. But the fault is not with the climate or the country, but with the people. If the people of Syria undergo any physical suffering (and they do) it is because they violate nature's laws and the violation carries along with it the penalty.

One of the agencies that militate against them in this respect is the comparative ignorance that prevails as to the plainest facts about medicine. Of course, all the people of a country, however highly civilized it may be, are not expected to have a comprehensive knowledge of medicine. But there are certain rudimentary facts that ought to be the common possession of all, not professionals only, in order to ward off all avoidable suffering, and in this respect the people of Syria are deficient. There is considerable ignorance about the constitution of the human body; and as to the nature of disease, some very curious notions prevail. For example, a variety of ailments are classified as "winds." The felon is called the "thorny wind." Cholera "yellow wind." And there are also winds of the side and of the hip, and of the chest, etc., so that you might imagine that every man was a new edition of Æolus, except that the winds are not under his control.

The laws of health are very little known, at any rate very little observed. Negligence of personal habits as to cleanliness is very common among the poorer classes, especially among the Mohammedans. Mohammedanism does not often go hand in hand with cleanliness. And if the Arabic proverb is true that "Cleanliness is of faith" (or religion) then Mohammedanism has very little of either. At any rate, it is one of the most productive causes of disease. It might sound rather strange to say that a people's religion could injure their health. But this is true at least in the case of Mohammedanism. It is an unhealthy religion. A brief consideration of some of its underlying principles and the practices of its adherents, will be sufficient to show that the above statement is not fanciful.

Fatalism enters the warp and woof not only of the Mohammedan's theology but of his every day life and practice. He has very little use for physicians, for no physician can alter the predetermined course of events and the fate of the patient; and he deems it entirely unnecessary to take any precautions against disease, even when an epidemic is ravaging the country. The

more intelligent classes of Mohammedans, however, have outgrown this belief in practice, if not yet in theory. They do summon medical aid to the bedside of their sick. But the common run of them are still wedded to their old belief, and act accordingly.

Polygamy also has its by no means small share to contribute to the unhealthy influence of Mohammedanism. In addition to the awful degradation of morals, it has a very derogatory influence on the physical constitution of parents and offspring. Moreover, it creates peculiar domestic circumstances that tend to the neglect of the proper nursing of children. The several wives of the same man are often too busy with their own rivalries and jealousies to attend to such trifling things as children. The children are allowed just to grow as best they can, without any attention being paid to their moral or physical welfare. And their propensities to filthiness in both respects are given free scope, so that a certain degree of squalor becomes a necessary adjunct of a Mohammedan community. This, in conjunction with other causes, manifests itself in a variety of diseases, among which those of the eye are most common: Strabismus, cataract and myopia are prevalent. And the number of blind men parading at the head of funeral processions, or hanging around about mosques and other public places, is remarkable. Any number of cases of myopia can be seen, some of them very extreme, indeed. I heard of a Mohammedan who was once asked to sign a document. Taking the pen, he raised the paper close to his eyes, and traced the signature. But on returning the paper, the signature was not there. It was found on his fleshy nose.

To do justice to Mohammedanism, however, one favorable fact about it must be mentioned. And that is that it enjoins upon its followers total abstinence from all intoxicating drinks. The Mohammedans, with rare exceptions, observe this injunction, to the shame, I am grieved to say, of their Christian neighbors. And by the way, the drink demon is becoming more and more serious. For formerly though almost all the Christian element of the population drank wine and *raki*, they did it in moderation and there were very few drunkards. But now the number of drunkards is awfully increasing and deaths from the effects of liquor are becoming more numerous.

A great deal of superstition prevails among the ignorant classes of the country. Mohammedans, as well as others, and many of these superstitions that bear on medical subjects are interesting on account of their oddity. A great number of diseases are attributed to the *evil-eye*, or some other magical influence. It is believed that certain people have a peculiarly harmful power residing in their eyes, and whenever they look with covetousness or evil will upon any object it is brought under an evil influence. A material object becomes liable to breakage or loss; a plant, to decay; an animal, to disease and death; and the danger is dreaded no less against man than against any other being. Babies especially are exposed to the *evil-eye*. A mother who has a healthy baby or one particularly pretty or 'cute (and you know *all* mothers have such babies) is greatly apprehensive for its welfare and takes active measures to shield it from all harm. She resorts to charms of many descriptions. Eggshells, blue beads and bones are regarded very efficient, and a triangular scrap of leather inclosing a scroll with some talismanic inscription is irresistible. In this country physicians try to

heal diseases by *prescriptions*, there they seem to do it by *inscriptions*. Another remedy that is helpful not only in cases of *evil-eye* but really in all diseases, is the following: Write a few verses of the Koran on a slip of paper, boil in water and administer internally or externally or both ways, and cure will follow, God permitting. This is of avail only in case of Mohammedans. For a Christian, verses from the Bible must be substituted. Sometimes a child of a weak constitution is made to wear a piece of the bone of a tiger or some other ferocious animal suspended on its neck. The idea being that since the beast is strong, and the bone the strongest part of the body, therefore it will communicate this strength to the wearer. A very bright idea, indeed!

But though the Syrian mother's love to her child be very tender, and her solicitude for its welfare very intense, yet there are certain of her practices as to child care that do not seem to me to be very apt to promote the child's robustness. The infant is cramped tight in its cradle and tied up in its swaddling clothes. The tighter the baby is swaddled the stouter it is believed to become when full grown. This practice seems to me to have a tendency to retard the child's development and to injure its vascular and respiratory systems by decreasing the capacity of its chest and hindering the free circulation of blood.

In addition to the above, natural prejudices and stereotyped systems of social habits play their part against the sanitary welfare of Syria. Among the Mohammedans, as you know, women are entirely excluded from all association with men. They are not allowed to show their faces, even to the nearest male relatives. The higher they are in the social scale the more strictly is this seclusion observed. So that even when the negative obstacle of fatalism does not stand in the way to prevent calling medical aid, this powerful prejudice comes up and makes it next to impossible for a male physician to examine the condition of a female patient. He has to form his diagnosis from the description of the father or husband. Sometimes, indeed, in very urgent cases, the hand of the patient may be stretched from behind a screen, allowing the pulse to be felt. But to see the face or tongue—never!

The first need of Syria, then, is to all that tends to break up these adamantine walls of prejudice and custom, and to dissipate these clouds of ignorance and superstition. We need general enlightenment among the people and a fair acquaintance with the primitive facts of the science of health. And we need all the agencies by which this can be carried on. We need to have instruction about physiology and hygiene introduced into our schools, and we need the *schools* in which to carry on the instruction. We need popular papers and magazines that make common the knowledge of the plain facts of medicine, and we need to have the majority of the people so educated that they can read them. Above all, we need to get rid of Mohammedanism and its superstitions and to have Christianity with its purity and enlightenment to raise the morals of the people not only, but also to promote thereby their physical and intellectual condition.

Another phase of Syria's need is to sanitary institutions of all kinds. Hospitals are badly needed. Though a few such cities as Beirût, Jerusalem and Damascus have their hospitals, yet the larger number of cities from twenty to eighty thousand people have

no such institutions. And indeed in that country, there should be a greater need of hospitals than in this. For owing to the ignorance among the masses of the people as to the proper ways of treatment and nursing, and owing to the lack of conveniences at their homes, it becomes very urgent that all cases of any degree of seriousness be brought not merely for treatment, but even for nursing, into suitable quarters and under competent medical supervision.

Then there are no insane asylums in Syria. The demented are allowed to go at large, wandering along the streets, sometimes objects to the jeers and practical jokes of heartless fellows, who lack but very little themselves of being in their places, and often presenting sights that are shocking to all sense of decency. Violent cases, however, or raving maniacs who are supposed to be dangerous are shut up, bound in chains and fetters and cast in some dungeon or cell where the harsh treatment brings to a speedy end their wretched existence.

Herein also Mohammedanism has its part to play. The Mohammedans believe that insanity is a species of inspiration. Insane people are peculiarly blessed from above. They are *ualis* or saints, and great respect is paid to them. Indeed this belief sometimes leads to practices extremely immoral.

When I said that there were no insane asylums in Syria I ought, perhaps, to have made *one* exception. For there is one such place known as the Monastery of St. Qurhayyah. It is a gloomy cave in one of the fastnesses of Mt. Lebanon, presided over by a number of monks, whose business it is to heal the insane people that are brought under their care. The cure is effected by frequent floggings and exorcism, which are supposed to drive the evil spirit out of the sufferers, for, contrary to the Mohammedans, they believe that insanity is possession by the devil. But to one witnessing their ways of treatment, the evil spirit would seem to reside in the monks rather than in their patients. At any rate, they often succeed, and oftener they succeed too much. They drive not only the *evil* spirit but even the very *life* spirit out of their patients.

Now Syria needs a few asylums conducted after modern plans and in the light of modern science in order to take care of these miserable wrecks of humanity, to restore to sanity those in whom there is any hope of recovery, and to provide a habitation for those that are hopeless.

Again, sanitary precautions of all sorts are needed in our cities. No good systems of sewerage or drainage exist. Even in Beirût, the most progressive of all Syrian cities, no satisfactory system is in operation. And in many of its streets the stench is unbearable and proves to be a prolific cause of disease. Then the cities are very crowded, the streets are narrow, sometimes not more than 8 or 10 feet wide, and sometimes they are arched over, or rooms are built across, so that the wholesome rays of the sun can rarely find an entrance into the houses. As to ventilation, it becomes out of the question. People here talk about the tenement districts of New York. I have seen some of them; they are bad indeed, but they do not compare with some portions of Beirût that I have seen, and still less with portions that I have not seen.

These are some of Syria's medical needs, but her greatest is to *medical men*. I do not mean merely to numbers. For though there is by no means the same proportion of physicians to population as in this

country or Europe, and though in larger parts of the country no medical help at all can be secured within many miles, yet the need is not of *so many more* but of *so much abler* physicians. Up to about twenty-odd years ago we had scarcely any men of ability in the medical profession. The land was under the sway of quacks, whose knowledge, when they had any at all, was limited to a partial acquaintance with Avicenna or Galen or some other old-fashioned writer, and to the old and even then out-of-date notions about medicine. They knew nothing about anatomy and their system of practice was based on speculation and theory rather than scientific fact and investigation. The way in which they acquired their education was peculiar. A few months' attendance on, or, it may be, acquaintance with, a physician was thought sufficient. Among the papers of my father I once fell upon the copy of an official report which he had presented to the governor of the district in which he held office after having made a tour of inspection concerning practicing physicians, their diplomas, qualifications, etc. In one of the villages of Mt. Lebanon a man was found practicing medicine and selling his drugs. Asked where he had received his education, he replied that he had accompanied Dr. Somebody for two years in the capacity of a groom, and now he started practice on his own hook, seemingly getting the profession by contagion. Another man seems to have got it by heredity, for he said that his uncle had been a physician before him, and that was the reason *he* was one also.

With such thorough courses of training, we might reasonably expect a proportionately scientific mode of treatment. Cupping, bleeding and cauterization were frequently resorted to. Herbs, more or less indifferent, and concoctions therefrom were administered in liberal doses, and if the patient survived it all it was not the physician's fault.

But the reign of ignorant quackery in Syria is now practically at an end. Among the very few wise things that the Turkish government has done have been the strict regulations as to licensing only physicians who bear the diplomas of a well-reputed medical college, and who stand a satisfactory examination before the Imperial Medical Board at Constantinople. But notwithstanding these restrictions, physicians of high ability are still few and badly needed. Our danger now is not from ignorant quacks but from licensed and so-called educated ones.

Besides thoroughly equipped medical men, Syria needs medical women—lady physicians. The state of society and the prejudices of the people, even among non-Mohammedan sects, being what they are, it is necessary that women be treated by physicians of their own sex. This is the only means possible to relieve them from considerable suffering and to save unborn generations a great deal of physical weakness and hereditary tendency to disease.

Thanks to the kind aid of the missionaries, those from this country especially, this, as well as other needs of Syria, have begun to be supplied. Indeed, our country is under unbounded obligation to the United States, not only for the greater part of the modern social, intellectual and religious development, but also for meeting the physical needs of the people. It is indeed a complete charity that seeks to compass *all* the needs of its objects. This is the genius of Christianity and missions are its manifestation. The American Mission in Syria now maintains the only

lady medical missionary actively engaged in her work. The American missionaries have given us the *first*, and for many years the *only*, medical college. From within the walls of that institution about two hundred men have gone forth fully equipped to practice the healing art, and are now scattered all over Syria, Egypt and other countries in the Levant.

In this connection allow me to address a few words to you, gentlemen of the graduating class, not by way of advice but as an appeal. You are now going forth to give to the world the fruit of your preparation in one of the first institutions of the land; you have had the rare fortune of being trained under professors of the highest ability and of national and international reputation. You have entered upon the fruits of the labors of centuries of progress in your profession, and now you bear in your hands one of the most beneficial boons that has been allotted to men. What use will you make of this power? Shall it be only as a money-making scheme, to take advantage of men's necessity and make it contribute to your financial interest? Nay! but let me repeat to you what I am sure your worthy professors have enjoined upon you once and again: *Do not degrade your profession to the level of a trade.* It is true that every profession must provide an ample support to those that practice it, and that in proportion to their ability; but this should not be the sole end. It should rather be the means to the greater and nobler ends, the advancement of the profession and the welfare of humanity.

The strides that have been made by the medical science in all its branches during the last fifty years are marvelous, but, as you all know, the possibilities have not yet been exhausted. The doors are still open for you to study, to investigate, to discover, to apply. For it is to your country that the world looks up for leaders in this as well as in other lines. *Be among these leaders.*

And then there is another aim that might well claim a place in your hearts. If one of the ends before you in your professional life is to promote the welfare of your fellowmen, one of the best means in which this can be done is through medical missions, one of the grandest philanthropies of the present century, and destined to hold a still more prominent place in the century to come. There are many lands not as highly favored as your own, in which teeming millions of humanity suffer and die in ignorance and misery, and it is within the power of medical science to reach them and alleviate their suffering.

But then there is a higher and still nobler mission that the physician can perform. It is not only to relieve physical pain, but by so doing to reach the hearts of the sufferers with cheer and consolation, to administer to them with the *physical* the *spiritual* remedy.

I have one more word to say. It is to discharge the pleasant duty of expressing in my own behalf and in the behalf of my own country, the warmest gratefulness to the esteemed professors of this institution. Gentlemen, tonight you have added an important item to the indebtedness of my country to yours, by giving us two young physicians, who, inspired by your spirit and electrified by contact with you, shall be bright lights in the medical firmament of Syria. And in the future, if you ever wish to attempt the impossible and trace the wholesome influence that your institution has exerted, be assured that Syria shall not prove herself the least receptive, and from her distant shores there

shall be borne across the face of the mighty deep a deeper and mightier gratitude.

FIRST AID IN RAILWAY EMERGENCIES.

Read at the Third Annual Meeting of the American Academy of Railway Surgeons, held at Chicago, Ill., Sept. 24, 1896.

BY JAMES E. PILCHER, M.D., Ph.D.

CAPTAIN IN THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY;
HONORARY FELLOW OF THE AMERICAN ACADEMY OF RAILWAY SURGEONS.

COLUMBUS BARRACKS, OHIO.

Introduction.—About 9 o'clock in the evening of the 11th of last August, during a blinding thunder-storm, an express train dashed into a small freight train a short distance outside of the passenger station at Columbus. W. N. S., the fireman of the passenger engine, an unusually vigorous man of 38 years of age, was hurled violently down from the cab to the Scioto River, twenty feet below. So tremendous was the force of his ejection from the engine cab that his body was completely torn from his right foot which had been caught in the wreck, leaving a horribly lacerated stump midway between the ankle and the knee, while the soft parts above the latter joint were also severely injured, rupturing the anastomotica magna and giving rise to a considerable hematoma in the thigh. Throughout the accident, this man retained entire self-possession and when found some time after the disaster, he was engaged in tying a portion of his cotton jacket about the injured limb to check the alarming hemorrhage which was occurring from the wound. Unacquainted with the means of properly tightening his extempore tourniquet, sufficient compression to close the arteries failed to be exerted, and when he arrived at the University Hospital, an hour and a half after the collision, the bleeding from the external wound together with that from the ruptured anastomotica had brought him almost to the point of exsanguination. At the hospital, he was so fortunate as to be admitted to the service of the senior surgeon, my distinguished friend, Dr. R. Harvey Reed—to whose courtesy I am indebted for the privilege of quoting the case—and his colleague Dr. W. U. Cole. The patient's wet clothing was instantly removed, he was wrapped in warmed blankets, hot water bottles were placed about him, and other measures designed to restore the normal temperature and revive the vitality were employed, such as alcoholic stimulants, hypodermics of strychnin and nitroglycerin, and injections of hot saline solution. The hemorrhage was controlled by the elastic ligature, and the limb amputated as quickly as possible at the juncture of the middle and lower thirds of the thigh. Very little anesthetic was needed and very little given. The patient rallied promptly from the anesthesia but, owing to his bloodless condition and the impossibility of correcting it, he gradually became delirious and about an hour before the end experienced a tonic spasm, after which he sank rapidly, expiring about eighteen hours after the accident, a victim of exsanguination.

This accident occurred in the midst of a city of a hundred and fifty thousand inhabitants, containing a hundred and fifty medical practitioners, numerous hospitals, and two medical colleges. There were a dozen physician's offices within five minutes walk of the locality of the disaster, not to speak of numerous telephones by means of which dozens more might

have been quickly summoned to his relief. But he bled to death! Here was a man of mature age and well-regulated mind who, notwithstanding his frightful injuries, was in full possession of all his faculties and anxious to apply for himself the treatment which would stay the approach of the king of terrors. Had he been instructed in the simplest elements of first aid, the application of the simplest form of improvised tourniquet, W. N. S. might today have been about the streets of Columbus with a healthy amputation stump upon which a suitable artificial limb could readily be worn, and the statistics of the skilful surgeon, who attended him, might have been increased by one more success in addition to the large number already enumerated in his case-books.

Railway mortality.—The average number of persons injured yearly in railway accidents during the seven years from 1888 to 1894 was 38,500, of which number 6,500 were killed, and in the year of the Columbian exhibition there were 47,000 casualties of which 7,000 were fatal. For the treatment of these cases numerous magnificent surgical systems have been devised. The surgical staff of so many of our railroads at the present day is so highly organized that to mention one would be an invidious distinction. The statistics of injuries accentuate the need for such organization and it is to the credit of humanity that so many railways have provided for it.

The field for first aid.—There is a period, however, for which most roads have as yet made no provision—the period between the occurrence of the accident and the arrival of the surgeon. The opinion has been advanced that on some roads the stations are so near together and the local surgeons so readily accessible that this period is inappreciable and does not require to be provided for. Esmarch in his Samariter-briefe has well shown the fallacy of the idea that such provision is required only in sparsely peopled localities, reciting an instance of a fire in the city of Berlin where, after an apparently suffocated person had been brought out of a burning house, it was two hours before a physician could be brought to the spot, the life of the victim being saved only because of a knowledge of first aid upon the part of the firemen. And even in our own case of W. N. S., it was an hour and a half from the avulsion of his leg to the application of the elastic tourniquet in the University Hospital, although the accident occurred within touch of the best possible surgical treatment. There is no question but that everywhere on earth emergencies are liable to occur in which life or death may hang upon the presence of a person with a knowledge of the simple elements of first aid, and no where is this more profoundly true than in the emergencies of railway practice, unless perhaps it be on the battlefield.

Existing first aid arrangements.—In order to ascertain what may have been done in this respect in the railway service, in the course of my study upon the present subject, I addressed to the chief surgeons of fifty prominent railways, a letter containing the following questions:

1. Have you any organized system of rendering first aid in illness or injury aside from your medical staff?
2. What, if, any, of the employes of your road are instructed in first aid?
3. What, in a general way, is the character and scope of the instruction?
4. What advantages have been derived from the instruction?

To these letters I received twenty-nine replies.¹ Of this number five replied in the affirmative, six in the affirmative to the extent of a first aid surgical dressing case with printed instructions for the use of its contents, and eighteen replied wholly in the negative. It is a fair presumption that those who did not reply at all, would also have given a negative answer. It is evident then that but little has been done in the organization of first aid in railway emergencies. Indeed, it would seem that even on the roads on which efforts, looking to the first-aid instruction of the non-surgical employes, have been inaugurated, a complete and definite organization has hardly yet been attained.

Advantages of first aid.—The advantage of first aid in those cases in which life may be saved by the prompt application of temporary assistance is evident, but it is no less a fact that it is of proportionate value in less serious cases. The ability to cope with possible injuries inspires men with self-confidence in emergencies. They are not so apt to lose their heads. And yet it can not be denied that even under comparatively favorable circumstances some men will become confused. Instruction in first aid will, however, reduce this to a minimum in accidents.

A knowledge of the subject is valuable, if for no other reason than because it will teach men to avoid improper or dangerous methods of treating emergencies. The use of the tobacco-quad saturated with the indescribable ingredients of the saliva of the habitual tobacco chewer, the cobweb with its collection of filth from all quarters, the sweat-permeated cloth torn from the dirty garment, and perhaps, worst of all, the mucus-laden handkerchief are banished from contact with open wounds. Cleanliness is learned and wounds do not come to the surgeon already infected by filth.

Familiarity with proper methods of handling the injured is of the greatest advantage in four respects: 1. It renders it possible to remove the wounded from wrecks more expeditiously, a feature which may be of vital importance in case, for example, of the not infrequent instance where fire is an accompaniment of an accident. 2. It may be an infinite saving of suffering to the injured. The infliction of pain in moving a patient is an evil so easily corrected that there is but little excuse for not knowing how to do it painlessly. The saving of unnecessary suffering to a patient means diminution of shock and a more favorable condition for the treatment of the surgeon. 3. It prevents the aggravation of injuries so frequently due to improper handling. A wealthy Englishwoman, in alighting from her carriage, slipped and sustained a simple fracture of the leg. The well-meaning and intelligent enough people, who helped her back into her carriage so that she might return home, had not been taught the way to lift and handle the disabled. That her leg was turned in the attempt and the simple fracture was transformed into a compound fracture, was not so much their fault as the fault of the neglect of the proper instruction of the public in such

¹ The gentlemen, who so courteously answered my questions, were: Drs. W. A. Adams, F. W. & D. C. Ry.; F. P. Bancroft, U. P. D. & G. Ry.; C. E. Brayton, N. Y., N. H. & H. Ry.; F. H. Caldwell, Plant System; G. P. Conn. C. & M. Ry.; H. P. Cooper, A. & W. P. Ry.; Walter Courtney, N. P. Ry.; C. M. Daniels, W. N. Y. & P. Ry.; C. M. Drake, Southern Ry.; W. H. Elliott, C. of G. Ry.; W. L. Estes, L. V. Ry.; W. J. Galbraith, U. P. Ry.; A. P. Grinnell, V. C. Ry.; S. S. Halderman, C. P. & V. Ry.; G. H. Hogeboom, A. T. & S. F. Railway; J. H. Jenne, C. V. Ry.; S. Marks, C. M. & St. P. Ry.; P. H. Millard, C. G. W. Ry.; S. Mitchell, J. T. & K. W. Ry.; R. D. Mussey, C. H. & D. Ry.; J. E. Owens, C. & N. W. Ry.; N. J. Pettijohn, K. C., F. S. & M. Ry.; J. F. Pritchard, M. L. S. & W. Ry.; R. H. Reed, C. S. & H. Ry.; W. B. Rogers, K. C., M. & B. Ry.; Stuart & Boyles, H. & T. C. Ry.; S. S. Thorn, W. & L. E. Ry.; J. F. Valentine, L. I. Ry.; F. B. Tibbals, M. C. Ry.

matters. Were all such cases fully known and recorded, there is not the shadow of a doubt that hundreds of instances of such aggravation of injuries would be found in the history of railway surgery. The prevention of such occurrences may detract a little from the experience of the surgeon, who will certainly receive less credit for the successful treatment of a simple wound than for the cure of a complicated injury, but it will improve his results, simplify his labors, and enable him to accomplish more work in a given time. 4. It is to the pecuniary advantage of the railway company for, (a) the fact of thorough preparation having been made for every emergency will give the public increased confidence in the road, which will result in increased patronage, and, (b) the diminished severity of injuries due to prompt attention and careful carriage will materially reduce the amount of damages which may have to be paid to the injured.

Hemorrhage is perhaps the complication of railway accidents in which first aid would be more particularly applicable, although it must be admitted that the bleeding is often surprisingly limited, especially in crushed wounds where the lumina of the injured arteries have been occluded by the compression which caused the accident. Nevertheless bleeding may be placed at the head of the list of complications, the failure to immediately correct which, may convert an otherwise curable injury into a fatal one. A Lieutenant-Colonel in the Army, while fighting at the head of his command, was wounded in the thigh by a band of hostile Indians, sustaining a division of the femoral artery. The surgeon was at the rear of the small command and, while a messenger was despatched for him, some of the line officers endeavored to arrest the bleeding as well as they could, but not being expert in the application of improvised tourniquets, they were not successful in entirely checking it. When the surgeon arrived in a few moments, the patient presented all the evidences of fatal hemorrhage, from which he never rallied. That was before the institution of first-aid instruction in the army. Now, every subaltern and a large proportion of the enlisted force would be competent to step in and apply an extempore tourniquet which would amply control such hemorrhage until the arrival of a surgeon, rarely far away in military service.

But hemorrhage is not the only accident in which prompt action may avert impending death. In cases of submersion under water as may occur in case of a fallen bridge, prompt action is notoriously of advantage. In cases of suffocation by smoke or heat, such as may occur in a railway fire, the prompt application of artificial respiration is equally efficacious. The advantage of prompt treatment even of apparently fatal shock is too well known to demand repetition; while the prompt and easily-learned treatment of heat stroke may also mean the difference between death and life.

A little acquaintance with the treatment of foreign body in the eye is apt to be of particular service to a railway man, since this accident is probably more liable to occur in his experience than in that of any other class of individuals.

First aid may be applied with advantage in many other less serious surgical incidents. Not only simple wounds, but bruises and sprains may be prevented by prompt and intelligent treatment from developing into serious and disabling injuries. While fractures

can not be permanently treated except by the surgeon, their treatment can be greatly assisted by the exercise of proper measures to prevent the aggravation of the injury and to conduce to the ease of the patient. Burns and scalds, on the contrary, when not severe or extensive, may be sufficiently treated by the first-aid man, while colic and diarrhea may often be controlled by the exhibition of simple remedies.

And, as already suggested, not the least advantage to be derived from instruction in first aid in railway emergencies is the obtaining of organized discipline and intelligent conduct in case of accident. Instead of careering like so many decapitated chickens or crowding about the injured like so many bucolics about a prize beef, the men will naturally fall into places where each one can be of the most service and order will readily be brought out of chaos.

So many, indeed, and so forcible are the arguments in favor of the thorough instruction of railway employes in first aid that the discussion might be prolonged almost indefinitely. But, admitting the desirability of such knowledge, we naturally fall upon the consideration of the questions, as to what men should be instructed, whether all should receive the same amount of instruction, how the instruction should be given, what facts should be taught, and whether men qualified in first aid should be distinguished by a badge to indicate their training.

Who should be qualified to apply first aid.—As employes who are in command of men may not only be required to apply first aid themselves, but to direct others in rendering assistance, such men as conductors, yardmasters, station agents and foremen of shops should particularly be instructed.

All men connected with passenger trains should be qualified, not only from the standpoint of humanity, because of the relief which they may afford to injured passengers, but from the standpoint of the interest of his railway company, since prompt attention to injured passengers may prevent aggravation of injuries and possibly increased claims for damages.

Both of these classes of men should be taught not only the application of first aid, but should be instructed in the organization of first aid parties in extensive accidents and in the best methods of showing others how to apply it.

All other employes should be taught the subject in a less complete manner perhaps, although in view of the changes which transfers and promotions may make, it would be well enough for them all to receive the same amount of training.

Substance of first aid instruction.—Of what then should the instruction consist? In a recent paper on "Methods of Instruction in First Aid," I recommended that the instruction of the enlisted men of the army be given in five lectures, each occupying a full hour; it might be of advantage in railway work to add a sixth lecture. The course thus arranged would be as follows:

1. The Human Body—the skeleton and the circulation in particular.
2. Bandages and Dressings—the triangular bandage in particular.
3. Wounds and Bleeding.
4. Broken Bones.
5. Unconsciousness—suffocation and shock in particular.
6. Other Emergencies—including the use of the emergency box.

It is impracticable, in the limited time at our disposal at present, to specify in detail the facts, methods and theories which should be taught. I have endeavored to do this in my little book on *First Aid in Illness and Injury*,² which may be familiar to some of you. It is worth while, however, to go over briefly the subjects that will naturally segregate themselves into groups suitable for treatment in the several lectures.

1. The lecture on the human body should include a simple description of the body, its chief component parts and the principal vital functions carried on by it; a little knowledge of bones and muscles; something about the nervous and digestive systems; more about the respiratory function and the organs involved in it, and still more about the circulatory system. Experience has led me to consider this introductory lecture as absolutely essential to a proper comprehension of the practical subjects to be taken up later. It is never safe to presume upon the prior existence of any anatomic or physiologic information whatever. Even the most intelligent laymen often display an amount of ignorance that would be laughable if it were not lamentable, and still less acquaintance with the subject must be expected in the less educated.

2. The second lecture, on bandages and dressings, is also foundation work, and its mechanical characteristics ought especially to appeal to the interest of the mechanically inclined railway employe. The triangular bandage, the basis of all surgical first aid, should be taught in all its uses. It is not sufficient simply to talk about it, but it must be shown in actual use. And even that is not enough, for its application can not be satisfactorily understood until every man has himself applied it in all its various modes of employment. The manner of improvising dressings and some suggestions as to the sources from which they may be extemporized is an essential feature of this lecture.

3. The third lecture, on wounds and bleeding, is the natural sequel of the first two—the practical application of the materials learned in the second upon the parts taught in the first. This is really the most important lecture in the course and may often with advantage be expanded into two, treating in some detail of wounds of various kinds, and in particular, crushed and lacerated wounds; reviewing the circulation of the blood and especially the course of the principal arteries, with the location of the most appropriate points for compression in order to control bleeding; the differentiation of the varieties of hemorrhage and the treatment appropriate to each, including the arrest of arterial bleeding by digital pressure and by the tourniquet, will all come within the scope of this lecture.

4. In the fourth lecture, on broken bones, the nature, character and most frequent location of fractures are to be taught, together with their possible effects on the tissues adjacent to this break. The signs of fracture and cautions against unnecessary handling may be followed by a description of the methods of retaining the parts safely and comfortably until proper surgical attendance may be secured. The improvisation of pads, cushions and other supports should also be considered in detail.

5. The fifth lecture, on unconsciousness, is a most important one in connection with railway emergencies, involving, as it does, the treatment of severe shock and collapse, cerebral concussion and compression of the

brain, as well as simple fainting. Suffocation in its various forms, including compression of the chest, drowning and inspiration of hot air or smoke, is most important. If inebriation does not often come under the eye of the railroad man, sunstroke certainly may, and convulsions sometimes do. The use of position, hot and cold applications, the administration of stimulants, the employment or avoidance of friction and the application of artificial respiration should all be well understood.

6. The sixth lecture, on other emergencies, may be a collection of the facts not taken up in the others, such as the removal of foreign bodies, the treatment of the effects of heat and cold—burns, scalds and frost bite—cramps and diarrhea, and the like. Here may also be taken up the use of the emergency box and its contents.

In connection with each lecture, some method of transporting the disabled should be taught. This proves an excellent relief to the monotony of a long talk and helps not a little in impressing the facts taught upon the minds of the hearers. Moreover, it is so exceedingly important a feature of first aid work, that advantage should be taken of repeated opportunities to impress its methods upon one's auditors.

Methods of instruction.—With regard to methods of instruction, each lecturer will determine the way in which he can himself best impress his audience. In a paper³ upon this subject in its military relations, read at the last meeting of the Association of Military Surgeons, I arrived at the following conclusions among others: 1. The best method of instruction is a combination of the lecture, the demonstration and recitation from a text-book, neither of these being sufficient without the accompaniment of the other two. 2. The best instruction is characterized by extreme simplicity of diction and the avoidance of all technicality of language. 3. The best instruction is progressive in character, beginning with anatomy and physiology and advancing to bandages and dressings, and then to emergencies proper. 4. The work is advantageously supplemented by home study of a first-aid text-book.

Excellent charts are available for assisting in the graphic presentation of the subject, and they should be freely used, but nothing can impress men so strongly as a demonstration upon a human subject, and this plan should be utilized whenever practicable. An excellent method in lecturing upon the circulation before male classes is to demonstrate the course of the arteries and veins by red and blue outlines painted upon the skin of a living man. It is not difficult to find men with sufficient enthusiasm to willingly serve in this capacity, and the subject is rewarded for his self-sacrifice by the especially strong impression which the lesson makes upon himself.

Recitations from a text-book, which are used with great advantage in military first-aid work, are not always practicable among the frequently changing forces of railway work, but I can not too strongly urge the great desirability of encouraging the men to the private perusal of a suitable first-aid book. Every station should be provided with one of these—one of the more complete works—and every train should have one in its emergency box. A most useful place for such a work would be in the drawing-room car together with the hotel directory and the railway

² "First Aid in Illness and Injury." By James E. Pilleher; fourth edition, 8vo, pp. 322. New York: Charles Scribner's Sons, 1897.

³ *Methods of Instruction in First Aid*, New York Medical Record, Sept. 5, 1896.

guide. But, more than that, each employe should be advised and encouraged to provide himself with proper literature upon the subject and, in the light of the lectures and demonstrations of the surgeons, he should study it carefully and conscientiously. This plan is followed with success in numbers of the National Guard organizations, where every member is required to provide himself with a first-aid text-book and to make it the subject of home study. Information received *viva voce*, as in lecturing, is easily forgotten and demands reinforcement by subsequent reading.

The emergency box.—While every man should be taught to extemporize dressings from any available source, it must not be forgotten that better results may be obtained by the use of properly prepared dressings. This is what contributes value to the emergency chest. Every ambulance association has devised one and not a few have been constructed by railway surgeons. I am inclined to think that the chief defect in these chests has been that too much has been left to the judgment of the railway employes. Such a box should not be stocked with a supply of bandages, a package of gauze, some antiseptic tablets and a paper of pins, each article by itself, to be combined as needed for accidents. In order to get at the articles which they need the first-aid men will handle over the lot with their travel-stained hands, until in a short time the entire chest is too filthy to be used. A plan which avoids all this and which also saves the layman the responsibility of grouping the proper articles, is the collection of all dressings into the form of first-aid packets. These packets may well be an extension of the military first-aid dressing packet. The form commonly used in the army was devised by Esmarch of Kiel and contains in a small space: 1, two compresses of sublimated gauze, each wrapped separately in oiled paper; 2, one roller bandage two yards long, of sublimated cambric with safety pin, and 3, an illustrated triangular bandage. One of these packets contains dressings ample for wounds of considerable size, and for very extensive ones two or even three may readily be employed. In addition to wound dressings, the box might with advantage contain a few simple remedies, put up in tablet form when practicable, and with exact dosage; diarrhea tablets, colic tablets, anodyne tablets and, in a bottle of colored glass studded with points to prevent confusion, a number of antiseptic tablets for making solutions for wound cleansing. A bottle of aromatic spirits of ammonia, some packages of bicarbonate of soda for burns, and a few light and small splints might be introduced with advantage; a pair of shears and of dressing forceps should not be omitted and a good first-aid book should always be added. Such an emergency box should form a part of the outfit of every conductor, station agent and foreman, who should be thoroughly instructed in its use and held strictly responsible for its availability and serviceability at all times.

Uniformity in first aid.—The course of instruction given should, as far as possible, be uniform for each road; indeed it would be better still if a uniform plan were adopted for all roads. Men transferred from point to point, or exchanged from road to road would not then be confused by varying instructions and, wherever they might be, they would naturally fall into suitable first-aid positions. Absolute uniformity, of course, would not be sought for—opportunity must be left for the individuality of the teacher—but the desired

result would be obtained by the adoption of a uniform syllabus of instruction.

Frequency of instruction.—The course of lectures should be given by each surgeon at least once a year to the men connected with his section of the railroad. On account of the constant change in the *personnel* of the employes, a not inconsiderable proportion of his hearers will be new each year and in any event no one can fail to be benefited by one or two repetitions of such instruction, particularly at annual intervals.

Rewards for proficiency.—The St. John Ambulance Association of England and other societies for the propagation of first aid hold examinations upon the subjects taught in their classes and issue diplomas and medals to those who pass. It is worthy of consideration whether a similar plan might not be of advantage in the railway service. If those men who had been found qualified were decorated with a red cross, to be worn in a conspicuous place, it would render them more easily discernible in case of accident and the possibility of winning the decoration might add a little to the general interest in the subject.

Conclusion.—The results of such organization, if thoroughly applied, will be surprising. In the accident in which W. N. S. made so gallant a fight against impending death, only two other persons were fatally injured. I am not so presumptuous as to assume that the percentage of cases, fatal without first aid, would be present in every railway accident, and assert that one-third of the deaths might be avoided by the proper administration of first aid, but I am prepared to assert, and that with the positiveness bred of actual knowledge, that by the faithful employment of first aid in railway emergencies a distinct improvement in the result of the treatment of railway injuries may be obtained, a material reduction in the mortality of railway accidents may be achieved, and an unspeakable amount of suffering may be saved to the unfortunate victims of future railway disasters. Simple in organization, inexpensive in application, easy in accomplishment, the results will be out of all proportion to the cost. The general adoption of first-aid, then, will not only benefit both the railway service and the traveling public, but it will be a distinct ethical advance introducing into railway work an era of realized responsibility, elevated humanity and genuine altruism.

DISCUSSION.

Dr. HENRY HATCH (Quincy, Ill.)—I was very much pleased with the paper just read and it coincided with my ideas, as I have claimed to be the first surgeon who has put emergency boxes up for a railroad at his own expense. I have devised some emergency boxes of my own which I have in use at the prominent offices in Quincy station; I put up seven of them. In the box I have adhesive plaster, carbonated gauze and absorbent cotton. I have the absorbent cotton put in separate bandages, and the gauze put in a jar, each containing about one-eighth of a yard. The adhesive plaster is put in tin boxes in little coils; in this connection, I have a little stick which I give instructions how to use as a torsion key, and in the cover of the box are printed instructions how to use this material. To the head of every one of the offices where the box is placed, I have taken pains to give special instructions. So far as the boxes are concerned on my part, they are original with me; I never had seen and did not know of any. It has had an excellent moral effect upon the men; while they do not know who put them in, they feel better toward the railroad—the C. B. & Q. They feel as though the railroad company had some heart and is looking to their interest. The C. B. & Q. also has

a relief system, whereby the men are entitled to surgical relief free by paying their monthly stipend to the relief association. While I have not had these boxes in but, I think, five months, it has been a saving to the relief department, because a great many of the smaller accidents have been attended to by the men themselves; and for that reason it would be a financial advantage to all railway companies to have these emergency boxes at every station and at every point in that station where there are liable to be accidents. I have one in the freight house, passenger depot, one in the switch office and round house, where they keep the engines. It is my intention to be at Galesburg soon to see the officials and try to induce them to put boxes along the line. I have sent one to Galesburg and one is up at the master mechanic's office. I am exceedingly pleased with this paper.

Dr. REED—In reference to the paper, which was an admirable one on the subject treated, and which has given us considerable material for thought, I wish to say that when I was appointed surgeon of the Pennsylvania Company some twelve or fourteen years ago, I found on the Pittsburg, Fort Wayne and Chicago Railway some old boxes scattered here and there, on engines, cabooses, stations and about the road. They were small tin boxes and contained some bandages, cotton I believe, and a few instruments, I do not remember just what they were, perhaps a pair of scissors, something of that kind; very few were complete, and the general superintendent, Mr. Thomas, called my attention to the matter and made the remark that they had been placed on the road years before that and the road was well supplied with them, but owing to the fact that no instructions had been given the men or given those in charge of the men, the boxes had fallen into disuse; when a man would hurt his finger, hand or arm, he would go to the box, pull out a piece of this material and bind up the wound, and close the box; perhaps when something more serious occurred that required the material, it was not there. That was one objection. Another objection was that under these circumstances they did not know how to use it—this was before the days of antiseptic surgery and dressing of an aseptic character—and as there was no one to keep the boxes replenished and no one to report when they were used, the boxes fell into disuse. But notwithstanding that fact, if this matter is taken up properly by the railroads, and proper parties instructed in the use of the material which should be placed and kept in them, I think that something very valuable can be developed out of it. Whether or not we can use all the suggestions made by the writer of the paper in practical work is a question. Those of us who have had some practical experience in this line on railways know that it is quite a task to instruct the employes in many things which we would be obliged to teach if it were carried out in full. For example, I was called on by the superintendent on the Northern Pacific Railroad, who had known me some years ago when he was on the B. & O., and asked to write out a few simple rules which would govern the men in an emergency, and he emphasized the fact that the rules should be so short and simple that they could be either remembered or read in a moment, and he suggested: If you make the rules explicit, if the men do read them they will not remember, and if they want to apply the rules under an emergency they will not take the time to read them. That was the practical difficulty. I also had a letter from a gentleman from one of the roads in California who had written to me, and it was strange that those two men should have written to me on the very same subject. Again, on the Pennsylvania road I was requested by Mr. Thomas to prepare rules, and the same thing occurred again; three practical men wanted rules, but insisted that they should be short and readily applied, without going into details. And the question comes whether or not we would be able to get the employes to read a long list of instructions and be able

to retain them so as to apply them. The plan is certainly an admirable one, and contains a great deal that I think we should consider, but I think it will require some practical work to bring it into full development.

Dr. SMITH (Streator)—I have had the pleasure of listening to the very good paper by Dr. Pilcher, also the pleasure of reading his book; I believe it would be beneficial to every chief and local surgeon to get Captain Pilcher's book and read it; I do not know any way that he could employ his time better. He gives some practical ideas and instructions. So far as this box is concerned it is a pretty good thing, but I think very poor without instructions; the first thing you know when a man has an accident he goes and tears off a bandage and puts on a chew of tobacco and lets it go for six or seven days, and then comes to the doctor, and you have a poisoned wound, may be syphilitic, and without instructions I do not believe the box amounts to much. Dr. Wood—I believe he organized the first surgical association on the Wabash—had these boxes, had printed instructions in the lid, and I do not suppose you can find one on the road. The Santa Fe, when they started up, had emergency boxes in every passenger and freight car, and when Dr. ——— took charge of the road I succeeded in getting two of them for Streator. I wish the gentlemen would see Captain Pilcher's book and read it; it is a good one.

Dr. McCURDY (Pittsburg)—In order that we may have the benefit of all the best knowledge, I think the best thing that can be done by the Association at this time is to see that copies of this paper reach every manager of every road in our country. In that way it will be able to do some good. As railway surgeons we know that everything that Captain Pilcher has said is of great importance and for him to prepare this paper as exhaustively as he has without having that paper reach the roads and bring some practical results would be a great pity; and I move you that this matter be referred to the executive committee with power to take this action.

Motion seconded by Dr. Reed and carried.

Dr. HARNDEN—I have listened to the paper with a great deal of interest. I suppose the author is competent to give a good paper and good advice on this subject, and there is no doubt but what theoretical advice is excellent, and if it could be carried out as he has indicated so ably it would be attended with good results. But in my experience in such matters I have found instructions to employes leave them somewhat in the position of a half-educated doctor—they kill more than they cure. In giving instructions to employes, especially as to the application of ligatures applied with the idea of controlling hemorrhage; I think nine times out of ten the hemorrhage will be increased for the relief is not intelligently applied. A method of teaching employes might be carried out so thoroughly and exhaustively as to render them capable to fulfil these instructions, but unless you append to a law a penalty you will not make it effective, and unless you append to these instructions some requirement under the head of organized relief association, or on the part of the management of the company requiring such employes to show by answers to questions or by oral examination that he has learned those instructions and remembered them and has some idea of carrying them out practically, then the instructions will not have accomplished much. I think about as amusing an instance illustrating the value of such instructions, a man came into my office one day and said a man was injured in the arm and there was considerable hemorrhage attending it; I went to him, and found both limbs above the knees wound tightly with cords, I asked what that was for, and one of the boys said he had heard that if you shut off the arteries in the limbs it would prevent hemorrhage in the rest of the body. That is about the way they would carry out instructions. And the recommendation of this same form was brought before the Erie Railway surgeons and it was discussed and it was decided to

place the matter in the hands of a committee to formulate instructions and recommendations to the manager of the company. The committee reported at the next meeting with a majority and minority report; the minority report was a long detailed list of recommendations and instructions to the employees and the majority report was a very brief one and consisted simply of some of the most simple forms of instructions; in case of hemorrhage elevate the extremities, which, as we all know would in a large majority of cases of ordinary hemorrhage, control it; this was one of the instructions, another was to place a clean towel or other clean bandage of some kind immediately over the wound and apply compression and run for the doctor, and I think that was about the extent of the instructions—they were very simple indeed. They were presented to the company and immediately adopted and circulated and placed in all offices and given to the employees. Now, I think our Fellow, Dr. Estes, chief surgeon of the Lehigh Valley system, by personal supervision of it, has been able to carry out some method of controlling hemorrhage by ligation, by which he has been able to accomplish some wonderful results. And I say Dr. Pilcher's ideas are most admirable if they can be carried out by personal supervision on the part of the head of the management or the relief department.

Dr. GARDNER—I have listened to the paper with a great deal of interest. In our own line [Southern Pacific] we have had boxes some time. The boxes alluded to that we have had on our line (with the exception of the passenger train from San Francisco to New Orleans, the limited, on that a box is placed in the dining car) were ordinarily only a few boxes placed along but they were failures; the contents were mistreated and when they were wanted they were not to be had. The emergency bandage is just the same as the army bandage, but we added the cotton. With that I have printed instructions with every package; these we have placed in the round house, the machine house and every caboose; in every caboose a dozen bandages and printed instructions in every box. We found it was impossible to give instructions to our employees because our road is far west and the employees change often and we do not have the different employees long enough to instruct them; I made an application for a thousand bandages and they were distributed to the different departments and gave great satisfaction; our instructions are simple and very short so anyone can adapt them.

Dr. REED—I beg the pardon of the Academy and ask permission to add one remark I intended to make and forgot. I wish to say Dr. Pilcher's book should be in the hands of every railroad surgeon, but what I intended to convey in my remarks is I think it will do better work in the hands of the surgeon than in the hands of the average employe. The instructions to the average employe should be short and concise, and be backed by intelligent instruction to the average surgeon, who is fully as ignorant as to what should be done in an emergency many times as the average man.

Dr. PILCHER—It has given me very great pleasure to learn from this discussion that the Academy is so nearly unanimously in favor of the extension of first-aid work in the railway service. The remarks, however, of the gentleman who seems to doubt its practicability, remind me of the not entirely unknown anecdote of the peripatetic old chap who was wandering about Southern Europe some four hundred years ago circulating a rumor that the world was round. Nobody believed him. But those of us who visited Chicago three years ago can say most emphatically that he was right. The fact that any particular individual had not seen it to be round did not make the world any less spherical. And the fact that some gentlemen, who have not made the effort, think that first-aid instruction will not be a complete success does not in any way militate against the fact that success in railway first-aid is not only a possibility but an actual living fact. Five roads have already used it to

some extent, and the chief surgeon of the Lehigh Valley Railway, Dr. W. L. Estes, writes me that upon his road, first aid has saved no less than seventy-five lives which would otherwise have been lost. These facts alone would seem to amply demonstrate that the doubts expressed by the skeptical gentleman are an unwarranted reflection not only upon the teaching capacity of railway surgeons but upon the intelligence of the vast body of railway men, many of whom are daily entrusted with matters requiring exceptionally keen judgment and comprehension, and all of whom are necessarily above the average grade of intelligence. Neither the public nor the railway service will tolerate such a reflection for a moment. First aid is not a theory nor an untried practice but it is a thoroughly proven instrument, the value of which has been amply demonstrated not only in railway work, but to a far greater extent in military and in civil life. No flag is so much honored today in the civilized world as the white field bearing a red cross, the symbol of aid to the injured and afflicted.

The point that has been suggested with regard to the possible danger of mistaking the inadequate information acquired through first-aid instruction for a complete medical education is a matter that every first-aid instructor should look after himself. In the little book of which some of the gentlemen have spoken so kindly, I have endeavored on nearly every page relating to treatment to call attention to the fact that the aid rendered is only temporary and pending the arrival of a medical man, who should be summoned at the earliest possible moment. I have too much confidence in the ability of our railway surgeons to have any doubt as to whether or not they will impress upon their men the fact that, except in the very simple cases, their assistance should attempt only to tide over the time until a surgeon can be secured. With regard to the emergency box of which so much has been said, I believe it to be an important feature of railway first aid, although it would hardly seem to deserve the prominence which has been thrust upon it in this discussion. The instructions in the emergency box are also important. No emergency box should be without its instructions, clearly printed and conspicuously placed, nor should it be without a copy of a good first-aid book, for the further information of its custodian at his leisure, not for hurried consultation in the face of the emergency. You all remember the peculiar cerebral condition which often takes hold of men in emergencies, and manifests itself either in amaurosis or paralysis of the center of comprehension, so that they can not grasp the meaning of any sort of printed matter. But the previous instruction in first aid not only enables men to apply the necessary treatment in the majority of cases without reading the printed rules, but in case they may desire to refresh their memories before applying first aid, it gives them the self-confidence which would enable them to go over the rule intelligently and profitably. But the preliminary teaching is indispensable! It is hardly necessary to repeat what I have already stated in my paper, that an emergency box gotten up after the plan described will do away with the objections already made to these first-aid helps, and the plan of issuing the boxes to certain individuals, who should be held responsible for their serviceability entirely obviates the difficulty arising from their becoming damaged or defective.

Some of the gentlemen have referred to the fact that the introduction of first aid into the railway service will require work. There is no doubt of that, it will require work, both upon the part of the railway surgeons and on the side of the other employees. It will require some expenditure also upon the part of the railway companies, but this will be more than counterbalanced by the amount of expensive litigation that will be avoided. Personally, I have no direct interest in the matter except that of a more or less frequent traveler who may on some occasion be in a position to be greatly helped by first aid. I speak in the interests of the thousands of injured

persons who might every year be helped by the adoption of systematic first aid in railway work. If, as a consequence of the increased confidence of the people, the receipts of the railways are increased I do not object. If, because of the diminished amount of litigation, the expenditures of the railways are diminished I should be pleased. But these are mere trifles, hardly to be mentioned in comparison with the enormous benefit to the great traveling public, which will accrue from the adoption of a system of first aid such as has been urged.

AMPUTATIONS.

Read at the Meeting of the Western Surgical and Gynecological Association, Topeka, Kan., Dec. 29, 1896.

BY J. P. LORD, M.D.

PROFESSOR PRINCIPLES AND PRACTICE OF SURGERY, CREIGHTON MEDICAL COLLEGE; ATTENDING SURGEON TO ST. JOSEPH'S HOSPITAL, OMAHA, NEB.

The reasons for presenting a paper upon this particular subject are, that the writer has had a considerable experience and observation in this line of work. It is a subject which has received little attention during the period represented by the age of this society, the profession having been fully occupied, studying and discussing the newer problems in our science and art, which have brought with them pressing demands for solution. It is only necessary to turn our mental skiascope upon the history of the last decade, in order to fully perceive and appreciate its marvelous achievements in these newer fields.

The development of specialism in surgery, with its perfected technique, has made its influence felt all along the line even to the "saw bones." When low, it may be said that to amputate a limb in a modern manner, that is, ideally, without drainage, and securing primary union, requires as much, and sometimes more, skill and experience than to do a hysterectomy.

Infrequently as some individual members of the profession are called upon to do an amputation, their experience is insufficient to keep them in line with the more advanced practices; therefore, inasmuch as the subject has received little recent attention, its consideration and discussion is thought to be desirable at this time.

The conditions necessitating amputation are so various that fixed rules can not be followed, either in determining the necessity for amputation, or the manner in which the amputation is to be done. With modern methods of wound treatment, there is not the same necessity for early amputation for injury, as formerly; this, in itself, saves many limbs and possibly lives. But when delay is made without the institution of proper methods, there is the same danger that drove our forefathers to immediate amputation and the necessary sacrifice of many limbs or portions of limbs, because the life should not be jeopardized. Crushing injuries and compound fractures represent this class of cases, and their successful treatment requires not only thorough surgical knowledge, but experience. A better understanding of my meaning can be obtained perhaps by the recitation of cases, of which we have, and doubtless all other surgeons have, too great a number, and is another reason why this paper is written.

A packing-house employe had great toe crushed by wheels of street car. His shoe and foot were necessarily very infectious from saturation with animal matter, and had been imperfectly cleansed, closely sutured and dressed with absorbent cotton. Septic lymphangitis and spreading gangrene occurred. Am-

putation at middle and upper thirds of legs; return in stump; reamputation middle of thigh, general sepsis and death.

Boy of 12 had foot crushed by street cars; no bones broken, soft parts over metatarsus badly injured and skin burst longitudinally on outer and inner borders of foot; wounds tightly closed by suture and small drainage tubes introduced by physicians called in emergency. Dry iodoform gauze and cotton dressing were secured by bandage; the scant discharge dried into dressing, sealing all parts of drainage. Presented third day septic lymphangitis, temperature 104.5, gangrene halfway to the knee, amputation three inches below the knee, flaps too doubtful to suture. Left wound entirely open, iodoform gauze loosely laid over end of stump between cellululo-cutaneous flaps, copious wet hot carbolized dressing applied. Dressed third day, slight loss of margin of anterior flap, trimmed with scissors and edge of posterior flap curetted, closed with silk-worm gut, primary union, but some pus; recovery uneventful.

These cases represent a class very common, a full half dozen of which could be detailed, from a comparatively recent period. This observation I have made: that general practitioners are too prone to make attempts at repair of these injuries, with results that are worse than useless, and often most pernicious, as illustrated in the cases reported. In cases of this character, the wounds should not only be left wide open, but freely enlarged, if necessary, to allow all discharges to find the most ready and free outlet. Not only this, but many free incisions should be made to allow free exit of the stagnated venous blood. In many of these crushed and lacerated wounds, the trouble may not be so much with the lack of arterial supply (though this may be much affected), as of venous return; the engorgement of the veins increasing the swelling, and devitalizing the tissues by the pressure, thus favoring and initiating the pathologic changes which are prone to culminate in a diffuse, acute, septic lymphangitis with accompanying thrombo-phlebitis and possibly gangrene. In addition to this treatment by free incision to guard against strangulation, the very large gauze, hot wet carbolized dressing is used by the author. This proving inadequate, constant irrigation by hot water is resorted to, which treatment has proven of greatest advantage to the writer in several almost hopeless cases of secondary compound fracture, and cases of crush injuries of the extremities.

In those instances where amputation is subsequently demanded, as well as many primary cases, it has been found that much of the limb can often be conserved by leaving the stump unsutured, thus placing no tax or strain upon the flaps of very questionable vitality. This course in secondary amputation admitting of the incision passing through tissues already much inflamed, the subsequent free drainage produced by this open method quickly restoring the waning vitality of the tissues, beside appreciably lessening the risk of amputation during the inflammatory period. In these cases a preference is also made for the wet carbolized dressings, which are always very ample in character, extending well above the affected part.

It has been demonstrated by the writer that the time-honored custom of going sufficiently high in an amputation to get flaps to cover, need not necessarily be followed in all cases, as is illustrated by the following:

Brakeman had right foot crushed by freight-car truck passing across metatarsus. Integument ruptured longitudinally upon inner and outer borders of foot, but the integument was entirely separated from deeper tissues to a point corresponding to the mid-tarsal articulation. The bones of the tarsus were not crushed, but laid bare for fully halfway on their distal ends. The metatarso-phalangeal joints were wholly disorganized and the tendons, both of the dorsal and plantar surfaces, were stripped of all attachments for many inches. As is often the case in railroad injuries, external appearances were no index to the concealed injury to the member. The skin flaps produced by the traumatism were nothing but skin. Even the subcutaneous fat on both dorsum and sole was perfectly removed. Then to get flaps of vitalized tissues, sufficient to cover stump, nothing short of a Pirogoff amputation would have sufficed. And some would have advised nothing short of going to middle third to get a good stump for an artificial member. But here is a man who went to sleep to have his toes amputated. Self-preservation demands that something be done less radical than some of the procedures referred to. It was my opinion that these accidentally made skin flaps would not live, but I felt actuated to give them a chance, and I therefore resolved to do what I termed a cheese-paring operation, and I made a section of the foot at a point where these questionable flaps would partially cover, if they lived. Disarticulation of the first metatarsal bone was made and the heads of the other metatarsals were sawn at this point, for the reason that the sawn surfaces would granulate more readily than an artificial surface. The flaps were not sutured, for their vitality was much in question. Loose gauze was placed across the stump. Generous padding and no pressure by bandage. Dressed on the third day. Flaps almost wholly devitalized, but no line of separation. Line fully formed in one week, and shreds removed only after sloughing began. When this process was complete, no flaps remained for covering the whole end of the stump. It occurred to me to stimulate the growth of a deep bed of granulations upon this surface so favorable for cicatricial tissues, and to eventually cover this surface by skin grafts. Peru balsam and vaselin, in proportion of about one to six or eight, was incorporated in the iodoform gauze and applied with most happy results, and in about two weeks a full third of an inch of firm, fine granulations covered the entire surface, deeply covering the bones, when after simply rubbing the granulations with gauze, Thiersch grafts were made to cover them, and the result was perfect. With an identical case I feel sure that I could save from an inch to an inch and a half more of the foot. This man walks with little imperfection in his gait, notwithstanding the fact that he has not even taken my advice to get a spring steel shank put into the sole of his shoe.

So large a proportion of amputations are necessitated by injury, the effects of the traumatism extending to, or even beyond the point of election or necessity, the tissues and the patient being in an unfavorable condition for the most perfect reaction and local regeneration, but few cases of primary major amputation admit of complete closure of the wound without drainage, though the only two cases in which this was tried were successful, one of which was not dressed until the fourteenth day. These were favorable subjects, and were selected cases, which are sel-

dom seen in the foregoing class; hence, the use of drainage is the rule.

Many cases also, where amputation is done for disease, are unsuitable for an absence of drainage. Suppurative osteomyelitis and tuberculosis furnish examples.

Cases where amputation is made for removal of a deformed or useless limb, or for disease such as sarcoma, and reamputation for neuromata, and painful stump, are of the class permitting the operator to attain to the ideal in this particular field of the surgical art. First of all, the patient is well, being neither depressed by shock, nor vitality lowered from loss of blood. Second, an opportunity for deliberate and perfect attainment of a sepsis, both of the patient and surroundings, as in other operations of election; and lastly, time, in which to secure perfect hemostasis and carefully coapt by buried suture the wound surfaces. The various cellulose-cutaneous flap methods, which have been so long popular, are not perfectly adapted to this method; hence the return of the musculo-cutaneous flap, made preferably by cutting from without inward with a small knife, instead of by transfixion, thus dispensing with the formidable catling.

There has been some discussion of late, concerning the advantages of the periosteal flap. That it does favor development of osteophytes, can not be disputed; that it does render the skin more freely movable over the bone, is true, and is a distinct advantage, especially in amputations by the skin-flap methods. When the bone is covered by a quantity of muscle, it is unnecessary in the writer's judgement. The statement made, that the end of the bone is more prone to osteomyelitis and necrosis without the flap, is not concurred in; this condition being induced by prolonged suppuration about the end of the bone; and in the presence of suppuration this apron of periosteum is prone to become devitalized and itself become a source of delay in resolution. I have often thought that the pressure made over the stump by the firm dressing, was sufficient to cut off the circulation in the periosteum, and that the trouble sometimes experienced in the end of the bone covered by granulations, was the direct result of suppuration started and maintained by the sloughing of the periosteal flap. When the periosteal flap is made, care should be exercised not to separate the muscles from it, and it should be so formed and adjusted, as not to favor the irregular development of new bone, when it may become a source of serious inconvenience.

The nerves should be redivided from one to two inches, varying with individual operations, after the limb is severed. When this is done, though the healing of the wound may be somewhat delayed, there is little danger of the growth of neuromata, it being my opinion that their development is due to irritation and inflammation incident to delayed union, when their divided ends are exposed to this influence, together with their subsequent involvement in the resulting dense cicatrix.

In a reamputation at the forearm for neuromata done last year my associate, Dr. Galbraith, after dividing the nerves two inches above the tumors (which were as large as Concord grapes), the ends of the radial and median nerves were united by catgut suture as in nerve suture, the ulnar receiving no such attention. The case was so treated for experimental purposes. Cases of this character showing a good percentage of recurrences, it was thought that this would

favor a more normal regeneration and repair of the divided nerve fibers. (It may be interesting to note that these nerves were from three to four times their normal size.)

It is a matter of common knowledge to those who have made the observation that when a nerve is divided the sheath retracts for a considerable distance, thus exposing the nerve to the irritation incident to the repair instituted for its encapsulation and protection.

Theorizing that this process may have its influence in the production of excessive cellular activity in the part, thus starting this abnormal growth of fibrous tissue upon the nerve ends, it has occurred to us to try, in cases seeming to demand it, the sliding of the sheath a considerable distance up the nerve before the nerve is divided, a procedure readily and quickly done.

To hasten repair of the several nerve ends and limit the tendency to excessive or abnormal regeneration, Professor Senn has recommended that a wedge-shaped piece be resected from the end of the nerve and the surfaces united by fine catgut. This method of dealing with the large nerve trunks is to be commended cause be founded upon scientific principles. Though it may be said that this will not permit of so high a section as when the nerve is simply cut high. It is the opinion of the writer that so-called neuromata will not form when the nerve is divided sufficiently high to remove the nerve end from the influences of prolonged suppuration at or near the wound surface, barring those cases where there would seem to be an inherent tendency to their formation. The writer's observation is, however, that an irritation is necessary to stimulate their growth, as above referred to, or from the involvement of the nerve end in the cicatrix. If our observations are correct these time-taking methods are useless and unnecessary except perhaps in very rare cases. And it will be a question in many cases whether time should be given to their employment. Certainly not in some.

Some cases of reamputation for sensitive or painful stump are unsuccessful for the reason that the condition is due to neuritis, the result of the original traumatism, or from the extension of inflammation from surrounding tissues. If treatment for neuritis is unsuccessful, excision of a portion of the nerves, or reamputation at a point above the disease may be resorted to, though frequently unsuccessful.

To close an amputation wound, without drainage, requires close attention to details; the knife should be keen, doing as little violence to the tissues as possible; tendons as well as nerves cut high; any redundant fat or shreds of tissue trimmed off; vessels ligated somewhat beyond the point of division of the surrounding tissues; for this purpose catgut is usually preferred. Shredded catgut used as an absorbable tamponade, may be used to arrest hemorrhage from the bone. Absolute hemostasis must be secured in every part, and a glazed condition of the wound obtained. This is more readily brought about if no irrigation is used. Its use impairs the regenerative powers of the tissues and should be avoided. If there is any probability of infection being present, needing to be washed away, success can not be expected. Great care should be taken also, that bleeding is not produced by the needle in making the buried suture, because a little bleeding exites more as is known by all abdominal surgeons. The tension of the sutures should be uniform, strangulation within the wound, or in the skin, being inimical to success.

Leaving a depended opening at the angle, as in a Stephen Smith, will sometimes enable the operator to dispense with the tubage drain, and also procure what is practically union throughout.

The dry dressing is to be preferred in these as in all aseptic wounds. The limbs should be properly supported, securing so called physiologic rest, this being favored also by perfect quiet on the part of the patient.

One great disadvantage of the tube is, that it of necessity remains too long. In an aseptic wound, twenty-four to seventy-two hours should be sufficient time for its purpose to be fulfilled. The first dressing usually not being made under a week, and the intervals of dressing being too long to secure its speedy removal, if it be only a portion at a time, infection is apt to occur before the wound is closed, because of the relaxation of precautions or from other causes.

The introduction of drains of iodoformized wick with gauze or silk attached and secured outside the dressing where they can be drawn upon and the drainage removed in twenty-four to forty-eight hours at will without disturbing the dressing, is practiced by some operators with excellent results and should be more generally employed.

The use of from thirty to fifty strands of catgut secured to the periosteum and from there radiating to the surface between buried sutures of the same material or silk has not been tried, for the reason that I look upon it as possessing in a measure the same objection as that possessed by the decalcified bone drain, which introduces into the wound too great an amount of material favorable to bacterial incubation.

According to Kocher, "the simplest and oldest methods have again become frequent. These are the circular incisions." A familiarity with all methods and their modifications will enable the operator to exercise his ingenuity and skill in making the most of individual cases with the varying conditions. With present-day methods less depends upon the method, than when union was commonly by granulation. Cicatrices after union by first intention are much less apt to be troublesome, even though unfavorably located. When complete closure of an amputation wound is made, there are several advantages possessed by the musculo-cutaneous flap method, which permits of the accurate coaptation of muscle to muscle and fascia to fascia. Dead spaces, subject to the accumulation of wound ooze, are eliminated, dependence not being placed on the fit of the dressing as in the skin-flap methods, though their special advantages render them justly popular.

SOME CLINICAL OBSERVATIONS OF MENINGEAL COMPLICATIONS, FOLLOWED BY DEATH AND POSTMORTEM EXAMINATIONS.

Read before the Upper Peninsular Medical Society, Jan. 12, 1897.

BY SAMUEL BELL, M.D.

MEDICAL SUPERINTENDENT OF THE UPPER PENINSULA HOSPITAL FOR THE INSANE.

NEWBERRY, MICH.

The dura mater, histologically speaking, is composed of two distinct membranes, the external being a dense fibrous membrane lining closely the interior of the calvarium; the inner surface is smooth, lined with epithelium and is a serous membrane. The dura mater is therefore a fibro-serous membrane; exter-

nally fibrous, internally serous. The latter is more intimately connected with the brain structure. In keeping with these anatomic facts each layer is subject to somewhat different pathologic conditions. The inner layer of the dura is far less frequently diseased than the outer; a chronic, simple inflammation of the latter may exist for an indefinite period prior to death.

It is frequently observed, as in case number one, in making autopsies, that it is difficult or impossible to remove the calvarium without considerable force, and often laceration of the dura is the result. In these cases the dura is firmly adherent to the calvarium and if we are careful to examine the latter we will find that it is thick and often heavier than normal, indicating an increase in the osseous structure and the spongy structure, or diploë, mostly disappeared. Dr. Weir Mitchell attributes to this condition the cause of many permanent and obstinate headaches, often overlooked during life.

Case 1.—E. W. E., aged 56. Widower over thirty years. Occupation, agent for a land company in which he held some interest, the duties connected with the same occupying very little of his time. Was refined and an exceptionally well-educated and well-read man. Had been in the past a prominent society man, but during the last ten years, although having the *entrée* into the best society, he refused all invitations and from choice lived in comparative retirement. He had only two or three intimate friends and was considered a "crank," or eccentric by those persons who met him often but did not know him intimately. He lived a solitary, lonely life in his office, to which his bedroom was attached. In business he was considered a man of exceptionally good judgment and acumen. Had always been extremely careful of his health and was fond of talking about his ailments; was also constantly taking medicine for catarrh (nasal), biliousness and nervousness. Was latterly of an extremely morose disposition.

About January 16 last he complained of some pain and slight swelling of left side of face, which he thought due to defective teeth. On the 18th he had a dentist extract the second and third molars of the left upper jaw. The pain and swelling continuing, he consulted a physician two days later, who found some slight swelling in the muscles of the inferior and temporo-maxillary region, hyperesthesia of the skin and sensitiveness of the mucous membrane. Pressure was painful at the points of emergence of the nerve trunks, especially so where the nerve enters the muscles. The ophthalmic division of the fifth nerve was not affected, but in the upper maxillary division the pain was marked along the upper teeth and there were painful spots along the auriculo-temporal nerve, the pain radiating in the region of the ear and along the lower jaw and teeth. He complained of intense pain directly over the temporal bone; mastication and talking were painful. Examination of the mouth and teeth showed nothing abnormal. Temperature was normal as was also the pulse. Bowels constipated. The case was diagnosed as facial neuralgia, and some of the nerve analgesics were prescribed with codein to relieve the pain; aconite ointment externally, and a saline for the bowels. This treatment not relieving the pain, which continued in the same locality, nitroglycerin and gelsemium were tried with little effect; also hot water bottles and other hot and soothing applications. The patient at this time, a week after calling in professional aid, was sitting up during the day in his office, but not going out of the house.

He took very little nourishment, had very little sleep at night, and was extremely nervous and forgetful. He refused to stay in bed during the day, and

after going to bed at nine at night, would get up and dress himself in two or three hours and sit up the remainder of the night. Began at this stage to develop symptoms of mental unsoundness; had illusions of hearing and sight, was unable to remember the combination of his safe, which he was anxious to open; could not remember directions for taking medicine, etc. The swelling of the face increased and the intense pain changed from the center of temporal region to the coronoid process. On examination of the ear, the anterior wall of the external auditory meatus was slightly swollen; the handle of the malleus was retracted; the short process very prominent; the drum membrane in consequence was drawn in, the two folds extending from the short process, which are ordinarily seen in chronic middle ear catarrh, were very prominent, and the membrane had lost its luster and presented considerable opacity. On the 30th, or about twelve days after being under medical care, he remained in bed, for the reason that he was unable, through weakness, to dress himself and unfit mentally to be trusted without a nurse. At this time his pulse and temperature were normal and continued so throughout the course of the disease. Bowels and skin normal; urine normal. He took very little nourishment—milk and egg, beef peptonoids and whisky.

Mental disturbance soon became more pronounced; he had illusions and became at times violent, so that it required two male nurses to attend him. Kept constantly trying to put his bed clothes on for socks and trousers and endeavored to get out of doors. One of his illusions was to pick the paper off the wall of the bed room in order to enlarge the room. He also fancied chairs were men and women, and refused food and drink. The swelling of face increased, with local heat and redness, while the pain diminished. The sub-maxillary glands were involved; the center of pain remained over the coronoid process; no fluctuation. Attempts were made to locate the abscess with aspirating needle, but without success. Application of cold to the swelling caused pain, and it was found necessary to give morphia hypodermically to quiet the patient—one-half grain at most, during twenty-four hours. Strichnia was given for the heart. Examination of the ear three or four days after his taking to bed, revealed the anterior wall more swollen, the view of the tympanic membrane leaving only the posterior inferior quadrant to be seen. This, however, did not show that the middle ear was acutely involved, nor did sharp percussion on the mastoid process at any time cause any pain. The mouth, throat and teeth were examined and found normal.

Dr. Conway, the dentist who extracted the teeth, states that Mr. E. had been complaining of pain in the lower jaw for about four years, but that from several examinations he could not make out any trouble.

I was called to see patient, in consultation with Dr. B. D. Harison, on February 5. Upon arrival, the patient was being held in bed by two powerful men, after having what was termed "attacks," in which his strength was very great, and required two of them to control him. His pulse was 84; the first and second sounds of heart could be heard; volume very much decreased and quite rapid in rhythm. Temperature normal. The pupils were equal and responded to light. Patient was asked to protrude tongue, which he did, and no paralysis of the organ was found.

A swelling was noticed on the left side of the face, which extended down over the superior and inferior maxillaries and below, including the sub-maxillary gland; the latter was swollen and enlarged but quite firm and gave rise to considerable pain on pressure. No fluctuation could be found.

Sensation was impaired; in both upper and lower extremities locomotion was very much impaired. The swelling on side of face extended to and narrowed the external auditory canal. Patient's tongue was coated with a yellowish brown fur; odor from breath was very offensive.

His talk was disconnected and he could not converse, but would answer questions after being aroused, though his intellect was very much impaired. He labored under delusions of going to fall or be injured; would not recognize friends or acquaintances unless his attention was particularly called to them. When asked if he knew such a person, who was his friend, he would answer in the affirmative, when his attention was called to the friend. He died ten hours afterward, the immediate cause being cardiac failure.

Postmortem, eighteen hours after death: Skull cap removed with great difficulty. Dura mater firmly adherent to inner table; dura also somewhat thickened. The sinuses distended with venous blood. Pacchionian depressions well marked on inner table, with corresponding bodies on membrane. Dura mater firmly adherent to pia along longitudinal fissure. An excessive amount of sub-arachnoid fluid; some venous congestion over whole surface. Slight adhesions noticed between pia and brain substance; more pronounced over base. Sections of cerebral tissue presented nothing abnormal, macroscopically; in fact there was no tissue, with exception of dura mater, which did present anything strikingly pathologic to the naked eye.

On the left side of the face and neck there was a large swelling. An incision into the substance disclosed quite a large abscess cavity behind the inner angle and ramus of the inferior maxillary, filled with about four ounces of very fetid pus. The cavity extended up to the external surface and base of skull inside of the styloid process of the temporal bone. The inner surface of the inferior maxillary was denuded at the angle and this extended up the ramus about an inch.

This case is of interest from a surgical as well as pathologic point of view. Pus was suspected, but was not located before death. The mastoid cells were not involved, neither did the pus cavity extend into the antrum of Highmore, as is frequently the case. The roughened condition found along the inner angle of the ramus of the lower jaw, extending upward toward the upper jaw and involving the canals which lead into and are in close proximity to the posterior cerebral lobe, would indicate the serious nature and location of the pus. However, the alveolar abscess was suspected and an examination made *per os*, but it was not detected. As is well known to surgeons, an alveolar abscess may perforate the antrum when attached to an incisor tooth or may open into the nares, or when connected with lateral incisors the abscess may perforate backward between the layer of the palatine process and superior maxilla, or between the periosteum and hard palate, or may also form fistulous openings on the face near the inner canthus or the under side of the malar bone. When connected with a lower incisor they open sometimes in

front of the chin, under the margin of the lower jaw. It is also known that pus from an alveolar abscess may pass down the neck, and one case is reported where it found exit below the clavicle, and in another fatal case it reached the arm pit. When the alveolar abscess distends the mucous membrane of the gum or cheek the diagnosis is easily made, and evacuation and incision is the remedy. In this case these conditions were not found, there being no fluctuation, either external or internal. The mental symptoms manifested by the patient, even before going to bed, indicated meningeal complications. The adhesion of the dura mater to the inner layer of the calvarium would indicate that they had been of long standing. There was a history of cephalalgia in his case which might be accounted for by the pathologic condition of the dura. The involvement of the brain and meninges might be attributed to two principal causes: First, the mechanical obstruction caused by the situation of the pent-up pus; second, the meningeal complications caused by sepsis or streptococcus meningitis. Such extensive adhesions as were found in his case indicated a chronic inflammation of long standing. While the cause of death was, no doubt, due to heart failure, the location of the abscess, involving the external carotid and other vessels which supply the brain, no doubt was responsible for the mental symptoms which developed in this case.

Case 2.—Mental disturbance following rheumatism. C. L. was a saloon keeper. He drank heavily and had been for two years afflicted with sub-acute gastritis and frequent insomnia. A few days before his last sickness he went hunting, sleeping nights in a log hut in the vicinity. Having a poor appetite he kept up on whisky. A day or two before my being called he came to town for a fresh supply of liquor. Often, before this time, his only food was malted milk and beef tea.

I was called to see him on November 26. The right shoulder was swollen and very painful; nausea naturally followed. Pulse full 110 and temperature 103 degrees. The following day the symptoms abated. On the third day his left elbow and wrist were badly swollen and painful and at night caused more or less insomnia. He had muttering delirium when he did sleep. On the fourth day his knees became involved, and subcutaneous nodules presented themselves on his thighs and forearms. At this time, also, acute delirium became continuous and the maxillary glands became involved. He lived till December 6, from the 3d to the 6th his condition remaining apparently hopeless. There appeared to be a prostration, almost equivalent to shock, from the disease itself; but one must not lose sight of the fact that he was a sufferer, or victim, of chronic alcoholism, indigestion and insomnia being with him common conditions.

No postmortem was allowed, yet it is altogether probable that, inter-maxillary and sub-basis, there were glandular pressure and confined pus sacs.

In this case pressure at the base of the brain might have caused the mental trouble, and paralysis of phrenic and pneumogastric functions, while the poison of the disease, *per se*, would have been sufficient to paralyze the vital functions.

This case presented many psychologic symptoms in common with the preceding one, and although a postmortem was not held, I am of the opinion that meningeal complications were, no doubt, present, involving the pia and arachnoid, and extending over the cortex and possibly over the base. Sensation was partially lost in this patient, as well as the power of locomotion. In neither of these cases did the temperature run high, and the meningeal symptoms developed so insidiously that they were liable to be overlooked by the general practitioner for pathologic conditions in other parts of the body, which might be responsible for the secondary brain lesions.

*Case 3.—*Patient was admitted to the Upper Peninsula Hos-

pital for the Insane, July 27, 1896. Male, age 34, married. Occupation, electrician. Family history fair; no insane relatives; quiet habits; very nervous temperament. Patient had had inflammation of the lungs three years previous; there was also history of rheumatism. Assigned cause, overwork and exhaustion. Previous to his admission he seemed influenced by delusions for some little time; was constantly active in the performance of unnecessary labor, generally something that ought not to have been done.

For the first two or three days patient took very little nourishment, and was quite restless and noisy about the halls, talking of his delusions, etc., but would talk rationally if you held him to a subject. He soon developed destructive tendencies and was also homicidal; appropriated any and every weapon he could get his hands on with the express purpose of killing one of the attendants. When questioned about his motives in this regard, he admitted his intentions without any apparent reluctance or feeling in the matter. He became very troublesome on this account, necessitating constant supervision.

The following is a brief account of one of his attempts to injure an attendant: "He rapped on his room door at about two o'clock one morning and stated to the attendant that he wished to go to the closet to get a drink. He had a sheet wrapped around him, apparently for protection, and started for the washroom; when he got as far as the door, he suddenly turned and struck at the attendant with an iron bar, which he had broken from the bed and had concealed under the sheet. The attendant was so close to him, and being on the alert for any emergency, that he easily warded off the blow." Patient admitted that he intended to kill the night attendant. All of these attacks occurred within two weeks of the date of his admission.

He then became very quiet, docile and apparently very much interested in reading and amusements, but still showed an extremely irritable manner, seeming, however, to try to suppress this as much as he could. From the beginning he entertained lofty and extravagant delusions regarding electricity, telephone lines, etc. He was constantly desirous of taking hypnotics, etc., so that he could get some sleep, claiming that since his admission he had slept but a very little, notwithstanding the fact of his apparently resting well every night, according to the night attendant's report.

The pupils of his eyes were constantly dilated, the right larger than the left; there was no variation in this condition all the while he was here. He complained constantly of severe headache. When first admitted, his demands for medicine were allowed to a limited degree, but we soon commenced to give him placebos. The effects of the administration of these seemed to be equal to those of the drugs he had been taking.

After he had been in the hospital about a month his delusions became more and more pronounced and were tinged with ideas of wealth. He commenced to be extremely irritable again, quarreling with patients, refusing to interview his friends, who came to see him often, and was constantly excited. He became more and more noisy and troublesome in talking of his schemes, etc., so much so that it was necessary to keep him away from the other patients on account of his disturbing them and exciting the whole hall. He gradually broke off from his usual habits of attending amusements, etc., and showed no regard for his former associates.

He soon became almost unmanageable; his mental activity became greatly impaired, so that it was impossible for him to talk rationally on any subject; he became very incoherent in his talk. His delusions of

wealth, etc., increased, and he also had hallucinations of sight and hearing, as expressed by his actions and talk. On the occasion of this latest disturbed spell he failed quite rapidly physically. He took considerable nourishment, but it did not seem to be assimilated.

It soon became necessary to place the patient in bed on account of his debilitated condition. He was very noisy night and day from this time on until the date of his death. For about one week before his death he did not seem to recognize any one. Unless watched, he would bruise and lacerate his body intentionally, without any apparent sensibility to pain.

For about two weeks before the patient's death the record of temperature, pulse and respiration showed a very slight abnormal element. His temperature at no time (and this was only recorded on one day) was over 100, and was most of the time normal. His pulse during this period ranged from 76 to 96. The respiration was about normal until two days before death, when it reached 24. There is no record of subnormal temperature. Patient died of exhaustion Sept. 30, 1896.

For some time before death there was rigidity and contraction of the muscles of the back of neck, indicating an involvement of the base, or basal meningitis. The headache was a prominent feature in the case; it was continuous and severe. The general surface of the body at times was very sensitive. The tongue was nearly normal at first, but later on became heavily furred. The temperature at no time ran high, neither did the pulse, excepting shortly before death. At first the pupils were contracted, but later dilated and irregular. The knee-jerk was at first very much increased, later diminished. A diagnosis was made of congestion of the brain or membranes, with possibly inflammatory exudate.

Postmortem made eight hours after death: The skull cap was readily removed; no adhesions of the dura to any part of the calvarium. The Pacchionian bodies were greatly enlarged and seemingly congested. The dura mater, to the naked eye, presented a normal appearance, but upon removal of the same it was found firmly adherent to the pia mater along the longitudinal fissure. The membrane was injected and hyperemic, the seat of serous exudate, and was slightly clouded. The meshes of the pia arachnoid were found to be infiltrated. The infiltration was not purulent in character, but rather of the nature of serum. These conditions were more noticeable over the cortex, although they seemed to extend to the base, and probably involved intra-cranial portions of the various nerves at this seat.

In making sections with the knife throughout the white matter there could be seen with the naked eye enlarged capillaries, and what appeared to be small clots were visible, and under the microscope marked congestion was found, and what appeared to the naked eye to be clots were found to be blood corpuscles which had found their way to the outside of vessels, and which represented a condition termed by pathologists "vena vasculosa."

The postmortem in this very interesting case confirmed the diagnosis made antemortem. The patient's insanity was, no doubt, caused by an increased circulation in the brain structure. The equilibrium of the vascular system in the nerve centers was not properly maintained, which resulted in serous exudate and adhesion of meningeal membrane, which extended over the cortex and base and caused death.

THE CHEMISTRY OF THE URINE IN DIABETES MELLITUS.

BY EDWARD L. MUNSON, M.A., M.D.

ASSISTANT SURGEON U. S. A., FORT ASSINNIBOINE, MONTANA.

The following article is the result of almost daily analysis of the urine in a typical case of diabetes mellitus, extending from the recognition of the disease to the death of the patient, a matter of eight months. On account of the confusion existing in the literature bearing on this subject it has been deemed best to synthetically prepare several of the abnormal bodies present in the urine of this case for the purpose of an experimental study of their properties.

Aceto-acetic acid.—The true history of this body begins with Gerhardt's discovery in 1865 that certain diabetic urines yielded a Bordeaux red on the addition of a solution of ferric chlorid. He did not, however, attribute this reaction to the presence of aceto-acetic acid but believed it to be due to the presence of ethyl aceto-acetate, an allied body responding to this test, since he observed that the distillate of such an urine contained certain quantities of acetone and alcohol, probably in the following reaction:

The alcohol present in this distillate, however, was probably a product of the sugar fermentation and its occurrence thus led to an erroneous conclusion. This theory of Gerhardt has not been confirmed by later investigators. Following Gerhardt's discovery, Rupstein, in a series of experiments, claimed to have isolated a substance apparently identical with aceto-acetic acid, which body has since been considered to give the reaction with ferric chlorid in diabetic urine. In 1885, V. Jaksch ("Ueber Acetonurie und Diaceturie." Berlin) made more extended investigations and published his methods and conclusions, bringing out many new facts with regard to the occurrence of aceto-acetic acid and acetone. He also claimed to have isolated this acid in the form of various basic salts, but the analytic results given by these salts did not confirm his claims, as they by no means closely agreed with the theoretic analyses. Although unknown to him, beta-hydroxybutyric acid, a body allied to, and isolated in practically the same way as, aceto-acetic acid, is nearly always present in urines which yield the ferric chlorid reaction. This body unites with cases in much the same proportions as aceto-acetic acid and has nearly the same molecular weight, a difference of only two hydrogen atoms. No method of separating these two bodies in the form of basic salts was as yet discovered and Jaksch's claim as to his isolation of diacetic acid can hardly be admitted.

Concerning the properties of diacetic acid but little is known. According to Ceresole (*Berichte der Deutsch. Chem. Gesellschaft* B. xv. S. 1326) it is a thick, colorless liquid of strong acid reaction and is miscible with water in all proportions. It decomposes easily below 100 C. breaking up in the production of acetone and carbon dioxid. According to Jaksch (loc. cit.) it decomposes in the urine on standing in 12 to 18 hours and a dissociation of its salts takes place on

bringing it down to dryness. It dissolves calcium and barium carbonates and if treated with nitrous acid gives carbon dioxid and nitroso-acetone. It never occurs free or in combination in nature except in the urines of patients suffering from diseases involving great tissue waste. It may be artificially prepared according to the method of Ceresole. (loc. cit.) Dissolve 4.5 gm. ethyl aceto-acetate (free from acetic acid) in a solution made by dissolving 2.1 gm. metallic potassium in 80 c. c. of water. Let stand for twenty-four hours and then slightly acidulate with sulphuric acid. It is then shaken with ether several times and this ethereal extract shaken with a fresh mixture of barium carbonate and water. The barium aceto-acetate at once goes into solution, the ethyl aceto-acetate remaining in the ether. This barium salt is very hygroscopic and is not crystalline. It does not give a precipitate with silver nitrate but yields a violet red color on the addition of ferric chlorid. The salt has the same properties. This reaction with ferric chlorid does not take place in the presence of free mineral acids. Aceto-acetic acid is a derivative of the fatty acid series and its relationship to propionic and butyric acids is as follows:

It is closely related to acetone, which is one of its decomposition products according to the following reaction:

to beta-hydroxybutyric acid, from which it is directly produced by oxidation

and to ethyl aceto-acetate, its ethyl salt, bearing the same relationship to this body that acetic acid does to acetic ether.

These several bodies are so intimately related it is evident that no violent chemic action is required to convert one into another, a mere oxidation or the decomposition of an unstable compound being sufficient to effect this change.

It was at first supposed that aceto-acetic acid was produced in some inexplicable way in the oxidation of sugar and several writers, among them Minkowski (*Arch. f. Exp. Path. u. Pharm.*, Bd. 18, S. 41) attempted to demonstrate a relationship between the ferric chlorid reaction and the sugar excretion.

Among other attempts at explanation the following series, which is chemically possible outside the body, was offered by Hugouneq (quoted in *Am. Jour. Med. Sci.*, October, 1887). Starting with glucose, he suggested stages consisting of alcohol, aldehyde, aldol, beta-hydroxybutyric acid, diacetic acid and acetone, the last body being very stable and incapable of further oxidation.

Further investigations showed conclusively that the oxidation of sugar was not the source of this body and V. Jaksch ("Ueber Acetonurie und Diaceturie," Berlin, 1885) advanced the theory that in this oxidation the acetone was directly produced and, if in excessive quantity, united with some fatty acid present in the system, perhaps formic acid, in the production of diacetic acid.

That the source of the diacetic acid is in the sugar is opposed by the fact that not every case of sugar in the urine is accompanied by an acetonuria or a diaceturia, and further that the presence of sugar in the urine does not appear to be essential since diacetic acid has been repeatedly demonstrated in the urines of various fevers, carcinoma and other affections characterized by excessive tissue waste. In the case upon which this work has been based the acid first appeared upon placing the patient upon a diet from which all carbohydrates were excluded, at once greatly diminished upon a return to a mixed diet—this diminution being permanent—and was markedly greater after a diet composed almost entirely of meats.

These points would show that the acid is not produced from sugar, but is produced by a splitting up of albumin. Wolpe (*Jahresbericht der Gesamten Medicin*, 1887) believes that the albumin breaks up into a number of bodies, one of which is beta-oxybutyric acid, this acid being converted into diacetic acid by a process of oxidation. This is the explanation which is most generally received. It has been thought by the writer that its origin might be found in leucin, a body formed in the cleavage of the proteid molecule, splitting up in the direct production of oxybutyric acid and other bodies. This theory is favored by the fact that no acid body from which oxybutyric acid can be readily derived has ever been found in urine. The formation of diacetic acid is by the oxidation of the oxybutyric acid, while the diacetic acid itself decomposes in the production of carbon dioxid and acetone. Should the production of the fatty acids exceed certain limits it is possible that the oxidation can no longer be carried on to acetone, with the result that they are excreted in the urine as diacetic or even oxybutyric acid.

Many of the following results are based upon experimental work upon the barium salt, which responds to the various tests for the free acid and is a much more stable and manageable body. It was found to be fairly stable, requiring six minutes of vigorous boiling to produce complete dissociation, while the free acid stood for several weeks in solution and in ethereal extraction without decomposition. On the addition of the barium salt to urine there was an immediate precipitation of the barium with a decomposition of the acid. On evaporation of this salt

decomposition occurs. Both the free acid and salt are readily soluble in ether, less so in alcohol and water. It was found to be fairly soluble in acetic ether and amyl alcohol, less so in benzol ether and chloroform. It gives a bordeaux red on the addition of ferric chlorid, yields iodoform by treating with sodium hydrate and Lugol's solution and also with ammonium hydrate and tincture of iodine, the so-called acetone test. The ferric chlorid reaction is therefore a decisive test in diagnosing an acetonuria from a diaceturia. The writer has found that diacetic acid gives the "diazo reaction" of Ehrlich, while acetone, oxybutyric acid and ethyl aceto-acetate do not. This is a ready and reliable test for differentiation. A free mineral acid decomposes diacetic acid, thus destroying the ferric chlorid and "diazo reactions." Ferrous sulphate gives a similar reaction to ferric chlorid with diacetic and is preferable since it can readily be made up in neutral solution. That the reaction with ferric chlorid lost by boiling is due to an actual decomposition rather than volatilization was proved by placing a portion of this acid in a hermetically sealed tube and keeping in steam for half an hour. On cooling and treating with ferric chlorid no reaction could be obtained.

The method of V. Jaksch for isolating diacetic acid from the urine is as follows: "Urine giving a strong reaction with ferric chlorid is slightly acidulated with sulphuric acid and directly extracted several times with ether, until the ethereal extract on evaporation no longer gives a violet reaction with ferric chlorid. These ethereal extracts are shaken with barium carbonate in water, when the acid goes into solution. The ether is then removed and the aqueous solution of barium diacetate filtered clear and evaporated down to dryness in vacuo over sulphuric acid." This method fails if oxybutyric acid is also present in the urine. To eliminate the possibility of the presence of ethyl aceto-acetate in this urine, 63 liters of fresh urine were distilled, it being known that this body split up in the formation of acetone, alcohol and carbon dioxid. A large amount of acetone was present in the distillate but no alcohol. This practically proved the presence of diacetic acid, since there are probably no other bodies which yield acetone on distillation except propyl alcohols, which have never been found in urine. Since all determinations of the diacetic acid by isolation can be by no means quantitative, through the facility with which it decomposes, its comparative insolubility in any extracting body and the synchronous occurrence of oxybutyric acid, no accurate estimations of the quantity of this acid present in the urine have heretofore been possible. The following method, which has been devised during the course of these experiments, can however be recommended as an easy and accurate way of making a quantitative determination. This method is as follows: Make up a solution of barium diacetate and determine its strength by adding to a known quantity an excess of sulphuric acid. The barium sulphate thus formed is precipitated out and weighed, the percentage of barium diacetate in the solution being readily calculated from this. Dilute this solution up to a known amount with water until only a moderate reaction is given on the addition of ferric chlorid. Add 1 c. c. of the urine to be tested to 9 c. c. of water and find out the least quantity of ferric chlorid required to bring out the maximum intensity of the reaction. Now tritrate in 9 c. c. of water a sufficient quantity of

the standard barium diacetate solution so that the reaction produced in each exactly matches in color. From the reading on the burette the proportion of diacetic acid in the urine can be exactly determined. By this method a quantitative estimation of six hours urine, amounting to 3.5 liters, was made. This specimen of urine contained 76.495 gm. of diacetic acid, an enormous quantity which well substantiates the theory that diabetic coma is due to an acid intoxication. In this connection experiment as to the delicacy of the ferric chlorid reaction showed it to occur in the presence of .0000973 per cent. of diacetic acid, while the reaction was strong in the presence of .00038397, as seen in a ten inch column. For clinical purposes, therefore, a urine in which .0005 to .001 per cent. of aceto-acetic acid occurs should be readily recognized. Careful experimental work upon known solutions of diacetic acid have shown that the test based upon the production of iodoform on treating with sodium hydrate and Lugol's solution or with tincture of iodine and ammonium hydrate can not be made quantitative.

Beta-hydroxybutyric acid was first chemically prepared and described by Morkownikoff and Wislicenus ("Watt's Dictionary of Chemistry") about 1870. It is, according to them, a slightly colored, viscid syrup, which shows no tendency to crystallize and readily abstracts moisture from the atmosphere. It volatilizes rather easily in water vapor and at once decomposes on heating to 120 to 130 degrees C., yielding a thickish acid distillate which, on cooling, deposits snow-white crystals having the composition $C_4H_6O_3$, and exhibiting all the properties of crotonic acid. It never occurs in nature except as a constituent of the urine in certain pathologic processes. It is best prepared by treating ethyl aceto-acetate with water and sodium amalgam, when the sodium salt of this acid is at once produced in the following reaction:

By slightly acidulating with hydrochloric acid, neutralizing with sodium carbonate, evaporating to a syrup, separating out the sodium chlorid formed, extracting with strong alcohol and allowing to cool, the sodium oxybutyrate is obtained. This may be still further purified by repeated alcoholic extractions. By adding sulphuric acid, shaking with ether and pouring off and evaporating this ethereal extract the free acid is obtained. The sodium salt forms anhydrous crusts made up of soft, sharply-pointed crystals, which are soluble in water and alcohol and are very deliquescent. The silver salt separates, on mixing the sodium salt with silver nitrate, in the snow-white capillary and interlaced crystals. The calcium, copper, lead and zinc salts, which are all very soluble and amorphous, are obtained by boiling the acid with the corresponding carbonates. The oxybutyric acid excreted in the urine has the same properties as above and in addition possesses the power of rotating polarized light to the left, the synthetically prepared body being optically inactive. A quantity of the sodium salt was prepared for experimental purposes. This salt was light brown in color and extremely hygroscopic—so much so that it was necessary to expose it to 115 to 120 degrees C. for half an hour and then

keep in a dessicator over sulphuric acid. This salt, with the free acid, gave neither the iodoform test nor the reaction with ferric chlorid although it had been claimed by Minkowski (*Zeitschrift für Biologie*, 1887) that it responded to the latter test. Oxybutyric acid and diacetic acid are frequently present in the urine at the same time and while the reaction with ferric chlorid is not a test for the former body its occurrence renders the presence of oxybutyric acid probable. Neither this acid nor its salts give the "diazo reaction" of Ehrlich. Stadelman (*Zeitschrift für Biologie*, 1887), Minkowski (*Zeitschrift für Biologie*, 1887) and Külz (*Arch. für exp. Path. und Pharm.*, 3, XVIII, S. 41) have all formulated methods for isolating oxybutyric acid from the urine as a salt. The method of Minkowski, probably the best and the simplest, is essentially as follows: A large quantity of urine (several liters) is thoroughly fermented and evaporated to a syrup. It is extracted with alcohol, this alcohol distilled off, the residuum dissolved in water and extracted with ether after the addition of a little sulphuric acid. The ether is then evaporated off and the remaining brown syrup treated with concentrated solution of silver nitrate, when the silver salt, in long shining needles, should precipitate out. Various other salts may be made by substituting solutions of the carbonates of these metals for the nitrate of silver solution. By this method, after adding 3 grams of sodium oxybutyrate to 1 liter of normal urine only 1.1286 gram of the same salt could be recovered. Külz's method (*loc. cit.*) of dehydration into alpha-crotonic acid proved to be uniformly successful. This method is as follows: "Take fresh urine which gives the ferric chlorid reaction, ferment thoroughly and precipitate with lead acetate. Filter clear and evaporate the filtrate to syrup. To this syrup add an equal volume of concentrated sulphuric acid and heat in a retort, collecting the distillate in test tubes packed in a freezing mixture. If oxybutyric acid be present in the urine alpha-crotonic acid will distill over and crystallize out in white plates in cooling. It will be recognized by its melting point, odor, etc. He believes that 100 c.c. is a sufficient quantity of urine to employ, but it has been found necessary in these experiments to use a very much larger quantity. This test is based upon the following reaction:

This method is by no means quantitative, fully 66% per cent. of a known quantity of oxybutyric acid being lost in its conversion into crotonic acid. A determination of the amount of oxybutyric acid in the urine can also be made by the polariscope since this body—the product or cell activity—rotates the plane of polarized light to the left, while the artificially made body is optically inactive. This property may be explained by the presence of an asymmetric carbon atom in the composition of this body and has been taken as a test for its presence in the urine by Minkowski (*Zeitschrift für Biologie*, 1887) and Wolpe (*Jahresberichte der Gesamten Medicin*, 1887). They take 100 c.c. of the twenty-four hours urine, remove the albumin and thoroughly ferment. After fermentation is complete, precipitate with lead

acetate and filter clear, examining the filtrate with the polariscope for the acid. It was found that this acid is optically weak and must be present in considerable quantity to answer this test. In the urine of this case the largest amount of this acid found was 4.513 grams in the twenty-four hours' excretion. This is far smaller than the enormous amounts observed by Stadelman (*Deutsche Medicinische Wochenschrift*, Nov. 14, 1889), Kirstein (*Deutsche Medicinische Wochenschrift*, April 11, 1889) and others, where the twenty-four hours excretion ranged from 75 to 90 grams.

While the most reliable means of detection is actual isolation as a basic salt, its occurrence in very small quantities or the presence of other organic bodies may render such isolation difficult or impossible. Dehydration into alpha-crotonic acid furnishes the best clinical method for the detection of oxybutyric acid. Very small amounts of this body are easily recognized by it, the strong pungent odor of even a minute quantity of crotonic acid being unmistakable. An evaporation of an ethereal extract gives the best results in this respect. The use of the polariscope, owing to the weak rotatory power of this acid, is but a rougher test by which additional confirmation of its presence can be obtained.

Ethyl aceto-acetate, it is now believed, never occurs in urine, although early investigation seemed to point to it as the cause of the ferric chlorid reaction. It is a liquid with an agreeable, sweet odor. It is slightly soluble in water, the liquid giving the reaction with ferric chlorid. It boils at 180 C. and is very stable. It behaves like a monobasic acid, which property is probably due to the position of the group CH_2 between two CO groups. It reacts with ferric chlorid and also with tincture of iodine and ammonia and with sodium hydrate and Lugol's solution. The reaction with ferric chlorid remains after boiling, while with diacetic acid this is not the case. Ethyl aceto-acetate does not give the "diazo reaction" of Ehrlich, while diacetic acid does. Its sodium salt can be extracted with ether from an alkaline solution, while diacetic acid can not. These two bodies can never be confounded with ordinary care, although considered as the same by Halliburton ("*Chemical Physiology and Pathology*") and Talamon (*La Médecine Moderne*, No. 14, 1891).

Alpha-crotonic acid never occurs as a constituent of the urine, but may result from the dehydration of oxybutyric acid. It is a body which on melting crystallizes out in white shining trimetric plates, which are sparingly soluble in cold water but are extremely so in alcohol and ether. These crystals melt at 72 C. and ebullition takes place on rising to 160.5 C. It unites with most metals to form salts which are permanent at ordinary temperatures but which decompose under 100 C. It is very volatile and possesses a powerful, unpleasant odor, which is quite permanent.

Acetone has long been recognized as occurring in certain cases of diabetes, and more recently has been found to be an urine constituent in other diseases also, especially such as are characterized by nervous or cerebral disturbance or are accompanied by high temperature and excessive tissue waste. To it was long attributed the production of various nervous and cerebral symptoms and even coma. Later experiments have shown, however, that this body possesses but slight toxic properties and that it is improbable that its presence could produce such grave symptoms. The

true history of acetone begins in 1857, when Petters (*Präger Vierteljahrsschrift*, xv, 6, S. 61), described a fatal case of diabetes in the urine of which he detected a body which gave the tests for acetone. In 1860, Kraulich (*Präger Vierteljahrsschrift*, xvii, Bd. 3, S. 58) made further investigations and, like Petters, arrived at the conclusion that acetone was formed by an abnormal intestinal decomposition. During the next twenty-five years experimental work on this subject was carried on by Lieben (*Annalen der Chemie und Pharmacie*, Bd. vii, S. 236), Kouska (Diss. Griefswald, 1873); Küssmaul (*Deutsch. Arch. f. klin. Med.*, Bd. xiv, S. 99) and others, but no satisfactory conclusions were reached. In 1885, however, a careful study of its occurrence was made by von Jaksch ("Ueber Acetonurie und Diaceturie," Berlin), who also discovered the presence of diacetic acid in diabetic urines. It was believed by Petters and Kraulich that acetone was formed by an abnormal fermentation in the intestines. Küssmaul, however, showed that this could not be the case. Jaksch and Kobert believed that acetone is never formed in the alcoholic fermentation, but is produced in the lactic acid fermentation. This is not the conclusion arrived at in this article. As has been previously stated, it is believed that an abnormal decomposition of albumin yields oxybutyric acid; this splits up into diacetic acid and this, on further oxidation, gives acetone—a diaceturia or oxybutyria occurring when the acids produced in this excessive albumin decomposition are present in larger amount than the system is capable of completely oxidizing to acetone. Acetone is a very clear, mobile, colorless fluid which boils at 56.3 C. It possesses a sweet, ethereal odor which is very characteristic. It is chemically prepared by the dry distillation of wood and the acetates, and is also a product of the oxidation of various organic compounds. It is a rather stable body, but under certain conditions may decompose in the production of acetic and formic acids. It yields iodoform on the addition of tincture of iodine and ammonia, and will produce indigo blue in alkaline solution on treatment with ortho-nitro-benzaldehyde. With a solution of sodium nitroprussid and sodium hydrate it turns red, the color soon fading, but reappearing on the addition of acetic acid. It will also dissolve the red oxid of mercury. Jaksch ("Ueber Acetonurie und Diaceturie") believes that acetone is only slightly toxic, but adds that under certain conditions it may produce severe symptoms of poisoning. Lewin ("*Toxicologie*") calls 5 to 8 gm. per kilo the fatal dose for the dog. He finds that a man may ingest 10 to 20 gm. in the twenty-four hours without producing serious discomfort. In the course of these experiments 10 gm. of acetone each were given to four healthy persons. No subjective symptoms of any sort were induced, nor could tests for acetone be obtained from the urine. There was an acetone odor to breath for twenty-four hours. Doses of 16 grams were administered to two persons without any effects. No acetone could be obtained from the urine. Twenty-five grams were given during two hours without effect. In one instance 36 gm. were given during two hours with the production of slight intoxication and a temporary rise in the pulse rate from 88 to 112. In this case the acetone odor to the breath persisted for forty-eight hours, while a test for this body could be obtained from the distillate of the urine. It is concluded that by itself acetone can be productive of no dangerous or

marked symptoms, but is of importance as showing a pathologic katabolism of the system and as being the forerunner of the much more dangerous diacetic and oxybutyric acids which in a steadily progressive diabetes must ultimately appear. Jaksch ("Ueber Acetonurie und Diaceturie") claimed that acetone was always to be found in normal urine and was consequently a product of normal metabolism. He claimed to have isolated an appreciable quantity by distilling 300 liters of normal urine. On the other hand, Moscatelli (*Archivio per le Scienze Mediche*, Vol. x, p. 231) has been unable to find acetone in healthy urines. He used 25 liters of urine from healthy persons and distilled, saving only the first few cubic centimeters that came over. These were then mixed and redistilled. The first five c.c. which came over were used for testing. By this method no acetone was found, although tests were used which were sensitive to half a milligram of pure acetone. Salkowski (*Jahresbericht der Gesammte Medicin*), has recently shown that any healthy urine distilled with sulphuric acid yields minute quantities of a body which gives all the reactions of acetone. He does not find this body on distilling such urines without the addition of sulphuric acid. In the course of these experiments 50 liters of healthy urine were distilled, without the addition of any acid, without giving the faintest reaction for acetone in the distillate. Acetonuria, in this case, only existed for a few days. Following the institution of an anti-carbohydratic diet, a diaceturia was produced which continued until the death of the patient seven months later. The amount of acetone present was at no time very large, in fact, a large acetonuria will probably never occur, since the system will probably not be able to decompose a large amount of oxybutyric acid in the production of acetone. After the occurrence of the diaceturia several attempts were made to find free acetone in the urine, but without success. This agrees with Jaksch, who never was able to find free acetone in an urine giving the ferric chlorin reaction. It has been claimed by Kallay ("Ueber Diabetes Mellitus"), Talamon (*La Médecine Moderne*, July, 1891), and others, that acetone in the urine is the cause of the ferric chlorid reaction. Acetone, either in the urine or synthetically prepared, gives no reaction with ferric chlorid. It has also been stated by Landois ("Physiologie"), and Kallay (loc. cit.), that the ingestion of acetone causes the presence of albumin in the urine, and that an acetonuria may be responsible for this frequent concomitant of diabetes. In the eight persons who were given acetone in amounts varying from 10 to 36 gm. no albuminuria could be detected, although frequent tests were made. Such an albuminuria is probably due to an over-excitation of the kidneys through the increased amount of work thrown upon them. Should acetone occur in considerable quantity, it will be recognized by its characteristic odor. It was found that 1 per cent. of acetone in a distillate of healthy urine, made with or without the addition of sulphuric acid, was readily perceptible to smell. Since a certain amount of acetone is yielded on distilling an urine containing diacetic acid, all tests for an acetonuria must be applied to fresh urine. It must be emphasized that diacetic acid gives the usual tests for acetone. A diaceturia is therefore to be recognized by the occurrence of either the ferric chlorid or the diazo reactions, since neither of these tests is responded to by acetone. The best method for the recognition of this body is that

of Gunning, the production of iodoform in the presence of acetone or the addition of tincture of iodine and ammonium hydrate.

All observers have found the excretion of urea in diabetes to be far above that of health, Cohnheim ("Vorlesungen ueber allgem. Pathologie"), and Strümpell ("Lehrbuch der spec. Path. u. Ther."), reporting cases in which the excretion rose as high as 125 to 150 gm. in the twenty-four hours. This increase may in great part be accounted for by the excessive amount of proteids which form the usual dietetic treatment of diabetes. A more important factor, and one which is but little considered, is the abnormal breaking down of the body tissues, it having been demonstrated that the excretion of urea is far in excess what could possibly be produced from the nitrogenous foods ingested. The urea in this case, on a mixed diet, remained at about three times the normal amount.

It has long been known that the excretion of ammonia in the urine is greatly increased in certain morbid processes, especially diabetes. In 1872 Frerichs noticed that the urine of diabetic patients previous to or during the occurrence of coma contained an extraordinary amount of ammonia. He therefore attributed the production of these cerebral symptoms to the poisonous action of this body, which he believed was produced by the action of an abnormal ferment upon the urea, decomposing it in the production of ammonium carbonate. This idea, as the so-called theory of "ammonemia" at one time gained wide credence, but has more recently been shown to be erroneously grounded. In 1889 Stadelman and Kierstein, working independently, published (*Wochenschrift für Klinische Medicin*) reports of work done on this subject. Starting with the observation that the ingestion of acids increased the ammonia excretion and that they exactly kept pace with one another, the reasoning was extended to those diseases in which there was a noticeable increase in the acid excretion. It was found by them that the quantity of oxybutyric acid excreted in diabetes ran exactly parallel with the excretion of ammonia. The theory of an "acid intoxication" was therefore proposed by them, believing that severe nervous and cerebral symptoms appeared only when the production of acid was excessive, and that coma supervened when the neutralization of these acids could no longer be effected by the quantity of ammonia available in the economy. They therefore recommend the determination of the twenty-four hours ammonia excretion as an easy clinical way of arriving at an approximate idea of the amount of acid excreted. The average ammonia excretion of a healthy individual being about .8 gm., they believe that an ammonia excretion of more than one gram may induce serious symptoms, while a rise to 2, 4 or 6 gm. denotes a dangerous condition and a marked liability to coma. On a diet composed exclusively of proteids the patient upon whom these experiments were based excreted an average of 8.4 gm. per diem. On a mixed diet the ammonia excretion fell over 25 per cent. One sample of urine, passed while the patient was on a rigid meat diet, gave an enormous yield of ammonia, far exceeding the maximum quantities given by Stadelman and Kierstein. This specimen was passed between 9 A.M. and 3 P.M. and amounted to 3.5 liters. In this were found 16.635 gm. of ammonia associated with an excretion of 76.435 gm. of diacetic acid and a total urine acidity of 142.8. This amount of ammonia should theoretically be able to neutralize some 90 gm.

of diacetic acid, and there was evidently an excess beyond what could combine with this body. The probable presence of oxybutyric acid would account for this discrepancy. Unfortunately, the full twenty-four hours' excretion could not be obtained, but had this proportion obtained for the usual urine excretion of ten liters the ammonia would have amounted to 42.32 gm., a quantity capable of neutralizing about 125 gm. of concentrated sulphuric acid.

Frequent determinations of the percentage of urine acidity were made in this case, and all examinations of the twenty-four hours' excretion showed an acidity far above normal. The percentage of acidity was about 25 per cent. less while the patient was on a mixed diet than while there was a rigid exclusion of the carbohydrates. It was also noticed that urine passed several hours after meat meals was much more acid than urine passed fasting or shortly before eating. All determinations of urine acidity should be accompanied by estimations of the ammonia, as according to Stadelman and Kierstein it is probable that the acids do not exist free, but in the form of ammonium salts.

OXYGEN INHALATIONS AND HYPODERMIC MEDICATIONS IN THE LUNG AFFECTIONS OF INFANCY.

BY R. S. WOODSON, M.D., U. S. A.

JACKSON BARRACKS, LA.

The difficulty encountered in procuring a supply of oxygen in the treatment of pulmonary affections leads me to believe that its efficacy is not appreciated by the profession at large. The text-books of recent date recommend oxygen inhalations in such cases, but in so vague a manner as to leave the average practitioner unwilling to undertake the trouble and expense necessary for its utilization. It is for the purpose of urging upon the more conservative members of the profession the extreme value of these remedial agents that the following case is reported:

I. L., infant daughter of Lieutenant L., aged six weeks, was attacked with broncho-pneumonia, with involvement of large lung area. The severity of the attack may be best expressed by relating that a very distinguished specialist called in consultation on the fourth day of her illness gave the gravest prognosis and recommended euthanasia. Up to this time the treatment consisted of oil-silk cotton-batting jackets, steam and medicated vapor inhalations, ammoniacal and alcoholic stimulation. The condition of the patient was that of marked cyanosis, Cheyne-Stokes respiration, carbon-dioxid narcosis, pulse weak, rapid and irregular. After the grave prognosis of the above-mentioned specialist the writer was left alone with the case. Two suitable rubber bags were procured, and with the means at hand afforded by the laboratory of the post hospital, Jackson Barracks, La., a sufficient quantity of pure oxygen was administered almost continuously to the infant, with the most marked and gratifying results. The previous cyanotic condition gave place to a healthy color, with a disappearance of carbon dioxid narcosis. The respiration became deeper and more regular, the pulse slower and stronger and a general tonic effect was noted. In addition to the oxygen inhalation and *pari passu* with its administration, hypodermic injections of digitalin, strychnin and atropia were employed as often as indicated, with an occasional injection of codein to control excessive coughing.

The method of administration was as follows: One-half a tablet of digitalin 1-100 grs., strychnin 1-60, atropia 1-100 were dissolved in a syringe-ful (30 m.) of water, 5 minims of which were injected at a dose. By plunging the needle boldly in over the region of the hip the infant will not experience pain, provided the needle is small and sharp.

The writer wishes to call attention to the accuracy of dosage and promptness of effect noticed with this form of therapeutic administration, and especially with these agents and to express his conviction that by these means the mortality of uncomplicated cases of broncho-pneumonia, even in the very young, can be brought very low. By this method the digestive apparatus is not interfered with, a point in connection with regular and sufficient nourishment of the highest import. The writer takes this occasion of urging extreme caution in the use of opiates and to express his preference for codein.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

BY CARL H. VON KLEIN, A.M., M.D.

(Continued from page 795.)

CHAPTER V.—SURGICAL INSTRUCTION AND LITERATURE.

Schools of surgery in Germany and Russia; Practical instruction at universities, polyclinic, clinic; Surgical instruction in Paris: Desault, Ecole de Santé, Pensions, visits to Pelletan, French students, Boyer; Surgical instruction in London: John Hunter, Edinburgh; Book-making of German surgeons, servilism, Latin or German; Mutilation of the German language by the French; Translation craze, esteem for foreign countries; Surgical periodicals, reviews; Text-books, prices of books.

With the sharp separation between medicine and surgery in Germany, and the wide gulf which between doctor and barber in respect to scientific acquirements and social position, it could not happen otherwise than that the study of surgery was a very different matter for the physician from what it was for the barber. The universities where the physicians heard surgical lectures, did not exist for the barber; he lacked both the money and the preliminary training of the gymnasium. The state had to provide for its higher education in other ways, since the beginning and the end of the wisdom which the barber apprentice took with him from the home of his master, was the noble art of shaving, bleeding and putting on plasters. With this object in view, special institutions of learning called *Collegia medico-chirurgica*, were founded. In these schools, with which an anatomic amphitheater was connected, various teachers lectured in anatomy, surgery, pathology, materia medica, chemistry, botany, and so forth; also the barbers were examined there, before they were given permission to practice.

One of the oldest institutions was that founded in Hanover in 1716, which was under the direction of the physicians-in-ordinary and court physicians. It received as students the journeyman barbers and the apprentices of the city. Upon payment of a certain amount (two thalers from the apprentices), they were given the bodies of criminals to dissect. Berlin followed and, according to a plan of Holtzendorff, instituted a collegium medico-chirurgicum, which was an enlargement of the anatomic amphitheater, at that

time the only medical school outside of the universities, in the kingdom of Prussia. This new institution was the first one in Germany which trained surgeons and physicians especially for the military service. King William I. desired to have in his dominions an institution where medicine and especially surgery should be taught just as well as in Paris, London and Amsterdam. In it medico-surgeons and thorough physicians should be trained for the low countries (north Germany), and for the army. At its foundation there were six professors and a "demonstrator of surgical operations," who gave public lectures daily, in the German language, in all branches of therapeutics. Henrici, professor of therapeutics, lectured four times a week on medical and surgical pathology. In the winter Buddeus gave demonstrations in the anatomic amphitheater, and lectured on wounds and operations, on fractures, luxations and mortality of wounds; he also exhibited bone-preparations, and gave instruction in sectional reports. The actual teaching of operations, bandaging, and the use of instruments was entrusted to the regimental surgeon Senff. Of the other professors, Ludolf taught materia medica, in connection with demonstrations in setting bones; Pott, pharmaceutics; Neumann, pharmaceutical chemistry with experiments. Finally, Schütz, in one semester expounded arithmetic, geometry and trigonometry, and in the other conducted practical experiments in the field. Berlin was proud of this school and imagined it was not only just as good as a university, but that it was not behind even the Paris institutions, indeed, that it surpassed them in many good points, because here lectures were held daily, in Paris only during certain months. The joy over its founding inspired one collegian to the following poetic effusion:

"What Leyden, Paris, Basil has rendered great,
Is now with equal skill achieved within our State,
Apollo, to your flock of Muses say, 'tis known
Berlin, through Frederick William, a Paris now is grown."

The hope of connecting a hospital for practical instruction with this school, was realized a few years later in the establishment of the Charité. In 1810 the college was dissolved and replaced by the medical and surgical academy for the army.

In *Dresden*, under August II. in 1748, at the suggestion of Pitschel, afterward surgeon-general, a medical and surgical college was founded. He describes the institution in a little work full of absurdities, and in a disgustingly servile hymn to Frederick August III. As army surgeon in Bohemia, Pitschel had convinced himself of the great irregularities in the Saxon hospital life as well as the gross ignorance of the hospital stewards and field apothecaries, not one of whom even knew oxymel simplex. After peace was restored, and when at the solicitation of several army surgeons, Pitschel gave lectures on diseases of the bone, the council of war commissioned him to outline a plan for a surgical school and to organize it within the barracks. In spite of the commission of the council he had many difficulties to combat. The people who lived rent free in the barracks would not move out; from the timber which had been hauled for the college building, a member of the council of war had himself a barn built, and finally, his colleague, Günther, surgeon-in-ordinary, published as his own the plan borrowed from Pitschel. His Majesty accepted Günther's, but he was publicly blamed by the people. After many trials, the death of the Duke von Weissenfels, who had left a number of anatomic prepar-

ations, gave the next impetus to the establishment of a school in which army surgeons as well as civil surgeons should be trained. Hänel taught therapeutics, Pitschel anatomy and Günther surgery. Each infantry regiment must send two, each cavalry regiment one, yearly, to complete the course. They connected with this school the surgical hospital, and in 1784 a lying-in hospital for twelve persons was added. The surgeon officiated at the same time as obstetrician. The Platner instruments and bone-preparations were bought and a library established. In the war for Independence Dresden saw the downfall of her school, but replaced it in 1815 by the surgical and medical academy.

Coeval with the establishment of these institutions, there sprang into existence in other parts of Germany larger or smaller schools with two or three year courses, and thereupon occurred a forward stride, considerable for that time, in the progress of surgery. Unfortunately many of them did little. Indeed, the lectures were not always held regularly. Schools of this kind arose in Frankfort-on-the-Main, Hamburg, Regensburg, Bruchsal, Braunschweig, Celle, Cassel, Gotha, Dillingen and elsewhere. In Heidelberg in 1783, Professor Schwarz founded a surgical institute and diverted the guild funds of that place, which were as a rule spent in feasting, to the creation of a library. At the same time Zürich established, through a society of physicians, a medical and surgical institution with seven teachers. The course was expected to cover three years, and the price for the lectures, excepting anatomy, for this time, was placed at twelve Louis d'or. In Braunschweig the preparatory studies cost three thalers a semester. Only a few schools enjoyed the advantage of hospitals; so the school of the Hofrath Trampel, in Meinburg, and also that in Landshut, where surgical patients were received for a fee of thirty kreuzers a day, were especially recommended. It is only in the present century that institutions for the education of first and second class surgeons have multiplied in Prussia; in Münster 1822, Breslau 1823, Magdeburg 1827, Greifswald 1831. But this growth was arrested in 1849, when the study of surgery was limited to the universities alone. Of the medical and surgical academy in Vienna and of the military medical institute in Berlin we will speak later.

The establishment of the German surgical schools nowhere met with more approval than in *Russia*. Catherine II. called the surgeon Mohrenheim from Vienna to St. Petersburg, as professor, and commissioned him to found such a school there, the first in *Russia*. A great building near the outlet of the Neva, with forty beds for practical instruction was planned, and in 1783 was dedicated. It was under the immediate protection of the empress. Thirty pensioners were appointed, who devoted themselves to surgery and were given free lodging, an allowance in money, etc. They were for most part Germans, or of German parentage. They received free instruction from seven professors in theoretical and practical medicine, surgery, anatomy, physiology, chemistry, botany, materia medica, pharmacy, obstetrics, ophthalmology, physics, and even in the German language, besides instruction in other languages. The teachers received a salary of 600 rubles each, together with a residence. Mohrenheim, who taught surgery, ophthalmology and obstetrics, performed the more important operations himself, but left the lesser ones to the students. If the pensioners passed the examinations successfully they

served six years in the ambulances, then as staff surgeons and division surgeons. The experiment with the German element turned out so well that a few years later the empress called German physicians and surgeons to Russia in order to appoint them in the provinces and to the surgical school in St. Petersburg. She gave the physicians from 600 to 800 rubles per year, with the rank of major; the surgeons 400 to 600 rubles, with the rank of lieutenant, and secured to them very liberal provisions in regard to pensions and the care of their widows and children. They could choose their own residence in the province. In 1786 eighteen German physicians and six surgeons, whose commissions as court surgeons Zimmermann had issued in Hanover; among others the Braunschweig city surgeon, Knockstedt, who became professor of anatomy. In the course of a year three new schools, with an income of 24,000 rubles, were established by the empress in St. Petersburg, Moscow and Kronstadt. Attached to each of these were fifty students, three teachers in medicine and three teachers for languages and drawing. The assistant surgeon received 150 rubles, each pupil 50 and each professor 1,000.

We will now turn to the *practical instruction in the German universities*. Until the 18th century the seats of learning in Germany had lecture rooms enough, but no patients. Medical instruction was everywhere limited to lectures in therapeutics and the students knew sickness only from their note books (*Medici ex commentariis*). What were the consequences? When the young men left the university, in spite of all their erudition, they could scarcely recognize erysipelas. They followed their text-books mechanically, and when left to themselves it was only with the greatest difficulty that they were able to push forward on practical lines. The university fills the memory and instructs the understanding of only the more capable and industrious few, and the greater number almost suffocate in the tasking of the memory (Baldinger). Even in the 80's the Vienna students must needs be satisfied if they were permitted to read over Van Swieten's Commentaries, since there were not even lectures on pathology. Stoll, the professor of medicine, lectured voluntarily on fever and chronic diseases, but this was only a fragment. In 1795 Professor Frank began daily free lectures on special pathology and therapeutics. Surgery in the universities fared no better. Barren and unfruitful it lay useless and unknown. The faculty took almost no interest in it of their own accord; they looked down on it contemptuously because it was in the hands of the barbers. For a long time it had no professor at all. One teacher expounded Boerhaave's "Aphorisms," another based his lectures on Heister's "Surgery." But because of the lack of hospitals the students saw no patients. This need was somewhat satisfied by the *policlinic* (klinische Institut, ambulirendes Klinikum), with which they were content for a long time. The professors took the students with them to the houses of their private patients, and allowed the poor to be gratuitously treated by the students, under their supervision. From this grew the custom of the younger physicians attaching themselves to those older in practice, in the rôle of assistants. Many civil authorities even required the young doctors to serve for a specified time under the direction of reputable physicians before they gave them permission to treat patients independently. Little came of this. The busy practitioner demanded as much as possible from

his assistant, but had no time or inclination to instruct him scientifically. The young colleague was never sent to the sick of the better classes, but if his name came to be often heard he was dismissed and another engaged. Although the polyclinics could not take the place of a hospital, they were of great value to the students. We will look more closely at those of Jena. For several years Professor Loder had taken his students to visit private patients. He also treated the poor, whose cure was paid for out of a fund made up by him and his pupils. So there grew up gradually a private polyclinic, which was in 1791 given to the public as "Medicinisch-Chirurgische Krankenanstalt," the gift being the result of an annual allowance from the Duke of Saxe-Weimar. In the first years Loder took charge of the medical and surgical practice alone, till in 1793 Hufeland undertook the medical cases; the court surgeon, Günther, was assistant. The institution took care of about 200 patients, the majority of whom received medicine and treatment free. There were also rooms reserved in the lying-in hospital for the special surgical cases. The patients came at a specified hour to the institute, which was open daily; only those who were bedridden were visited by the students. It was their duty to visit the acute cases two or three times a day, the chronic cases once. If a student neglected this duty he forfeited his semi-annual allowance. In important cases Loder and Hufeland accompanied the students. Separated into practitioners and auditors, they kept journals, which were from time to time examined by the professor, and they themselves, under supervision, prepared most of the medicines, in a little laboratory. The polyclinic developed in a gratifying way, and in the first three years was attended by fifty-two practitioners and seventy-five auditors, and in the year 1796 treated about five hundred and forty patients. Since the entire cost amounted to 800 thalers, while the Duke gave only 260 thalers, the professors were obliged to renounce their respective fees and even to apply the honoraria of the students to its support. Similar ambulatory clinics existed in many universities; in Göttingen, and Halle, where the clinic was enlarged for surgical cases and endowed with 1,000 thalers, until, in 1806 a hospital was built. Reil had charge of the medical, Meckel the surgical cases.

The center of practical instruction should be in actual *university clinics*, which really only began to develop in the eighteenth century. The impetus to found the first clinic in Europe was given by the German students in Padua in 1578. At their instance it was decided that the two professors, Albertino Bottoni and Marco degli Oddi, who were already physicians in the hospital of St. Francis, should give lectures beside the sick beds, and from time to time open bodies to ascertain the seat of disease. Unfortunately, dissections were soon forbidden. This first clinical instruction, as it appears, did not long continue fruitful, and the clinics established after the manner of this one, in Pavia and Genoa, had no especial consequence. Accordingly they did not approach in merit, as bearing on the general introduction of clinical instruction, the clinics in Utrecht and Leyden; for it was in Holland first that these arose, through the labors of Heurnius, Schrevelius, Kyper, de le Boë Sylvius, and especially through Boerhaave's magnificent results, and thence spread to the universities of all nations. The instruction consisted principally at the bedside, where the students were entirely passive. Indeed,

Heurnius, who established the first clinic in Holland as collegium medicum practicum at Leyden, and conducted it alternately with Schrevelius, soon came to the conclusion that the students must be induced to do more investigating at the bedside. He brought this about, and required them to make their diagnosis. This method, however, was very distasteful to the students, and Heurnius desisted from it, and thereafter contented himself with his lectures. But this system of examination seems to have been already instituted by Kyper's celebrated successor, Sylvius, and to have been one of the forces which carried the fame of the Leyden clinic over all countries (v. Ziemssen). Boerhaave's clinic (1714) became the mother school for all others and the model of that one which Van Swieten founded in Vienna in 1754. Only the brilliant result of this *first clinic in Germany*, which was so important in the development of medicine, induced the other universities of the fatherland to establish such clinics, which they had until then regarded as unnecessary (Göttingen 1780, Prague 1781, Kiel 1788, Leipsig 1798). Because of their undeveloped state there was much left to be wished for, even to the end of the century. The sick rooms allotted them were frequently too small and too low and bore no relation to the number of students and patients. Of these last there were indeed no lack, but there was a lack of the necessary diversity of cases. Professor Frank requested for his medical clinic twenty beds, no more and no less, which, evenly divided between the sexes, gave the students sufficient opportunity to observe, and did not rob the teacher of too much time. The beds in the ordinary hospital were to stand three feet apart, in the clinic about six feet apart, so that the students might have room enough. He wanted twice as many beds for the surgical clinic, because a number of patients with fractures and luxations consumed so little of the students' time, that a more frequent change was not necessary. No doubt much was done in the last half of the century for surgical clinics; yet, in the beginning of this century, there were a number of German universities that had nothing of the kind. We have seen in the foregoing chapter how the surgical service was managed in the Berlin Charité, and in the Vienna general hospital. In the latter, besides the polyclinic, there was a temporary clinic especially designed for instruction. When the school of medicine, surgery and practice was removed from the hospital, Professor Stoll, successor to de Haën, taught medicine; he had the right to select from all of the patients taken gratuitously, any whom he wished, for purposes of instruction, in his two rooms, which contained twelve beds. The same number and the same right, belonged to the professor of surgery, Professor Steidele, who every day, after the clinic, gave a lecture in surgery and a course in operations on cadavers. In the Charité there were two clinics, whose teachers belonged to the university, but the hospital had no further connection with the university, and they were not under the same management. Professor Reinlein directed a second institution of learning in the Vienna hospital, where surgeons were given special instruction in medical science. The students could assist at all ordinations of physicians and surgeons, and had access to the house of refuge and the lying-in hospital. Interest in surgical education arose quite early in Würzburg. When the university was reorganized in 1734 the professors were permitted to take students to patients in the hospital. This permission was the

first impetus to the establishment of clinical instruction. The professor of anatomy and surgery taught theoretic surgery, while the demonstrator of anatomy and surgery (called also *opérateur*) of Julius hospital, gave instruction in practical surgery and bandaging, at the bedside of the patients in Julius hospital. The chief surgeon chose two assistants from among the students (Obergesell and Untergesell), who helped him, and were excused from the payment of fees. C. C. von Siebold, who was at the same time academic teacher of surgery and chief surgeon of Julius hospital, was the first one who was in a position to give surgery students the advantages of a surgical clinic. Ophthalmology received very scant attention in Germany. Austria set a good example. When the general hospital of Vienna was founded, two rooms in it were assigned to Jos. Barth, and in 1812 a special ophthalmic clinic, with sixteen beds, was opened there under Professor Beer. All the walls, chairs, beds and dishes in them were colored green, to soften the light. In the Charité of Berlin, in 1816, a clinic in surgical ophthalmology was instituted.

If the German wished thorough training in surgery, which it was nearly if not quite impossible for him to get in his fatherland, he had to go to France or England. Such journeys were at that time not infrequently undertaken. If money was lacking for it, the treasuries of princes and bishops and even of the magistrates of certain cities, were opened for the maintenance of promising young men. In foreign countries ample opportunity was offered to study anatomy and to see surgical patients and operations. German surgeons who were not trained in Paris were not trusted at all; the reputation of the surgical school in Paris had extended through the whole world, and whoever came from there was proud to be its pupil.

Surgical instruction in Paris was carefully cherished even in the first half of the century. Every year three public courses in operations on cadavers were held in the royal garden in the collegio medico and collegio chirurgico at St. Cosmes, to which every one was freely admitted. All had free entrance to the great hospitals, where the most important operations of the most celebrated Paris surgeons could be witnessed every day, and in the Charité there were private courses in operations. The students also heard anatomy, gratis, in these three places, and had besides great opportunities to prepare in the Hôtel Dieu and in the Charité, as well as in the private houses of Winslow and Duverney (1725). They even found opportunities for operating on the living, under the direction of Le Dran. With all this, even in France, surgery was still separated from medicine in the second half of the century, which was paralyzing to instruction. They were taught in separate institutions, and here, as in Germany, an implacable hatred and party strife was cherished. Whatever was taught from the chair, lacked practical illustration in the hospital, and *vice versa*. So the faculties in Paris before the Revolution, although they were surrounded by the most important hospitals, did not possess a single sick room. The Ecole de Chirurgie, dedicated in 1779, had in their splendid building, situated in one of the narrowest streets of Paris, only a few beds at their disposal, much too few for their 700 or 800 students. Here all the surgeons of France were instructed free of charge, in an amphitheater that accommodated over 1,000 hearers. In 1785 Louis and Chopart taught physiology there, Fabre and Tenon pathology, Sabatier

and Pelletan anatomy, and Sue, with Lassus, taught operations. In the afternoon the colleges were better attended than in the morning, because in the afternoon about 350 barbers, who served their customers in the city, changed their coats and ran to the colleges. Montpellier was an exception. There clinical instruction was combined with the *École de Médecine*; hence a physician from Montpellier was preferred to one from a Paris school. There *Desault* lectured, whose zeal overcame all the objections of the state. After three years in the *Charité*, he went in 1785 to the *Hôtel Dieu*, that great cavern, where patients were lost in the crowd, and were never made to serve the advancement of medical science. Whoever was acquainted with Paris and knew that prestige and money were worth everything there, must be surprised that *Desault*, who had neither, but owed everything to his knowledge, came to occupy the first place in France. Young, active, free from prejudice and national pride, he began to teach and train a large number of students. It was now for the first time appreciated how important to the advancement of practical surgery the *Hôtel Dieu* might have been, and of how little use it actually had been. *Desault* gave instruction at the sick beds, and created thereby the *first surgical clinic in France*. Every morning they began with the polyclinic, *Desault* examined the patients and spoke of their cases; then the internes read the history of the more important cases that left the hospital that day. They then proceeded to the operations. After explanatory remarks had been made, the patient was brought into the amphitheater and operated upon by *Desault* in the presence of the students. He even showed the opening of an abscess, so that all could see. For the sake of the school, he employed only the best methods in his operations. Then came a succession of dissections, visits, and finally a lecture on some surgical subject. The morning instruction lasted three hours every day. The credit of first lecturing at the bedside of the patient belongs to *Desault*; he did not stop with superficial visits, but took the student to the bedside, and there instructed and questioned him. There were many obstacles in the way of this innovation. The nuns, who were all-powerful, in the *Hôtel Dieu*, intrigued and cried out that operations were performed in public, and that it was contrary to feelings of humanity; complaints against *Desault* were daily poured in on the administration, and envious colleagues disparaged his efforts. But all obstacles were surmounted by his perseverance. According to the statement of his great pupil *Bichat*, *Desault* did not possess the gift of eloquence, but there was a certain fire in his discourse, which illumined all he said. His carriage, his gestures, indeed his whole appearance, changed momentarily according to what he wished to express. His school soon became the center of surgery; the number of his hearers increased daily, and those of the public institutions decreased, a fact which especially vexed his adversaries. Foreign nations sent pupils to Paris, under the express conditions that they hear his clinical lectures, which were the first of their kind. Not only most of the surgeons of the hospitals in Paris and the provinces, but also the higher army physicians, were trained by him; he was indeed the teacher of most of the good surgeons, and there were few large cities where the pupils of *Desault* were not among the best surgeons. In the twelve years that he was chief of the hospital, the sum of practical

knowledge which accrued to French surgery was greater than in the fifty preceding years. His successors were not in a position to continue instruction according to the method introduced by him, as they could not cope with the clergy and the nunneries; they fell back again into the old beaten path.

(To be continued.)

OPENING OF "THE WALTER GARRETT MEMORIAL BUILDING" OF THE PENNSYLVANIA HOSPITAL.

PHILADELPHIA, APRIL 24, 1897.

The managers of the Pennsylvania Hospital, having decided two years ago that the requirements of modern surgery demanded greater facilities than the hospital possessed at the time, appointed a committee to visit hospitals in other cities and confer with the surgeons of the institution with regard to necessary improvements. Under the guidance of Mr. Addison Hutton, architect, plans were drawn for important additions to the institution, and the work was energetically pushed to a conclusion. Through the liberality of a former president of the board, Mr. Wistar Morris, principally, the erection of a new series of buildings, upon the Spruce Street front, was undertaken and completed, which now contain the entire surgical division of the hospital. Last year, work on the remaining portion of the comprehensive plan was begun. The magnificent operating pavilion, receiving wards and children's wards, embodied in the large building known as the "Garrett Memorial," at the corner of Eighth and Spruce Streets, is now finished and was opened by the managers April 24. Addresses were made by Drs. Thos. G. Morton, J. M. DaCosta and J. B. Chapin, of the medical staff. The announcement was made that this building, believed to excel any of its kind in the world in completeness of its appointments, had been erected solely through the liberality of one member of a family of philanthropists, to which the hospital was already largely indebted for most generous gifts.

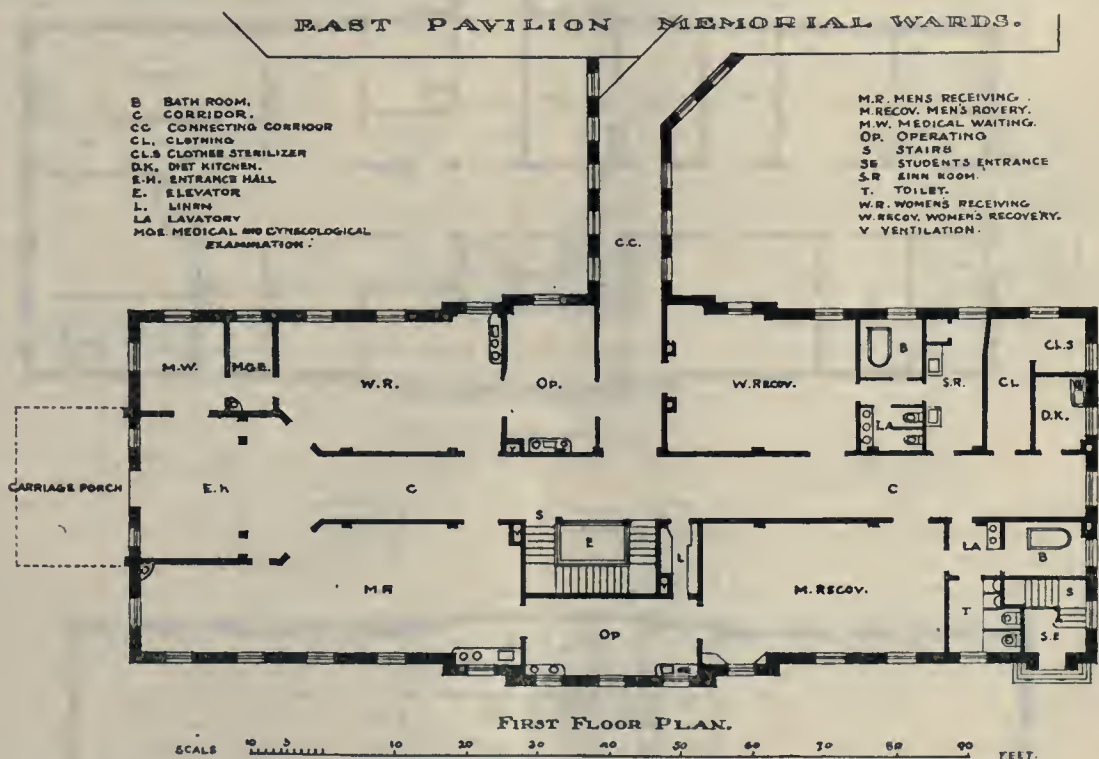

Description of the building.—Entering from the Eighth Street or eastern gate of the hospital, midway between Spruce and Pine Streets, and turning to the north, a broad cemented drive and sidewalk lead to the doors of the new building, about one hundred feet distant. A large glass porte-cochère overhangs the entrance, so that the injured and sick as they are brought by ambulance, police patrol or private conveyance, can be taken into the building without exposure to the weather. The first floor is but a single step above the grade. Passing through wide doors, one enters a large and well-lighted vestibule or lobby. On the left, opens a waiting room for ambulatory medical cases awaiting examination and perhaps admission, next to which is a smaller room in which physical examinations may be conducted. Upon the left side of the lobby is located the clerk's desk, connected by telephonic communication with every portion of the hospital; there are here placed benches for those inquiring after friends or accompanying the injured. At the farther end of the lobby, a wide central hall extends to the stairs and elevator, and also to the corridor connecting this building with the other buildings of the hospital. Upon either side of this hall, opening at an angle to the lobby, are doors leading to the receiving wards—that on the right for men, and on the left for women. The men's receiving ward, measuring 53x18, termi-

nates at the farther end in doors leading into a small operating room. Cases not to remain in the hospital will receive dressings or minor operations in these rooms, and then depart as they came. But those patients who are to remain will pass from the operation and dressing rooms through other doors, into a large reception ward. This ward will contain fifteen beds and in it all patients will be undressed, bathed and put in proper condition to be distributed to such portions of the main buildings as their disease or injury may require. At the northern end of the ward opens a passage communicating with the baths and lavatories. Patients found to require serious operations, after being prepared as far as possible in this apartment, will then be transferred to the second floor.

The women's receiving ward, to the left of the lobby, is similar to that for men, but not so large. It likewise opens into an operation and dressing room at its northern end, and beyond is a similar but smaller ward. Patients recovering from anesthesia after minor

oven, in which clothing infected with disease germs or vermin may be steamed or baked sufficiently to destroy effectually not only all parasites, but their eggs as well, a very important consideration for the protection of the hospital from such pests. At the extreme northern end of the corridor to the left is placed a diet kitchen from which to serve food to those temporarily occupants of beds in the quiet wards. Sufficient beds are provided in the reception wards to house all who may be admitted between sunset and morning, so that the quiet of the main wards may never be disturbed by entry of new patients during the night, or at any other time by those in danger of speedy death, or recovering from the effects of ether, or under the influence of liquor.

At the exact center of the building, on the right hand, a capacious elevator runs from basement to roof, surrounded by iron grill work, and a broad marble staircase. Opposite the elevator and stair shaft is a corridor, nine feet wide, leading at right angles to

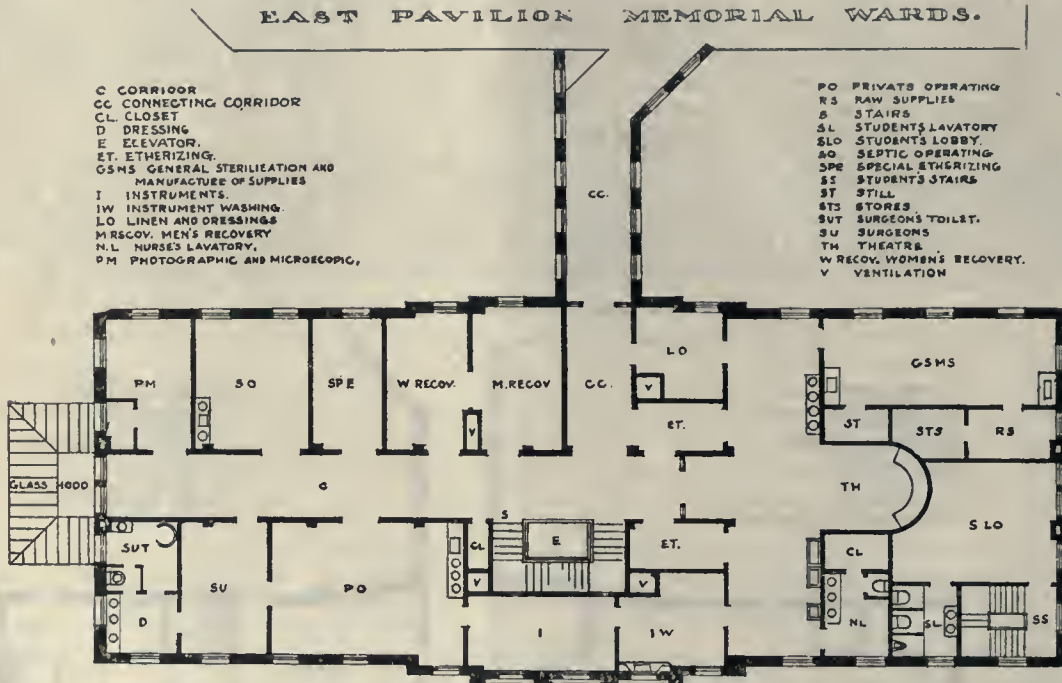

operations will be detained in the reception wards until they are in condition to return to their homes. Sunstroke cases, as heretofore, will not be taken into the receiving wards, but will be treated in the cool, deep basement, or in large tents in the airy grounds surrounding the building, until fit to be removed to the main wards. Beyond the women's bath and lavatories, but communicating also with the main hall, is an apartment where scullery work is done for all the wards of the floor. Here will be a flushing sink for washing utensils, sinks, racks for drying, and a steam-closet wherein all articles of clothing, etc., may be warmed or dried rapidly. When it is considered how many of those coming to a hospital are cold and wet and shocked by exposure, loss of blood and concussion, it will be seen how useful this novel feature will be. Next, on the north, and opening only to the hall, is a room devoted to temporarily ticketing, bagging and storing the clothing of each patient. From it opens a small room containing a steam and hot air sterilizing

the main corridor of the basement of the hospital, thus affording ready access to all the basement corridors of the whole institution and to the elevators running upward therefrom to the various divisions and wards. The receiving wards will thus become the distributing center for all cases admitted. Patients will here be examined, cleansed, put to bed, receive preliminary treatment, and be classified for distribution to the appropriate wards. Persons destined to occupy private rooms will pass at once through the corridors, on wheeled trundles, to the elevator leading to those apartments, without passing through the receiving wards.

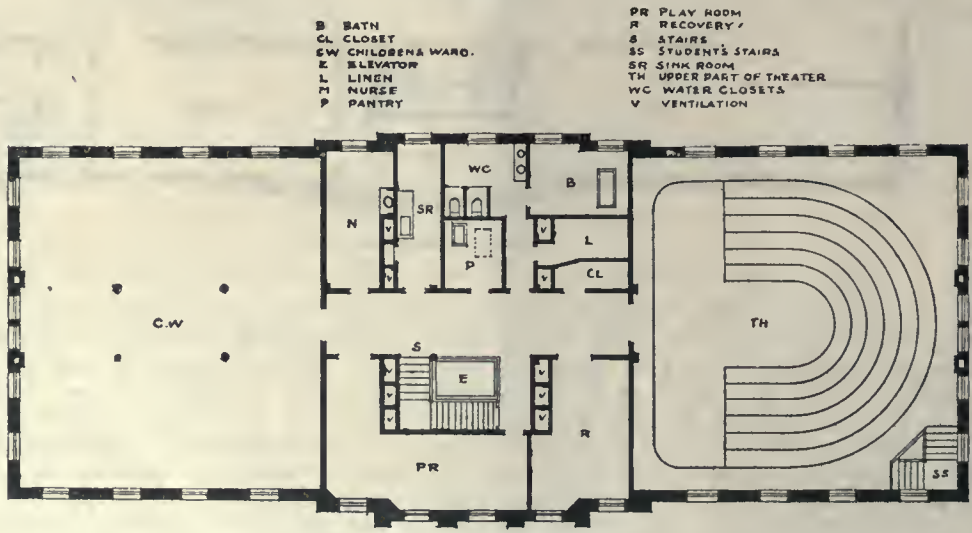

Ascending to the second floor, the visitor finds himself surrounded by the most complete series of rooms and arrangements to facilitate modern surgical treatment that has yet been installed by any hospital in the world. To the right, as he alights from the elevator or ascends the beautiful marble staircase, large double doors lead into the great amphitheater, or

main operating room, where clinical instruction will be given. On either side of these doors, in communication with the corridor, as well as the amphitheater, are two rooms where patients can be quietly etherized before being taken into the operating theater. This amphitheater, measuring 45x46, is lighted by a great glass dome covering its entire center, and many plate glass windows surrounding it on all sides. But, as if this were not sufficient, the whole central

roomy and comfortable iron and wood suspended chair, very different from the hard wooden benches to which medical students have been so long accustomed. Behind the actual operating space, a clear area of 13x46 extends from one side of the building to the other, which facilitates ingress and egress of beds and permits the assemblage, without crowding or confusion, of those appliances and conveniences which have become necessary to the highest develop-

SECOND FLOOR PLAN.

THIRD FLOOR PLAN.

portion of the roof toward the north has been made transparent by great sheets of thick plate glass. Under the glazed dome stands the operating table in a large open space, surrounding which on three sides (toward the north) arise seven tiers of seats, numbering in all 200. These seats rise abruptly, so that every spectator will have a free view over the heads of all sitting below him. Each student will have a

ment of the healing art. On either side of the operating space are located sinks, flushing tanks, wash basins, pipes bringing steam for heating and sterilizing, and other pipes from which sterilized water can be drawn of any desired temperature, from a splendid brass water filter and sterilizer on the right side of the area.

There are also provided steam closets for heating

blankets and linen, racks holding swinging bottles of antiseptic solutions, movable tables for instruments and dressings and other appliances. A cluster of electric lights above the operating table afford light at night, and electrical apparatus is also provided for resuscitation and treatment.

The spectators or students enter the amphitheater by a special gate and door opening from Eighth Street, at the corner of Spruce. This entrance, approached by a flight of broad granite steps, is one of the principal architectural features of the building. Ascending a short stairway, a large student's lobby is reached, from which open a coat room and lavatories, while, again ascending the stairs, the area surrounding the amphitheater above the seats is entered. Thence, flights of descending steps render all of the seats easily accessible. It will be noted that by this arrangement the students are practically kept outside of the hospital; their relation to the operating and lecturing portion of the room will be similar to that of an audience to the stage in a place of entertainment, except that the floor of the operating space is some four feet below the first tier of seats.

On the right hand of the area, behind the operating space, doors open to the nurses' dressing room beneath the seats. Here all nurses who are to assist at operations will invest themselves in sterilized linen clothes and prepare themselves with the same care as the surgeons for carrying out the antiseptic details. This room has washbasins and other necessary fittings, as well as a water-closet. Upon the other side of the amphitheater, a door leads under the seats into a long room where all the dressings of the entire hospital will be manufactured. This apartment is fitted with a battery of four high pressure steam sterilizers, sinks, and all other apparatus, such as cutting and winding machines, that go to make up a small factory for surgical supplies. Directly opposite this room, across the area of the operating room, is another room devoted to storage of the finished supplies, which room also communicates with the corridor to facilitate distribution of the supplies to those coming for them from the various wards and smaller operating rooms.

Leading to the south out of the operating area, is a small room devoted to washing and sterilizing instruments. Next to the south, is the instrument room where is aggregated the surgical armamentarium in five large cases of plate glass and enameled iron. South again of the instrument room is the private operating room. This large chamber is devoted to such operating as is done upon private patients or when the amphitheater is in use by another surgeon. It is fitted complete for all ordinary purposes, and is perfect in its appointments as the main operating room, but will contain no provision for onlookers.

The remaining rooms in this suite along the south side of this building, are devoted to the private use of the medical staff. The first is a sitting and consulting room; the second a dressing room, while a third comprises a lavatory and bathroom. All of the rooms between the instrument room and surgeon's lavatory, besides communicating with each other, open upon the main corridor.

Upon the west side of the corridor are located two rooms for the recovery of male and female patients from the effects of anesthetics before being transferred back to the wards. Next a room for etherizing patients for the private operating room. Next again, is an entirely novel feature, namely, a room devoted

exclusively to operations upon cases affected with virulent and dangerous infectious diseases, such as lockjaw, anthrax, glanders, tuberculosis, gangrene, etc. This room is lined throughout with hydraulic cement, and has doors and windows of such special design as will permit it to be filled by live steam under slight pressure. The plan is to here operate upon virulent cases and then leave everything that has been used in the room. The doors will then be securely fastened, and, from attachments in the corridor, steam will be turned on from pipes suspended all around the cemented walls so as to flood the chamber with an element absolutely destructive to all germs. After a sufficient exposure to this agent, the room may be cooled off and entered. It is thus expected to do away with what has been a great danger in the past from these virulent cases that from time to time must be admitted and occasionally communicate infection to other persons. The last room on this side of the corridor, the southwestern corner, is to be devoted to microscopic and photographic work. It will contain a dark room, sinks, and other necessary appliances and will be especially fitted for elaborate use of the Roentgen X-ray, fluorescent screens, and skiagraphy.

The second floor, or operating suite, connects by corridor with the main floor of the surgical pavilions of the hospital, so that patients are transported the shortest possible distance between the wards and operating rooms.

The entire third floor of the new building has been assigned to a large children's ward, comprising space for twenty-five beds, nurse's room, pantry and diet kitchen, sink and utensil room with steam drying closet, baths, lavatories, a small isolation ward, and a large cheerful playroom and sunbath.

SELECTIONS.

On New Tuberculin Preparations by Robert Koch.—After a long silence, R. Koch addresses (in the *Deutsche medicinische Wochenschrift*, April 1) the profession with new theories and facts on the subject of tuberculin and immunization against tuberculosis. The results are more likely to startle the medical world in a still higher degree than the tuberculin era. But experience has been sufficient to guard this time against over-enthusiasm, and will enable the scientific world to form a closer analysis of the subject and perhaps give some new directions.

According to Koch, immunity may be brought about by only one factor, but it is not necessarily so; it can be composed of two components or perhaps more. One is simple and pure immunity to toxins, as in tetanus (Behring, Kitasato). It disappears after several weeks. Another is pure bacterial immunity, exclusively against the body of the bacterium, like immunity against cholera and typhoid fever (Pfeiffer). The ideal immunization must therefore have the purpose to protect the animal or human body against every danger and not only against the one single danger derived from the microorganisms.

In men there is apparently no immunity against tuberculosis, and cured individuals are more susceptible to infection, but there can be observed under certain conditions an immunity in this disease. The observation of miliary tuberculosis in man and guinea pigs shows that there is, as a rule, a stage where the bacilli disappear, which in the beginning were present in great number. This true bacterial immunization comes generally too late for the victim. These observations have given occasion to Koch to discover a method by which such immunization can be produced at a time which is valuable to the vic-

tim. He starts from the fact that immunization can only take place in such cases where the body is inundated in a short time by bacilli in great number, and he finds in this fact the explanation why in an average case of localized tuberculosis, there is no apparent immunity. The bacilli in the body are only in small number and grow slowly, mostly surrounded by necrotic tissue, and are absorbed only after a long time after their death and following chemical decomposition. Where the bacilli grow in large number, as in cavities and on the surface of mucous membranes, they are not absorbed at all and therefore general immunization can not take place.

In his efforts to obtain artificial immunization he is, therefore, guided by his theory that such immunization is only possible when numerous tubercle bacilli are distributed rapidly in the body and come into actual contact with living tissues, as in military tuberculosis and in experimental guinea-pig tuberculosis. As nearly as possible similar conditions must be created. In his effort to produce this he met with considerable difficulty, as bacilli distributed throughout the body in large quantities are only very slowly absorbed. He therefore considers that bacilli which are unaltered in their structure are not suitable for immunizing purposes. To facilitate their absorption he followed in general three different processes: First, treatment of the bacilli with chemicals and heat; second, extraction of bacilli; third, destruction of the bacilli by mechanical means.

The treatment with chemicals (diluted mineral acids or boiling in concentrated alkalies) gave preparations which were slowly absorbed, and this process was followed by two great changes in the composition of the bacillus with a destruction of the immunizing power.

Through extraction of the bacilli by glycerin and the employment of the absorbable constituents he arrived at tuberculin, whose diagnostic value he emphasizes and to whose therapeutic value he adheres. But he believes that only immunity against toxins, no bacterial immunity, can be produced by it. The reactions produced by tuberculin, which according to his statement are essential for the immunizing effect, subsided before an absolute cure is perfected. Hence his efforts to produce a bacteria immunizing preparation. The extraction of the bacilli with a decinormal solution of sodium hydrate without complete filtration of remaining bacilli, gave a preparation which he calls *TA* (alkalin extract), with not entirely satisfactory results, on account of the difficulty of absorption of the remaining unaltered bacilli. After filtration to remove them the immunizing power was too much decreased. To make the constituents of the bacilli easier attackable for the absorbing elements of the body, Koch resorted to their complete destruction by mechanical means.

The necessity of such procedure seemed confirmed through the observation of certain constituents of the tubercle bacilli, namely, two chemical bodies, which Koch classifies among the group of "unsaturated fatty acids." The first is soluble in dilute alcohol and readily saponified by sodium hydrate, the second is only soluble when boiled in absolute alcohol or ether and very difficult to saponify. Both are stained intensely by carbolic fuchsin and retain stain after being treated with dilute nitric acid and alcohol. The extraction of the first variety of fatty acids leaves the second, which retains the stain and therefore is the bearer of the specific staining of the tubercle bacillus. These latter "fatty acids" can slowly be extracted by hot sodium hydrate and the process may be followed under the microscope. The "fatty acids" leave the body of the bacillus in stainable drops, the bacilli retain their form from the beginning, but do not take up the specific stain. Koch believes that these fatty acids form a protective "cover" against absorption of the bacillus in the body. Hence the necessity to destroy this protective cover.

By crushing and pulverizing the perfectly dry and virulent cultures in an agate mortar and centrifuging a suspension of

the powder in distilled water until no more stainable bacilli are present, Koch derived two preparations, which contain all immunizing properties which can be obtained from the bacilli. The opaque fluid above (oben) the sediment after centrifugation is called *TO*, the sediment or remainder (Rest) is named *TR*, which is treated by the centrifuge again until no sediment derived from constituents of the bacilli remains and a clear fluid is obtained.

TO shows after first staining with carbolic fuchsin and afterward with methylene blue, purple cloud-like formations, while *TR* shows masses stained blue. Fifty per cent. glycerin does not change *TO*, while it precipitates *TR*. Koch therefore thinks that *TR* contains those constituents of tubercle bacilli, which are not soluble in glycerin, therefore not contained in the glycerin extract. *TO* has similar qualities as tuberculin and corresponds in efficiency with the alkalin extract *TA*, except that there is no danger of forming abscesses after subcutaneous application. The immunizing properties are very similar.

TR acts decidedly immunizing. It causes reaction in tuberculous individuals if too large doses are employed, but the effect is entirely independent of the reaction. With tuberculin *TA* and *TO* it is necessary to produce reaction in order to produce curative effects; not so with *TR*. "The value of this preparation is expressed by Koch as follows: That *TR* represents all immunizing factors contained in the culture of tubercle bacilli is evident from the fact that a man who is immunized against *TR*, even if all reactions were avoided, does not react any more to large doses of simple tuberculin and *TO*, he is immunized against all components of the bacillus. I have observed this property of *TR*, which appears to be of utmost importance, in such a large number of cases, that there can not be any doubt as to the correctness of the observation."

Koch further gives some technical details about the preparation of *TR* and directions for its therapeutic employment, which consists in subcutaneous applications with avoidance of reaction, until the highest possible dose (20 mgr.) can be arrived at.

In a summary of the animal experiments he points especially to the progressive changes in liver and spleen, disappearance of the necrotic yellow foci, in place of which he found grooves on the surface, which give to the organ an uneven characteristic appearance (cicatrizations). A cure of tuberculous guinea pigs, in which the disease, as is known, progresses very rapidly, could be perfected by Koch only when treatment was early begun one or two weeks after inoculation. This rule applies also to man. Very advanced cases, especially those with secondary infection particularly by streptococci, are only rarely accessible for the specific treatment of tuberculosis. Koch excludes in general those patients with a temperature above 38 C. (100.4 F.). He has treated a number of suitable patients with lupus, and has to report without exception considerable improvements. He speaks only of improvements, though not a few cases would merit the expression cured, which he does not wish to adopt before a sufficiently long period without relapse has passed. In lupus he obtained continued improvement with very slight local reactions. In pulmonary tuberculosis the increase of râles was the only local symptom, which soon subsided. The quantity of sputum decreased even after a few injections and often it subsided entirely, with a corresponding disappearance of râles and decrease of the area of dulness.

In conclusion, Koch believes that possibly other methods, perhaps combinations with *TO* or with serum preparations, which are obtained with *TO* or *TR*, may lead to better and speedier results. But he maintains that further improvements of the preparation as such can not be expected.

It is apparent that the long looked-for article of Koch makes us richer by one new theory of immunity in tuberculosis, but

great reserve will be necessary as to the acceptance of the therapeutic conclusions thereby gained. We have certainly to await the promised publication of his experiments on animals and men before we can judge further. As far as it can be conceived the results he has arrived at in guinea pigs are identical with that of other experimenters. In this country the experiments with preparations from the tubercle culture, which were published some time ago by Professor Klebs, showed in guinea pigs the same grooves and disappearance of necrotic parts in liver and spleen. He demonstrated microscopically the regressive changes taking place in the tubercular tissue and published photographic reproduction of the appearance of the liver and spleen in experimental animals, proving the possibilities of artificial immunization. It is to be wondered how little credit in general Koch gives to other experimenters outside of the "Institut für Infektionskrankheiten," and particularly those working in this country. As to his discovery of fatty acids in the bacilli, which fact induced his idea of the necessity of employing mechanical means to favor the solubility of the bacilli, it seems evident that these acids are originated from the fats, which were observed long before Koch, especially in this country. Hammerschlag and Nensky observed them first and Dr. de Schweinitz of Washington made the first quantitative determination. Independently of the latter, Professor Klebs has published in the *JOURNAL* the results of his experiments (July 25, 1896). He found two fats in the bacilli, with different fusing points and gave an exact statement of their physical and chemic quantities and especially he pointed out that these fats are the single cause of the specific staining of the bacilli. Abell of Baltimore further found glycerin in the alcoholic ethereal extract, explaining the high hygroscopic quality of the bacilli.

All the important results of these tedious experiments of prominent scientists in this country are completely ignored by Koch, or if known, no credit is given for them. In the interest of true science it is to be regretted that Koch and the other members of the "Institut für Infektionskrankheiten" try to assume an autocratic leadership of the whole scientific world. Nevertheless the way opened by Koch through his tuberculin and his latest experiments allow reasonable expectations in the "causal therapy" of tuberculosis, but it will need the work of others and the combination of many factors, to reach an absolutely satisfactory result.

Lake Erie as a Source of Civic Water Supply.—The continued presence of *typhoid fever in any municipality is as inexcusable as vermin in a modern dwelling*, and indicates a degree of shiftlessness and apathy not consistent with modern methods and needs.

Lake Erie, the water supply of Buffalo, as well as of the cities of Toledo, Cleveland, Dunkirk, Erie and Ashtabula, is subject to periodic upheavals, due to its shallowness and the strong west and northwest winds occurring during the winter and spring months. As a result Buffalo has roily water during five or six months of the year, beginning with November or December and lasting until May or June. It will be interesting, therefore, to compare the results obtained by the city chemist and city bacteriologist of Buffalo and see how they agree or disagree.

Both chemic and bacteriologic examinations of the water should be made, at least once weekly, to determine its character as a safe or dangerous water for domestic use, and if contamination is shown to exist, the services of an engineer be enlisted to detect, if possible, the cause and origin of such contamination. This last proposition is the one to which I wish to call attention. Who is to decide whether a water is potable, if the chemist and the bacteriologist do not agree? Up to within a few years ago a chemic examination of water was deemed sufficient to decide its potability, and upon the decree of the chemist the water was either accepted or rejected.

The chemist was generally able to detect the presence of decomposing organic matter, either vegetable, animal, or both, which in his analysis was indicated by the presence of ammonium compounds and the oxygen-consuming power of the water. The ammonium compounds, particularly the albuminoid ammonia, are usually the result of putrefactive fermentation of nitrogenous matter, and water of high purity should contain from none to .041 parts per million, while in impure water it ranges upward from .082. The chemist is only able to say that a water contains organic matter in the process of fermentation, but can not say how virulent or innocent are these destructive agents. It is now generally accepted that organic matters, which by one means or another find their way into surface waters, are oxidized and eventually reduced to simple substances by the operations of microorganisms, and not by mere chemic changes independent of them. In other words, the oxidation of impure, polluted water is the result of bacterial activity; but what is their nature?

The decree of the bacteriologist is now imperative in deciding the pathogenic or non-pathogenic character of the bacteria. The water from artesian wells contains no bacteria, while that of sluggish streams, lakes and rivers receiving the sewage of large cities contains millions of colonies per cubic centimeter. Authorities consider a water having 250 bacteria per cubic centimeter, or less, as entirely safe and usable.

It is now generally recognized that the mere enumeration of the number of colonies which develop from a water under investigation is not a sufficient indication upon which to found an opinion as to its potability. The greater number of colonies, the more organic pabulum is present for these microorganisms. The bacteriologist is not able as yet to give any definite idea of the amount of such organic matter, while the chemist is able to do so with considerable precision. But the bacteriologic examination may prove of great value if it succeeds in demonstrating the presence of certain pathogenic bacteria, and in thus preventing the use of a dangerous water. Moreover, the number of colonies is an index of the probable quantity of organic matter which may come from a dangerous source; and the dangerous pathogenic bacteria are not only likely to be present in such water, but they can more readily multiply in it. The number of varieties of non-pathogenic micrococci found in water is about thirty, and pathogenic micrococci two—the staphylococcus pyogenes aureus and the micrococcus Biskra. Of the non-pathogenic bacilli seventy-nine varieties have been found, while of the pathogenic bacilli sixteen varieties, including the bacillus of typhoid fever, of cholera, and the bacillus coli communis. These three varieties are the most important findings possible of a bacteriologic examination, and are positive proof of the presence of alvine dejections in the water.

In January, according to the city chemist, the water was in good condition, while the bacteriologist again found the bacillus Janthinus, and reported the water to be in "very poor condition" for the first half of the month and a gradual improvement the last half. The number of typhoid deaths decreased to five. In February and March both officials found the water in good condition, also evidenced by the death rate and the typhoid deaths, three and four respectively.

For the months of April and May there exists a disparity between the two reports, the chemist claiming that the water was in "excellent condition" during May, while the bacteriologist found the water "not in good condition," because of large bacterial contents. The deaths from typhoid fever were four—an unusual time for typhoid to be present. For May the chemist found evidences of contamination, while the bacteriologist, on the preceding day, considered the water in good condition, containing on that day only 270 bacteria per cubic centimeter. In June both officers found the water in good condition.

Reviewing the opinions of the city chemist and the city bacteriologist, it is evident that the disparity occurs whenever the water is in an improper and unhealthy condition, and when such is the case, it is only fair to assume that some error has been committed favoring the water.

The bacteriologic examination as well as the chemic analysis are, therefore, alike necessary in demonstrating the purity and safety of a drinking water, and neither should be omitted when the least suspicion exists as to its contamination. The consumers should be immediately warned of the dangers of using such water in its raw state, and should be enjoined to make some attempt at purification, either filtering, boiling or condensing. This applies not only to those cities whose water supply is open to contamination, but to every city having a public supply.

Besides the chemist and bacteriologist, the water department of every city, whose supply is liable to contamination, should have the services of an engineer whose fame does not rest upon his theoretic knowledge and bureaucratic propensities, but upon his practical information on the laws of hydrology and hydrodynamics. Such an one, well versed in the hydrography of his locality, could almost prognose the condition of its water supply and be an important aid to the city's health department. As such he would be able to render the same valuable services as does the local forecaster in meteorology, and give warning several days beforehand of marked changes in the quality of the water. While the chemist and bacteriologist are only able to detect impurities after contamination, the engineer could foresee these changes and give sufficient warning, or attempt to overcome the impending contamination before the city mains and reservoir are filled with the poisonous liquid.

Our present knowledge of the water supply question leads up to five propositions, as follows:

1. That the water supply of any city or village should not in any possible way be liable to pollution or contamination from the sewage of any other community.
2. That the sewage of a city should not be emptied into any watercourse not having a current of three to five miles per hour, and then the sewage entrance should be at a distance of one mile or more from the intake.
3. When the water supply of any city or village is a navigable stream, the water should be sand-filtered before pumped into the city reservoirs or water-mains.
4. That for ordinary drinking purposes the water should not be taken in its primitive or raw state, but be either filtered, boiled or distilled and aerated.
5. Both chemic and bacteriologic examinations of the water should be made, at least once weekly, to determine its character as a safe or dangerous water for domestic use, and if contamination is shown to exist, the services of an engineer be enlisted to detect, if possible, the cause and origin of such contamination.—*Dr. W. C. Krauss, in the Cleveland Journal of Medicine*, March.

PRACTICAL NOTES.

Successful Treatment of Sciatica with Copalba.—Dr. Glorieux reports three cases of obstinate chronic sciatica cured in a brief period with 40 to 50 drops of copaliba a day, divided into several doses and taken on wafers.—*Semaine Méd.*, March 24.

Sterilization of Glycerinated Vaccine Pulp.—Exposure of the pulp to a temperature not over 30 to 37 degrees C. and for not longer than twenty-four hours, will kill the staphylococcus aureus and albus, without injuring the vaccine.—*Semaine Méd.*, March 31.

Methylene Blue in Headaches.—Benno Levy recommends methylene blue as extremely effective in curing headaches. He prescribes it in gelatin capsules: methylene blue (Merck) and pulverized nutmeg ññ 0.1; one capsule four times a day. One

capsule brings relief and four usually complete the cure.—*St. P. Med. Woch.* from *Berlin klin. Woch.* No. 45, 1896.

Treatment of Chilblains with Compression.—Dr. E. Müller, observing that chilblains burn and sting more when the blood pressure in them is increased, has treated them successfully by compression. The member is first elevated for a while to reduce the amount of blood in it as much as possible, and then narrow strips of sticking plaster, 10 to 15 cm. long, are applied, lapping over each other, entirely covering the chilblain, and drawn so tight that the swelling is forcibly compressed over the entire surface.—*St. Petersb. Med. Woch.*, March 13.

Still Another Carcinoma of the Liver Extirpated.—Schrader describes a case operated seven years ago. The patient, a woman of 30, has been perfectly well since she was relieved of the neoplasm, 4x3.5 cm., which was removed through a large wedge-shaped opening, the wound in the liver cauterized and its edges sewed carefully to the edge of the wound in the peritoneum, thus making the wound in the liver extra-peritoneal. The abdominal wound was sutured as usual; there was no fever, and the wound had firmly closed over in eight to ten weeks.—*Deutsche med. Woch.*, March 11.

Two Hitherto Undescribed Symptoms in Addison's Disease.—Renner calls attention to a couple of phenomena that accompany this disease but are not mentioned in the text-books, the intolerable pruritus and the presence of numerous wart-like elevations scattered over the surface of the skin. He describes a typical case of the disease in which these wart-like prominences grew more numerous toward the end. At the necropsy the left suprarenal capsule was found in a state of cystic degeneration, with a cavity containing caseous products.—*Presse Méd.*, February 27, from *Ver. Bl. f. Pfaelzer Aerzte*, Vol. xii, No. 3.

Case of Goitre in a Syphilitic Cured by Thyroid Treatment.—The goitre had begun to develop five years before. At first it had yielded to electric treatment, but soon returned and resisted every form of medication and treatment, until thyroid tablets were administered, commencing with one and increasing by one every third day, up to five. The "effect was prodigious," and in less than four weeks the goitre had entirely disappeared. The syphilis was in the tenth year.—*Presse Méd.*, February 27, from *La Policlinique*.

Resorcis in Whooping Cough.—Roskam now has a record of 200 cases of whooping cough treated locally with a 2 to 3 per cent. solution of resorcis applied to the glottis on a fine sponge, every four hours during the day, commencing at 6 A.M. and once or twice during the night. In 200 cases the children were cured in less than fifteen days, and the general health improved rapidly from the first. Others report equally favorable results. Some administer the resorcis internally at the same time.—*Annales de la Soc. Méd.-Chir. de Liège*, March.

Modern Progress in the Treatment of Gout.—All that we can claim over the ancients is that we have a more rational conception of the diet required, although the most eminent authorities still disagree in regard to the particulars; that we have discovered in the amines powerful therapeutic aids, although none of the combinations yet discovered, piperazin, lysidin, lycetol and urotropin, are free from serious disadvantages, but the way is indicated for new and truly effective discoveries, and we also have found that there is a peculiar affinity between uric acid on the one hand and urea and salicylate of soda on the other.—*Deutsche Méd. Woch.*, March 11.

Iron and Arsenic in Anemia.—If the chemical transformations in anemic subjects are studied, the cases can be classified into two categories: 1, those in which the nitrogenous transformations are diminished and the oxidation decreased; the coefficient of nitrogenous oxidation falls to an average of 75 per cent. from 80 or 82 per cent.; 2, those in whom the oxidation and nitrogenous transformations are increased. The

medication beneficial in the first category is directly contra-indicated in the second, especially iron, which increases oxidation, and arsenic, which modifies these processes. The failure of iron in some cases, and its success in others, is explained by these facts.—*Semaine Méd.*, March 31.

Educating the Left Hand.—Bueno de Miranda describes in *O Brazil Medico*, January 22, his method of extirpating a subglottic polypus of the larynx with epiglottic complications which rendered it necessary to use the laryngoscopic mirror and the probe while extirpating the tumor. He accomplished it by educating his left hand until he could hold two instruments firmly with it; the mirror, held between the third phalanx of the middle and ring finger, the handle resting in the groove between the thumb and palm; and the probe, with its point wrapped in cotton, held between the third phalanx of the middle and fore finger, the handle resting on the pulp of the thumb. The two handles were pressed firmly together, the instruments crossed. By this means the right hand was left free to extirpate the neoplasm with ease.

Router's Method of Operating Uterine Fibromas.—1, opening into the anterior and posterior culs-de-sac through the vagina; 2, laparotomy and treatment of the adnexa according to indications; 3, exteriorization and enucleation of the fibromas; 4, enlarging the incisions into the culs-de-sac; 5, hemostasis of the broad ligaments with an elastic band placed astride each ligament, around which it is twisted twice, and the ends tied with a silk ligature; section of the pedicles; ablation of the tumor; 6, toilet of the peritoneum and drawing the elastic fastenings into the vagina; they drop off spontaneously in twenty to forty days. His experience has been nineteen cures and four deaths with this technique.—*Presse Méd.*, March 27.

Pneumococcus Peritonitis in Children.—This disease can be readily diagnosed and as it yields at once to surgical intervention, Prof. F. Brun describes the symptoms so all can recognize it, in the *Presse Méd.*, of February 27. It commences with violent pain in the abdomen, fever, vomiting and diarrhea. In a short while this general commotion subsides, and the fever assumes the characteristics of a suppuration fever, while a dull, thick tumefaction appears in the iliac fossa above the pubis, in some cases with fluctuation. This local lesion is significant alone, but it assumes almost pathognomonic importance when it is accompanied by the special sign which he has found mentioned in nine of the fourteen cases on record (Lucas-Championnière, Jalaguiet, Kirmisson), the swelling and inflamed appearance or fistulization of the umbilicus. In these fourteen cases, three died; one recovered after spontaneous evacuation through the umbilicus and into the vagina. The remainder recovered after laparotomy. His own experience has been four recoveries in five cases. The operation required is very simple, scarcely more than opening an abscess. In the fourteen cases, all under 15, the diagnosis was confirmed by bacteriologic investigation, and all but three were females. He suggests that the latter fact may elucidate the methods of peritoneal infection, as in every case where the lesions were clearly defined they were located in the lower part of the serosa.—*Presse Méd.*, February 27.

Ascites in the Omentum.—A comparative study of this rarely recognized form of hydrops appears in the *Revista de Med. y Cir.* of February 25, the author, Dr. A. P. Miro, having had occasion to observe three cases. Relief and cure were obtained by puncture at a point midway between the xiphoid appendix and the left anterior, superior spine. The syndrome differs from that of ordinary ascites by the location of the pain and pressure in the epigastric instead of the hypogastric region, the gastric dyspepsia and sensation of fullness in the stomach after eating, the dyspnea after eating at first, and later, continuously, aggravated by moving about, and assuming the horizontal position, or by the slightest pressure on the epigastric

region, which may even cause syncope. There is resonance in the epigastric and hypogastric regions, with an area of dulness in the center, encroaching from above downward. The first point where fluctuation can be distinguished is in the upper part of the abdomen. The epigastric region is the first to protrude, and the last to subside after puncture. One case he described, required the introduction of a certain amount of artificial serum to counteract the effects of the withdrawal of over sixty liters of fluid in the course of twelve punctures, after which the patient recovered and has been in perfect health during the eighteen months since. He ascribes the accumulation of the fluid in his cases to the closing of the foramen of Winslow by congestion of the neighboring organs from the use of alcohol and highly seasoned food.

The Morphology and the Chemie Products of the Diplococcus Pneumoniae and Some Results of Vaccination.—Auld (*British Medical Journal*, March 27, 1897, p. 775) points out the difficulties surrounding isolation of the diplococcus of pneumonia in pure culture, as well as the variability in virulence that the organism displays. He describes the following as a delicate test for the purity of the growth: On the surface of sloping agar a streak-culture forms a very fine dew-like moisture, absolutely transparent with reflected light. If the slightest trace of opacity can be detected, the culture is impure. From the blood of inoculated animals that yielded a pure growth on agar were obtained an albumose and organic acid. Injection of the former into a vein was followed by shock and a fall in temperature, with subsequent elevation. No other pathologic effect was observed, although the animal lost in weight. Intrathoracic injection of the albumose was soon followed by marked dyspnea and elevation of temperature. When the animal was killed, pleurisy and consolidation of the lung were found, while the blood and the serum proved to be sterile. Injection of the albumose beneath the skin of the ear was followed by local inflammation and elevation of temperature, with loss in weight. Intravenous and intrathoracic injection of the organic acid was unattended with noteworthy disturbance. From pure cultures of the diplococcus in artificial media an albumose and an organic acid were obtained similar to those obtained from the blood, and exhibiting the same reactions when injected into a vein or the chest, or beneath the skin. It was found that animals treated cautiously with pure cultures were rendered immune. The same result could be secured by the employment of the toxin isolated either by evaporation or by precipitation with alcohol. Immunity was similarly conferred upon other animals by injection of the serum of animals thus rendered artificially immune.

Precocious Maturity.—Morse (*Archives of Pediatrics*, April, 1897, p. 241) reports the case of a female child that weighed fourteen pounds at birth and had large breasts and a little hair on the pubes, which at the age of two months had become considerable. At the age of nine months a bloody vaginal discharge was observed, and at this time the child weighed twenty-eight and one-half pounds. The discharge recurred at monthly intervals, increasing progressively in amount until it reached that observed in adults. At the age of 14½ months the girl presented the general appearance of a child of three years. With her clothing she weighed thirty-six pounds and her height was 32½ inches. The breasts were prominent and each contained a mass of glandular tissue as large as a pigeon's egg. The nipples were well developed and surrounded by a dark pink areola and a little hair. The mons veneris and the labia majora were large and covered with a profuse growth of hair. The labia majora were well differentiated and fairly large. The clitoris was distinct but not disproportionately large. The hymen was distinct and easily distensible. The vagina was distensible and contained rugæ, and the cervix was distinctly felt. From a study of this case and of those recorded in the

literature the conclusion is reached that precocious maturity is a physiologic congenital anomaly of development. Menstruation is never the first symptom, but is always preceded and accompanied by others. Menstruation most often appears in the first two years and is accompanied by ovulation. The attributes of maturity are not all acquired before the age of seven or eight years. Sexual desire is soon developed and pregnancy may occur early. Menstruation may continue as long as when it begins at the normal time. The etiology of precocious maturity is unknown and the relation to precocious menstruation is obscure. There is no medical treatment. As the mental development of the unfortunates afflicted with this condition is usually far less than the sexual and physical, they must be carefully guarded against voluntary or involuntary intercourse.

Removal of Tonsil, Floor of Mouth and Half of Tongue by External Pharyngotomy for Epithelioma.—Morton (*British Medical Journal*, March 27, 1897, p. 780) reports the case of a driver on a locomotive engine, 55 years old, who came under observation with a history of a "pricking soreness" at the back of the tongue and in the throat, which had been present for five weeks. He could swallow only liquids and these only on the left side, and with much pain and difficulty. Inspection of the interior of the mouth disclosed a hard, ulcerated, warty growth on the back of the right side of the tongue, involving also the floor of the mouth between the back of the tongue and the jaw and the junction of the tongue and the anterior pillar of the fauces and extending on to the tonsil. Only one enlarged submaxillary gland could be felt. When the patient was anesthetized a hard growth could be felt in the tongue, extending to the middle line, and the tip of the finger could just be passed behind it, down the pharynx. The trachea was first opened and a Hahn's cannula inserted, and later the lower part of the pharynx plugged with a sponge as well to prevent the entrance of blood during inspiration. The left lingual artery was then tied and the mouth on the right side opened exactly as in excision of the tongue by the method of Kocher, the right lingual artery being tied at the same time. Some enlarged submaxillary lymphatic glands were removed. The growth was found to have infiltrated deeply into the tongue toward the hyoid bone and the tongue had to be divided close above the great cornu and somewhat beyond the middle line, thus leaving rather less than half the organ. The cheek was then separated upward from the jaw just in front of the masseter and the jaw divided at the junction of the body with the ascending ramus, so that on traction outward of the latter the tonsillar region could be seen fairly well. The growth was fixed to the external pterygoid muscle, a portion of which also was removed. The pharyngeal wall, where infiltrated by the growth, was also adherent to the external carotid artery, but it was readily peeled off. The tongue was not separated from the tonsil and the diseased portion of the pharynx, but all were removed in one piece. The growth had not invaded the jaw, but the periosteum was stripped off with it. The jaw was wired at the end of the operation and the stump of the tongue sutured to the soft tissues on the inner side of the front of the jaw. The operation was rather a protracted one, but was followed by but little shock. The patient was nourished through a tube introduced into the stomach and left *in situ*. The mass of growth in the tongue was about the size of a walnut and of the typical hardness of epithelioma, of which also it presented the microscopic appearances. The tracheotomy tube was retained for ten days and the stomach tube for rather more than a month, but by firmly plugging the external opening into the pharynx the man could swallow fairly well three weeks after the operation. In the course of six weeks the opening in the neck had so far contracted as to just admit the end of the thumb, and five weeks later it was only a minute sinus. The man could now eat mince-meat and speak so as to be understood, and he had gained flesh to a considerable extent. Four months after the operation the sinus in the neck was closed and the man returned to his work. There had been no sign of recurrence seven months after the operation.

Typhoid Fever in Infancy.—Dr. W. P. Northrup, in the *Albany Medical Annals*, March, takes for his thesis the position that typhoid fever is a rare affection in infancy. He says: At the New York Foundling Hospital, in twenty-five years, there is no record or remembrance of a case. This statement is made on the authority of Drs. O'Dwyer and J. Lewis Smith. In my own experience of fourteen years at the same institution, clinically, no case has been seen. I may add that from my first entrance into the service, Dr. O'Dwyer and myself have been literally looking for it. Furthermore, in 2,000 necropsies upon subjects under three years of age, for which statement I am personally responsible, no typhoid fever was verified. Of the 1,800 infants and children usually under the care of the institution, 1,100 are out at nurse in the environs of New York, Staten Island, Hoboken, Jersey City, Westchester County, Astoria, Williamsburg, Long Island City and intervening points, beside the crowded parts of New York and Brooklyn. All these are under three years, and a majority under two years. For the most part the food of these children is milk and water. Above the first year probably the milk is not warmed, to say nothing of boiling. Children drink copiously of water. There have been now 25,000 infants from the Foundling Hospital living about among the community and no case has returned with recognizable typhoid. They are not specially protected, but rather unusually exposed. Let it be remembered, too, in this connection, that our large hospitals receive their full typhoid crop of adults from just these localities, not a few of them finding their way to my own service at the Presbyterian Hospital. A child over one year old will receive from her ten dollar-a-month nurse many delicacies, but the milk will be the main feeding, and that milk will often be procured at the corner grocery. Corner-grocery milk is almost a by-word for unreliability. After watching for twelve to fourteen years for a case of sporadic typhoid in infancy, I entered into an investigation with other institutions. I will refer to one. The New York Infant Asylum in eight years has not had a case of typhoid, 10,000 cases of illness having been observed in that time and 700 autopsies made (Holt). From the experiences of the New York Foundling Hospital and the New York Infant Asylum the statement seems justified that typhoid fever in the first two years of life is rare. On the other hand, in the presence of overwhelming infection (over-abundance of virulent bacilli in long continued contact), an infant, though naturally little vulnerable, may succumb to the epidemic infection. In the Stamford (Connecticut) epidemic, in which 406 individuals were attacked, I saw four infants sick of undoubted typhoid; 4 in 406. One was 13 months old, one of three in a household of four attacked, all having typical typhoid. The manifestations in this infant were fever, prostration, dry tongue, pallor, characteristic eruption, feelable spleen. One was 16 months, two were 22 months; of the latter age one died early in the disease with broncho-pneumonia. This is the only autopsy on a typhoid patient under two years of age I have ever made or have seen. It will be urged that the unusually careful management of milk designed for infants, its warming and sometimes its boiling, have much to do with the rarity in this period of typhoid. That may be true. Infants under one year are largely wet-nursed, too. Above one year I think it is the experience of most that the infant is given largely unboiled milk; they prefer it and are considered large enough to take it. Especially is this so in the associations from which the above experience has been gathered. Here is a chance, says Dr. Northrup, to make use of the newly discovered method of exact fever diagnosis, namely, the agglutinative serum test. If, and when this test shall have been applied, he expects that our Baltimorean and other experts in fever will find it expedient to revise their assertions as to the vulnerability of the human subject to typhoid fever in the first two years of life; except perhaps in times of epidemic prevalence with a superabundant and virulent contagium, such as the comparatively immune (if so let such immunity be demonstrated) constitution of the infant can not withstand or overcome.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the ASSOCIATION living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, MAY 1, 1897.

MEDICAL LEGISLATION IN 1897.

The progress of so-called medical legislation in the year 1897 has not been pleasant in many particulars. The Department of Health Bill in Congress has not been reported. Medical bills in New Hampshire have not been acted on. In Missouri we believe the osteopathy bill was slaughtered, but in Illinois the same bill, one of the most objectionable that could be offered, has passed its second reading, and there is great danger of its ultimately becoming a law. This curious measure is entitled "A Bill for an Act declaring the treatment of diseases of the human body by the system, method or science commonly known as osteopathy, and as taught and practiced by the American School of Osteopathy of Kirksville, Mo., not to be the practice of medicine within the meaning of section ten (10) of an act entitled 'An act to regulate the practice of medicine in the State of Illinois,' etc." This interesting bill recognizes the American "School of Osteopathy" of Kirksville, Mo., which is the only attempted recognition of an individual medical school in the statutes. An amendment in the senate committee erased the words "as taught and practiced at Kirksville, Mo."

In Michigan a bill, which gives color to the existence of the most objectionable forms of quackery, has been introduced, and curiously enough is supported by one wing of the profession who think anything better than nothing. Dr. MACLEAN, of Detroit, and his associates have been doing valiant work in attempt-

ing to defeat this bill, but the result is not yet definitely decided.

In Delaware the opticians have a bill, which is doubtless likely to pass, creating the degrees of Graduate Optician and Doctor of Refractions; the effect of which is to do away with the services of the oculist.

In Iowa the Practice of Medicine Act has passed.

In Wisconsin the Practice Act will probably pass.

Taking it altogether, we are of opinion that in the matter of legislation, Illinois bids fair to become worse than any State in the Union. Every quack in the State it is said, has "put up" his money to secure the passage of the "osteopathy" bill; while the bill of the Illinois State Medical Society, drawn with care and backed by the most able and respectable practitioners in the State, was strangled in committee.

We once more advise our brethren to take a part in political conventions and primaries, sufficiently active to become known to the lawmakers.

RHEUMATIC PERINEURITIS.

Of the nature of the causative agent of the group of symptoms that we are accustomed to designate acute rheumatism we have as yet little definite knowledge, although it is generally believed that they are dependent upon the presence in the blood of some toxic substance or substances, perhaps lactic acid, perhaps products of bacterial activity. In some cases microorganisms have been found to which specific etiologic qualities have been attributed, but the data of this kind are not yet sufficient to justify a final conclusion in the matter.

It seems probable that so-called acute rheumatism is of multiple etiology or that it occurs in several different forms. In favor of this fact the occurrence of arthritides, with or without pronounced constitutional manifestations and serious complications, in connection with a number of infectious diseases, *e. g.*, syphilis, gonorrhoea, scarlatina, smallpox, would seem to constitute weighty evidence.

Whether so-called muscular rheumatism represents an attenuation of the rheumatic intoxication or a distinct affection, must for the present remain an open question. Myalgia may arise from a variety of causes, toxic and otherwise, and the rheumatic poison may naturally be responsible for some cases.

The involvement of the serous membranes other than the articular synovial sacs in a considerable proportion of cases of acute rheumatism must be looked upon as a manifestation of the activity of the primary cause of the disease rather than as a complication of the articular affection. That under the conditions thus briefly pointed out the nervous system sometimes suffers, should occasion no surprise, and it is probable that the cerebral symptoms not rarely observed represent a manifestation of such involvement.

That the peripheral nerves also are sometimes affected, is pointed out in a recent contribution to this subject by STEINER (*Deutsches Archiv für klinische Medicin*, B. 58, H. 2, 3, p. 237), who from a study of a considerable number of cases of acute rheumatism in the Wieden Hospital of Vienna arrives at the conclusion that in this disease the perineurium, like the serous membranes, is often the seat of inflammation, and not as a secondary manifestation from contiguity to an affected joint, but rather as a common effect of the primary cause. This perineuritis may run a course parallel with that of the affected joint or it may be the more conspicuous manifestation. It may attend mild cases, as well as those of severe degree; and it may develop before the joint affection, at its height or during its decline. While age and the general condition appear to be without predisposing influence, females seem to suffer rather more commonly than males. Good therapeutic results may be secured under these conditions by conjoining potassium iodid with sodium salicylate in efficient dosage. Ringing in the ears may be overcome by the use of ergot. If pain be severe the coal-tar analgesics may be administered. The treatment may have to be continued for a long period of time. When the heart is sound hot baths followed by hot packs may render excellent service.

THE MONTREAL MEETING OF THE BRITISH MEDICAL ASSOCIATION.

The Canadian committee of arrangements for this meeting have already manifested an alarm that is grotesque, in supposing an invasion of American physicians would destroy the honor and dignity of this Association meeting.

In their frantic efforts to prevent this they have secured the services of the *Medical Record*, who urges all persons not specially invited to stay away. Then, as if they doubted the personal influence of the *Record*, they send to other journals a circular letter explaining that a few noted persons are to be invited, and that they are quite unable to accommodate the others. The committee evidently have a very limited knowledge of medical gatherings and are following the counsel of still more limited intelligence. The attempt to discourage the attendance of physicians from the United States is both a psychologic and business blunder. The effort to invite a few leading men and thus discriminate outside the members of the Association is unfortunate, unless very discreetly carried out, and confined to men who have clearly won the title of leaders by original work. The assumption that any great number of physicians would be anxious to attend this meeting, because it was the British Medical Association is pure "anglomaniā." The average medical man of the United States is familiar with society gatherings and is not likely to go far

from home among strangers as a mere visitor. Few medical men, comparatively, attend their own medical and national conventions, even when near at home, and it would require something very unusual to attract any large number to Montreal. If the committee had been wisely counseled they would have gone on quietly providing for the members first, then arranged for new members and members by invitation, who could, on the payment of a certain fee, be admitted to all the meetings. This would have brought in a good revenue, and a number of colonial members, materially increasing the power and usefulness of the society. Should the sections become crowded with papers, cut off all discussion and confine the readers to five or ten minutes time for reading. There would be no confusion, no unwieldy crowds, and all who had paid would be entitled to join in the festivities. Those who had not paid could look on as strangers, free and independent. Under any circumstances, not more than two or three hundred persons would have come from the States, and the most of these would have been listeners and sight-seekers.

Of course our Canadian cousins may be a little nervous, and being unfamiliar with such entertainments have some fears of the presence of too many plebeians from the States. The idea of suggesting that only those who are invited should come is childish in the extreme. It assumes that this Association is the great close medical corporation of the world, and that the American physicians are suffering for a chance to be present at the meeting. Also, should they come they would be unable to control them, and these physicians are in manners coarse, lawless and undesirable. There are about thirty members in the States, who are entitled to participate in the meeting, as they belong to the British Medical Association, and certainly less than a third of those will attend, and why the committee should be alarmed at the presence of those who are not members is unexplainable. It is certainly a reflection on the honor and culture of the medical men of the United States to ask them to stay away before any expression of voluntary attendance has been manifested. The zeal of the *Record* is alike offensive in supporting such an absurd position. The British Medical Association, like our ASSOCIATION, should be free and independent, and its management should be capable of controlling any crowd of members and visitors who may come. Every Section should be independent to adapt itself to the conditions of the meeting. The Montreal committee are not making their duties less, nor winning respect from the profession by sending out vaguely worded circulars to keep people away, even from the States. While the profession at large have only general interest in this Association meeting, it seems lamentable that any journals in the States should notice, or even publish any letters conveying

the morbid fears of the committee, which to say the least are implied insults to the honor of the profession. The Montreal meeting should be a most notable event in the medical history of the year, but it should be managed as all other meetings of physicians are, and as it is always managed when it meets in England, that is, on broad scientific and business principles. It should be for the members alone and invited guests and the presence of a crowd of visitors and listeners should never create the slightest apprehension, but rather be considered as a compliment. A wise committee would seek to enlarge the membership from this crowd and not repel them, but impress upon them the value and need of belonging to such an association.

THE INFLUENCE OF HIGH ALTITUDE IN AGGRAVATING SURGICAL SHOCK.

From a consideration of the relation between high altitude and surgical shock WETHERILL (*Annals of Surgery*, April, 1897, p. 430) recommends in the performance of surgical operations, and under conditions of surgical shock generally, the patient should be spared the loss of every drop of blood possible. The importance of this precaution increases greatly as higher elevations are reached and the atmospheric pressure is correspondingly diminished. Anemic and exsanguinated patients are more susceptible to surgical shock at high altitudes than at sea-levels, and must be more carefully prepared for operations; extra precautions against shock must be observed both at the operation and afterward. Increasing shock after injuries or operations must be construed as strong presumptive evidence of continuing hemorrhage. It must be made clear that there is no hemorrhage before the ordinary remedies (cardiac stimulants, transfusion, etc.) are employed. The reflex effect of oozing is to cause a continuation of shock, which must be regarded as conservative in its tendencies while bleeding is still going on. In treating shock after surgical operations or injuries, the first and most important point is to arrest completely all further loss of blood. The depleted vessels should then be supplied by some means with an increased volume of fluid at a high temperature for the heart and blood vessels to contract upon, so that the circulation and the blood-pressure may be speedily reestablished. In abdominal operations this may be effected by leaving a large quantity of hot salt water in the abdominal cavity; or the abdomen may be opened afterward and the fluid introduced, thus securing at once the application of heat to the great abdominal nerve centers, as well as the mechanical pressure and support of a large volume of fluid upon which the abdominal viscera may contract, and thereby restoring to a degree the intra-abdominal pressure, as well as supplying water for absorption into the circulation. The sustained Trendelenburg position is, for obvious reasons,

an important accessory. Diffusible and cardiac stimulants, with heat to the surface, and all other means for the reestablishment of the circulation in its full force and volume, may now be freely employed. Natives and thoroughly acclimated persons are not as susceptible to the greater surgical shock in the higher altitudes as are others; long residence and the gradual compensatory changes in blood pressure, in vaso-motor action and in muscular support of the blood vessels, having adapted them in a great measure to the lighter atmospheric pressure and to the conditions incident to this. Surgical operations upon unacclimated persons from lower altitudes, and those that involve much loss of blood, are fraught with more risk from shock as the altitude is increased, and extra precautions for its prevention are imperative with such patients. This being borne in mind, and proper precautions being observed in the preparation of patients at the time of operation and afterward, as good results may be expected at high as at lower altitudes. In surgical shock at high altitudes every means should be used for the prevention of shock through the nervous system and the resultant blood-stasis, *i. e.*, the surface heat should be preserved, time in operating should be saved, exposure and unnecessary handling of the patient's viscera should be avoided, etc.

A MILITARY PATHOLOGIC PROBLEM.

The editorials in several of our English contemporaries within the past few weeks on the subject of the apparently growing evil of venereal infection in the British army are interesting if not altogether satisfactory reading. It appears that the average number actually *hors du combat*, as one might say, out of the seventy thousand Europeans in the military service in India, from venereal diseases is nearly nine thousand, certainly a very large figure when we consider that it necessarily does not include those still suffering from the later less disabling manifestations of the disorder. An average number of forty-five soldiers to every thousand are constantly in the hospital and this of course only includes the most severe types of the disorder, not those who can still do some duty though possibly still unfit for active field service. The ratio of hospital admissions per year for these affections was, taking the mean for three years, in the British Indian army, 433 per thousand. Comparing this with the figures for other European armies the magnitude of the evil is the more manifest—the comparative statistics for Germany being 27.3, Russia 43, France 43.8 each per thousand. In some Indian cantonments it would seem the annual hospital admissions for this cause exceeded in number the whole strength of the garrison, in Cawnpore, for example, with a force of 902 the hospital admissions were 967 in 1895. There appears to be no doubt but that there has been a very pronounced increase within the last year or

two; in 1895 especially when venereal disease attacked the British army to an altogether unprecedented extent. It is naively said in the report of the Departmental Committee appointed to consider the question of this prevalence, that this state of affairs does not appear to be attributable to increased immorality in the army, for drunkenness and crime have decreased and the soldier is more than ever surrounded by social and educational civilizing influences. The opinion of our British confrères appears to be that the remedy for this deplorable state of affairs is in the reënactment of the contagious diseases acts as applied to these disorders. Under former conditions the enforcement of these was, if one is not mistaken, accompanied by some rather objectionable features, such as the *quasi* enlistment of native women as recognized camp or barrack prostitutes, and a possibly harsh and indiscriminating system of personal inspection. It is unreasonable, however, that the reaction against measures that thus outraged public conscience should go so far as to disable the army authorities from exercising in a humane and decent way some sanitary jurisdiction in this particular direction. Simply placing venereal diseases in the same category as other infectious diseases, and requiring their reporting and if needed their isolation whenever their active existence becomes known to the authorities, and this would be a legitimate sanitary regulation, ought to go far to diminish the evil, and if properly carried out it need offend no one's moral or esthetic sensibilities. That this is not done seems a little remarkable, considering these facts.

There is another point of view from which the subject can be considered, and that is the real national peril from the present condition of affairs. According to a report made to the Royal College of Physicians, out of some thirteen thousand soldiers returning from India in 1894 over 60 per cent. were infected, many of them with the most virulent type of syphilis. The average number of hospital admissions in the British home forces, 203.7 per thousand, is over four times that of the continental European armies, and this difference is probably largely due to the influence of the Indian service. The large number of short-service men returning to civil life must be a serious peril to the community and the continuous existence of so badly infected a body of young and reckless men, though presumably under discipline that should be capable of exercising some restraint upon their spreading their diseases, is a source of constant danger. With such facts known, moreover, the soldier is degraded in the public estimation and the *morale* of the army must be affected to some extent together with its morals. ORTHERIS and MULVANEY are picturesque in fiction, but their attractiveness is marred if we consider them in the light of these revelations.

In this country we have but a small standing army and even were its condition as bad as is that of the British force, which is not the case, the matter would be less serious. But the time may come when we will be compelled to occupy and garrison outlying and tropical territories and have large detachments constantly in service in such regions. Then it will be well if our military sanitarians take a lesson from the experience of those of Great Britain and avoid their mistakes and their misfortunes. In the present showing by the English medical publications, the condition of the British army is reminiscent of the military experiences of the sixteenth century—the history of the siege of Naples and an incident of that of Madrid, as given by D'ISRAELI in his "Curiosities of Literature." War in all its aspects is an evil even when it is a necessary one, and it is attended with many other evils, some of which like the one here discussed, ought to be more or less avoidable. While the demoralizing influences in time of peace of army life should be reduced to a minimum by every possible means, it is due to the community in general that every reasonable measure should be taken to make the soldier and the ex-soldier less formidable in a pathologic point of view.

THE PHILADELPHIA MEETING.

It is hardly necessary to remind our readers of the unusual interest which will center in the coming meeting at Philadelphia. Already the arrangements are so far completed as to indicate, not only an unusual number of excellent papers, but a large attendance of leading physicians from all parts of the country. The sneering criticism of a few dyspeptics, and the far-off cries of those who have fallen back in the march, are still heard. The committee of arrangements have gone on quietly arranging for at least five thousand persons including visitors and sight-seekers and all their aunts, uncles and cousins. While the meeting is exclusively for members and invited guests, there is no alarm or morbid fears of being overwhelmed with the crowds. No letters are written to medical editors for publication, advising medical men to stay away, as not welcome. On the contrary, every effort is made to induce physicians and their families from all parts of the country to come and enjoy the occasion. Even the belated no-code men of New York, and the deserters and the frantic critics, and all prodigals from their father's house are urged and most cordially invited to come back and help us celebrate this coming half century of our existence. It should be a pleasure as well as a duty to come out and hear what the leaders and the great army of the profession are thinking and writing about. Every physician has a personal interest in the many new questions of medicine which are coming up with greater frequency every year. He can not understand these topics from the printed page, he must hear them from

the authors and teachers personally. He must see the men and have their voices to catch the inspiration of the themes. The colleges and teachers of Philadelphia have opened their doors for clinical lectures for a week or more before and after the meeting, to enable all who would like to become familiar with Philadelphia methods of treatment in the clinics and hospitals. This will give every medical man some practical returns for his time, and make the occasion a most memorable one. Every member of the ASSOCIATION should take pains to invite his medical neighbors to attend this meeting, and become members of the ASSOCIATION, and every member should rejoice at the opportunity to break away from every day life, and mingle with others who have similar interests and tastes with himself. There are no more important and enjoyable occasions in the professional lives of the medical man than these National gatherings.

Questions of codes and of management, and efforts to win its honors, are all healthy signs of progress and movement, and give the scientific side of the meetings caste and clearness not to be found in dull mutual admiration societies of local growth. The annual meetings are becoming more and more important scientifically every year. Many of the best and most advanced studies of modern medicine are presented in the papers read. This is amply confirmed by any examination of the pages of the JOURNAL for the past year. That this is true is still further confirmed by the fact of the increasing frequency of quotation from this JOURNAL by foreign authors and medical journals. The oft-repeated comments by smart medical journals, that the meetings were not up to the average in the quality and vigor of papers, are very often signally disproved by the frequent republications of its papers, and generous quotations by authors and medical works. The authors of papers should remember that the JOURNAL has won a place among the great publications of the world, and its readers are not confined to this country alone, but every section of the globe where medical science is studied, is reached by its weekly issues. Hence, authors should be more careful in the construction and style of their studies and conclusions. Often the excellence of a paper is marred by obscurity of style and expression, and the necessity of being clear and concise is apparent to all readers. The JOURNAL should have better prepared papers than ever before. Its representative character clearly requires it, and every writer should feel that this part of his paper should have the same careful attention and study that is given to the thought conveyed. A glance at the advanced publication of the program in the JOURNAL, giving the titles of the papers to be read, is sufficient to show the character of the coming meeting. The Section dinner is a new feature which will bring increasing interest to each one in a closer acquaint-

ance with others of the same special line of work. In this way one of the strongest means of sustaining scientific work is used and the narrowness and personality is widened, and workers along the same lines are able to better use and judge of the work of others. The more closely the members are brought together, the less friction and antagonism will exist. Philadelphia is an ideal city to meet in, its quiet atmosphere and great hospitals and colleges, and strong leading medical men, make it a very desirable place to visit. The committee of arrangements will have all the business details so complete that each one can enjoy all the meetings, general and sectional, without any confusion or crowding. Again we urge every one to come and show their interest in American medicine, and in the great evolutionary movement upward to higher and wider conceptions of science and its relations to every-day life.

THE PASSING OF KERR.

The medical profession of Chicago congratulate themselves that at last the layman who drew a salary of five thousand dollars a year, for attending the office occasionally and signing his name as Health Commissioner to documents drawn by Dr. REILLY, has been relegated to the purlieus of his ward, and that Dr. ARTHUR R. REYNOLDS has been reappointed to the same office from which KERR unjustly ousted him.

Many do not admire the general outcome of the city election, but this feature of it is as welcome as the flowers of Spring.

THE JOURNAL SPECIAL TRAIN.

Medical gentlemen from Illinois and vicinity, the Pacific Coast and the Northwest, who intend to be present at the great jubilee meeting of the ASSOCIATION, are invited to go by the JOURNAL SPECIAL, which will go by the Pennsylvania Railway without change from Chicago to Philadelphia. See their advertisement in another column.

CORRESPONDENCE.

A Basis for Medical Statistics.

CHICAGO, ILL., April 24, 1897.

To the Editor:—German medical papers have recently published a number of articles on puerperal morbidity based on statistics of hospitals in Berlin, Dresden, Marburg and other cities. The value of these statistics is much lessened by the knowledge that the investigators had not worked on similar lines or according to uniform methods. Some quoted rectal temperatures; others used the axilla. There was not a complete agreement as to the physiologic limit of temperature, though most of the investigators properly considered any rise above 38 degrees C. as pathologic. It was further noticed that considerable variation in the percentage of puerperal fevers occurred in the tables based on the readings of the thermometer by nurses and on those by the physician. Koblanck of Berlin, took the axillary temperature of patients during the last seven months of the period of eight years for which his

table was compiled. He got 27 per cent. of puerperal fevers, while during the preceding years the percentage was 10.

If such defects occur in hospital work, how much worse must the case be in general practice and in municipal statistics! Indeed it is practically impossible to compare the statistics of different cities because there is no uniform classification of diseases used by the health authorities of those cities. Even in the annual reports of a single city, one will frequently find much contradiction between the tables published. This shows that even in a single health office there may be an absence of clear and definite ideas as to classification. In this connection it may be mentioned that Dr. Heckard, the registrar of the Chicago Health department, has already set on foot a movement to bring about uniformity in classification of diseases in all the large American cities.

I would suggest that the AMERICAN MEDICAL ASSOCIATION should at its coming meeting appoint a Committee on Statistics, the duty of which should be to outline a basis for the compilation of reliable medical statistics. It should not only coöperate with Dr. Heckard's efforts in the field of municipal statistics but should endeavor to bring about harmony and thoroughness of statistical work in the wider domain of medical science.

The following scheme might be followed:

1. Municipal statistics of vitality, morbidity and mortality.
 - a. Agreement as to classification of diseases.
 - b. Reports of birth, diseases and deaths; compulsory by penalties; paid for by fees (as in Massachusetts and New York); or resulting from the education of a sense of civic duty among the public and the medical profession.
2. Hospital statistics, in which the German reports mentioned above show that there is ample room for improvement.
3. Private statistics. Uncertainty of diagnosis is the chief cause detracting from the value of statistics derived from private practice. Hence they should be divided into two large groups:
 - a. Verified, either by postmortem examination or by scientific investigation (microscopic or bacteriologic).
 - b. Non-verified, which represents what are now commonly called "medical statistics," being tables of judgments based on mere clinical grounds or often on simple guesses.

In all compilations, the class of verified diagnoses should be kept widely distinct from the class of non-verified cases.

A committee working on these or similar lines could formulate rules which would guide the profession to make clear and useful reports about cases; it would be a center point to which suggestions on this subject could be sent; and it would eventually, I believe, bring order into a field which is now mere chaos.

DAVID JESSUP DOHERTY, M.D.

The Eyes and School Work.

CARLINVILLE, ILL., April 24, 1897.

To the Editor:—When my friend and classmate, Dr. A. C. Simonton of San Jose, Cal., in his reference to the character of the paper the JOURNAL should be printed on said, "we as sanitarians and hygienists ought to practice what we preach," I am inclined to offer the following, which was issued by me by request, as a leaflet to the school teachers in my vicinity in reply to a newspaper query, as my contribution as a member of the Section on Ophthalmology, to which you refer the matter. While it deals with the character of the paper the JOURNAL should be printed on, it does also with much other matter germane; as to the mere tint of the paper, the Doctor is theoretically correct. Yet I think my preference is largely an idiosyncrasy or personal equation; I would prefer blue. White is best for all. "With your permission I will answer your queries of last week: 'Why should so many school children wear glasses? Is it because of bad light, or bad atmosphere, or bad print in text books, or inherited weakness, or is the race becoming

blind?' To which I will add, or is it an increasing demand made on the children for eye work, and a knowledge that relief from its pains may be enjoyed by their assistance?"

"I think the queries very pertinent, and I am satisfied many children, teachers and parents will compliment you for asking the questions. Bad or imperfect light requires an increase of the visual effort and contributes to eye tire, worry and exhaustion, for in all eyes vision at the near or reading point is a voluntary muscular effort. With bad light and small print, and fine lines in geography and other branches of study, the objects to be seen distinctly must be looked at longer. The length of time of steady fixation necessary, causes fatigue of muscles, nerve and retina, in which the object seems to change its color and fade. Therefore, the light of school rooms should be as perfect daylight as the confining walls will permit, and admitted so the pupils may have the greatest advantage over its imperfections.

"The print of the school books ought to be like this, at least as large as No. 10 Pica, or 12 English—black and well leaded, so the lines are twice the length of the short letters apart, and the letters should be a little wider apart than the width of the bar of the letters, to be read with ease 12 or 15 inches. The paper should be smooth but not glossy.

"Will publishers of journals, newspapers] and magazines please take heed.

"The blackboards ought to be a clean black, not gray with chalk, and all work put on them should be so large that the area of each letter will cover at least the square of an angle of five minutes and the area of a square of the bar of the letter, at least a square of the angle of one minute for the distance of the scholar who is to view it. For the distance of one hundred feet the greater area is about two inches square—four square inches—and the lesser area three-eighths of an inch square; for seventy feet, $1\frac{1}{4}$ and $\frac{1}{4}$; fifty feet, 1 and 3-16; forty, $\frac{3}{4}$ and $\frac{1}{8}$; thirty, 9-16, and 1-10; twenty, 6-16, and 1-16. Divide the square of the greater angle into twenty-five equal squares and you will have the relative size of the two. The spaces between the bars and letters should also be equal to the lesser, or one-fifth the greater area.

"Bad atmosphere, want of ventilation, is enervating and impairs muscular tonicity, so necessary to keep up eye tension for acute visual purposes. But with all possible care on these points many eyes will be sacrificed by the increasing demands on children of today for mere literary attainments.

"The eye work required of children now is double if not treble what it was twenty or thirty years ago, and the clamor of all is yet for a higher grade at a tender age.

"In the class of what you would call inherited weakness we find our earliest wrecks.

"There are three different conditions of the refractive apparatus of the eye that constitute this class of weakness. I refer to the conditions of myopia, hyperopia and astigmatism. These three errors of the refractive apparatus of eyes are susceptible of many different degrees and varieties of combination, and when either exists it places the eye at a corresponding disadvantage, and precipitates sooner or later a failure of clear and comfortable vision. When the error is corrected it restores clear and comfortable vision and places the eye again at an advantage.

"Now, when amid the conditions of bad light, bad air, bad print on glossy paper, and overwork, we find a child pained with headache, red eyes, eye ache, nervous, and can not fulfill

the requirements of school with comfort, we search for an error of refraction, which if found, is corrected, if need be, with glasses. Again, the fact that very many children and adults have a greater or less amount of some one or more of these errors, and when rendered uncomfortable by it the knowledge that comfort and its privileges can be enjoyed by its correction with a pair of specially arranged glasses, it need not be wondered that many will wear them." A. C. CORR, M.D.

The Osteopathy Bill.

(COPY)

CHICAGO, April 26, 1897.

DEAR SENATOR GRANGER:—I have looked over the Osteopathy Bill, as introduced by you, and do not know what arguments were brought to bear upon you to father it, but the Bill is one which will be very unjust to the medical profession in this State, if allowed to pass; besides, it would make the State the dumping ground for quacks.

Personally, I would be very pleased to hear that you will quietly pocket the bill, or do something to stop its passage.

I am faithfully yours,

Senator Flavel K. Granger, JOHN B. HAMILTON, M.D.
Illinois Senate, Springfield, Ill.

ILLINOIS STATE SENATE,
SPRINGFIELD, April 27, 1897.

JOHN B. HAMILTON, M.D., Chicago:—Yours of 26 inst., was received by this morning's mail. My bill exempting graduates of schools of osteopathy from the requirements of the medical act, was passed by the Senate without opposition. The amended bill to the present act, perfected by the medical schools of the State, now lies in committee, without any friends to support it. So I conclude my bill is in touch with the public demand, and further medical restrictions are not looked upon favorably. Hoping your fears as to being overrun with quacks may not be realized, I am

Yours very truly, F. K. GRANGER.

Railroad Rates.

HYANNIS, MASS., April 17, 1897.

To the Editor:—Please state in the next issue of the JOURNAL for the benefit of the members residing east of the Mississippi, and especially in New York State and in the New England States, which railways in those sections have granted members and their families, who intend to attend the "grand jubilee meeting" of the ASSOCIATION, reduced rates and what procedure is necessary to obtain such privilege?

Very truly yours, ALBERT PICK.

ANSWER: We understand that all railways in the United States have agreed to a rate of one and one-third fare for the round trip.

PUBLIC HEALTH.

Preventive Inoculations of Bubonic Plague.—Only 4 of the 2,000 persons inoculated by Haffkine to March 4, have been attacked by the disease, according to a statement in the *Semaine Méd.*, March 24.

A Few Cases of Smallpox.—Twenty cases in all have occurred in New York City since March 1, nine of which have been removed from Randall's Island Asylum and schools. The first cases seem to have had no history.

The School as a Focus of Contagion.—The last report of the school inspectors in New York City report that out of 3,913 children examined, 258 were excluded. There were found besides seven cases of measles, five of diphtheria, one of scarlet fever, thirty-one contagious eye diseases, and 169 parasitic diseases of the head, while mumps, whooping-cough and

chicken-pox contributed in a minor degree to the sum total of the disqualifications for attendance.

Inoculations with Rinderpest.—Professor Koch, who has been studying the rinderpest in South Africa, announces that the results obtained with serum inoculations confer immunity to such an extent that he is convinced that thousands of cattle can be saved every day by their means. He has inaugurated a course at Kimberley, Cape Colony, to instruct others in his methods.

The Bubonic Plague in Bombay.—The latest advices bring the cheerful intelligence that the plague is abating in virulence, and that the refugees are beginning to return to the Presidency. Thus far, however, the mortality has not declined below 50 per cent. Haffkine's serum claims better results than that of Yersin's, at least so says a telegram to the London *Lancet*.

A Death from Yellow Fever in New York Harbor.—A young naturalist died from yellow fever in the Swinburne Island Hospital April 22. He was a passenger by the Columbian Line steamer *Finance* from Colon, and belonged to a party of naturalists sent out by the Frank Blake Webster Company, of Hyde Park, Mass. They stranded in Central America and he was compelled to dispose of part of his effects at Panama in order to pay his passage home. Yellow fever having been reported at Colon, Dr. Doty, as a precaution decided to remove the sick man to the hospital. After the room on board the steamer had been disinfected she was allowed to go to her pier. The corpse remained on the island.

The Milk Typhoid Epidemic at Kirkcaldy, Scotland.—In the report bearing on the late typhoid epidemic at that place, recently submitted by Sir Henry Littlejohn of Edinburgh, he states that in this epidemic just brought to a close there were 193 cases, with a mortality of 20, or 10.4 per cent. The origin of the outbreak was, in his opinion, clearly traced to a dairy. The Kirkcaldy town council have awarded to Dr. Mackay, medical officer of health, and Dr. Curror, 100 pounds each, and Mr. Braid, sanitary inspector, 50 pounds, for the services rendered by them during the epidemic. Sir Henry Littlejohn, in his report, highly praises the ability and energy displayed by Dr. Mackay in coping with the epidemic.—*British Medical Journal*.

Inspection of American Meat Supply to Great Britain.—Dr. P. H. Bryce, Secretary of the Ontario Board of Health, has issued a pamphlet regarding the meat supply that is exported to Great Britain. The importance of full information on this subject is apparent when it is stated that during nine months in 1896, England received 436,223 cattle, of which the United States sent 308,159, and Canada 71,670; while the bacon from the United States during the same nine months amounted to 207,000,000 pounds. In 1896 the legislature of Ontario passed "An Act for the Inspection of Meat and Milk Supplies in Cities and Towns," empowering municipal councils to establish public slaughter houses and authorizing local boards of health to take measures for ascertaining the purity of public milk supplies and the general health of the cows; local boards are further authorized to provide for the testing of every such cow with tuberculin by a veterinary surgeon. Councils or boards availing themselves of the powers conferred by the act are required by it to conform to the regulations in that behalf from time to time adopted by the provincial board of health, and, with a view to encouraging the introduction of meat and milk inspection, the provincial board has now published a description of a slaughter house suitable for a town population of 5,000 persons, together with a plan, an elevation and an estimate of cost. In the testing of cows with tuberculin "a 10 per cent. solution of normal tuberculin is to be injected to the amount of from one to four cubic centimeters according to age of animal. . . . The temperature must thereafter be taken regularly every three hours for a period of

from twelve to fifteen hours. . . . Any notable rise of temperature indicates the existence of tuberculosis." Cows that give the tuberculin reaction, if they are wasting and show clinical signs of lung disease, shall be destroyed and the carcasses safely disposed of; but if they are in fair condition, they may be either fattened as speedily as possible for slaughter, or their milk, after boiling for half an hour, may be given to pigs or calves. The pamphlet concludes with a description of the inspection of meat at Buffalo. Returning to the inspection of cattle intended for the wholesale trade or export, they are inspected individually, and if found healthy to outward appearance they have a metal tag punched into the ear bearing a number of a continuous series, and a detailed statement of the numbers in any given lot is daily made and forwarded to the central bureau at Washington; also a note of any animals condemned, stating cause. These animals tagged as inspected are admitted to interstate trade, but if for export, are again inspected before going on board ship. So complete is the system of registration that, as an inspector in the Deptford market, London, stated to a Canadian friend, "The Americans are quite surpassing you Canadians, for we can trace any animal found diseased by that tag back to the very farm it may have come from in the Western States. We are getting afraid of

For practical sterilization this instrument has given perfect satisfaction; it is light, portable in small space, yet when fully extended, ample for all instruments, dressings, towels, operating coats, etc., one needs in ordinary operative work.

The instruments are boiled in a soda solution (1 per cent.) in the lower pan, the steam rising through the perforated bottom of the second pan to sterilize the dressings which have been placed in it. The top section has no bottom, being simply a collar for increasing the size of the steam chamber when much space is needed, and may be left off if desired, as the cover fits either section.

There is no difficulty in bringing the instruments to the required degree of heat, nor in sustaining for any required time the temperature of boiling water in the steam chamber.

The lamp is an open one for the combustion of alcohol, its flame will boil three pints of water in the instrument pan in four minutes. A plate, waiter, or instrument tray with a little water in it should be placed under the stand and lamp for the lamp to rest in; this is to prevent the burning of the table by

1, instrument pan. 2, steam chamber for dressings, etc.; bottom perforated. 3, section for increasing size of steam chamber; has no bottom. 4, lid for steam chamber; fits 2 or 3. 5, lamp and stand. 6, sterilizer "nested" for packing in carrier. 7, carrier; ample room for sterilizer and many other instruments.

your Canadian cattle." The quarantined animals at the yards are further examined, and if proved diseased on killing are all *tanked*, as the expression is. This work is being extended to the investigation and stamping out of tuberculosis and actinomycosis by inspection of herds. The latter must necessarily be largely carried out by State authorities.

NEW INSTRUMENTS.

AN IMPROVED PORTABLE STERILIZER FOR SURGICAL INSTRUMENTS AND DRESSINGS.

HORACE G. WETHERILL, M.D.

PROFESSOR GYNECOLOGY, UNIVERSITY OF DENVER, DENVER, COLO.

In the *University Medical Magazine* for August, 1896, I described "A Compact Portable Sterilizer for Surgical Instruments and Dressings." The use of this sterilizer for some months has led to alterations and improvements which make it much more satisfactory than the original instrument. The illustration shows its present form when set up for use, as well as when ready for packing.

the reflected heat of the lamp, and the occurrence of fire from the boiling over of the alcohol in the lamp if by any oversight it has been overfilled. A light folding frame is provided for the sterilizer to rest upon when the lamp is used; of course when other sources of heat are at hand, it and the lamp may be dispensed with.

The whole instrument knocks down in very small space for carrying about, and readily goes into an ordinary dress suit case, or a telescope bag 15 by 9 inches, 6 inches high, leaving plenty of room in the sterilizer, as well as in the bag about the sterilizer, for other articles.

As none of the joints of this sterilizer are dependent upon solder, it will endure any degree of heat short of that which will fuse the copper of which it is made; and if the heat is so regulated as to avoid scorching the dressings, the steam chamber may be taken off the water pan, and used as an oven, so drying and doubly sterilizing its contents.

The best features of this instrument as now designed are, its light weight, its knocking down into very small space for carrying about, its great capacity and efficiency, its simplicity, and best of all its small cost, as compared with other sterilizers.

ASSOCIATION NEWS.

Section on Practice of Medicine.—Program :

TUESDAY, JUNE 1ST.—AFTERNOON SESSION.

1. Address of Chairman. The Treatment of Dilatation of the Heart. John H. Musser, Philadelphia, Pa.
2. The "Schott Treatment" of Cardiac Disease. W. B. Camac, Baltimore, Md.
3. The Prognosis and Therapeutic Indications in Heart Disease. D. L. Rochester, Buffalo, N. Y.
4. A case of Anasarca with Apparent Chronic Nephritis and Dilated Heart, with recovery. F. Billings, Chicago, Ill.
5. Reduplication of Heart Sounds (by invitation). C. F. Hoover, Cleveland, Ohio.
6. The Use of Digitalin, with Reference to Dose. Henry Beates, Philadelphia, Pa.
7. True Angina Pectoris. T. L. Maddin, Nashville, Tenn.
8. The Prognosis and Therapy of Heart Disease in Childhood. Henry Koplik, New York, N. Y. Discussion opened by F. A. Packard, Philadelphia, Pa.
9. Report of a case of Chronic Recurrent Endocarditis; Mitral Insufficiency; Enlarged Liver; General Edema and Ascites; Returning Compensation. H. W. McLauthlin, Denver, Colo.
10. Gonorrhoeal Endocarditis. W. F. McNutt, San Francisco, Cal. Discussion to be opened by W. S. Thayer, Baltimore, Md.
11. Two Cases of Abdominal Aneurysm. James C. Wilson, Philadelphia, Pa.
12. Tracheal Tugging. Harry Toulmin, Philadelphia, Pa.
13. The Relation of Digestive Disturbances to Cardiac Disease. H. W. Rogers, Cleveland, Ohio.
14. The Relationship of Organic Disease of the Heart to Pulmonary Tuberculosis. G. W. Webster, Chicago.
15. The Diagnosis of Pericardial Effusion. A. O. J. Kelly, Philadelphia, Pa.
16. Hydrotherapeutics. S. C. James, Kansas City, Mo.
17. Internal Medicine a Specialty in Itself, and its Relation to the Recognized Specialties, Particularly to Bacteriology. G. B. Harrison, Washington, D. C.
18. The Physical Treatment of Chronic Cardiac Disease (in so-called Schott Method). H. N. Heineman, New York, N. Y. Dinner of the Section at the Aldine Hotel at 7 P.M.

WEDNESDAY, JUNE 2D—MORNING SESSION.

19. Discussion on Sero-diagnosis in Typhoid Fever: *a*, Principles Underlying Sero-diagnosis, William H. Welch, Baltimore, Md.; *b*, Sero-diagnosis, Wyatt Johnston, Montreal, Canada; *c*, Clinical Report on Sero-diagnosis, R. C. Cabot, Boston, Mass.; *d*, Clinical Report on Sero-diagnosis, W. H. Bloch, Baltimore, Md.; *e*, The Serum Test for the Diagnosis of Typhoid Fever, H. M. Biggs, New York, N. Y.; *f*, Clinical Report on Sero-diagnosis, S. S. Kneass, Philadelphia, Pa.; *g*, Clinical Report on Sero-diagnosis, J. H. Musser and John M. Swan, Philadelphia, Pa.
20. Elsner Method of Diagnosis in Typhoid Fever, Mark W. Richardson, Boston, Mass.
21. Observations on Two Examples of Typhoid Meningeal Infection (by invitation). A. P. Ohlmacher, Cleveland, Ohio.
22. Relapses in Typhoid Fever. Wm. Osler, Baltimore, Md.
23. Differential Diagnosis of the Continued Fevers. J. A. Witherspoon, Nashville, Tenn.
24. Diet in Typhoid Fever. F. C. Shattuck, Boston, Mass.
25. Statistics in Hemorrhagic Typhoid Fever. R. G. Curtin, Philadelphia, Pa.
26. Perichondritis of the Larynx in Typhoid Fever, with Specimens and Photographs; Photographs of Intra-uterine Amputation and one of Elephantiasis. M. H. Fussell, Philadelphia, Pa.
27. Typhoid Fever. J. E. Woodbridge, Cleveland, Ohio.
28. The Rational Antiseptic Treatment of Typhoid Fever. H. O. West, Galveston, Texas.
29. The Treatment of Typhoid Fever. J. N. Upshur, Richmond, Va.
30. One Hundred Cases of Typhoid Fever. H. G. McCormick, Williamsport, Pa.
31. A Plea for Intestinal Antisepsis in the Treatment of Typhoid Fever in Conjunction with the Brand and other Methods of Treatment. Joseph Leidy, Philadelphia, Pa.

WEDNESDAY, JUNE 2D—AFTERNOON SESSION.

32. The Diagnosis of Leprosy. James C. Wilson, Philadelphia, Pa.
33. Hydrophobia. C. W. Dulles, Philadelphia, Pa.
34. The Clinical Symptoms, Bacteriologic Findings and Post-

mortem Appearances in cases of Infection of Human Beings with the Bacillus Pyocyaneus. L. Barker, Baltimore, Md.

35. Some Observations on Grippe. J. Sharp, Kansas City, Mo.
36. Trichinosis and the Trichina Spiralis. F. A. Packard, Philadelphia, Pa.
37. Notes on an Epidemic of Cerebro-spinal Meningitis. H. A. Moody, Mobile, Ala. Discussion to be opened by Simon Flexner, Baltimore, Md.
38. The Diagnosis and Prophylaxis of Scarlet Fever. E. Foster, Augusta, Ga.
39. Myxedema, with Report of Two Cases. J. M. Anders, Philadelphia, Pa.
40. Report of a Case of Raynaud's Disease. G. A. Fackler, Cincinnati, Ohio.
41. The Treatment of Exophthalmic Goitre and other Vasomotor Ataxias with Preparations of the Thymus Gland and of the Adrenals. Solomon Solis-Cohen, Philadelphia, Pa.
42. Light Headaches. J. K. Mitchell, Philadelphia, Pa.
43. A Reliable and Harmless Way to Diminish and Cure Over-fatness. W. T. Cathell, Baltimore, Md.
44. The Importance of the Habit of Prognosis to the Development of the Individual Physician. Louis F. Bishop, New York, N. Y.
45. Plasmodium of Malaria, Illustrated by Lantern Slides. Judson Daland, Philadelphia, Pa.

THURSDAY, JUNE 3D—MORNING SESSION.

46. Some of the Clinical Uses of the X-Rays in Medicine. P. H. Williams, Boston, Mass.
47. The Application of the Roentgen Rays to Medical Diagnosis. C. L. Leonard, Philadelphia, Pa.
48. Miliary Tuberculosis. J. T. Whittaker, Cincinnati, Ohio.
49. Tuberculosis Antitoxin. Prof. E. A. de Schweinitz, Bio-Chemical Laboratory, Department of Agriculture, U. S.
50. Anti-tuberculin. J. McFarland, Philadelphia, Pa.
51. A Report on Treatment of Tuberculosis. D. L. Rochester, Buffalo, N. Y. Discussion to be opened by S. Solis-Cohn, Philadelphia, Pa.
52. Oxytuberculin in Tuberculosis. J. O. Hirschfelder, San Francisco, Cal.
53. A Further Report on the Treatment of Tuberculosis by Iodoform Inunctions (by invitation). L. F. Flick, Philadelphia, Pa.
54. Curability of Pulmonary Tuberculosis. E. B. Borland, Pittsburg, Pa.
55. Title not given. Paul Paquin, St. Louis, Mo.
56. Some Deformities of the Chest in the Light of its Ancestry and Development. Woods Hutchinson, Buffalo, N. Y.
57. A Study of Certain Physical Signs of Disease of the Chest. J. N. Hall, Denver, Colo.
58. Pneumonia; its Etiology, Pathology and Inferential Treatment. A. A. Young, Newark, N. Y.
59. Management and Treatment of Malignant Types of Croupous Pneumonia. D. S. Campbell, Detroit, Mich.
60. The Hot Bath in the Treatment of Pneumonia. J. Eichberg, Cincinnati, Ohio. Discussion to be opened by J. P. C. Griffith, Philadelphia, Pa.
61. Cheyne-Stokes Respiration. N. S. Davis, Jr., Chicago.
62. Multiple Neuritis in Influenza. H. B. Allyn, Philadelphia, Pa.

THURSDAY, JUNE 3D—AFTERNOON SESSION.

Meeting at Houston Hall, University of Pennsylvania, 34th and Spruce Streets.

63. Discussion of Anemia, its Causes, Pathology and Treatment. *a*, The Nature and Varieties of Anemia, Alfred Stengel, Philadelphia, Pa.; *b*, The Relation of Infection to Anemia, A. C. Abbott, Philadelphia, Pa.; *c*, The Alterations in the Blood and Methods of Determination, A. E. Taylor, Philadelphia, Pa.; *d*, The Salivary and Gastric Functions, S. M. Hamill and D. L. Edsall, Philadelphia, Pa.; *e*, The Nervous System in Anemia, Joseph Sailer, Philadelphia, Pa.; *f*, The Spinal Cord in Pernicious Anemia, C. W. Burr, Philadelphia, Pa.; *g*, Disorders of the Organs of Special Sense in Anemia, Wm. Campbell Posey, Philadelphia, Pa.; *h*, The Treatment of Anemia, William Pepper, Philadelphia, Pa.; *i*, The Hydratic Treatment of Anemia, Simon Baruch, New York, N. Y. Discussion continued by W. S. Thayer, Baltimore, Md.; R. C. Cabot, Boston, Mass.; J. S. Herrick, Chicago, Ill.
64. A Consideration of the Pathology of Unusual Forms of Hockkin's Disease (Lymphosarcomatosis). Simon Flexner, Baltimore, Md.
65. Leukemia. F. W. Thomas, Marion, Ohio.
66. A Case of Acute Lymphatic Leukemia with Streptococcus Infection. J. B. Herrick, Chicago, Ill.

67. Lymphatic Leukemia, with Report of a Case. T. G. Ashton and A. H. Stewart, Philadelphia, Pa.

FRIDAY, JUNE 4TH—MORNING SESSION.

68. Discussion on Gout. To be opened by Woods Richardson, Buffalo, N. Y. *a*, The Gastro-intestinal and Hepatic Relations and Manifestations of Gout, Charles Stockton, Buffalo, N. Y.; *b*, The Cardio-Vascular and Renal Relations and Manifestations of Gout, N. S. Davis, Jr., Chicago, Ill.; *c*, The Naso-Pharyngeal and Pulmonary Manifestations of Gout, Harrison Allen, Philadelphia, Pa.; *d*, The Nervous System in Gout, Charles K. Mills, Philadelphia, Pa.; *e*, Special Senses, Charles A. Oliver, Philadelphia, Pa.; *f*, The Relation of the Alloxur Bodies to Gout, or a Uric Acid Diathesis, with Demonstration, T. B. Fitcher, Baltimore, Md.; *g*, The Relation of Uric Acid to Neurasthenia, F. S. Pearce, Philadelphia, Pa.; *h*, The Cutaneous Manifestations of Gout, John V. Shoemaker, Philadelphia, Pa.; *i*, The Treatment of Gout, H. C. Wood, Philadelphia, Pa.

Discussion continued by J. I. Whittaker, Cincinnati, Ohio; J. B. Marvin, Louisville, Ky.; William Osler, Baltimore, Md.; Wm. E. Hughes, Philadelphia, Pa.

69. Some Remarks upon the Uric Acid Diathesis and its Treatment. Charles F. Craig, Danbury, Conn.

70. Rheumatoid Arthritis. David Riesman, Philadelphia, Pa.

71. A Further Report on Tachochymia (Dilatation of the Stomach). Max Einhorn, New York, N. Y.

72. On the Local Treatment of Diseases of the Stomach, with Special Reference to the Employment of Silver, Alumol, Ichthol and Bismuth; Description of Newer Apparatus for the use of the same. D. D. Stewart, Philadelphia, Pa.

73. A Remarkable Case of Gastroxynsis, with Symptoms Simulating Hepatic Colic. D. D. Stewart, Philadelphia, Pa.

74. As to the Utility of a Knowledge of the Percentage of Hydrochloric Acid in the Stomach Contents, and the Practical Value of Certain Commonly Employed Methods for its Estimation. D. D. Stewart and Henry Leffmann, Philadelphia, Pa.

75. Gastroptosis. Charles D. Aaron, Detroit, Mich.

76. Relation of Fat Necrosis and the Pancreas. H. U. Williams, Buffalo, N. Y. Discussion to be opened by W. L. Coplin, Philadelphia, Pa.

77. The Diagnosis of Abdominal Effusion and Growth. James Tyson, Philadelphia, Pa.

78. Clinical Aspects of Jaundice, with Illustrative Cases. T. S. Latimer, Baltimore, Md.

79. Chronic Inflammation and Ulceration of the Duodenum, with Resultant Reflexes. J. M. Allen, Kansas City, Mo. Discussion to be opened by Boardman Reed, Philadelphia, Pa.

80. Cirrhosis of the Liver. J. B. Marvin, Louisville, Ky.

81. A New Test for Lactic Acid. J. P. Arnold, Philadelphia, Pa.

FRIDAY, JUNE 4TH—AFTERNOON SESSION.

82. Conclusions from a Year's Examination of Urine. J. A. Scott, Philadelphia, Pa.

83. Nephritis without Albuminuria. A. R. Edwards, Chicago, Ill.

84. The Curability of Bright's Disease. Elmer Lee, Chicago, Ill.

85. Demonstration of Diabetic Blood and Urine Tests. Ludwig Bremer, St. Louis, Mo.

86. The Treatment of Diabetes. F. P. Norbury, Jacksonville, Ill. Discussion to be opened by James Tyson, Philadelphia, Pa.

87. Case of Primary Renal Tuberculosis. J. D. Steele, Philadelphia, Pa.

88. The Medical Treatment of Appendicitis. W. F. McNutt, San Francisco, Cal.

89. The Treatment of Cancer by Zinc Mercuric Cataphoresis. C. B. Massey, Philadelphia, Pa.

90. Experience in the Treatment of Epilepsy According to the Method Suggested by Niemeyer. Matthew Woods, Philadelphia, Pa.

91. Medicine as an Exact Science. W. J. K. Kline, Washington, D. C.

92. Eighteen Years of Observation of Pulmonary Tuberculosis in Asheville, N. C. J. H. Williams, Asheville, N. C.

93. To What Extent are the Symptoms of Disease as Usually Treated Conservative. W. C. Spalding, New York, N. Y.

Section on *Materia Medica, Pharmacy and Therapeutics*.—Program.

TUESDAY, JUNE 1ST.

1. Address of Welcome to the Delegates from the American Pharmaceutical Association.

2. Chairman's Address. Warren B. Hill, Milwaukee, Wis.

WEDNESDAY, JUNE 2D.

3. Discussion of Subjects Referred to the Section on *Mate-*

ria Medica, Pharmacy and Therapeutics, by the American Pharmaceutical Association.

4. On the Therapeutical Properties of Alcohol and the Reasons Why None of the Fermented and Distilled Liquors Used as Beverages Should be Recognized in the U. S. Pharmacopoeia as Medicinal Agents. N. S. Davis, Chicago, Ill. Discussion, Paul Paquin, St. Louis, Mo.

5. Dismissal from the U. S. Pharmacopoeia of Spiritus Frumenti, Spiritus Vini Gallici, Vinum Album, Vinum Rubrum. Replacement of official wines by vinegars. Dismissal of all tinctures having a fluid extract of the same drug official. Substitution for such tinctures and fluid extracts, a 50 per cent. tincture under a distinctive title. Change of formula for Dover's Powder back to that of the 1890 U. S. Pharmacopoeia by using potassium sulphate in place of sugar of milk. Discussion, H. C. Wood, Philadelphia, Pa.

6. Patent Medicines and Our Patent Laws. F. E. Stewart, Detroit, Mich.

THURSDAY, JUNE 3D.

7. Report of the Committee on Joint Investigation. Strophanthus. *a*. Comparative Investigation of the Varieties of Commercial Strophanthus. Smith Ely Jelliffe, New York City, N. Y. *b*. Composition. Alfred R. Dohme, Baltimore, Md. *c*. Physiologic and Therapeutic Action; a Clinical Study. R. W. Wilcox, New York City, N. Y.; *d*. The Pharmacology of Strophanthus. E. M. Houghton, Detroit, Mich.

Constituents of Viburnum Barks. Professor Coblentz. Guaiacol Valerianate and Creosote Valerianate. Frank Woodbury, Philadelphia.

Carvacrol Iodid. A. H. Cohn, Milwaukee, Wis.

The Experimental Basis of the Dietetic and Medicinal Treatment of Hyperacidity and Gastritis. J. C. Hemmeter, Baltimore, Md.

FRIDAY, JUNE 4TH.

8. Nuclein Solution; a Clinical Study. Oscar R. Tomlinson, Mt. Vernon, N. Y.

9. The Effects of Serum and Special Antitoxins in Pure and Mixed Cases of Tuberculosis. Paul Paquin, St. Louis, Mo.

10. Anti-streptococcic Serum; a Clinical Report. Harold Sorby, Chicago, Ill.

11. The Serum Therapy of Tetanus. A. F. Lemke, Hospital, Ill.

12. Thyroid Extracts. W. H. Neilson, Milwaukee, Wis.

13. Treatment of Mental States by Toxins. O. A. King, Lake Geneva, Wis.

14. Practical Difficulties of Psycho-therapeutics. G. V. I. Brown, Duluth, Minn.

SOCIETY NEWS.

Ninth International Congress of Hygiene and Dermagraphy, which was to have opened in Madrid next October has been postponed until April, as the Spanish Government is otherwise occupied at present.

St. Louis Medical Society held a regular meeting April 17. Papers were read by T. F. Prewitt, on "Resection of both Hip-Joints for Tuberculosis," and J. B. Ross, on Pathologico-Histological Notes on Mastitis Glandularis Cystica (Reclus) and Mastitis Diffusa Nodosa (Phocas).

American Medical Editors.—The following has been written to the Editors:

My Dear Doctor: At a meeting of the Committee of Arrangements it was decided that the next Dinner of the American Medical Editors' Association shall take place in Philadelphia, at the Aldine Hotel, on Tuesday, June 1st, at 8:30 P.M. It is confidently expected that this will be a most enjoyable and successful occasion. We write, therefore, to ask if you will inform the Chairman by return mail if we may expect you to be present, and also if you will include the names of any friends that you may desire to invite. The subscription will be \$5 per plate including wine. It is earnestly desired that you will give this matter immediate attention so that all arrangements may be completed.

The annual meeting will be held at the Aldine Hotel at 7 P.M.

Yours sincerely,

JUDSON DALAND, Chairman,

319 S. 18th Street, Philadelphia.

H. A. HARE, President of the Association.

Second International Congress of Railroad and Maritime Sanitation and Hygiene, convenes at Brussels next September, to discuss questions of great practical importance to the profession and to the public, and incidentally to lead to a better appreciation by the public and the administrations of railroads, etc., of the immense services rendered by the profession. We note among the addresses to be delivered: "Should the medical service form a part of the administration, or should it be connected with the employes' organizations? Quantitative determination of the chromatic sense. Simulation of optic and aural disorders. Accident service, etc." For further details see *Gaz. Med. de Liège*, March 4, or apply to Dr. De Lantsheere, rue de l'Association 50, Brussels.

The Eighteenth Balneologic Congress met at Berlin in March. Neisser spoke of "Balneotherapeutics in Syphilis," stating that he considers mercury the only certain remedy for this disease; it acts directly upon the specific virus and diminishes the dangers of heredity. Iodin is ineffectual in the early stages and is only adapted for tertiary phenomena. There is no mineral water that can take the place of the mercury, and some, like sulphur waters, directly counteract its effect, as they form in combination with it an insoluble mercurial sulphid. But in some cases of intolerance of mercurial frictions, electric sublimate baths can be advantageously combined with it. Mineral waters, on the whole, favor mercurial treatment as they promote general metabolism. The effect of the mercury is also enhanced when it is more rapidly eliminated from the organism and more frequently renewed, than when it is stagnating in it. In every case saline waters and "drink cures" can be recommended. He prefers injections to inunctions and urged that every physician should be familiar with the treatment of syphilis, as he disapproves of the idea of specialists for this disease. Winternitz of Vienna stated he had never treated a case of Basedow's disease with hydrotherapeutics that had not been very much benefited by it. Cold applications at the back of the neck always improved the cardiac action, and temporarily arrested the tremor. Similarly favorable results were obtained by packs and compresses in reducing the hypertrophy of the gland, and the sweats. But the chief benefits of hydragric treatment are felt in the metabolism and the disturbed functions of the organism. Hydrotherapy in this disease must go hand in hand with a strictly regulated diet. He has entirely cured the severe attendant diarrhea with milk.

We notice that in one of the discussions a member observed that: "Sleeplessness is always an indication of commencing paralysis." Eulenburg of Berlin proclaimed anew the advantages of "Motion Therapeutics" in cerebral and spinal diseases, and described various cases in which marvelous benefits had been derived.

BOOK NOTICES.

Transactions of the American Association of Obstetricians and Gynecologists, Vol. ix. For the year 1896. Philadelphia: Wm. J. Doran, 1897.

We have already given an abstract of the proceedings of this flourishing society (*JOURNAL*, Oct. 10, 1896, p. 811) and it only remains to congratulate the Publication Committee upon the handsome setting they have given the papers and the high grade of work the society is doing.

An excellent biographic sketch of the late Hiram Corson by Dr. Thraill Green of Easton concludes the volume.

Forty-three members attended the meeting which was held at Richmond, Va., under the presidency of our colleague, Joseph Price. The next annual meeting will be held at Niagara Falls, N. Y., Aug. 17-20, 1897.

Transactions of the Eighteenth Annual Meeting of the American Laryngological Association, 1896; pp. 303. New York: D. Appleton & Co. 1897.

This meeting was held in Pittsburg, May 14, 15 and 16, 1896, under the presidency of our colleague, Dr. W. H. Daly.

Forty Fellows were present. Brief obituary notices of Professor Wilhelm Meyer of Copenhagen and Wm. Chapman Jarvis of New York are included in the minutes of the meeting.

The papers are of a high standard and several of them would find an appropriate place in a work on general surgery. The papers on Sarcoma of the Nasal Chambers by Dr. A. A. Bliss of Philadelphia, on Naso-pharyngeal "fibroid" Tumor by E. F. Ingals, Chicago, and on Deviation of the Nasal Septum by Dr. Jno. O. Roe, are of interest to general surgeons as well as to the laryngologists.

The volume is well printed and the illustrations unusually good.

Sixth Annual Proceedings of the Association of Military Surgeons of the United States, held at Philadelphia, May 12, 13 and 14, 1896. Pp. 442. Cleveland: Medical Gazette Publishing Co. 1896.

This handsome volume contains, besides the minutes of the meeting, the addresses and papers presented. All of which are interesting and some of them of enduring value. The original papers in the volume are by Col. C. H. Alden, U. S. A.; Major D. A. Kuyk, Va. Vol. Inf'y.; Capt. J. J. Erwin, O. N. G.; Capt. J. E. Pilcher, U. S. A.; Major Geo. W. Adair, U. S. A.; Lieut.-Col. W. H. Forwood, U. S. A.; Col. Dallas Bache, U. S. A.; Lieut. H. R. Stiles, U. S. A.; Major Valery Havard, U. S. N.; Major Jno. Van R. Hoff, U. S. A.; Commander Jno. C. Wise, U. S. N.; Capt. Myles Standish, Mass. Vol. M.; Capt. J. M. Banister, U. S. A.; Major P. F. Harvey, U. S. A.; Major Paul R. Brown, U. S. A.; Lieut. H. G. Beyer, U. S. N.; Lieut. H. L. Chase, Mass. V. M.; Capt. C. E. Woodruff, U. S. A.; Capt. Louis La Garde, U. S. A.; Lieut. Thos. C. Craig, U. S. N.; Major C. C. Foster, Mass. V. M.; Major D. M. Appel, U. S. A.; Lieut. H. A. Arnold, Penn. N. G. This volume will go into the library as a valuable addition to the literature of military surgery. The next meeting will be held in Columbus, Ohio, May 25, 26 and 27.

First Aid in Illness and Injury. By Capt. JAMES E. PILCHER, M.D., U. S. A. Pp. 322. Fourth edition; 12mo (\$2 net). New York: Chas. Scribner's Sons. 1897.

This book has been regarded with much favor by those engaged in "first aid" work, and by the medical officers of the National Guard. It contains a great deal of elementary information in anatomy and physiology, and has also embodied in it the recent regulations for the drill of the hospital corps of the army. The language of the author is well chosen and his teachings are sound. There are few books of this class that are superior for the purposes and uses of the national guardsman.

International Clinics. A quarterly of clinical lectures on medicine, neurology, surgery, gynecology, etc., and specially prepared articles on treatment, by professors and lecturers in the leading medical colleges of the United States, Germany, Austria, Great Britain and Canada. Edited by JUDSON DALAND, M.D., Philadelphia: J. MITCHELL BRUCE, M.D., F.R.C.P., London, and DAVID W. FINLAY, M.D., F.R.C.P., Aberdeen, Scotland. Vol. i. Seventh series. 1897. Pp. 352. Philadelphia: J. B. Lippincott & Co.

There are forty-five clinical lectures in this volume representing a wide range of cases, and they represent the views of gentlemen having at their disposal a vast amount of material; the result is that a volume is produced of the highest practical value. General practitioners desiring to keep pace with modern views of treatment, in many cases far in advance of those promulgated in the text books. The publishers have done their work well.

Saint Thomas Hospital Reports. New series. Edited by Dr. T. D. ACLAND and Mr. BERNARD PITTS. London: J. & A. Churchill. 1897.

Hospital reports are always welcome because they seem to bring us face to face with the actual treatment of disease, and to practitioners they have perennial freshness. The text-book and the monograph may be scientific but marvelously dull, but the hospital report has an ever present interest.

The contributors to this volume are F. R. Walters, W. W. Wagstaffe, H. H. Clutton, Robert Cory, Henry Betham Robinson, T. H. Kellock, F. F. Caiger, W. Wellington Lake,

Chas. R. Box, C. S. Wallace, W. H. Tate, Herberfly Toomes, A. H. P. Downey, E. C. Stabb, H. G. Turney.

The volume under consideration is fully equal to its predecessors.

Twentieth Century Practice. An International Encyclopedia of Modern Medical Science. Edited by Dr. THOMAS L. STEDMAN. In twenty volumes. Vol. ix. Diseases of the Digestive Organs. Pp. 820. New York: William Wood & Co. 1897.

In many respects this volume will naturally be the most popular of the series on account of the subject. The contributors are C. A. Ewald, M.D., Berlin; Kendal Franks, M.D., Johannesburg, South Africa; V. P. Gibney, M.D., New York; Carlo Gioffredi of Naples; Werner Kummel, M.D., Breslau; Johann Mikulicz, M.D., Breslau; Jno. B. Murphy, M.D., Chicago; Mariano Semmola, Naples; Alfred Stengel, M.D., Philadelphia; Jno. B. Walker, M.D., New York.

The names of the authors insure high class work and the reader is not disappointed. The volume is profusely illustrated and uniform in style with its predecessors. The volume has made good its claim to fairly represent the medicine of the present day.

NECROLOGY.

FRANK ABBOTT, M.D., New York University Medical College, 1871, died suddenly of cardiac disease at his home in New York city April 20. He was born at Shapleigh, York County, Maine, Sept. 5, 1836, and was descended from one of the Puritan settlers in that part of the country. When twenty years old he became a student in the office of a dental surgeon in Onida, and then removed to Johnstown, N. Y., where he practiced as a dentist until 1863, when he came to New York and finally after a medical course received the usual degree. Notwithstanding his membership in the New York Academy of Medicine and other medical associations, his bent was toward dentistry, and in that specialty he attained an enviable prominence. In 1866 upon the formation of the New York College of Dentistry he was appointed clinical instructor, then Professor of Operative Dentistry and Oral Surgery, and finally in 1869 the Dean of Faculty, a place which he held up to his death.

JAMES CALDWELL MORTLAND, M.D., at Edgerton, Ohio, April 20, 1897. He was born May 23, 1834. After studying a year in the medical department of the University of Michigan at Ann Arbor, he practiced his profession at Edgerton, Ohio, until the fall of 1870, when he entered the Bellevue Hospital Medical College of New York city, and was graduated March, 1871. Returning to Edgerton he resumed practice until his death. As a professional man he was upright, honest and faithful in his duties and obligations. He was free from any encroachment upon the rights of others. In the language of the school, his was a practice of which it might be said, There was no poaching there. As a citizen he was honored and respected and loved by all. He was a member of the AMERICAN MEDICAL ASSOCIATION.

Prof. NICOLAI VON ZDEKAUER, M.D., aged 82. The Nestor of Russian physicians in age and influence, Physician to the Court, president of numerous scientific societies, etc. There has not been a single medical, hygienic nor sanitary measure of importance adopted in Russia in the last half century that did not owe something to him. Son of a Vienna medical man established in Russia, he rose to the utmost eminence, and all unite in extolling his culture, affability and intellect. He was one of the first who took a course of lectures from Scoda in one of the Vienna prisons, in the then much ridiculed and abused art of percussion and auscultation. When he returned from a tour of inspection of foreign hospitals, etc., in 1857, his report led to a complete reformation of the systems of heating and ventilating in vogue in Russia, not only in hospitals, but in theaters, hotels, palaces, etc. His contributions to medical literature were numerous and important.

JAMES A. ETHRIDGE, M.D., a well-known physician of Macon, Ga., died March 14 from the effects of chloroform. Dr. Ethridge was about to undergo an operation for fistula, and almost at the first inhalation of the chloroform his pulse and

respiration ceased, and every effort to resuscitate him failed. Upon a preliminary examination of Dr. Ethridge no contra-indication to the use of chloroform could be discovered by the physicians in attendance. Dr. Ethridge was about forty years of age, and had practiced his profession successfully in Macon for many years. He was a member of the Board of Health of Macon, visiting physician to the city hospital, and surgeon to the Georgia Southern and Florida Railroad.—*Atlanta Medical and Surgical Journal.*

ANDREW OTTERSON, M.D., New York University Medical Department, 1844, died April 14, in Brooklyn, N. Y., of which city he was a health commissioner for three terms. He was born Feb. 22, 1822, near Amsterdam, N. Y., and was the son of a Dutch Reformed clergyman. On the occasion of the fiftieth anniversary of his entrance into the medical profession the Kings County Medical Society of which he was an ex-president, tendered him a banquet whereat many notables were present. As a sanitarian his opinion was held in esteem.

Prof. CARL SATHERBERG, aged 84, was one of the pioneers in Swedish gymnastics. For thirty years chief of the Stockholm Orthopedic Institute and his orthopedic appliances were awarded prizes at numerous European expositions. Besides his fame as a physician, he made a name for himself as a writer and poet, and composed a number of songs that are still very popular in Sweden.

J. J. MARSTON, M.D., McGill University, Montreal, 1863, on April 17, was found in his office chair, dead from cardiac disease at his home in Cheyenne, Wyoming. He served as a surgeon under Sheridan and Custer in their stirring Indian campaigns. A son in Princeton University and a widow are his survivors.

WM. GOODENOUGH WHEELER, M.D., Geneva Medical College, New York, 1845, a native of Columbus, N. Y., died April 17, at Chelsea, Mass. During the civil war he was an examining surgeon for the United States forces. He had reached the age of 76 years.

Dr. MORVAN, France, in his 79th year. A scientific investigator, public-spirited citizen and able practitioner. Although located in an obscure corner of Bretagne his name is familiar by its connection with various affections, among them the analgesic paresis, known as Morvan's disease.

SHERMAN S. STREET, M.D., of Arkville, N. Y., died April 2, aged 94 years. After having been graduated in Vermont, he began practice at Roxbury, N. Y., about 1840, but during the anti-rent difficulties, removed to another part of the same county. He retired from practice only within a few years of his death.—L. H. Colladon, M.D., Geneva, Switzerland, aged 55.—Dr. Durozier, Paris, aged 71. Known as a writer on cardiac pathology.—John Wilson McLean, M.D., College of Physicians and Surgeons, New York, 1859, died at his home in Norwalk, Conn., April 19, in his 60th year.—Enos L. Brooke, M.D., Pennsylvania Medical College (now extinct) 1848, died April 9, from accidental burns at West Pikeland, Chester County, Pa. He was in his 80th year.—Leroy McLean, M.D., Albany Medical College, New York, 1855, died at Troy, N. Y., April 23, in his 67th year.

MISCELLANY.

Professor v. Esmarch has been honored in many ways on the occasion of his silver wedding celebrated in February at Kiel, where in his 75th year he is still teaching with undiminished energy and popularity. His wife is the geborene Princessin Henriette zu Schleswig-Holstein-Sonderburg-Augustenburg, and aunt of the German Empress.

Osteomalacia.—Meslay reviews the literature on this subject and dismisses medical treatment as ineffective, while with surgical treatment success has been definitely and permanently secured in 80 per cent. of the cases treated. Porro who first applied surgical treatment to this disease, now has a record of 56 cases with 32 successes, 24 failures, and 70 double castrations resulting in 58 cures and 12 failures.—*Gaz. Méd. de Paris*, March 27.

The Generosity of Madame Charcot.—The widow of the late Professor Charcot has resigned the annual pension of 2,000 francs which she received from the state in favor of other widows and children of professors or *agregés* of the Faculty of

Medicine of Paris who have died without leaving provision for their survivors. Madame Charcot has refunded all the money she has received from the pension since the death of her husband.

The Great Emerson on the Horse-chestnut.—A pleasant anecdote recorded of Ralph Waldo Emerson is a story he told of a friend who carried a horse-chestnut as a talisman or protection against rheumatism. "He has never had it since he began to carry it; and indeed, it appears to have had a retrospective operation, for he never had it before."

Care Required From Old Person.—The supreme court of Nebraska holds, in *Village of Culbertson v. Holliday*, Jan. 7, 1897, that the law does not require of an old person the exercise of greater care to avoid injury than it requires of a young and vigorous one. It requires of each the exercise of ordinary care. It requires of neither the exercise of extraordinary care.

New Attempts in Sero-therapeutics of Infective Diseases.—Weissbecker has continued his experiments with children in pneumonia, typhoid or scarlet fever, making one injection in each case of 10 c.c. of serum from the blood of patients convalescing from the same disease. The effect varied in different cases, but all experienced immediate and permanent euphoria, and were able to eat afterward with continuous good appetite. The injection also materially shortened the duration of the disease in some of the cases.—*Semaine Méd.*, March 24.

A Medical Man's Valuable Collection of Chinese Works.—The late Dr. Lockhart, the first medical missionary sent to China by the London Missionary Society, presented to the society before his death a remarkable collection of Chinese books and works relating to China and neighboring countries, in ten European and fifteen Oriental languages. The *London Times* says that at a special meeting, held in the Mission Hall a fortnight ago, the Rev. R. Wardlaw Thompson, foreign secretary of the society, stated that a catalogue, which the Rev. Goodeve Mabbs had just completed in three large volumes, showed the library to consist of 2,600 bound works and an enormous number of pamphlets. Dr. Lockhart had spent £1,000 on the books; the present value of the collection was much higher. The collection included works not to be found in the British Museum and was without a rival in the world.

Elements of Damage.—Disfigurement, the supreme court of Iowa holds, Dec. 12, 1896, in *Newbury v. Getchell & Martin Lumber and Mfg. Co.*, is a proper element of damage to be considered in personal injury cases. And such is said to be the general rule. But the court holds that a minor can not recover the cost of medical attendance; not, at least, until he has paid the bill. The explanation given is that the father, or, in the event of his death, the mother, is primarily liable for the bill, and, in the absence of proof to the contrary, it must be assumed that it is charged to him or her. If so charged, the minor can not recover for it. If not so charged, until it is paid, the liability is still, as stated, primarily that of the father or mother, and it must be presumed that he or she will meet the obligation.

Turkish Hospital Service on the Greek Frontier.—That the Turkish soldier is a formidable fighter has been long known, but it will be a matter of surprise to most people to learn from the military correspondent of the *Times* that Turkish organization has made rapid strides during the last few years, especially in the matter of military railways and hospitals. Writing from Salonika with Edhem Pasha's force, the correspondent refers to the creditable state of the medical service. He says: "The main hospital here is as good as many in Europe and has a large reserve supply of beds and medicines; the doctors are properly trained and the ambulances well equipped and officered. A very reasonable order has just relegated all the Christian military surgeons to the depots, while the fighting line is to be supplied with Mahomedans only. A little dysentery is the

only disease from which the entire army of occupation, more than half of which has been brought from the distant provinces of Anatolia, has suffered."

"Sound Health."—"Sound health," as used with reference to an application for life insurance, the supreme court of Wisconsin says, in the case of *Boyle v. Northwestern Mutual Relief Association*, Feb. 23, 1897, has been defined to mean a state of health free from any disease or ailment that affects the general soundness and healthfulness of the system seriously. The word "serious," it adds, is not generally used to signify dangerous, but rather to define a grave, important or weighty trouble.

Non-essential Experience of Expert.—Where there is no apparent connection between the experience acquired by a physician in a certain capacity and his qualification as an expert in a given case, the appellate term of the supreme court of New York holds, in *Brown v. Third Ave. Co.*, Feb. 26, 1897, that it is not error to exclude questions relative to such experience, when he is being qualified as a medical expert in such case. To illustrate, the court holds that it is not error to rule out questions regarding the duties of the witness as a member of a board of health where there is nothing to show that the duties of a member of a board of health would give the testimony of the witness greater value in the case.

Successful Laprotomy in the First Hour of Life.—Professor Bayer recently performed a radical operation on a newborn infant with a very large umbilical hernia, rupture of the sac, and eversion of almost the entire large and small intestines. He enlarged the mouth of the sac, replaced the intestines, excised the hernial sac, and closed the wound, using 20 grams pure chloroform, which was well tolerated. Recovery was prompt and uneventful. The choice between Breuss' percutaneous ligature, Olshausen's extraperitoneal method and the customary laparotomy with excision of the sac and suture of the mouth, is in favor of the latter, which is the best and most reliable in cases like the above. There are thirty-three cases on record with twenty-six recoveries; the present is the third on record performed during the first hour after birth, and the first in which there was rupture of the sac, which is an unconditional indication therefore for laparotomy in umbilical hernia.—*Cbl. f. Chir.*, April 3, from *Prager Med. Woch.*, No. 31, 1896.

The Treatment of Fractures by Massage.—From a careful consideration of the subject Woolsey (*Medical News*, March 20, 1897, p. 353) expresses the opinion that the treatment of fractures, especially occurring near joints, by immobilization, whether ambulatory or not, leaves something to be desired in, *a*, the time required; and *b*, the functional result obtained. The treatment of such fractures by massage and passive motion shortens the time required for bony union by one-third or one-half, and vastly improves the immediate functional result. This mode of treatment is especially applicable and important for fractures near joints. Its application is easy. It relieves pain and swelling, hastens callus formation and solidification, and prevents atrophy of muscles and stiffness of joints and tendons. Splints should be applied in the intervals between the daily applications for fifteen or twenty minutes of massage for the first ten or twenty days, according to the nature of the fracture and the tendency to displacement, or until consolidation occurs. This treatment, in conjunction with the ambulatory plan, promises an ideal method. Oblique fractures of both bones or of the only bone of a limb or fractures near the middle of the limb, with a tendency to displacement, should be immobilized until consolidation has begun to take place. Ambulatory treatment is indicated for the latter class of fractures, for fractures of the lower extremities in the alcoholic or the very aged, and for fractures of the neck of the femur in the aged. The plan of immobilizing the limb for a short time

in the best possible position, and then applying massage and passive motion, promises equally good results and especially adapts the method to private practice, in which it is particularly indicated on account of the shortened time required for union and the excellent functional results.

The Hospitals of London in Howard's Time.—The *Scalpel* quotes from "An Account of Lazarettos" by John Howard, some of the defects that existed in some of the London Hospitals, only a little more than a hundred years ago. The time of the publication of this book was 1789. Of Guy's Hospital he says: "That the wards in this hospital are in general too low. In the old wards the beds and testers are of wood and infested with bugs. In all the hospitals the beds are old and crowded against the walls. . . . I am fully persuaded that very much depends upon the patients lying on clean beds. The beds must be very offensive from the succession of patients with the various disorders who lie on them." At the Westminster Hospital a sum was paid every year for the destruction of bugs. Upon this he observes: "If the annual sum paid in several hospitals for the destruction of bugs were expended in airing, beating and brushing the beds, the end would perhaps be better answered. For in the country, where the air is fresh and freely admitted into lodging rooms, there were few or no bugs. In the hospitals in Sweden I observe a very good mode of sweetening the beds; on every fine day a certain number were brought into the open air and beaten and brushed on a deal machine made for the purpose. I could wish that such a practice were adopted in our hospitals, and that the rest of the bedding were more frequently washed and aired." At London Hospital, Whitechapel, he notes: "1, no cisterns for water, the vaults offensive; 2, the medical and chiralurgical patients are together; 3, in a dirty room in the cellar there is a cold and hot bath which seems seldom to be used; 4, the wards had not been whitewashed for some years; 5, it has not within or without the appearance of neatness; 6, no vegetables are given to the patients." At Saint Bartholomew's he notes "that the wards being doubled have not the advantage of opposite windows." At the Middlesex Hospital he observes, "the rooms are damp and dirty." At St. Thomas's he tells us "there is no water closet."

Western Reserve University; A Four Years' Course.—In the College number of the *JOURNAL* the Medical College of the Western Reserve University, Cleveland, Ohio, was tabulated as requiring three years of attendance before graduation. We are pleased to announce that four years of study are required by this institution.

New York.

MONEY FOR THE HOUSE OF REFUGE.—During the present session of the State Legislature the Senate Finance Committee voted \$32,700 to put the Refuge in good sanitary condition. There is a movement on foot to place the institution at once under the control of the State Board of Charities, who with more absolute power may manage with more satisfaction.

A MEDICAL COLLEGE BURNED.—A fire of unknown origin broke out at 3 A.M., April 23, in one of the buildings of the New York Infirmary for Women and Children, which in repairs alone will cause a loss of \$20,000. The building in question was devoted to uses of the Woman's Medical College, but the main buildings in which the Infirmary is situated escaped. These were occupied by about one hundred nurses and patients, fifteen of the latter being children. There was no excitement and every precaution had been taken. An ample insurance will cover the loss on furniture, surgical and scientific instruments.

Hospitals.

The finance committee of the Evanston, Ill., Hospital Association has begun an active canvass for funds with which to erect a new hospital building. The estimated cost is \$26,000. —At the regular monthly meeting of the Mary Thompson Hospital for Women and Children, Chicago, Dr. Lucy Waite of Chicago was elected chief physician and surgeon of the hospital, to fill the vacancy caused by the resignation of Dr. Marie J. Mergler. —At the annual meeting of the board of directors of the Central State Hospital, Virginia, trustees, the following officers were elected: superintendent, Wm. F. Drewry, Petersburg; first assistant physician, R. C. Styll, Hollins Institute; second assistant physician, James R. Garlick, Richmond; third assistant physician, John M. Henderson, Southampton County. —At the annual meeting of the Eastern State Hospital, Virginia, trustees, the former officers were re-elected. —The annual meeting of the directors of the Western State Hospital at Staunton, Va., was held April 15, and the officers were re-elected.

THE PUBLIC SERVICE.

Army Changes. Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from April 10 to 28, 1897.

Capt. Nathan S. Jarvis, Asst. Surgeon, is relieved from duty at Willet's Point, N. Y., to take effect on the expiration of his present leave of absence, and ordered to Ft. Huachuca, Ariz., instead of Ft. Clark, Texas, for duty.

Major John Van R. Hoff, Surgeon (Vancouver Bks., Washington), is granted leave of absence for one month, with permission to apply for an extension of one month.

First Lieut. George D. Dashon, Asst. Surgeon (Washington Bks., D. C.), leave of absence granted is still further extended to include May 1, 1897.

Capt. Edward C. Carter, Asst. Surgeon (Ft. Harrison, Mont.), is granted leave of absence for one month, with permission to apply for an extension of two months.

First Lieut. Carl R. Darnall, Asst. Surgeon, upon return of First Lieut. Frederick P. Reynolds, Asst. Surgeon, to Ft. McIntosh, will proceed to Ft. Ringgold, Texas, and report for temporary duty during the absence on leave of Capt. Walter D. McCaw, Asst. Surgeon.

First Lieut. Leigh A. Fuller, Asst. Surgeon, will proceed from Ft. Meade, S. Dak., to Ft. Harrison, Mont., and report for temporary duty at that post during the absence on leave of Capt. Edward C. Carter, Asst. Surgeon.

Capt. Ogden Rafferty, Asst. Surgeon, is granted leave of absence for three months, with permission to apply for an extension of one month, to take effect upon his relief from duty at Ft. Bliss, Texas.

Capt. James D. Glennan, Asst. Surgeon, is relieved from duty at Ft. Sill, Oklahoma Terr., and ordered to Ft. Clark, Texas, for duty, relieving Major Henry S. Kilbourne, Surgeon.

Capt. Walter D. McCaw, Asst. Surgeon, is granted leave of absence for one month, to take effect upon arrival at Ft. Ringgold, Texas, of First Lieut. Carl R. Darnall, Asst. Surgeon.

Lieut. Guy C. M. Godfrey, Asst. Surgeon, is ordered by the Secretary of War, as necessary for the public service, to proceed to St. Paul, Minn., and report in person to the commanding General, Dept. of Dakota, for temporary duty in that Department, and when his services shall no longer be required to return to his proper station at Ft. Sheridan, Ill.

Major Charles Smart, Surgeon, is ordered to proceed to Ft. Sill, Oklahoma Terr., at the proper time to accompany Troop E, First Cavalry, on a practice march, for the purpose of making a thorough test of the emergency ration recently established by the President, and when his services are no longer required with the command to return to his station in Washington, D. C.

PROMOTIONS.

First Lieuts. Francis A. Winter and William E. Purviance, Asst. Surgeons, to be Asst. Surgeons with the rank of Captain after five years service, March 9, 1897.

Change of Address.

Brown, M. M., from Chicago to Plipin, Wis.

Clausen, J. J., from Chicago to 1327 E. 8th St., Kansas City, Mo.

Dodd, Oscar, from Reliance Bldg. to 108 State St. (Columbus Mem. Bldg.), Chicago.

Danforth, I. N., from 903 W. Monroe St. to 758 Adams St., Chicago.

Edmunds, G. W. A., from 420 to 260 Webster Av., Chicago.

Farquhar, E. M., from Chicago to Early, Iowa.

Gardner, E. D., from Davison to Hancock, Mich.

Ghon, Albert L., from 8 W. 127th St. to Reform Club, 233 5th Av., New York, N. Y.

Hand, W. R., from Kensington to Elbow Lake, Minn.

Hummel, A. L., Adv. Agency, from 108 Fulton to 100 William St., New York, N. Y.

Haven, Jos., from 90 Warren Av. to 57 Gordon Terrace, Chicago.

Johnson, L. D., from 103 Dekalb St. to 819 W. Harrison St., Chicago.

Matee, R. J., from 107 W. 5th St. to cor. Van Buren St. and Wayne Av., Dayton, Ohio.

Price, J. R., from 722 W. Division St. to 792 N. Washtenaw Av., Chicago.

Robinson, F. B., from Venetian to Reliance Bldg., Chicago.

Schultz, R. E., from 566 Ogden Av. to 891 Sawyer Av., Chicago.

Sena, E. J., from 31 Washington St. to Room 406 100 State St., Chicago.

Sherman, W. P., from 12010 Stewart Av. to 707 W. 120th St., West Pullman, Chicago.

Seller, C. from 1523 to 1719 Chestnut St., Philadelphia, Pa.

Weldner, Calvin, from Westford, Mass., to L. Box 274, Manchester, Conn.

Ziegler, Joseph, from 125 to 100 State St. ("The Reliance"), Chicago.

ADDRESSES.

ADDRESS DELIVERED AT THE OPENING
OF THE GARRETT MEMORIAL BUILD-
ING, PENNSYLVANIA HOSPITAL.

PHILADELPHIA, APRIL 23, 1897.

BY J. M. DA COSTA, M.D., LL.D.

PHILADELPHIA, PA.

It is difficult for anyone intimately connected with an institution so old and renowned as the Pennsylvania Hospital to estimate fully the influence on thought and action of its very antiquity and renown. From the rooms that preceded the one we inaugurate, from the old rotunda, from the newer building in which until now successive generations of eager students assembled, have gone forth lessons that stamped themselves into the professional mind; lessons that stood by the listener in many a trial; lessons of readiness, of expertness, of cool determination in the surgeon; of profound analysis, of keen detection, of skill in meeting untoward symptoms, in the physician. In the rooms that were anterior to this, have stood and taught those who were not unworthy successors to Rush, who for thirty years was the most conspicuous medical figure in this hospital, as indeed, by his learning, captivating eloquence and ardent zeal he was the most conspicuous figure in the profession in the United States; and to Physick, the dignified surgeon, who bringing with him into our century the appearance and manner of another time, stood before his class with his hair powdered and clubbed, their idol, as in the tones of his cultivated voice he gave admirable illustrations of the conservative surgery of which he was the great exponent. In those rooms taught John K. Mitchell, the versatile and gifted, with the eye of genius foreseeing the part minute organisms play in the production of disease; George B. Wood, as methodical and accurate in his statements at the bedside as everywhere in his respected career; William Pepper, clear in his descriptions and consummate in unraveling obscure processes; William Gerhard, take him for all in all, the greatest observer and clinician America has produced; John F. Meigs, inheriting with his famous medical name an interest in this hospital from the illustrious and inimitable teacher whom also it is our boast to have had on our list, and showing here the same skill and kindness that made him the most sought after physician in the community. In the old rooms also has been heard the voice of Barton, the pride of his colleagues, whose wonderful skill and ingenuity remained a tradition for long years, joined to regret for the early retirement from a profession in which, still young, he attained the first rank; of Norris, the truthful, honest, conscientious gentleman and teacher; of Joseph Pancoast, the brilliant surgical artist, devising processes that seemed to be the result of intuition, and practis-

ing long before it was taught, a kind of antiseptic surgery, of which he himself did not recognize the importance or wider application; and of Agnew, the most esteemed man of our day in the American profession, cool, skilful, daring, yet of the soundest judgment, and a clear, concise, admirable teacher.

Thus from the days, 130 years ago, when Bond enthusiastically, with the full approbation of the managers, introduced clinical teaching into the Pennsylvania Hospital, and therefore on this continent—for it was in this hospital that the first bedside instruction in medicine was given—up to our time, there has been a succession of men bestowing publicly their best thought and experience, without reward, or thought of reward, on those who were to come after them.

It is scarcely possible for one who has been long associated with this hospital, and watched its workings with the eye of affection, to abstain from mentioning the present and his colleagues. But if I may not speak of the living, I know and feel the influence they exert; I am aware of the love they bear this ancient and renowned institution; I see and hear in many ways how worthily they strive to emulate and equal the best records of the past, and to let the teachings of the Pennsylvania Hospital be distinguished, as in the past, for truthful exposition, sound practice, for enlightened, not blind, conservatism, for earnest wish and endeavor to contribute to medical progress.

The traits of the many distinguished teachers that have been connected with the hospital, and the influence of the character of the hospital itself, have made indeed a great school of both practical medicine and surgery developing on rational lines. The men have formed part of the hospital, the hospital has formed part of the men. Nor is it only by oral teaching that the Pennsylvania Hospital has been helping to mold and guide the generations that have come here for instruction. It has also done its part in addressing the wider audiences to be reached through writings. It has given many an enduring gift to the profession at large. From this hospital has emanated or been chiefly promulgated the simplest, most direct and most useful treatment of fractures, recognized and commended the world over; the method of manipulation in the reductions of dislocations; the use of animal ligatures in surgery; the distinction of typhoid fever as a separate form of fever in America, and as preëminently the fever of this country; some of the earliest, and to this day the best, descriptions of remittent fever and its consequences; the connection of joint affections with spinal diseases; the now universally adopted treatment of sunstroke by ice, and other forms of treatment that have become standard. To this, and it is but a partial list, may be added the description of many new operative processes by such masters in the art as Barton, Pancoast, Agnew, Levis; essays and clinical lectures innumerable by observers

like Gerhard, Stewardson, Pepper and Hutchinson. And all have the same stamp of directness, truthfulness, careful observation and practical value. It is greatly to be regretted that so much of this literature is scattered, and has not been collected in the way Guy's Hospital and other great hospitals bring together the work of their men. Some years ago the attempt was made, and two volumes were issued; but the undertaking had to be abandoned with reluctance on account of the expense, with all the greater reluctance because the volumes were most warmly received and lauded.

But to return to the clinical teaching of the hospital. It has taken a profound hold on the medical mind of the country, more profound, perhaps, than we who live in large centers realize. If I may be pardoned for speaking of what has happened to me personally, and of what is, I know, equally the experience of my colleagues; I have often, when summoned out of town into a remote region, met a physician who, as soon as the immediate cause of our conference had been attended to, would ask me about some person whose malady he had heard expounded ten, fifteen, or twenty years before at the Pennsylvania Hospital; or quote, in support of his view of the disorder before us, a case there seen, and describe it so vividly that it seemed as if it had been but yesterday met with. And once, in the wilds of Colorado, encountering a middle-aged man who introduced himself to me he asked, almost as his first remark, "Did the patient brought before us at a clinic," the date of which he mentioned, "recover"? "What were the subsequent symptoms?" "And did all turn out as supposed?" I am ashamed to say his memory of all the circumstances was better than mine, and I could only give him a general answer, which, I fear, lowered me greatly in his estimation.

This wide diffusion of knowledge, this living interest in the doings of a hospital, is one of the advantages of clinical teaching, and it is certain that the hospital that neglects it, neglects a great means of doing widespread good. Moreover, it shuts itself off from the world; it has no ardent friends everywhere with its name on their tongues; it becomes purely local in its character and aims. It never takes rank with the first institutions of its kind, and must be content with a second- or third-rate reputation. Establishments for the sick existed in the time of the Romans. Hospitals, as we understand the term, have been founded since the fourth century. They were spoken of in the Council of Nicæa in the year 325 as institutions well known and deserving support and encouragement. The *Hôtel Dieu*, with its motto, *Medicus et Hospes*, began to receive the sick and destitute about the year 600. The Grand Hospital of Milan, with its several thousand patients, occupies the same building it did in 1456. But who has heard or knows anything of these hospitals, unless from their walls has gone forth something that has taught and been made of use to others; something that, in the minds of regardful men, has become identified with the progress of investigation and of ideas; something that, thrown on the billows of thought, has been carried far onward in the ocean of knowledge.

Clinical teaching, rightly conducted, is a benefit to the sick. There is an opinion that it is only of use to the medical profession, and especially to those about to enter it. To them, indeed, it is invaluable, and through them to whole communities. But it is valua-

ble, too, to the patients themselves. The very publicity of it, the hundreds of critical eyes with which it is observed, ensure that the best thought is given to the helpless and the sick. There must be accuracy, there must be the most strenuous efforts for relief, where there are many keen watchers; and the influence of all this is that the habit thus acquired is transferred toward work, which in its turn becomes more exact. There is very rarely any objection on the part of the patient to having his case publicly investigated. On the contrary, he likes it; he regards it as a mark of interest. To most teachers it has happened to see offended women bursting into tears, because, owing to inability to do so in the time allotted, they had not been taken to the clinic room after being spoken to about it; they were provoked at the favoritism thought to have been shown. Then it must be always remembered that the very ill, or any whom it might possibly injure, are not brought before a class. No one with a spark of humanity thinks of such a thing. Certainly in this hospital the claims of patients have never been subordinated to bedside teaching, and judging by the past, and the record to which we hold, never will be. We recognize, indeed, that we bring to this new room much from the time gone by. We are sensible that the old memories, the old traditions, the old spirit, are moving with us into this admirably arranged edifice. We feel their power, and no member of this ancient hospital can be unmindful of the strength of their hold on his fullest exertions and truest sympathies.

But the splendid room in which we are assembled has other uses than merely those connected with teaching. It is but a part of this Garrett Memorial Building which will be alike a lasting monument to the generous philanthropists that endowed it, and to the forethought, the sagacity, the advanced knowledge of those that planned it. Here is seen in a completeness, nowhere, I believe, as yet equaled, an operating pavilion in which to make modern surgical treatment with its marvelous antiseptic results even more than ordinarily successful. The most minute details are attended to; years of professional experience have contributed to their elaboration. It is the perfection of mechanical ingenuity, the apotheosis of cleanliness, and, with its numerous attractive appliances, its movable tables, its large brass instruments, its adjacent tiled and marble dressing rooms, would be fascinating, if one could only prevent a thought of the grim purpose of all this beauty from entering the mind. Then in this building with its combinations of means, other most valuable arrangements are manifest. There is a room devoted exclusively to operations upon those with infectious diseases that can be filled with live steam at a slight pressure; a room for the employ of the X-rays; there is electric apparatus for resuscitation and treatment; there are rooms for etherization. Then in other parts of the building, for it is more than a mere structure for lecturing and operating purposes, are rooms with every facility for immediate treatment of those brought here too ill or too severely injured to be moved further; there are "quiet" or recovery wards for those whom noise might injure, or who have passed the worst stages; and receiving wards for the reception and distribution to the appropriate places of all patients who are not too ill to be at once assigned to the main medical or surgical hospital. Here then is a building of wide intent and beneficent purpose, planned to meet what years of thought and experience have shown to be most desirable, and exe-

cut in a manner that makes it not only a credit to the Pennsylvania Hospital, but to the city and the country.

This building, too, is only one of the improvements that the present Board of Managers has gradually effected. They have step by step transformed the hospital. An admirable school for nurses with a separate building erected by the generosity of the Misses Blanchard; a surgical hospital due to the munificence of the family of their former president, Wistar Morris, whose memory it worthily celebrates; an endowed outdoor department with every facility, the gift of William E. Garrett, Jr., one of the same family that gives this Memorial Building; the reconstruction of the old building in a manner that makes it the equal of any modern hospital; now this thoroughly adapted structure—surely all this shows careful thought, far-sighted action. The community which believes in them has little by little, occasionally in large sums, supplied them with the means, and, as it is seen how they are used, the springs of benevolence are expanding into broad streams. But they never can be too broad; the need is still great. This hospital, once to a considerable extent supported by those who entered it, is now almost entirely a free hospital, open at all times to those of every nationality and every creed. It still spends more than its income in their support; but, owing to the feeling of attachment and pride which the community has for it, and the reliance on a management which one of my former colleagues in an address has described as an active, intelligent body which never wastes, never misappropriates, it meets all demands and increases steadily. It instinctively attracts to it both in its managers and warm friends those who love their fellowmen, who have a genius for philanthropy, and calls forth the large bequests that, in virtue of the affection and trust it has inspired, have alone made possible the changes in this hospital which are so splendidly transforming it. If it continues to grow on these broad lines it will not be long before, in addition to its antiquity and renown, it will be cited as being one of the foremost developments of the hospital idea in its best form among the modern hospitals anywhere. How all this would have delighted the benevolent souls who founded it! How gladly Bond would be with us today, viewing the growth of what his humanity suggested; and if, at the first meeting of the managers in December, 1756, to inspect the new wards before the sick were admitted, they could have foreseen to what the hospital would attain what would have been their gratification! Perhaps the then president of the board, the great American, Benjamin Franklin, did; and we can see in the pleasure in his benign face, in the light in his large gray eyes, that there has come to him the vision of what, through the natural sciences so dear to him, through the intelligent care of successors as worthy and as true to their trust as the friends that there surrounded him, had grown to be structures as complete as his imagination could have pictured, and as full of such appliances as his genius would have delighted in, and have surely added to. If there could come to us from that vision into the unseen world an expression of the appreciation it occasioned, warm words of approbation would surely reach those whose crowned efforts we are today inspecting.

But in all the changes you, the directors of this great charity, are effecting, one appeal we still make to you for action in a matter we know you are contemplating,

and the importance of which our daily work forces on us. Give us a laboratory, commensurate with the dignity and reputation of this hospital. It will be one more claim to gratitude, not only of the profession, but of the ill and injured, and in its far-reaching results, of science and of posterity. It is no longer possible. It is becoming scarcely conceivable, that physician or surgeon can recognize disease as completely, or treat it as well as it can be treated, without the aid of laboratory facilities. Good work he may still do; but it will not be his best, and very far from the best that can be done. The time has passed for mere bedside labor, and in justice to the sick and injured, in justice to those exposed to possible contagion, laboratory work must supplement or guide professional effort. Crown then your work with what is a recognized need of the day, crown it with what will have the beginnings in it to develop with the wants a portentous future; crown it with a laboratory that now and in times to come will gladden those who look for guidance to this famed institution.

But we know well that for the great plan of which the completed structure we are now in is but a part, neither means nor opportunity exists to accomplish everything at once. For all that has been done already there is true appreciation and gratitude. For the building which is formally opened today let us here express it: It stands as a monument of generosity, of enlightenment, and of ideas carried to perfect conclusion. Noble was the thought that conceived it; noble the thought in one who bore the name of a family that was already among the great benefactors of this hospital to add to a large bequest all that was needed to make the ardently desired beneficent plans a reality. In this Garrett Memorial Building, with an equipment in which nothing that the most advanced science can suggest is absent, pain is to be abolished, the best possible results ensured to the injured and distressed. From here lessons will go forth that will penetrate into every hamlet. Men now, and men in years to come, will, during many an arduous struggle of a long career, turn to it with a sense of gratitude to the generous donor through whose aid many of their difficulties are smoothed, by giving them an opportunity of witnessing how difficulties could be best overcome. And, further, he who is brought to these emergency wards, stricken or so injured that he can not be moved another step without the gravest risk, the most destitute, the most wealthy, will be treated with appliances and in a manner that not many years ago the most powerful of the earth could not have commanded, and will learn to give thanks reverently that there were noble-minded souls that so splendidly and thoughtfully provided for his dire necessities.

ADDRESS

BY THOMAS G. MORTON, M.D.

PROFESSOR OF ORTHOPEDIC SURGERY IN THE PHILADELPHIA POLYCLINIC;
SURGEON TO THE PENNSYLVANIA HOSPITAL, THE ORTHOPEDIC
HOSPITAL, ETC.

We are here assembled to celebrate with appropriate ceremony the opening of the latest addition to the resources of the Pennsylvania Hospital, the "Walter Garrett Memorial," designed to be occupied as a reception pavilion, a clinical, operative and lecture hall and a surgical ward for children. The managers of the hospital, ever mindful of the best interests of the institution under their care, having decided that increased facilities must be provided in order to keep pace with the modern rapid strides of

improvements in surgery, one year ago authorized the construction of this building. Under the supervision and direction of Mr. Addison Hutton and Dr. Thomas S. K. Morton, this memorial building has been planned and constructed. No pains or expense have been spared in the effort to make this the equal of, if not superior to, any other structure of its description in the world. I may add that it has been erected through the generosity of a member of a family of philanthropists, to whom the hospital is already greatly indebted for very generous gifts.

Permit me briefly to invite your attention to the admirable internal arrangements of this building. All the sick and injured brought to the hospital, either by our ambulance, the police patrol or otherwise, are admitted at the southern entrance of the main hall, on the first floor; where all details connected with the patient are immediately recorded. Male patients are taken into the large reception ward on the right of the hall, and female patients and children into a similar ward on the left.

Patients with illness or injuries which do not require their admission into the general wards will here receive appropriate temporary treatment, after which they will be dismissed and directed to return to the out-patient department on Spruce Street.

Patients who are to remain in the hospital for treatment are transferred from the reception ward to the large room beyond, where they will be bathed and otherwise put in proper condition before being taken to the main wards in the hospital appropriate to their disease or injury.

Should an important surgical operation be required, after the same preliminaries as far as possible, the patient will be brought by the elevator up to this hall.

On the first floor, conveniently situated, there are also baths and lavatories, flushing sinks, a steam closet where bedding and clothing may be warmed or dried rapidly, and rooms for ticketing, bagging and storing clothing. One small room contains a steam sterilizing oven, in which infected clothing can be thoroughly cleansed and germs and vermin destroyed. At the northern end of the corridor is a well-appointed diet kitchen.

In the center of the building on the eastern side is located a capacious elevator, of most approved pattern; it is surrounded by a beautiful broad marble stairway. From the first floor there is direct communication with the basement of the hospital by an enclosed corridor, thus affording ready access to all the various wards. This building, it will be seen, therefore becomes the center of distribution of patients to the entire hospital.

All patients admitted to the hospital between sunset and morning will be temporarily accommodated in this building, so that there need not be any disturbance during the night in the general wards, which heretofore has often been unavoidable.

On the second floor, upon which we are at present, the complete series of rooms and arrangements to facilitate modern surgical purposes are not equaled by those of any other hospital in the world. Large double doors lead from the landing or stairway into this commodious clinical or main operating hall. Situated to either side of the corridor and in communication with this clinical hall are rooms where patients can be etherized before being brought into this room for operation.

This hall has excellent acoustic properties, and it

is brilliantly lighted by the ample, glazed dome during the day, and by Welsbach and electric lights at night. The students or spectators enter by a special gate upon Eighth Street near Spruce, and on approaching this hall will find, on the landing halfway up, a coat and toilet room. The seats, which as you notice are in seven tiers, number in all two hundred, are so arranged that there is no obstruction to observation from any portion of the room.

On either side of this operating space, as you may have observed, are sinks, flushing-tanks, wash-basins and pipes for bringing steam for sterilizing purposes. There are also two large water sterilizers, the largest ever made, and here, too, are steam closets for heating blankets, etc., racks for supporting glass reservoirs holding antiseptic solutions; here are also movable glass tables for the dressings and instruments. Behind, and to one side of this operating space, there are doors which open to the dressing rooms for nurses, utilizing for this purpose the space beneath the seats. Nurses who are to assist in the operations, here prepare themselves, their hands and clothing, with the same scrupulous care as the surgeons.

On the other side are rooms in which the sterilized dressings for the entire hospital will be manufactured in accordance with the requirements of antiseptic, with the aid of four high pressure steam sterilizers. Retiring rooms for patients recovering from the effects of anesthetics are also suitably and conveniently arranged. A novel feature on this floor is a room where operations may be performed on patients having virulent and dangerous diseases; after which everything in the room will be subjected to the antiseptic action of live steam, thus destroying all germs and overcoming, in great measure, the danger of communicating contagious disease.

The small operating rooms also situated on this floor are most convenient and complete. An enclosed corridor connects with the main floor of the surgical pavilions of the hospital, so that patients may be transported by the most direct route to the other parts of the building, or from thence to this hall.

On the third floor is a spacious children's ward, capable of accommodating twenty-five beds, with all the conveniences for the little patients and their nurses, including a bright playroom and sun parlor.

I would call your attention particularly to the most approved system of heating and ventilation, to the cemented floors, to the lighting, which is either by gas or electricity, and to the absolutely fireproof character of the building.

At this time you may very properly inquire the necessity for this outlay, and for all the costly appliances to which your attention has just been directed. To properly reply will require a very brief exposition of the facts and theories upon which the modern system of antiseptic surgery rests. If a ray of sunlight be permitted to enter a dark room, innumerable particles of so-called "dust" are seen floating in the pencil of light. These moving atoms have been ascertained by the late Professor Tyndall, to be principally living germs, microscopic in size, and believed to be of vegetable origin and character. Many of these germs are harmless, while others cause serious or fatal disease. Therefore, we exclude from wounds all living germs, and so prevent blood poisoning, or septic infection.

Surgery today is so surrounded by precautions that absolute antiseptic can be secured. The various

apparatus and appliances to which your attention has been directed, and has been found to be capable of destroying disease-generating germs, and the means taken to attain the object, form collectively in surgery what has been termed the antiseptic treatment of wounds.

Sterilization of dressings or of instruments is the complete destruction of any living microorganisms present and the prevention of the growth of others. Water is usually sterilized by boiling, surgical dressings and instruments by moist or dry heat, and wounds during operation are kept free from germs by the use of germicide or aseptic solutions. The importance and necessity of antiseptics in surgical manipulation has, as you know, only been recognized within a comparatively recent period.

The method, however, of purifying water by the use of heat has been known and practiced by the Chinese for many centuries, both for household purposes and for washing wounds. It is also a curious and interesting fact that the precaution was adopted by Cyrus the Great, twenty-four hundred years ago. Herodotus, the Father of History, in referring to the expedition of Cyrus against the Assyrians, says, "The great King, in his warlike expeditions is provided from home with cattle and all other necessaries for his table. There is also carried with him, water of the river Choaspes, which flows near Susa, for the King drinks of no other; wherever he goes he is attended by a number of four-wheeled carriages drawn by mules, in which the water of the Choaspes, being first boiled, is disposed in vessels of silver."

The consideration of the very complete appointments of this surgical building, leads me to remark that the great development and present position of usefulness of the Pennsylvania Hospital is the result of an evolution, due not entirely to its management, which has ever been prudent, efficient and successful, and as such has elicited universal commendation, but in simple justice to those who have passed away, it may be said that the reputation of the Pennsylvania Hospital is in great measure due to the character of its medical staff.

Let me briefly direct your attention to the remarkable personnel of the members of the Medical Staff who served this hospital in its early days, the men who contributed so much to the reputation of the institution, which they so faithfully served.

I find that between the opening of the hospital, and the close of the century, from 1752 to 1799, inclusive, there were twenty physicians all told who served on the staff and devoted themselves to the care of the insane, the sick and injured. They were all men of exceptionally high character, eminent not only in their own vocation, but having acquirements and accomplishments which made them leaders in the community, and active and influential in all its social affairs. They held positions of great responsibility and honor in public life; they had great literary ability and were classical scholars. Most of them had traveled and had been graduated abroad, and they were always received with marked attention in the medical centers at London, Oxford, Edinburgh, Bonn, Berlin, Vienna, and in Italy. They were preëminently men of affairs, and were constantly being called upon to take an active part in the administration of Government. It will, I think, be a matter of surprise to you, as it was to me, when looking into the lives of those medical men who served before the opening of this century, to find how important were the public services rendered, apart from their arduous daily professional work.

Thomas Bond was the originator of the Hospital. At the outbreak of the Revolutionary War, when past his sixtieth year, he entered the military service of his country, and rendered distinguished service by organizing the Medical Department of the Army. He was the founder of the Humane Society, and its first president, Thomas Graeme, was a Judge of the Supreme Court of the Province of Pennsylvania. He had previously been a member of the Provincial Council and subsequently was Collector of the Port of Philadelphia and also Naval Officer.

John Redman was the first president of the College of Physicians of Philadelphia; he was one of the most active of the eminent men who organized that honorable society and was a member of the Common Council of Philadelphia.

Thomas Cadwalader was a member of the Provincial Council of Pennsylvania, and Medical Director of the Army Hospital.

William Shippen was twice elected by the assembly of Pennsylvania a member of the Continental Congress.

John Morgan, at the time of the war between Great Britain and her Colonies, and France, held a lieutenant's commission in the Army, but he acted chiefly as a field surgeon. During the Revolution he was appointed by Congress, director general and physician-in-chief to the general hospitals of the American Army.

William Shippen Jr. was physician-in-chief to the flying camp, and Congress elected him director general of all military hospitals of the armies of the United States.

Preston Moore was provincial treasurer and trustee of the general loan office.

James Hutchinson, when on his way home from France, was entrusted with dispatches from Franklin, then American minister. His vessel, when off the American coast, was chased by a British ship of war, and being determined to save his dispatches, he left in an open boat and, landing under the fire of the enemy, succeeded in his mission; but the vessel was captured and everything belonging to him, including his valuable medical library, which he had carefully collected in England and France, was lost. He became surgeon-general of Pennsylvania, subsequently senior surgeon to the flying camp; was a member of the committee of safety, and he was frequently consulted by Washington on matters relative to the medical department of the Army.

John Jones served in the colonial army in 1775, against the French. He was the intimate friend of Franklin, and his physician during his last illness, and physician to General Washington. He was president of the Humane Society of Pennsylvania.

Foulke was president of the Executive Council of Pennsylvania.

Caspar Wistar was present at the battle of Germantown, but unable on account of religious principles to carry arms, he sought the wounded and was active among those who were administering relief; while Physick, on account of his valuable services to medical literature and medicine, bears the honorable title of "Father of American surgery."

And what shall I say of the immortal Benjamin Rush, the physician of the port of Philadelphia, fleet surgeon of the Pennsylvania navy, physician general of the military hospitals of the middle department of the American army, treasurer of the United States

Mint, a member of the convention of Pennsylvania for the adoption of the Federal Constitution, a member of the Continental Congress, a signer of the Declaration of Independence, and recognized by all as the American Sydenham?

Thirteen of the twenty medical officers referred to were active in organizing the American Philosophical Society, several were founders of the College of Physicians of Philadelphia, and also of the College of Philadelphia, which afterward became the University of Pennsylvania, while ten became professors in the latter institution; several were honored abroad by election to membership in the Academy of France, the Royal Society of London and other foreign associations. Is it any wonder that the reputation of this hospital advanced so rapidly with such brilliant men in its service?

Volumes could be written to record their merits and embalm their memories; but all may be condensed in the single statement, that with them education never militated against personal goodness, for whether in peace or war, in pestilence or plague, in poverty or wealth, they worked nobly "for the good of their fellow beings and the glory of God."

If Franklin, who was the first secretary and afterward president of the Board of Managers, could today revisit this hospital, which he was so largely instrumental in establishing, he would find that wonderful changes had taken place. To begin with, at the time of his death in 1790, only the east wing was built, for the center and west wing were only commenced and finished about the close of the last and early part of this century. He would now find nothing remaining of the hospital, as he knew it, save the walls of the east wing, while the original plan as afterward completed has, within the last year or so, been subjected to an entire internal remodeling, and other buildings than those originally planned have been erected upon the grounds. He would even find the electric fluid which he successfully conducted along the string of his kite, now successfully employed in the institution whose corner stone he laid, as the customary means of sending the human voice to each portion of the entire range of buildings, and also of illuminating the halls and wards.

In conclusion, I wish to direct attention to the important educational services rendered by this institution. The Pennsylvania Hospital may properly be styled the Mother of American Hospitals from the fact that it was the first hospital in this country; but its reputation, which extends through the length and breadth of our land, has been gained not alone because of the tens of thousands of sick and injured charitably cared for, but also from the fact that medical instruction, bedside and clinical, has been a prominent feature from 1752 to this present time, and has been the means of disseminating the best medical thought and practice all over our country. The hospital, during its earlier days, stood forth as the sole representative institution for medical education, offering the only means for systematic instruction in medicine and surgery on this side of the Atlantic Ocean, and this instruction which has continued for nearly a century and a half, was permitted to suffer only a temporary interruption inseparable from the social disturbances accompanying the War of Independence, when the hospital was occupied by Colonial and British troops for their sick and wounded.

The number of students attending the hospital

lectures became so great toward the close of the last century that the managers, instead of crowning the center building with a dome, according to the original plan, decided to utilize the space by converting it into a clinical lecture room, and it was used until 1868, when the present, but now abandoned, octagon clinical hall was opened. Thirty years have now elapsed, and the building then considered the best for the purpose which could be planned, has now been found unsuitable, and has been superseded by this structure. What a like term of years in the near future may evolve in hospital construction, it would be presumptuous to even consider; but it really seems as if perfection has been attained and all possible surgical requirements met, by the erection of this magnificent building, which is this afternoon formally presented to the contributors of the hospital.

ORIGINAL ARTICLES.

PAST AND PRESENT OBSTACLES TO THE RADICAL CURE OF HERNIA, WITH DEMONSTRATIONS.

Read at the Third Annual Meeting of the American Academy of Railway Surgeons held at Chicago, Sept. 23, 24 and 25, 1896.

BY PROF. E. WYLLYS ANDREWS, M.D.

SURGEON TO THE WABASH RAILWAY.
CHICAGO.

Foremost among the obstacles which formerly stood in the way of success with radical cure of hernia was sepsis. This was no more true of hernia than of other abdominal work, but in the days now past when all wounds suppurred in the course of healing and when it was rightly thought that opening into the peritoneum was almost a sin, hernia work could not and did not prosper.

Directly dependant upon this obstacle of sepsis (including septic peritonitis) was that of timidity or conservatism, which acted as a blight upon the best surgeons up to about the time of Macewen's method. This tended in two ways to prevent progress: 1, by limiting the extent of the work, thus promoting half measures; 2, by leading many authorities to condemn radical-cure work altogether.

A third obstacle to success by operators of the past has been the extreme multiplicity of operations proposed and the complicated nature of many of them. It is hardly profitable to dwell upon obsolete methods but I have only to remind you of the names of Cooper, Gerdy, Wood, Heaton, Warren, Ball, Nussbaum, Barker, Sewell, Russell, Czerny, Macewen, McBurney, Woelfler, O'Hara, Lucas-Championnière and ask how many of us can even remember the multitude of methods these names stand for. You may turn over old treatises and scarcely come to the end of radical cure methods you will find. Through them all runs the perverted idea of trying to avoid the simple and essential feature of the modern method, namely, laying open the hernial canal. There were subcutaneous sutures with or without invaginating the scrotum. There were operations for "sewing the pillars." There were ingenious transplantations of muscles, fascia, bone plates and sponge grafts to plug up the canal. There were injections of irritants and astringents which as you know had an extensive use at one time and are still exploited. There were numerous forms of lacing and narrowing the canal by sutures passed in from without.

What has become of them all? They have been abandoned the world over because of their danger or inefficiency. The crux of radical-cure work is in the question of recurrence. Hitherto the rise and decadence of hernia cures have been like morning and evening of the same day. Of the scores of ingenious operations in the pre-antiseptic era not one, even the most rational, but was followed by such a train of relapses as soon to bring it into discredit. It will surprise any one, who will take time to look over the standard treatises of only five or ten years ago, to find how distrustful the best surgeons were of all radical-cure work. The conscientious writer could but admit that the numerous relapses and the occasional deaths made the operation hardly advisable. This feeling of distrust was intensified by the fact that many of the methods which failed so signally had been widely heralded in the beginning as infallible.

With the improvements of Macewen and Bassini began a new era. The "open method," the key to success was introduced. Although I think the Bassini method superior to Macewen's, it is fair to give Macewen credit for the central idea, that of dealing directly with the internal abdominal ring. We must not omit to mention that our own Dr. Henry O. Marcy claims to have used essentially the same method some years before either the Scotchman or the Paduan. In inguinal hernia there is but one strategic point, the internal abdominal ring. If this be reconstructed everything else below that point can be ignored. No operator would attempt to obliterate a scrotal sac as a means of preventing return of a scrotal hernia, any more than he would put a bandage around the scrotum instead of a truss above. It is just as irrational to attempt the closure of the external ring or whole inguinal canal while neglecting the internal ring, which is the only practicable point of preventing the return of the hernia.

Now the modern operations, while they are immeasurably superior to the old, also have some obstacles, and as many of you know I have tried to avoid these by a new operation, the imbrication method, which a number of other American surgeons have used with satisfaction.

Among these may be mentioned Dr. L. L. McArthur, Dr. Jas. Burry, Dr. L. Greensfelder and Dr. Bailey of Chicago, some of whom report that they have adopted it after extensively using other methods. Dr. Cole of Montana (five cases) and a number of my professional friends at various places have kindly informed me of their success with it.

Dr. Wm. J. Mayo of Rochester, Minn., has had a large and successful series of herniotomies. He informs me that he uses the imbrication method in large hernias but continues to employ Bassini's operation for those having moderate or small-sized rings. This is in accordance with my own experience, the need of something to supplement Bassini's method having been found very apparent in certain hernias.

I have preferred in my own work to adopt the new method in every case, as it adds no complexity and certainly gives greater security, but I must admit that Bassini's operation in the favorable cases with small rings gives excellent satisfaction also.

To select my method for the bad cases is at once a high compliment and a severe test of merit, too severe, in fact, to be fair, unless cases be classified in making up statistics.

Having stated that even modern operations encoun-

tered obstacles, I am prepared to sustain the proposition by reference to nearly two hundred herniotomies which I have made mostly within the past six years by every method now at all recognized.

Kocher's method ("Verlagerung's Methode," I, II and III) in spite of the eminence of its author, seems to me a step backward, in that it is not an open dissection of the canal. The twisted or sharply flexed neck of the sac drawn outside the external oblique can not but form a funnel or dimple on the peritoneum. The suturing of the aponeuroses is inefficient, blind and endangers the cord in any but the most expert hands. Furthermore the retraction of the sac by the forceps is not practicable except in cases which pass through the external ring, and not always in them. I have seen many sacs, large and small, which never could have been so treated. It is not possible to determine beforehand whether this is true or not. We have, therefore, in Kocher's operation a method which may or may not be applicable to any given case and we may be forced to change our plan after beginning the operation.

O'Hara's operation is somewhat like Kocher's, with certain steps left out.

Macewen's operation, with its pad of folded sac, is in my judgment easily overestimated. That the sutured and puckered sac really unites into a solid mass in all cases I know of no way of proving. That serous exudate and adhesions gradually give way we do know to be a fact. Nevertheless I have sometimes used the Macewen sac treatment in connection with Bassini's and my own operations in preference to cutting it off. We should be careful not to place too much reliance upon the treatment of the sac as a step in radical cure. The sac is a result, not a cause of the hernial protrusion, and its removal is an incidental not a decisive factor in its cure. If the aponeurotic walls are left weak a new sac will have no trouble in forming, whatever has been done with the old one.

Macewen's suture closing the whole thickness of the abdominal wall into one mass destroys obliquity of the inguinal canal and the natural valvular arrangement. The same thing is true of Halsted's modification of Bassini's operation. With this last admirable operation fewer obstacles are met and its popularity in America, which seems to have exceeded that in Europe, is, in my judgment, well deserved.

As you know, Bassini's essential improvement consists in a careful suturing of the posterior wall of the inguinal canal, so as to reconstruct the internal abdominal ring. To do this it is necessary to split open the canal, to draw aside the cord temporarily and to get rid of the sac permanently.

The suturing of the posterior wall of the canal is a species of plastic operation. It restores the length and obliquity of the canal and contracts the internal ring so that it will transmit the cord, and only the cord, from within outward. The hernia can not now descend because it is stopped at its very point of exit. If it had been stopped at some other point—say in the canal or at the external ring—it would sooner or later make a way in the looser tissues around the obstruction and reappear to the discredit of surgery. Herein lay the weakness of the older methods. They did not go to the strategic point, the internal ring. The external oblique aponeurosis is sutured by Bassini over the reconstructed canal *edge to edge*. This is entirely changed in my operation as will be seen. [The writer, with Dr. Allport's assistance, here dem-

onstrated upon the cadaver the complete Bassini operation and followed this by performing on the opposite side his own or the imbrication operation.]

Now as my subject is "Obstacles," permit me to refer to some drawbacks even to the success of the Bassini operation just seen. As certainly as you do a number of these operations you will come upon cases where its execution is difficult. These are cases of large internal ring with corresponding defect or absence of the posterior wall of the canal. They are not always large hernias, but sometimes the defect is so great that no muscular nor tendinous tissue appears between the ring and the rectus border. Now the repair of the posterior wall becomes difficult because it involves suturing into apposition structures wide apart. It is well enough to place one or two of the lower stitches into Ponpart's ligament and the rectus sheath, but when these tissues must be depended upon too largely to repair the posterior wall the result is very unsatisfactory.

The obvious remedy for such a defect is the use of a flap from some neighboring part to fill this gap.

It seems to have occurred to several operators to attempt this in various ways. Flaps formed of fascia lata and even of a portion of the thigh muscles, such as the tensor vaginae femoris, have been suggested. Woelfler advocated the use of the anterior sheath of the rectus muscle turned outward and sutured into the ring and posterior wall. The problem is to rebuild this deficient wall with a flap of some analogous tissue, which can be brought into position with ease and certainty without additional dissection or damage to other parts. To this end I use the structure nearest at hand, the *upper* segment of the divided external oblique, sliding it gently from its former position in front of the cord to a corresponding one behind it. Observe that its fibers are not changed in direction or even separated from the muscle behind. It is simply incorporated *with* the material Bassini uses in the posterior flap. I can not insist too strongly on the importance of using all the conjoined tendon and transversalis fascia present as part of this flap, since some operators have seemed to think it only necessary to include the layer of aponeurosis of the external oblique. This may be a kind of "imbrication" but it is not my method. Here I desire to call attention to the smooth firm appearance which the canal presents with this new structure incorporated. Of its strength and its unimpaired nutrition there can be no question. The question first suggested on seeing this step in the technique, is whether perhaps we have put the parts under too great tension (see Coley & Bull, Sajous' Annual, 1896, Vol. III). The fact is that there is never great tension here as shown by the ease with which these deep sutures are drawn. The overlapping is only 2 or 3 cm. Is it not true that in a dilated canal the anterior wall is stretched, and that, by thus disposing of the upper flap, we simply make the tension equal in front and behind the cord? Consider, also, how much firmer the union must be between overlapping surfaces than between those united edge to edge as by Bassini.

The *lower* flap of external oblique aponeurosis now remains as a covering to the cord, and is gently laid and sutured overlapping the upper with the cord between them. It is perfectly obvious to you that we now have the same anterior wall as before to the inguinal canal, namely, this aponeurosis. The external ring is also restored as before or perhaps a little

smaller. Into the posterior wall, however, is introduced a new and strong layer. Three layers now occupy the place of two and are so interwoven that they support each other and the tension is equally shared by the two lines of suture. I attach some importance to this point as I have found that in the Bassini method the deep row bears all the stress, and the edge to edge union of the aponeurosis over the cord is not always perfect.

I can not refrain from stating that I have found the principle of imbrication applicable to other purposes such as uniting abdominal wounds after ordinary celiotomy near the linea alba and linea semilunaris; but in this part of the subject I can not hope to interest you at the present time.

DISCUSSION.

Dr. COLE—I had the pleasure about a year ago of witnessing a demonstration of this operation by Dr. Andrews upon a living subject, and since then have had an opportunity to make the operation in five cases, and while that comparatively does not amount to very much, yet I wish to say the operation is to my mind an ingenious improvement upon the Bassini operation and one that will prove satisfactory. Before seeing Dr. Andrews I was prejudiced in favor of the Kocher operation; in suitable cases I still think it is an admirable operation, but I do not think it is so well suited to the average case presented as the practical modification and improvement by Dr. Andrews. You all know what the feature of the Kocher operation is, putting the sac through the upper torsion and making a new operation. I think I have done the operation in three or four cases.

Dr. MAYO—I wish to thank Dr. Andrews for his very clear demonstration of his method of operating for the radical cure of inguinal hernia. He is to be especially congratulated that he has wasted so little time on the peritoneal sac. In the past the treatment of the sac has been altogether too much insisted upon. The peritoneum and skin are the coverings of a hernia and neither has any particular retentive strength. Dr. Andrews wisely shows this in a negative way by dealing almost entirely with the muscles and aponeurosis. The proper restoration of these structures settles the question of radical cure. The sac may be cut off, or as done by Macewen, puckered up about the internal ring; it matters little so long as it is not allowed to evert between the important muscular and aponeurotic structures and prevent their firm union. Like the sac, the skin has no retentive power and is important mainly from the fact that it can only by great difficulty be rendered reliably sterile, and as suppuration is one of the most common causes of failure by introducing relatively weak scar tissue in the place of structural union of tissues, the greatest care in dealing aseptically with the skin is absolutely necessary. Dr. Andrews' method of placing the sutures is a good idea, for in case suppuration should take place the deeper parts of the wound might escape. Greig Smith long ago pointed out that scar tissue is essentially the same between different tissues and always unreliable and that it should be covered by normal structures if possible. Bassini's operation does this most admirably, the line of sutures of Poupart's ligament being protected by the over-lying flap of the external, and the sutures in the external oblique being protected underneath by the deeper tissues pulled under by the previous line of sutures. But when the space of the internal ring is large the traction necessary to bring the conjoined tendon to Poupart's ligament at the lower angle is great and the union endangered by cutting of the sutures. It is to this class of large hernias it seems to me Dr. Andrews' operation can be beautifully applied; it readily protects this weak point by the strong external oblique fascia which is drawn under in his method. Hal-

sted's operation is one which depends on scar tissue union in one line from within out and succeeds only by leaving in permanent silver wire sutures which act as an internal truss. I have done the Halsted operation a number of times with good success. The Kocher operation is defective in drawing the relatively weak sac between the muscles. After an operative experience of 125 cases of radical cure I had come to the conclusion that the Bassini was the most rational operation and I now practice it almost exclusively. Dr. Andrews' modification of the Bassini in the large hernias, where the defect in the abdominal wall is considerable, will be of great value.

A MEMBER—I am very glad indeed to have had this very clear description; it seems to me to be one of the best operations I have ever seen. I never have had much experience—in all probably thirty cases—but on the majority I did the Halsted operation, except in introducing the stitches I devised a little scheme of my own. I used altogether the heavy common gut but instead of inserting the sutures in the same manner as Halsted does on the side, I insert the suture on the top about a third of an inch and draw it out again on top, so instead of the edges coming in contact, the edges were turned into the canal; so you have an edge turned down and that seems to me to abate the tendency to a new hernia forming in the new ring, as in the Halsted operation, because in this method of inserting stitches you have instead no raw bulging edges. This edge where it is carried on the upper ring projects downward, and that downward projection interferes with the proper union and a new hernia is formed. My greatest difficulty is to draw it tight enough to be safe and at the same time to prevent strangulation of the cord. My cases have rarely recurred; the oldest, I think, is a little over six years old; most of them have been in the hospital and I have seen very little of them afterward; some of them I have traced two years, but I have heard of but one or two out of twenty of that method that have lapsed. One case I have had under observation continuously; I was an attendant in the hospital at that time; he had a very large hernia which had troubled him for twenty or thirty years. In this case my upper suture above the cord gave way, causing a protrusion; as soon as I discovered that I opened it and trimmed the edges and inserted a new suture, and that is six months ago and it is very good yet.

Dr. ANDREWS—Of course I am gratified to hear of Dr. Cole's favorable report of cases done by my method. I had the pleasure of meeting Drs. Cole and Galbraith a year ago and showing them my operation, but to hear that this method has been introduced as far as Montana is a surprise. The Kocher operation, like others which depend upon the sac, only seems to me a step backward. Sac adhesions are untrustworthy to retain a hernia. Farther, can any diagnostician tell us whether or not he has congenital hernia before operating? How can Kocher's method be used without a separable sac?

As to the sac, it does not make any vital difference what you do with it. You know the operation of O'Hara consists of cutting off the neck of the sac and retracting the stump, without, however, the deep sutures of Kocher. He leaves the scrotal part of the sac in the scrotum and no harm results in most cases. In a few cases I have dealt with the sac by pushing it back entire. This was when one was found having no distinct neck. Of course a majority of cases have so well-defined a sac that it is easy to strip it gently from its bed and ligate it off. I was particularly pleased with Dr. Mayo's remarks on the sac question. We must not put dependence upon peritoneal tissue for permanent repair, but upon careful reconstruction of the aponeurotic walls. I stand firmly on this principle as embodied in Bassini's and my own method, and distrust the type of operations depending upon sac closure or adhesions. In case of a very large cord or any veins, I do not advocate removing any of them; I always leave two fair-sized veins on the cord and I think one needs to take special pains to avoid

the artery; it is not difficult as it is large, and if you get your artery mixed in with the sutures I think it would most certainly cause gangrene of the testicle.

HEREDITARY ATAXIA—FRIEDREICH'S DISEASE.

A Clinical lecture delivered before the Woman's Medical School of Northwestern University.

BY DANIEL R. BROWER, M.D.

PROFESSOR OF MENTAL AND NERVOUS DISEASES WOMAN'S MEDICAL SCHOOL, NORTHWESTERN UNIVERSITY; PROFESSOR OF MENTAL DISEASES AND THERAPEUTICS IN RUSH MEDICAL COLLEGE, ETC.

[Reported by Conner R. Scheffer, M.D., Clinical Assistant.]

We have before us today, as patients, three members of the same family. In the antecedent history, we can neither see any positive evidence nor gain any information as to venereal disease or alcoholism, two of the most prolific causes of lesions in the nervous system; but we do find a striking record of pulmonary tuberculosis. On the maternal side, two aunts and two uncles, as well as the grandmother, died of this disease. The mother, a French-Canadian, is living and in good health. She is small in stature. On the paternal side there is a history of health and longevity, but we are told that the children were "scrofulous." The father, of the same nationality as his wife, died somewhat over a year ago, of organic heart trouble. So far as our uncertain knowledge can testify, the cousins have had no diseases other than those common to childhood.

In the immediate family there were eleven children, four of whom are not living. Three of these died of acute illnesses, while the fourth was a hydrocephalic baby. There are two grown sons apparently healthy. Three young daughters are in a poor physical condition, having enlargement of the post-cervical glands, and are markedly undersized. We will now turn to the patients.

Case 1.—This boy is 12 years of age, and American born. For the last four years he has had trouble in walking. It began with a slight stagger and has been steadily, and during the past year rapidly, increasing. Notice his style of locomotion. The toes are brought to the ground first, and the feet are widely separated. This is suggestive of spastic paraplegia. He can not walk at all with his eyes closed. There is incoördination of the upper extremities also. There is no atrophy. The deep reflexes are absent, but the plantar, a superficial one, is still intact. This difference is due to the separate paths taken by the sensory fibers upon their entrance into the spinal cord. The deep reflexes enter the posterior columns directly, while the superficial pass into the cornua through Lissauer's zone, and it is not until the posterior horn is involved that the superficial reflexes are lost. Rectal, vesical and sensory symptoms are entirely lacking. Notice the back; scoliosis is a common accompaniment of this disease. There is a double curvature similar in outline to the letter S.

Case 2.—This boy is 21 years old, and was born in Canada. His ataxia has been progressive from the age of 14. His gait is like his brother's, but with a much more widened base, and you see he can not walk at all without the aid of a chair, which he pushes in front of him. There is the same incoördination of the upper extremities, and something that was not found in the first case, a difficulty in speech, shown by his thick, halting articulation. Reflex irritation and the spinal curvature are the same, and in addition to the latter, we have another common deformity, the

turning up of the great toe, which was noticeable a few moments ago. It is not a constant symptom. Frequent pains are present in this case, but notice that they are of late development.

Ophthalmic examination reveals no ciliary or pupillary diminution of reflex, but the field of vision is abnormally contracted in every direction. Nystagmus is not demonstrable today.

Analysis of urine gives negative results. Analysis of blood shows 82 per cent. of hemoglobin, and the excellent record of 4,870,000 red corpuscles.

Case 3.—This young woman is 24 years of age and Canadian by birth. Variola was the starting point of her disease nineteen years ago. The ataxia has progressed until the lower limbs have reached the paralytic stage, and the upper ones an advanced incoördination, the speech becoming more and more faltering, until it is at times unintelligible. Atrophy is pronounced, and the superficial, as well as the deep, reflexes are abolished. There is the same double spinal curvature here, and the hyperextension of the great toe. The last few years have developed lancinating pains in the limbs. The mind is much impaired. Ophthalmic examination, rendered uncertain by corneal opacity and enfeebled mental condition, shows no abnormality. Analysis of urine reveals nothing further than a high specific gravity with an abundance of urates. The analysis of the blood gives us 58 per cent. of hemoglobin, and the extremely poor record of 1,330,000 red corpuscles.

The stigmata of degeneracy is very marked in all three cases, as observed in the tables below.

Diagnosis: These are cases of Friedreich's disease or hereditary ataxia.

Symptoms: 1, the ataxia, beginning in the lower limbs and extending to arms and tongue; 2, the spinal curvature; 3, gradual development of paraplegia; 4, loss of knee jerk; 5, that the symptoms began in childhood; 6, the absence of Argyll-Robertson pupil, of anesthesia, of vesical symptoms, of severe pains, of intention tremor, of spasticity of the gait. These several symptoms readily differentiate these cases from posterior spinal sclerosis and multiple sclerosis.

As to cerebellar heredo-ataxia, I believe the form of the disease before you is identical with it in pathologic process, the one beginning in the cerebellum and giving eye symptoms and exaggerated reflexes in the start, and traveling downward; the other commencing in the lower region of the cord with loss of reflex and no sensory or eye manifestations, and passing upward, finally involving the cerebellum.

Pathology: The seat of the morbid changes is at first the posterior and lateral columns of the cord, later the anterior cornua and finally the nerve structure. In some cases there is developmental failure; in others, an inflammation resulting in a steady encroachment of the connective tissue on the nerve elements.

Prognosis and treatment: The prognosis of the disease is clearly demonstrated before you. We have no cure. Our province lies in protecting the other children as soon as one case is diagnosed. The family surroundings should be the best hygienically, and every care taken for the prevention of infectious disease, which hastens the development of the ataxia. A nutritious diet is necessary, and medical treatment when indicated by the general physical condition. For the disorder itself nerve stretching might be palliative. Alterative treatment coupled with the best

of hygiene, will give as good results as we are able to bring about by the science of today.

CASE 1.	CASE 2.	CASE 3.
Height, 4 feet 3½ inches.	5 feet 2 inches.	Well developed.
Occiput, full.	Full.	Flattened.
Bregma, sunken.	Flattened.	Narrow and low.
Forehead, full and narrow.	Narrow and low.	Dark.
Hair, dark.	Dark.	Considerable.
Hair on face.	Scanty.	Normal.
Hair on body.	Considerable.	Right more developed.
Face, sunken.	Sunken.	Tubercle on right.
Zygomata, normal.	Left more prominent.	
Ears, a, long and narrow; b, Darwinian tubercle on left.	Jug-handle shape; left higher than right.	
Nose, defects to left.	Defects to right.	Normal.
Thyroid gland, enlarged.	Almost a goitre.	Goltre.
Eyes, right higher than left.	Left higher than R.	Sunken.
Jaws, lower arrested, width upper 2¼ in.; high vault ½ in., anterior post. 1½ in.	L. arrested, w. u. 2¼ in., h. v. ½ in., a. p. 1½ in.	W. u. 1¾ in.; h. v. ½ in.; a. p. 1½ in.
Alveolar process, hypertrophy.	No abrasion.	Hypertrophy.
Teeth, six permanent lower, and upper abrasion.	Abnormal muscular development of right shoulder; double spinal curvature.	Abrasion, upper lateral missing.
Body, arrest of chest walls, post.-cerv. and lng'l glands enlarged, double spinal curvature.	Unusually full.	Double spinal curvature; emaciat'n
Breasts, —.	Flattened.	Right not so fully developed as left.
Tibla, flattened.	Flattened.	Flattened.

Dr. Mary Hollister and Dr. Eugene S. Talbot furnished the ophthalmic and anthropologic data respectively.

INFLUENCE OF DIET, IN A CASE OF DIABETES MELLITUS, UPON THE ABNORMAL CONSTITUENTS OF URINE AND UPON THE GENERAL CONDITION OF THE PATIENT.

BY EDWARD L. MUNSON, A.M., M.D.

ASSISTANT SURGEON U. S. ARMY,
FORT ASSINNIBOINE, MONT.

Clinical History.—The patient was a married man, 33 years of age, and of excellent previous health. There was no history of any neurosis, but he stated that his mother had been a great sufferer with neuralgia and had periods of great mental depression. His life had chiefly been spent in open-air work, and on the first of March he had obtained a position as policeman, his weight at that time being 148 pounds. At about that time he first noticed a polyuria and white spots, which evaporating drops of urine left on his shoes. The diagnosis of his condition was not made, however, until the following August, when loss of weight and increasing weakness compelled him to resign his position. He came, on the last day of September, under the care of the writer. At that time his weight was 132 pounds, the general condition was fair, except for emaciation and weakness, with occasional cramps in the legs and a dull pain in the lumbar region. Up to this time his diet had consisted almost entirely of carbohydrates, especially the sweeter pastries, cake, etc., there being an especial craving for such foods. He had never been a spirit drinker. Physical examination showed sound heart and lungs, liver slightly decreased in size, spleen small. There was marked tympanites. On this date the twenty-four hours urine amounted to 8,360 c.c. There was a specific gravity of 1,027 and it was neutral or faintly acid to litmus. No odor of acetone could be detected either in the breath or urine, although a small amount was demonstrated to be present in the latter by Gunning's iodoform test. No reaction with ferric chlorid could at this time be obtained. Sugar was present to the amount of 11 per cent. making a daily excretion of 920 gm. The urea excreted amounted to 67 gm.

October 3, patient placed on rigid proteid diet for forty-eight hours. Thirst is much increased and there is a severe frontal headache with malaise. The urine, on testing with ferric chlorid, gives a strong, ruby-red reaction. It is strongly acid to litmus. Amount 9,370 c.c., specific gravity 1,030, sugar 4.25 per cent. The iodoform reaction had increased in volume fifteen to twenty times.

October 4, appetite greatly increased; otherwise condition unchanged; sugar 1.25 per cent. Ferric chlorid and iodoform reactions greatly increased.

October 8, general condition unchanged; weight 125 lbs.; sugar 3 per cent.; iodoform and ferric chlorid reactions still increasing.

October 12, severe frontal headache for two days; much vertigo and patient feels weaker; sugar 2.25 per cent.

October 16, headaches continue with increasing severity; spasmodic twitching of facial muscles; weight 122 lbs.; sugar 3.25 per cent.

October 22, general condition the same; characteristic urine reactions increased; sugar 5 per cent.

October 26, patient nervous and depressed; frontal headaches continuous. Patient fainted but recovered in a few minutes. Sleep very poor and bowels obstinately constipated; urine shows 0.1 per cent. of albumin; sugar 2.25 per cent.; ferric chlorid reaction shows a maximum intensity; weight 118 lbs.

November 6, condition gradually becoming worse; appetite enormous and considerable dyspepsia. Patient is very weak; sleep poor; memory failing and mind wanders at times, especially at night; urine reactions the same; sugar 5 per cent.

November 12, persistent headache with facial neuralgia; vertigo frequent and insomnia great; sugar 6 per cent.

December 6, mind wanders continually and patient is subject to great depression; much vertigo, nervous irritability and insomnia.

December 7, pulse 108, weak and intermittent; pains all over body. Patient is slightly delirious a considerable part of the time and very despondent and melancholic; urine reaction with ferric chlorid very large.

December 9, cerebral symptoms somewhat improved and sleep obtained by use of hypnotics; bowels badly constipated and much dyspepsia present; sugar 6.25 per cent.

December 14, condition is unchanged; appetite enormous; urine reactions marked; sugar 5.25 per cent.

December 26, has visited in the country for a fortnight; felt much improved at first, but the last few days has had severe headache and vertigo; sugar 6.25 per cent.

January 15, great mental depression with muscular weakness; tormenting frontal headache; urine passed in twenty-four hours 7,230 c.c.; sugar 5.25 per cent.; ferric chlorid and iodoform reactions very large.

January 20, patient is depressed and delirious at night; has bad dreams and sleep is poor. Bromids are given in small doses with relief; weight 112 lbs.; urine in twenty-four hours 7,880 c.c.; sugar 5.25 per cent.

January 28, general condition unchanged, no improvement; sugar 6.25 per cent. Ferric chlorid and iodoform tests very large.

February 3, condition is unchanged; urine passed in twenty-four hours 9,680 c.c.; sugar 7.25 per cent.

February 8, condition is worse; headache is so severe as to induce frequent fits of crying; sleep is poor and vertigo almost constant; amount of urine 10,900 c.c.; sugar 7 per cent.

February 16, patient threatened with collapse. Vomiting; is unable to walk up stairs. Pulse 128, weak and intermittent, with shallow and hurried respirations. For weeks appetite and thirst could not be satisfied. Weight 108 lbs.; sugar 7 per cent.

February 20, condition somewhat improved as regards headache and cerebral symptoms. Urine 9,150 c.c.; sugar 6.5 per cent.; urine reactions strong.

February 22, the condition of the patient steadily becoming worse, it was thought advisable to stop the treatment by proteid diet and allow carbohydrates with the addition of eggs and milk. The patient was encouraged to use alcohol freely, particularly in the form of eggnog, and was urged to restrict the quantities of drink taken as far as possible.

February 26, patient much improved; cerebral symptoms almost disappeared; appetite much less but thirst increased. The patient drank thirteen quarts of milk in the twenty-four hours. The ferric chlorid reaction in the urine much diminished.

February 29, great subjective improvement. Patient feels much better and stronger.

March 3, feels perfectly well except for muscular weakness. Twenty-four hours urine 9,469 c.c.; sugar 7.75; ferric chlorid reaction greatly decreased in intensity.

March 8, strength returning; no cerebral symptoms. Weight 113 lbs., showing a gain of five pounds on this treatment. Ferric chlorid reaction only moderate: sugar reaches its maximum on a carbohydrate diet 9.5 per cent.

March 14, patient rides or walks out every day for short distances; had bad dreams but no other cerebral symptoms. Urine 9,820 c.c.; sugar 7.5 per cent.

March 18, still improving; sugar 7 per cent.

March 22, one month after employing a mixed diet the patient finds himself subjectively better in every way. He has gained in weight and muscular power and the previously marked cerebral symptoms have almost entirely disappeared. Headaches and vertigo, which were formerly almost constant under a proteid diet, are now only occasional and not as severe as formerly.

March 28, patient feels well except for muscular weakness.

March 29, no headache. Patient sleeps well. Ferric chlorid reaction still persists, but is only a small fraction of its former intensity while under a proteid regimen.

April 1, condition unchanged; sugar 5.75 per cent.

April 5, patient still improving, although is still very weak. Sleeps well and has little cerebral trouble; sugar 6.5 per cent.

April 9, has been working out of doors and contracted considerable bronchitis. Otherwise in good condition, although has had two severe headaches which were, however, of brief duration. For experimental purposes the patient was put temporarily on a purely meat diet; sugar 7 per cent.

April 12, patient's cough worse. Headache troubled him yesterday. Urine passed after two meat meals gives an intense ferric chlorid reaction and contains 12.43 grams of ammonia. If the ammonia was excreted for the full twenty-four hours in the same ratio the daily excretion would amount to about fifty times that of health.

April 14, cough much worse with severe pain under left scapula; pulse 120 and weak; respirations short and hurried, 51 to the minute. Physical examination shows dulness on percussion under left scapula, with fine crepitant rales. Temperature 104.4. Diagnosis: Pneumonia. A "pneumonia jacket" was ordered and small doses of morphin with ammonium carbonate administered.

April 15, patient suffering great pain, to quiet which morphin in sixth-grain doses was given by mouth. Physical examination showed extension of the pneumonic process. Pulse 106; 102.6. Eggnog given every two hours.

April 16, has been suffering extremely all night as he refused to take the morphin. Temperature 104.4 and pulse 140. At the desire of the family small doses of morphin were given subcutaneously as were also stimulants. At this time the patient endeavored to urinate but was unable to do so. Shortly afterward he became quiet under the morphin, the action of the heart steadily growing weaker in spite of careful stimulation. Death followed five hours later. About one hour before death he broke into profuse perspiration, the first one in a year. Unfortunately a postmortem examination could not be made.

Influence of diet.—That the ingestion of various food stuffs exerted a marked influence upon the excretion of certain abnormal constituents of the urine was very noticeable. Although, according to the accepted treatment of diabetes, there should have been a great diminution or absence of sugar from the urine while under a proteid diet, in this instance such a diet has had by no means the effect which was to have been expected. Before proceeding to a discussion of the influence of diet upon the several constituents of the urine individually, it may be well to make a general statement to the effect that an exclusive proteid (meat) diet has in this case been observed to directly produce and increase the quantity of certain of these bodies, that this state of things is accompanied by, and is probably in part the result of, an excessive tissue waste and that these abnormal bodies so produced are probably important factors in the production of cerebral symptoms which may so increase as to ultimate in fatal coma. It has also been observed that a return to a mixed diet from a proteid regimen greatly increases the amount of certain of these bodies, this increase being accompanied by marked physical and mental improvement. As has already been stated, this patient came under treatment feeling perfectly

well except for muscular weakness. His weight at that time was 132 pounds. Subsisting almost entirely upon carbohydrates, there was a sugar output of about 980 grams in the twenty-four hours. A rigid exclusion of all carbohydrates was now ordered, the patient being allowed the usual diabetic bill of fare but, from choice, subsisting almost wholly upon meats and animal broths. On October 3 the sugar excretion had fallen to 4.25 per cent., the following day, five days after instituting treatment, bringing the sugar down to 1.25 per cent., the smallest amount to which it ever fell while under the care of the writer. On October 8, there was a rise to 3 per cent. and on October 22, after considerable variation, it reached 5 per cent. During the next three weeks there was a fluctuation of several per cent. on both sides, and on November 12 it had risen to 6 per cent. From that date until February 20, a period of fifteen weeks, there was at no time a variation of more than 1 per cent. from this point. The proteid diet, then, during the five months of its continuance, had succeeded in permanently diminishing the sugar excretion not quite one half. The quantity of urine eliminated daily continued at about the same point—9 liters. Accom-

forms, together with eggs and milk. The use of gruel, rice, oatmeal, bread, etc., was encouraged. Following this treatment, on February 22, the sugar excretion amounted to 6.5 per cent. February 28, it had risen to 9.75 per cent. March 3, there was a slight fall to 8.75 per cent., while on March 8, two weeks after giving a mixed diet, it reached 9.5 per cent., its maximum under this treatment. March 14, it stood at 8.5 per cent., and on March 22, exactly one month after instituting a mixed diet, the sugar secretion had again reached the 6 per cent. mark, which had so long been the average under proteid treatment. There was no great subsequent variation from this point.

But it may be objected that nothing had been gained by a mixed diet, since the sugar excretion remained at about the same proportion. It must be reiterated that the quantity of sugar excreted is in itself of no importance and that a patient with a large sugar secretion is in no more immediate danger of death than one secreting a fraction of that amount. In fact, from a study of this case, the writer is convinced that a patient secreting only a few grams of sugar on a strictly proteid (meat) diet is in a far more precarious condition than one who excretes

panied by what symptoms had this reduction of some 5 per cent. of sugar been accomplished? On February 20 the patient weighed 108 pounds, showing an actual loss of body weight of 24 pounds. Progressive weakness had confined him to his room for the past three months and severe dyspepsia had resulted from excessive ingestion of proteids. Severe cerebral and nervous symptoms had been almost constant for three months. He was daily subject to severe headaches, vertigo and neuralgia; memory had failed and the mind frequently wandered, these symptoms deepening in several instances to slight delirium. There had been one fainting fit, and sleep had been obtained with difficulty and was disturbed by bad dreams and nightmare.

It may be objected that all these physical and mental symptoms were due to the natural progress and increasing severity of the disease itself and that there was necessarily no relationship between them and the diet administered.

On February 22, however, the patient being apparently on the verge of coma and collapse, the treatment by proteid diet was abruptly discontinued and all meat interdicted, the patient being allowed moderate amounts of carbohydrates in easy assimilable

several times that quantity under a carbohydrate or mixed diet. Following the return to a mixed diet this patient showed rapid improvement in every way. He had made an actual gain in weight of twelve pounds, while his strength had so returned that, instead of being bedridden, he was able within a few days to take short walks and drives. The most noticeable and complete change, however, was the almost immediate disappearance of the cerebral symptoms, not relatively but absolutely. There was hardly a trace of cerebral trouble for several weeks, while under a proteid diet headaches and vertigo had been of almost constant occurrence. Sleep was readily obtained and was refreshing, while all traces of depression and melancholia had disappeared. Furthermore, a return to proteid diet was followed by a return of headaches and vertigo.

The following curve shows the sugar excretion between September 29 and April 10, and is based upon the full twenty-four hours urine in each case. It will be readily seen that, in this case at least, a purely proteid diet was not followed by a great permanent increase in the sugar output nor did a return to a mixed diet permanently increase its excretion. In this instance, therefore, the treatment by an exclusive

proteid diet in the hope of cutting off the sugar supply and so preventing its appearance in the urine has entirely failed in its object while at the same time it has apparently induced and aggravated those mental and physical conditions which are premonitory of coma. On the other haad, these symptoms have abated at once on a return to a mixed diet.

During work on the sugar excretion it was noticed that the percentages of sugar varied greatly at different times in the twenty-four hours. Urine passed in the early morning contained only a relatively small quantity of sugar, but this steadily increased until the maximum was passed at about the middle of the afternoon. It then gradually diminished and the urine passed in the late evening only contained a small amount. Such a variation in the excretion of sugar will show the necessity of basing all quantitative estimations upon the entire twenty-four hours' excretion. The ferric chlorid reaction, showing the presence of aceto-acetic acid, could not be obtained from this case previous to beginning treatment, but it appeared with considerable intensity within forty-eight hours after the institution of a proteid diet. It was also noticed that this reaction obtained its maximum two or three hours after a meat meal and was least in the urine passed just previous to such inges-

siderable increase while under the latter treatment. This fact, in connection with the fact that the urine acidity always rose after the ingestion of large amounts of meat by this patient would seem to show that the amount of diacetic acid excreted depended entirely upon the amount of proteid which the system was obliged to decompose. If diabetic coma is due to an acid toxemia, as is now generally believed, a too rigid meat diet must without doubt be a main factor in its production.

The following curve shows the urine acidity so found under both mixed and proteid diet. Under a mixed diet there is a decrease of 14.69 per cent. of acidity, although the acidity under both conditions of diet was in excess of what it was possible to attribute to acid phosphates.

With regard to the excretion of ammonia under mixed and proteid diet it was found by a large number of experiments that while under a meat diet the ammonia excretion was about twelve times that of health, but that the change to a mixed diet was at once followed by a decrease of about one-third in the ammonia excretion.

In this case, then, the restriction to an exclusive proteid diet resulted in a diminution of the sugar excretion about one-half. This was accomplished at

tion. These latter facts were repeatedly noted. This is evidence in favor of the theory that diacetic acid is produced directly in the decomposition of proteid—more especially of the albumin ingested, but also to a certain extent of the body tissue itself—and is not, as has been advanced, a result of the oxidation of sugar.

With regard to oxybutyric acid, the amount of this body present in the urine of this case was at no time large and probably never exceeded 3 to 5 grams in the twenty-four hours. There was, however, a marked increase in the amount of this acid while under a mixed diet. This agrees with Hugounenq (*Am. Jour. Med. Sci.*, October, 1887), who seems to be about the only one who has observed the influence of foods on diabetic urine, and who believes that a meat diet is a prime factor in the production of this body.

For the purpose of supplementing the results given by the ferric chlorid reaction determinations of the acidity of the same specimens of urine were also made. The results so obtained approximated very closely with the variations of the ferric chlorid reaction, showing that aceto-acetic acid was the chief factor in the production of the high urine acidity found in this case. Determinations of the urine acidity in urines passed under proteid and mixed diets showed a con-

the expense of the general health and comfort of the patient, and was accompanied by the appearance and progressive increase of certain abnormal constituents of the urine which were of far more clinical significance than was sugar itself. A return to a mixed diet, in which moderate amounts of carbohydrates were allowed, resulted in the immediate physical and mental improvement of the patient and decrease of the abnormal bodies in the urine. Furthermore, this mixed diet did not permanently raise the sugar elimination beyond what it had been for some months under proteid diet.

CYSTITIS IN WOMEN.

Read at the Nashville Academy of Medicine, Dec. 17, 1896.

BY WILLIAM D. HAGGARD, JR., M.D.

ASSOCIATE PROFESSOR OF GYNECOLOGY IN THE UNIVERSITY OF TENNESSEE, NASHVILLE, TENN.

There is no more prevalent, distressing or intractable malady in the whole range of gynecic affections than cystitis. It is a subject that rarely comes up for discussion in medical societies. It seems that our appreciation of the difficulties and limitations in its treatment, combine to render our interest in the disease lukewarm. Your essayist feels like apologizing

for its introduction before this presence, especially as he has nothing new to offer; yet the extreme distress attending it so far exceeds the majority of conditions that enlist our interested therapeutic and surgical endeavors, that a review of some of the obstacles to its cure and an invoice of our resources should be of the utmost moment.

A perusal of the classical literature on the subject is a most ponderous undertaking, and the detailed description of trivially remote and ridiculous idiopathic causes begetting a host of vaunted remedies is disquieting and mystifying.

Sepsis, "the leaven which leaveneth the whole lump," is the key to both etiology and treatment. The failure to appreciate the causative factorage of pus-producing germs; the rational methods for their extermination and the correction of their depredations, is the entire solution to the misinterpreted etiology and unsatisfactory treatment in the hands of our predecessors. Hitherto the inflammatory and other ailments of the female urinary system, has been illy understood, and lagged in the wonderful progress made in collateral branches of our art, particularly in the revised pathologic conception and treatment of the associated organs.

The most incisive changes in the diagnostic phase of these disorders have been wrought by the perfected cystoscopic methods devised and popularized by Prof. Howard A. Kelly. His labors have led to a more correct appreciation of the infective nature of these maladies, together with the proper means and instruments for their detection and direct treatment. For long, urinary diseases in the opposite sex have been endowed with the best efforts of general and special surgeons, but the corresponding class of diseases in women has been the step-child to obstetrics and the "ugly duckling" in gynecology. The monumental labors of Kelly, supplying methods for differentiation, has placed the keystone of accurate diagnosis to the arch of symptomatology and treatment builded by Skene and Emmet.

While recognizing that the overwhelming majority of cases of inflammation of the bladder result from pyogenic microorganisms introduced from without, the instrumentality of such causes as exposure to cold, retention and decomposition of urine, calculi, foreign bodies, entozoa, neoplasms, tuberculosis, mechanical injuries, croupous and diphtheritic inflammations, and the secondary infection from rupture of an adjacent pus collection, is unquestioned. Yet unclean catheterization must stand the impeached sponsor for the majority of cases of this affection. The extension of septic urethritis, particularly gonorrhoeal, is another source of infection. It is to the prevention of these two large classes of cases that I desire to refer especially. Unclean, rather than unnecessary catheterism, should be the subject of censure. I believe that more cases in obstetric practice should be catheterized and fewer cases in gynecologic surgery. The over-distended bladder in parturient women, unsuspected by the patient and unnoticed by the nurse, should always be the subject of closest scrutiny from the accoucher. Do not wait for dribbling, but insist upon careful measurement and computation of the total daily amount of urine. Urination should be encouraged, even to allowing the woman to sit up on the bed-pan in normal cases after the first few hours. In difficult cases, and where the patient is unable to pass her water, systematic clean withdrawal should be practiced.

In the post-operative care of gynecologic cases, I am especially anxious to encourage voluntary urination, by allowing hot water to trickle over the vulva, by vaginal irrigation, where there is no outside operation or gauze within, and this failing, by hot enema (unless there is sphincter repair). These methods faithfully employed are usually successful. I can commend enemata as the most effective of all methods to encourage micturition. These means failing, the method of catheterization is all important. I append the rules for preparing catheter, and precautions necessary in passing it, in use in the Woman's Hospital.

1. Catheter to be boiled in boric acid solution 4 per cent. for ten minutes.
2. Catheter to be brought to bedside in the vessel of solution in which it has been boiled.
3. Nurse to place patient in proper position for introduction of catheter.
4. Prepare the parts by washing with bichlorid solution 1-3000.
5. Nurse to scrub hands with brush, soap and water for three minutes.
6. Scrub nails and hand with brush and bichlorid 1-1000.
7. Nurse not to touch anything after cleansing hands except catheter, great care being taken not to touch bed, clothing or anything else with catheter before its introduction.
8. This order of preparation as suggested must be followed.

These instructions are printed, placed in suitable places in each ward and cottage and also reproduced in the "Rules for Nurses." Such rigid measures are in pleasing contrast to the routine of "drawing the water under the bed-clothes." They will also serve to accentuate the essential features: Aseptic condition of catheter, antiseptized field of manipulation, clean hands, and the maintenance of an unbroken chain of asepsis throughout. As "a chain is no stronger than its weakest link," so the slightest inconsistency in technique may frustrate our most elaborate details. The use of the family jar of vaselin is a common error. In reality no lubricant is needful, but if it were, its sterilization should be a matter of course. It may be added, that glass or metal catheters are preferable to rubber, for obvious reasons.

The prevention of extension in gonorrhoeal urethritis should enter largely into our active combative efforts in this disease. With the onset of *ardor urinae* the urethra should be irrigated, after the conclusion of the daily disinfection of the vagina, with a 1-20,000 solution of bi-chlorid. The instillation of a few drops of 4 per cent. cocain solution should precede the irrigation, which should be confined to the urethra by pressing its proximal end well up under the symphysis so that none of the fluid enter the bladder.

The habit of long retention of urine by women, through motives of modesty, or inability to evacuate the bladder at regular or suitable intervals, is mentioned as a cause. Over-distention causing a cutting off of the blood supply to the mucous membrane of the bladder, with total or partial death, has resulted in an exfoliation of the entire mucous membrane in sheets and flakes. Jewett reports such a case after retention ninety-six hours amounting to nine pints. I will also mention the danger of accidental chemical injection of the bladder in the subsequent care of plastic cases in gynecology. One of the most desper-

perate and aggravated cases of cystitis I ever saw occurred from the accidental introduction of the irrigating catheter into the bladder and injection of quite a quantity of bichlorid solution 1-5000, in a tight restoration of the posterior vaginal wall. I have known that accident to happen sufficiently often to have a special irrigating tube made for these cases that will not go into the urethra.

Decomposition of urine is in most cases the result of bacteria ingress. Ammonia salts from the broken down urea convert the normal slight acidity of the urine into a marked alkalinity, thus precipitating amorphous phosphates, which unite with the magnesia salts to form the ammonio-magnesium compound, the crystals of which are such a constant constituent of cystitic urines. This chemic change continues as long as the decomposing agent is present. The other casual factors are self-explanatory.

In the initial stages of inflammation of the bladder the mucous membrane undergoes the pathologic changes incident to catarrhal processes of that tissue elsewhere, which are intensified by the resulting abnormal condition of the urine. In the presence of pus the mucous membrane breaks down in shreds and admixing with the pus in the urine gives the characteristic sediment in turbid phosphatic urine. Prolonged irrigation is necessary to remove this debris to allow of cystoscopic inspection. The involvement may be localized in hyperemic patches, or general to some demonstrable point of irritation or infection. Blood may be extravasated under the membrane from contraction on overcharged capillaries, which appear in ecchymotic spots. It also may cover over certain abraded areas after extravasation.

The anatomic changes in the chronic form, like the natural history of this affection, is more a change of degree marked by an arbitrary chronologic standard. A constant change, however, of chronic cystitis is the hypertrophy of the bladder wall and the lessened capacity from resulting contraction.

After thickening of the bladder wall, occlusion of the ureters occurs with damming back of the urine, causing dilatation of the ureters and renal pelves, hydro-nephrosis. Infection, also, extending will give rise to pus kidney. Diphtheritic inflammations may result in any amount of destruction, that sometimes perforates the bladder and involves adjacent structures.

Frequency of micturition and intense burning, bearing-down pain, during and immediately afterward, are the most evident symptoms. The frequency sometimes amounts to literally 100 times a day, and the constant desire sometimes keeps the woman on the vessel for hours at a time. The pain in severe cases becomes excruciating, causing the patient to scream out in frenzy. It is a clinical picture pathognomonic and distressing. Retention is rare and incontinence infrequent in acute cystitis. Hematuria depends upon the intensity of the inflammation and may vary from a few drops at the end of urination, to such a considerable quantity as to appear almost pure blood. There is an aching, bearing-down feeling of weight in the perineum that is sometimes associated with rectal tenesmus. The supra-pubic region is tender, and the discomfort is increased sometimes with the slightest jar. The legs are drawn up in the recumbent posture, and if the sufferer is able to walk, it is accomplished with pain causing her to shamble in a stooping position.

In graver septic and diphtheritic cases, constitu-

tional symptoms supervene; fever, chills and sweats, sometimes delirium, ending in suppression, uremia and death.

The appearance of the urine is characteristic in chronic cystitis. It is murky and filled with shreds that may be seen floating around. If allowed to stand it will present a thick, slimy sediment that sticks to the bottom of the receptacle when it is inverted. If bacterial fermentation has occurred, either within or without the bladder, the deposit will consist of the alkaline phosphates of a dark brick-red color. Microscopic examination will demonstrate the crystals in the last condition and abundant pus cells, sometimes with red corpuscles as well, frequently entangled in long mucous cylinders. Bladder epithelium will be scattering and more or less abundant, in the acute and chronic forms, respectively. It is quite impossible to discriminate between cystitis and pyelitis by the epithelium found microscopically. The presence of pus or blood gives a decided reaction for albumin. The odor is ammoniacal and fetid. Specific gravity is variable and inconsequential. The absence of the findings in clinical manifestations of cystitis, distinguish cystitis from irritable bladder, a reflex from some cause that patient examination will often reveal.

Aside from the distinct gain in making direct applications to localized diseased areas, the most valuable aid of the cystoscope is the exact diagnosis of the existing condition. Kelly found a sinus communicating with a tubercular ovary which would have been impossible otherwise. In addition to furnishing visual inspection of the entire vesical mucosa, it affords means for determining the presence or absence of disease of one or both ureters and kidneys, which otherwise might be regarded as a cystitis. The accuracy and value of this procedure is scarcely paralleled in mechanical aids to diagnosis, since the introduction of the clinical thermometer.

I believe it is an axiom in medicine that the greater the number of remedies recommended in a given disease, the less reliance can be placed in any of them. This is typically true of the disease under consideration. The whole list of balsams and oils, astringents and antiseptics, acids and alkalies, diuretics and opiates, have been used with routine empiricism. Irrigations have been practiced with nearly everything that is soluble in water, and many drugs that are not. Some misguided enthusiast inspired with a great love for "the eternal fitness of things," has even recommended irrigation with normal urine. I spent the greater part of six months of my residence in a large hospital washing bladders, and have about settled its scope and limitations, at least to my own satisfaction. Instead of using the multitude of irrigating solutions that have been urged by this and that observer, I think we may reduce the number to about four, which are employed for as many reasons. For ordinary purposes normal sterilized salt solution (dram to the quart) is the most useful fluid, in that, it is readily soluble, more cleansing than water, non-irritating and sterile. In chronic cases with alkaline fermentation, a half saturated solution of boric acid seems to be more efficacious. Kelly recommends bichlorid solution 1-100,000, increasing the strength by taking off 5,000 until about 1-20,000 is reached. The infinitesimal strength suggested may be the explanation of why bichlorid has been almost excluded from the bladder.

Salicylic acid is an excellent germicide and is especially efficacious in penetrating the thick slimy coat.

of muco-pus that invests the bladder wall. Eight grains dissolved in an ounce of alcohol and added to a pint of hot water is equal in efficiency to Thiersch's solution. The sovereign remedy in the treatment of inflamed mucous membrane is nitrate of silver, one-tenth to one-half per cent. Stronger solutions should be avoided, and if it causes much pain, a strong salt solution should be injected to convert the nitrate into a harmless chlorid.

All local means are quite inferior to the direct application of remedial agents through the cystoscopic tube, which insuring application to the affected area only, allows the employment of much stronger solutions of silver, 3 to 10 per cent. once a week.

The correct apparatus for bladder irrigation should consist of a glass jar or fountain syringe with gravity tube and glass catheter. The distal end of the rubber tube should have a glass tip to connect by a short piece of tubing with the catheter. The tip facilitates detachment from the intermediate rubber tube instead of the catheter itself. The detachment and readjustment causes unnecessary pain. Where the organ is intolerant to even a few ounces, the little glass piston syringe should be used.

In this synopsis of treatment as frequently occurs in actual practice, I have hastened to the local means to the exclusion, thus far, of the general systemic management, a neglected but important matter.

In the early cases, patients should be put to bed and composure enjoined. She should have a mild non-stimulating diet, milk being the chief article, occasionally dashed with cream to prevent the constipation. Salines here as in all pelvic inflammations are invaluable. Relief from pain had best be obtained if possible from topical means, viz.: the quite hot vaginal douche, Sitz bath, hot-water bags, or compresses to the hypogastrium. Internal medication should be confined to correcting abnormal conditions of the urine; acetate of potash for hyperacidity and benzoic acid for excessive alkalinity.

It is unnecessary to state that many cases are intractable to all forms of medication, and it is fortunate that there remains a perfect assurance to these wretched individuals of complete and entire radical relief. I refer to the artificial vesico-vaginal fistula as applied to the cure of otherwise incurable cases of cystitis in women by that venerable benefactor to suffering women, Dr. Thomas Addis Emmet.

This operation, like the plastic operations devised by Dr. Emmet, is unique in that it has remained unchanged since it was given to a waiting world by its illustrious originator.

The two essentials of rest and drainage are fulfilled and by the union of vaginal mucosa to vesical mucosa patulency of the opening is insured. The beneficence of this procedure to the afflicted sufferers is best proven by their disinclination to have the fistula closed. The operation is best performed in Sims position. The vesico-vaginal septum just behind the urethra is fixed with a tenaculum and incised in the middle line, with knee-bent scissors, on the point of a block-tin sound introduced through the urethra. The mucous surfaces of bladder and vagina are united by silver sutures. Irrigation and time complete the cure. The sutures are removed on the tenth day.

The only caution I will urge is the reiteration of the advice of the great master himself: "Do not close the opening too soon, six months is an average time."

It is a gratifying circumstance that one of the most

dreaded maladies that woman is prone to, is curable by one of the simplest and most satisfactory operations in surgery.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

CHAPTER V.—SURGICAL INSTRUCTION AND LITERATURE.

(Continued from page 840.)

During the violent epidemics which prevailed among the troops in the field the enormous number of six hundred physicians and surgeons died within eighteen months. The lack of these was sorely felt, because instruction had almost come to a standstill during the Revolution, and out of eleven French schools scarcely two remained in the least active. At this time Chaussier, who had been called from the convent to Paris, and had rendered the greatest service in the reorganization, founded, in coöperation with Fourcroy in 1794, the nucleus of three new schools in Paris, Montpellier and Strasburg. They founded the *Ecole de Santé* in Paris, one of the finest fruits of the Revolution, which through the need of the moment, proved a brilliant success, and forced into the background the medical schools which had previously dominated in Montpellier. It accomplished the union of medicine and surgery, while at the same time it trained physicians and surgeons, among whom there was no division, except that the few who showed a special inclination for it, devoted themselves particularly to the larger operations. Legally every student was obliged to study theoretical and practical surgery. In order to have the necessary number of students, each district must furnish a certain quota: Paris 300, Montpellier 150, Strasburg 100. The state allowed each student 1,200 livres, and vouchsafed to him free access to the practical lectures. Medicine and surgery, together with all the accessory sciences, and also the history of medicine, were taught and twelve chairs, each with an ordinary and extraordinary professor, were created. In the Paris school Chaussier expounded anatomy and physiology, Fourcroy medical chemistry, Lassus and Percy, after the death of Chopart, surgery, Pinel medicine, Lallemand and Sabatier operation, Baudelocque obstetrics; Pelletan and Boyer, after Desault's death, conducted the surgical clinic, Corvisart the medical. Chaussier was a very eloquent and active teacher, who created a new terminology in anatomy and established regular quiz-practice. The study of anatomy was always prized very highly by the French surgeons, in-so-much that most of their literary activity began with such writings, followed by surgical works. Among the most interesting lectures were those of Fourcroy, which were generally so crowded that many were turned away, in spite of the fact that his lecture room accommodated about 1,200 students. He charmed by his unconstrained, penetrating and polished discourse, and frequently blamed his own countrymen because they so neglected the literature of other nations, while he himself valued so highly the services of the German chemists. Lallemand lectured on operations on the hard parts; Sabatier, in clear but somewhat rapid diction, treated of the soft parts.

For practical instruction there were three clinics in

use, in the Hôtel Dieu, in the Charité, and the clinique de perfectionnement in the hospital of the Ecole. The last had twenty-eight beds for difficult and unusual cases, but especially for operation cases, which the professor asked from his colleagues. This did not work well, as a rule, for according to an old custom, those came almost always to the Hôtel Dieu and the professor retained them there. He had in any case to give instruction concerning them, and nothing was more natural than that each professor should keep the most interesting material for himself. Upon the establishment of the school, Desault gave the surgical instruction in the Hôtel Dieu. In this brilliant period so much was being accomplished that the men of the Revolution sought to unite these clinics as closely as possible with the Ecole. But Desault was not greatly interested in it, because he had not been asked for advice at its founding, and in general did not approve of the plan. It might have been also that his prejudice against the accessory sciences, of which the Ecole made very much, contributed to keep him aloof from it. He died soon after. His successor, Pelletan, let things take their own course. The two men were not to be compared. While Desault studied his lectures with the greatest care and never neglected them, Pelletan frequently failed to give a lecture, was negligent, egotistical and poor in results. He divided the lectures with his assistant, the young Giraud, who after the death of Desault, with his pupils, Bichat, Boyer and Lallemand, were among the best teachers of surgery in Paris. Both conducted *pensions*, a provision at that time very useful and beneficial to the cause of instruction. They took young men into their houses and to their tables, gave them instruction in operations privately, took them to visit patients, and reserved for them the best places at the operations in the hospitals. Pelletan charged 1,000 francs quarterly, but fulfilled his promises badly, while Desault furnished board about two-thirds cheaper and favored his pupils in every way possible.

The surgical clinic in the Hôtel Dieu had two rooms, one for men with about 300 beds, and one for women with 150, closely crowded together. Instead of pursuing Desault's method, and performing the operations altogether in the amphitheater, Pelletan almost always operated on the patients in their beds. Let us accompany him upon a *surgical visit*, in order to learn about them along with the *French students*. In the morning, at six o'clock, it begins. As soon as Pelletan enters the room the noise and the running about commence. He and Giraud are followed by thirty internes, to each of whom a certain number of beds are allotted; behind these other students with their clattering wooden shoes. These were generally worn during the Reign of Terror, because of the lack of leather, and continued to be used by most of the students on account of the dirt. Each one pushed in behind Pelletan, so that they often trod upon his feet. When a patient is bound they all crowd to the bedside, in consequence of which only six or eight students can see well. "La jugulaire," cries the surgeon; that is, here a bleeding is to be made on the V. jugularis. Those behind climb upon stools and punch each other in the ribs in order to get forward as much as possible; finally the surgeon is so crowded that he himself scarcely has room. A "Silence, messieurs!" does not suffice. The noise grows louder. A "diable!" or "au nom de Dieu!" follows. Noise and crowding increase, so that the foremost students are pushed

over the bed of the patient. It becomes dark around the bed, even on a clear day; "la chandelle!" calls the surgeon; "vous m'étouffez!" the patient struggling for air; "l'eau fraîche!" a student, to refresh his fainting comrade. "Je vous donne un pair de soufflets" sounds from the other side. A student breaks through a bedstead and laments. Pelletan does not know how to help himself; crowded with instruments around him, he takes a handful of blood and calls out, "Je vous jette le sang dans le figure." Under such circumstances the operation is completed. This confusion moves Pelletan to perform a few operations at four o'clock in the morning and to cut the visits short. There was generally a mistake in the clinics, which the visits rendered too hurried; students were not examined, therefore they lounged about inattentively. Sabatier's lecture furnished another student picture. This surgeon was very cordial to strangers and usually gave them a place in the enclosure. The students murmured over this because they could see nothing, but their professor did not change his method. One day, when a few friends were present, a chorus of a thousand voices cries, "Out from the enclosure!" Sabatier, usually a very quiet, peaceable man, sprang up and cried, "I hope, fellow citizens, that I am allowed the privilege of admitting into this enclosure anyone I desire!" Immediately all was still. Sabatier seated himself, whereupon loud and general applause arose, one of the sudden changes of sentiment which one sees almost daily in other things among the French (Wardenburg). The students were classified, according to their accomplishments, into *commencans*, *commencés* and *avancés*, and in regard to their attendance at lectures, were summoned from time to time by the professors. This strictness was occasioned by foresight for the army, for the *avancés* could, if necessary, be assigned to the field. Two examinations were held yearly. In the Charité *Boyer* officiated as second surgeon, along with the genial but indecisive first surgeon, *Deschamps*. Boyer, a former assistant of Desault, in the best years of his life, was uncommonly active, earnest and decisive, and operated with a steady and sure hand; in fact, one of the best of the Parisian surgeons. His private instruction was of the best, as well as the most popular. Boyer conducted dissections, gave lectures on anatomy, surgery and operations, conducted courses in operating, and examined the students. Since he took only two private pupils, for a certain fee, one could accompany him in his private practice.

The medical clinics attached to the Ecole de Santé in Hôtel Dieu, accomplished nothing; their instruction did not amount to anything; by reason of the hurried visits they were of no real benefit; they ran from one bed to another, inspected so quickly and so incompletely, that they scarcely had time to see, much less to think. There was no instruction tablet at any bed. *The medical clinic of Corvisart, in the Charité, the first which was opened in France*, was much better. According to the statement of his pupil, Dupuytren, he made it the most famous of that time, and there in a period of fifteen years the most excellent physicians of France were trained. Corvisart, an eager follower of Stoll, made very accurate sections, and as a practitioner he was much sought. The Ecole possessed a beautiful library of about 24,000 volumes, which was built up during the revolution, out of the libraries of the Académie de Chirurgie and of the defunct societies. It was under the protec-

tion of Sue and Moreau. It was free of access, but lent only one book at a time to each student. Among the collections, the cabinet of surgical instruments was accessible to all, and was very complete, having been especially enriched by the bequest of Desault. The pathologico-anatomic cabinet contained Desault's specimens, many of wax, and the collections of the veterinary school of Alfort.

The German saw in Paris, the center of the sciences, everything at once, which he could wish for the study of medicine, but no one traveled to Paris for the sake of medicine, and in 1783 Loder wrote from the French capital: "Whoever comes here to study medicine appears to me as one who should go to Constantinople to get instruction in the orthodox Lutheran creed." There was no doubt that the French physicians, in respect to medical knowledge, were behind the Germans; the reverse was true in surgery. Hôtel Dieu had the greatest attraction for the German surgeon. In order to make the most systematic use of this, he had to select and study the most interesting patients, ingratiate himself especially with the internes, and on afternoons accompany them to the sick-beds. In these visits it was the policy to push when one was pushed, in the effort to get as near as possible to the surgeon. The foreigner could nowhere find collections as complete as in Paris. All the practical lectures of the Ecole were very good, and it offered fine facilities for private courses, as well as for anatomy (Bichat) as for surgery. For quick information there were printed collected lectures in the Ecole, with yellow, white and red covers; an almanac was also issued which bore, now a national, now a royal imprint, giving information concerning the institution, the teachers, their residences, etc. Close beside the school lived several booksellers, who dealt chiefly in medical works.

A rare opportunity to see and to hear was offered in like measure in England. It was a principle there that from the beginning of their studies, the students must see the sick daily, while in Germany they began with theoretic lectures, in England the manual part of surgery must first be mechanically learned. One must see the sick, how they were operated upon and bandaged, and then for the first time he studied the propedeutic branches. Although properly only a single famous school existed, in Edinburgh, still there were in London many distinguished physicians and surgeons who gave private lectures, offered courses, and instructed young men in the hospitals. In London there was a mass of material for surgeons and a great many operations were performed. The "pupils" could assist in the hospitals, in bandaging, bleeding, caring for fractures, and the like, and enjoyed free access to the patients at all hours. In special cases, which occurred outside of the regular visiting hours, the boxkeeper, who looked after the bandaging materials, would summon the students for a fee of half a guinea. Certain English teachers, like their French colleagues, took boarders into their houses for 80 to 100 guineas, gave them lectures, and took them to visit private patients. Percival Pott was the best and most popular surgeon of his time in London. In this respect the genial *John Hunter* came next, although his discourse was difficult to understand, as his speech and expression were peculiar. Furthermore it was painful to him to speak, as it was to his brother William, and always cost him much effort. The powerful man, who did not fear a fight with leopards, always took thirty drops of laudanum before the first lecture

in every course in order to overcome somewhat his nervousness. He never depended upon his memory. By reason of his genius and penetrating understanding, his lectures, which were accompanied by the exhibition of beautiful specimens, were of the greatest importance. John Hunter gave an especial impulse to the science by the founding of several societies. In 1767, he with Fordyce and the mechanic Cumming, founded a private society of scholars, which met in a coffee house after each sitting of the Royal Society, and discussed the latest discoveries in all branches of science. Later he founded for the London students the Lyceum Medicum Londinense, which held meetings every Friday, and gave a prize of six guineas in gold to the student who wrote the best thesis on a given question. In the winter of 1786 he founded in his own house a medical club, and invited there every Sunday all the prominent physicians and surgeons of London, as well as strangers who were recommended to him. Here numerous guests met in the evening from 8 to 11, discussed scientific questions and were served with coffee, tea and refreshments. Else, Bromfield and Blizard were good surgical teachers. Blizard attended very regularly, and met many colleagues who would not willingly soil their fingers and never touched a patient except at the first examination and operation, but he left no patient who was not bandaged by himself, or by the students in his presence. London possessed excellent museums. The most famous was that of William Hunter, which was rich in the rarest specimens, and once in the week was open, free to the public. Besides, Hunter possessed fine collections of shells, corals, petrifications, a coin cabinet which was said to surpass even that of Vienna; also a library. By his will these collections were to be used for thirty years by his heirs for the benefit of Drs. Baily and Cruikshank of London, to further their lectures; at the end of that time they went to the University of Glasgow. Next after this, was the museum of J. Hunter (of which more later), Rackstrow, with many anatomic and pathologic preparations. Even then as now, the English surgical instruments were the best, but were very dear; an umbilical truss for adults cost ten guineas, a simple inguinal truss, five guineas, a double one, six guineas. The articles of the instrument-maker, Savigny, in London, illustrated and described in catalogues, were world-renowned. Shel-drake was called as truss-maker to the Westminster hospital; he also wrote much concerning rupture and deformities. The beadle of the Collegium Chirurgicum made very good bougies.

We have mentioned that the cost of living and of visiting the London hospital drove many young men to *Edinburgh*, in which University a spirit of freedom dominated all the medical sciences. Here the first English clinic was instituted. The students organized medical societies, where by the exchange of their ideas they developed themselves symmetrically and learned to express themselves with facility. Therefore, the most of the Edinburgh inaugural addresses with their compact, unvarnished descriptions, without the adornment of the tedious citations of German works, raised the university to great honor. They first became known in Germany through the *Göttinger Anzeigen*, in which H. von Haller recommended them for imitation. Edinburgh possessed a fine academic hospital, which was erected at the suggestion of Alexander Monro, and possessed a number of emi-

nent surgeons, among them that same Monro with his two sons, Benjamin Bell and others.

The facts given show very plainly that Germany, by reason of the lack of hospitals, and of facilities for a thorough practical training, stood far behind foreign nations. No wonder then that the German surgeon in his home was thrown upon the study of books. Let us therefore make a few observations, concerning the *literature of the subject*. In the first half of the century the leather-bound books of the German surgeons, appeared almost regularly with a verbose dedication to some distinguished patron; then followed the preface which was adorned with some kind of religious sentiment, praise of the divine goodness and humble thankfulness for the providence which vouchsafed the author health and time to write the book. Very often the close friends of the author had urged him, and he had unwillingly published it. He did not forget, however, to take some notice of the possibility of unfavorable criticism. The conclusion of the preface was made up of two or more expressions of good will by colleagues in Latin or German verse. The following poem from C. L. Walther's "Med. chir. Schatz," of the year 1715, will serve as an example:

As the honey bees of Hybla yield us their sweet stores,
They seemingly invite us to share in their industry.
A song for all humanity the busy insect pours,
A peace song for all nations that war by land and seas;
Herr Walther in his labors heeds the lesson of the bees,
He falters not nor wearies, and counts no labor vain,
And his life is consecrated to the healing of disease.
Rich success crowns his endeavor and to all the world is gain.
This book of so rare value, Science claims it for her own,
And for each it holds a treasure, let who wishes freely ask.
Would the poet sing his praises, let him sing of work well done.
I bespeak a wreath of laurel justly crowning his long task.
May God grant that, like the roses, he may bloom another year
With a second season's harvest, rich and plenteous, ripe and fair.
To his most honored colleague these few lines are hurriedly addressed
by
CARL ANDREAS HARDE, Surgeon, Halle.

In the books themselves, which were generally insipid and prolix, the Almighty was asked for his blessing on every important operation. At the end the author took a pious leave of his reader. The copperplates in most of them, were of extraordinary beauty. Comparing with these the writings of the second half of the century, we find that the later books lack the poetic effusions, but the turgid dedications, and the pious prefaces in which the authors seek to defend themselves against ungrounded and malicious criticism, remain very much the same; and also the insipid exhortations to others to write books in which a surgeon frequently first asked learned physicians whether or not his works deserved to be published. As, for example, Bilguer assures Theden he never would have become an author, if he had not been inspired by Zimmermann, and begs the pardon of the physicians when he, in speaking of a medical question, ventures into their territory. C. C. von Siebold waged a ceremonious war with his friends before he published his surgical daybook.

The *servility* of the former century had also affected the scholars and physicians so that they often assumed a groveling attitude toward high rank and wealth and were dazzled by external glory. They were not ashamed to dedicate altogether insignificant works, scarcely three or four pages long, to princes and dukes. And the thanks? When Morand presented the *Memoirs of the Akademie der Chirurgie* to Pope Benedict XIV., he received an answer from the Pope. E. Platner says in this connection that a German prince showed this honor to every insignificant French author on similar occasions, but to a German he would scarcely condescend to be gracious. In 1764 Pro-

fessor A. F. Pallas dedicated his "Surgery," to the "Hoch- und Wohlgeborenen, Hoherfahrenen und Hochgelharteten Herrn, Herrn Albert Freiherrn von Haller," his great, most gracious and honorable patron. In order to honor the celebrated A. G. Richter, they admitted his infant yet in its cradle to membership in the Academy of Göttingen, and one of the teachers, Köler, dedicated to it in its fourth year, as the "best and most hopeful of boys," synopses for the study of the Latin language. The physicians joined in the adulation given to the hero of Germany, Frederick the Great, after the battle of Rossbach, insomuch that George Forster in Berlin complained that even the most reserved and intelligent people deified the king, and groveled foolishly. The *Berliner Medicinisch-chirurgischen Nachrichten* was dedicated to the crown prince, Frederick, by Professor Schaarschmidt, and the Surgeon-Generals Bilguer and Schmucker, dedicated their "Chirurgische Wahrnehmungen," to his majesty, and Surgeon-General Theden, his new "Bemerkungen und Erfahrungen." The medical biographer Börner launches the following rhapsody: "Your most glorious royal majesty of Prussia, in whose blessed person are united the wisdom of Solomon, the spirit, courage and strength of Alexander the Great, the benignity of Emperor Titus, a possessor of true learning, a protector of the Muses, a patron of scholars, King Frederick." Even the philosophic Zimmermann, who went to Berlin in 1771 to be operated upon for rupture by Schmucker, was so dazzled by Frederick the Great, that his friend Meckel, in whose house he lived, could write the following: "Zimmermann, completely enraptured by the exceeding glory of his royal majesty, felt as though he had been given a new life, that he should have the fortune to see and to honor personally the greatest wonder of our century, our most wise king of Prussia. For the well known kindness and humanity of our most gracious monarch, not only called the English surgeon before the throne but quickened and uplifted him at the first glance, into a sort of amazement, at the most gracious and beneficent words and speech to such a degree that, completely enraptured with joy and love, he was for an hour and a half a spectator and admirer of this royal genius, of his great learning and wisdom, and of his deep insight even into medical science. He often said that these precious hours had fulfilled the desire of his life, and that he had arrived at one of his most glorious days, when he was able to see and speak to and love the hero of his century." Later, Zimmermann wrote to Meckel in French that he had slept well every night during his sickness "except that one in Potsdam, when after the interview with the king, he was made sleepless for joy, as if in an ecstasy of delight."

(To be continued.)

SOCIETY PROCEEDINGS.

Medical Association of Georgia.

Abstract of Proceedings of the Forty-eighth Annual Meeting, held at Macon, Ga., April 21, 22 and 23, 1897.

FIRST DAY—MORNING SESSION.

The Association convened in the Academy of Music, and was called to order at 10 A.M. by the President, Dr. GEO. H. NOBLE, of Atlanta.

Prayer was offered by the Rev. F. M. REESE of Christ Church.

Addresses of Welcome were delivered by Dr. W. F. HOLT

and Hon. N. E. HARRIS, of Macon, the response to which was made by Dr. FRANK M. RIDLEY, of La Grange.

The Society elected 101 new members.

After the presentation of the report of the Committee of Arrangements by Dr. Howard J. Williams, of Macon, and the report of the Committee on Program, by Dr. Louis H. Jones, of Atlanta, the reading of papers was proceeded with.

The first paper read was by Dr. M. A. CLARK, of Macon, entitled

ENTERO-COLITIS OF INFANCY.

The author prefers the term entero-colitis to intestinal catarrh, because it more fully expresses the pathology of the disease. While in adults and children we recognize enteritis and colitis as separate and distinct diseases, yet in infants the symptoms are not sufficiently well marked to enable us to differentiate them. The inflammation of the small and large intestines may be ulcerative, membranous, or, as is more frequently the case, a simple inflammation of the mucous and submucous linings of the intestines.

Causation.—Cold is often a cause of entero-colitis, and in a majority of the severer cases, it plays an important part. The most important factors, however, in the causation of this disease are temperature and diet, which the author considered at some length. The majority of fatal cases are bottle-fed infants. Of 1,943 fatal cases reported by Holt, only 3 per cent. were wholly breast-fed. All writers agree that outside of the cities, especially in the rural districts, it is of far less severity.

The author then dwelt upon the symptomatology, diagnosis and prognosis of the disease.

Coming to the treatment, he said the first and most important duty of the physician is to prevent disease. So in this disease, we must consider preventive treatment. Every infant should wear throughout all seasons flannel next to the body until the period of infancy is passed and childhood well established. With reference to diet, the all-important factor, not only in the cause of this disease, but also in the cure of it is diet. In the majority of cases the infant is bottle-fed, yet we find some severe cases that are breast-fed. In every case we must examine the milk to see that it is suitable, and when not, have the diet changed at once. All writers are agreed that next to mother's milk, cow's milk is the best food for infants. The many ways of preparing the milk have been so well shown by Smith, Rotch, Holt and others, that the author simply referred his hearers to their valuable works.

At the onset of the disease, when the tongue is heavily coated and the stools of a greenish color, he gives a laxative. He finds tannigen a most valuable remedy for diarrhea. It is insoluble in the stomach, and in the intestines is converted into tannic acid, the best astringent. By its use he has overcome what would have proved to be prolonged and severe attacks of this disease. The pepsin is an aid to digestion and tends to suppress nausea. Where there is much tympanites bismuth is an excellent remedy. The author remarked concerning this drug that we are often disappointed in its results because it is given in too small doses. He does not hesitate to give a child of six months 20 grains of the subnitrate every two hours, when the stools are frequent and the bowels tympanitic. The salicylate is recommended by some as being more antiseptic. He prefers the subnitrate, as he gets better results from its use. With tannigen, the ideal intestinal astringent; bismuth, the reliable antacid; water, the great cleanser, and hyd. perox. the most potent antiseptic, with strict attention to diet and clothing, we may reasonably expect the majority of cases to recover.

Dr. K. P. Moore, of Macon, reported some very interesting and unusual cases in abdominal and gynecologic work.

FIRST DAY—AFTERNOON SESSION.

Dr. HENRY R. SLACK, of La Grange, read a paper with this caption:

BLUE PYOKTANIN IN THE TREATMENT OF INOPERABLE MALIGNANT GROWTHS,

and reported five cases. The author at first referred to contributions on this subject by Professor von Mosevig and Willy Meyer. He speaks of its advantages as follows:

1. Its analgesic effects are marked, as patients soon rest easily without the aid of morphia.
2. The improvement of the function of the part involved. A man who could hardly speak so as to be understood talked without difficulty after the third injection.
3. The improvement in general health which has taken place in all five of the cases.
4. The element of hope that is added to the life of suffering men, brightening the remainder of their sojourn.

While the author does not claim to have cured his patients,

still he has relieved their pains and rendered them less burdensome to themselves and their friends. He agrees with Dr. Meyer in von Mosevig's conclusions, that it has been proved by practice, that parenchymatous injections of inoperable malignant growths with pyoktanin can produce disappearance of malignant tissue, though in exceptional cases, and can heal neoplastic ulcerations. Pyoktanin, when properly used, is certainly a palliative treatment for cancer that deserves an honest, hopeful trial, for by its use many have been relieved and some cured.

Dr. J. B. MORGAN, of Augusta, read a paper entitled

THE TREATMENT OF CUTANEOUS CANCERS.

In discussing the treatment of skin cancers, it is well to understand at the beginning that the author does not intend to define the different varieties of cancer, or to discuss the different theories as to their etiology. A fact of paramount importance in the successful treatment of cancers of the skin is that everything depends upon early and thorough removal of all diseased tissue. The general consensus of opinion now is that all cancers can be cured, if thoroughly removed before the epithelial cells have infiltrated the connective tissue and neighboring glands; for it is generally conceded that it is the proliferation and infiltration of the epithelial cells which cause cancer to invade other tissues and organs and become disseminated through the system. This being the case, the only treatment that can offer anything like a cure, is the one which has for its object the early and complete removal, or destruction, of all the morbid epithelia. In cancer, where we find no limiting membrane, no sharply defined guide as to the extent of the infiltration beyond the tumor mass, other local means than the knife may be more properly indicated for its successful removal. The object of the author's paper was to emphasize this point. He is a strong believer in the use of the knife in suitable cases, and frequently employs it.

In the last four years he had treated fourteen cases of skin cancer with caustics, and in not a single instance has he seen the slightest indication of a recurrence. Five of the cases were from three to four years old; three of them from two to three years old, and the other six were treated within the last two years. One of the number died from pneumonia three years after being operated upon; the others are all living and in good health. Caustic potash quickly liquefies tissue, and at one sitting a very large tumor can be destroyed. Chlorid of zinc as a caustic can be used in stick form, in solution or in a paste. It causes more pain than either caustic potash or arsenious acid. Bougard's paste is one of the best means we possess in the treatment of small cutaneous cancers. To apply these caustics successfully demands a certain amount of experience, but which anyone can acquire after applying them two or three times. The greatest cause of failure in their use is the neglect to treat the case energetically until thoroughly satisfied that all diseased tissue has been removed.

Dr. S. RUMBLE of Goggansville followed with a paper entitled

PUERPERAL ECLAMPSIA, WITH REPORT OF CASES.

The author presented the following conclusions:

1. That puerperal eclampsia is a disease the etiology of which is as yet *sub judice*.
2. That it often develops after the uterus is emptied of the product of conception.
3. That morphia is the most positive and prompt remedy which can be used to arrest the eclamptic seizure. It obtunds nervous sensibility and arrests muscular spasm. It counteracts irritation of the nerve centers, whether the irritation is due to a toxemia or is of a reflex character.
4. That veratrum is not only an unreliable remedy, but one fraught with danger in this disease.
5. That chloroform and chloral hydrate are excellent adjuncts to morphia in arresting the spasms and maintaining the equilibrium of the nervous centers.
6. That cerebral congestion is a result and not the cause of the convulsion. Hence the author does not favor blood letting.
7. We can do a great deal in lessening the frequency, if not the ratio of mortality, in this disease by timely and proper prophylactic treatment.

Dr. M. B. HUTCHINS of Atlanta reported

TWO CASES OF MALIGNANT TUMOR AFFECTING THE BREAST AND THEIR TREATMENT

and made some remarks upon malignant growths in general.

Case 1.—Mrs. A. G., age 38; occupation, housework and washing. Scirrhous of the right mammary gland. She first noticed a "small lump" in the right breast, just above and to the right of the nipple. She stated that her husband had struck her there several times. Has had one child. No abscess of the breast. Examination showed a hard, rather well-defined

tumor the size of a small orange in the middle and upper part of the gland. The upper part of the nipple was slightly retracted. There was occasional stinging sensations. The essayist could feel no enlargement of glands either at the lower border of the muscle or in the axilla. The patient weighed 175 pounds and was in robust health. She had quite a mustache and chin beard.

Drs. L. P. Stephens and J. L. Campbell assisted at the operation. Every antiseptic precaution was employed. Elliptical incisions were made well away from the borders of the tumor, in the healthy skin, from the narrow part of the pectoralis major to the sternum and down to the pectoral sheath. The sheath of the muscle and the mammary gland were removed by a clean dissection, no tearing, leaving a clear wound with only the muscle fibers at its floor. There was no perceptible gland at the lower edge of the muscle, nor could any be felt in the axilla. The excision was done in less than ten minutes. There was very little hemorrhage. Redundant fat under the edges of the incisions was trimmed away with scissors, then the flaps were made with a knife. An inch incision was made in the lowest part of the gland cavity for drainage. It was necessary to ligate but one artery in the whole wound, hot water and torsion controlling the rest of the bleeding. The wound was brought together with four deep tension sutures of silkworm gut, about an inch apart. Then a continued suture of catgut was made from the outer end to near the inner, where a small opening was left for drainage with 10 per cent. iodiform gauze. The line of suture was covered with iodiform one part, boric acid five parts, then many layers of 10 per cent. iodiform gauze, salicylated cotton and three wide bandages were applied; the arm being included finally and additional support given the wrist with a towel. Two days later the gauze drain below was removed and the incision closed with one suture. Five days after the operation all dressings were removed. The surface was perfectly clean, and the wound seemed to have healed *per primam*, except at the outer end and at the internal drainage opening. The gauze was removed from the latter, being followed by about half an ounce of bloody fluid. After pressure to remove any remaining fluid, another piece of gauze was inserted. The low drainage incision was granulating nicely, with a little oozing of bloody serum visible. Dressings were made as at the time of operation. Eight days after the operation the inner drainage and the four tension sutures were removed. There was perfect primary union save at the two extremities. Suture removed from the lower drainage incision also. This wound was clean and healing. Surface covered with a lighter dressing and the arm left free. Two days later only the lower drain remained unhealed. Healing was complete in the lower drain eighteen days after the operation. At the inner end of the main incision there was a lump of compressed fat. Patient was seen nearly four months after the operation for the last time. The inner half of the united wound showed perfect union, the outer half a line of cicatrix. A small cicatrix marked the site of the lower drain. There was no sign of recurrence, nor of glandular involvement. She left the city and the author has not seen her since. He was informed that she remained in good health. The operation was done in this case with full knowledge of its probable incompleteness, this being due to the wishes of the patient and to the fact that it was preferable to complete it at such later time as it should become necessary. Four months later the time seems not to have arrived.

Case 2 was similar in many respects to the one reported and was successful in its results.

A paper entitled "Influenza with different Phases and Nervous Tendencies," by Dr. W. O'DANIEL of Bullard's was read by title, at the request of the author.

SECOND DAY—MORNING SESSION.

Dr. J. S. TODD of Atlanta contributed a paper entitled
CAUSE AND PREVENTION OF TUBERCULOSIS. IS IT A CURABLE DISEASE?

The author stated that tuberculosis, so long as it remained an unmixed infection, was not a deadly disease, and he believes it to be in this stage one of the most easily curable of the bacterial diseases. Except in the form of acute miliary and meningeal tuberculosis, it was but seldom the direct cause of death. As soon as it became a mixed infection, and was something more than tuberculosis, it then took rank as the most fatal of all diseases now afflicting mankind. In combatting this disease there were two points of attack, and if the wisdom and skill of the profession be directed to these the death rate from tuberculosis would be much reduced in the near future. The first and most important method of dealing with the disease consisted of the application of preventive measures. Second, the one with which he was now concerned, consisted of the

treatment of the disease while it remained an unmixed infection. When this was done tuberculosis would cease to be "the terror of the laity and the cross of the physician."

Dr. J. C. OLMSTED of Atlanta followed with a paper on "Expert Testimony in Criminal Cases involving the Plea of Insanity."

Dr. V. D. LOCKHART of Maysville reported an interesting and instructive case of cystocele complicating labor.

Dr. E. H. RICHARDSON of Atlanta read a paper entitled "Atypical Fevers."

Dr. W. L. CHAMPION of Atlanta followed with a contribution entitled

MEDDLESOME INSTRUMENTATION IN URETHRAL DISEASES.

The author stated that with our knowledge of the anatomy of the urethra and of the dangers of passing small steel instruments, false passages should be a thing of the past. The soft bougies, though not as durable as the steel sounds, accomplish the same results, and should always be used when a small instrument is called for; and even the larger ones are just as serviceable and produce less pain on introduction.

The routine practice of passing sounds into the bladder in treating strictures in the penile portion of the urethra is not only useless but bad surgery. There is always a liability of infecting the bladder and producing irritation of the prostatic urethra. The short, straight sound passed through the stricture accomplishes the same result as the curved instrument, and the danger of producing complications is lessened.

In treating stricture of the urethra by dilatation, how often should we pass an instrument? This question has been written upon, argued and discussed at length, and there seems to be a wide variance of opinion as to the length of time that should elapse between the sittings. In the use of sounds for the treatment of stricture there can be no fixed law in regard to the intervals to be allowed between the sittings.

Each case must be watched separately, and the results of the introduction of the instrument noted, so as to determine when to use the instrument again. His opinion is that the majority of men not studying the effects produced by an instrument passed through an organic stricture, influenced by the patient's desire for a rapid cure, are prone to pass instruments too often, thereby setting up an acute inflammatory condition and prolonging the treatment. The author's experience in the treatment of urethral strictures coincides with that of Dr. Keyes of New York.

With reference to internal urethrotomy in the deep urethra, there were men who did this operation with but few accidents, but the best practice was to positively refuse to interfere unless the patient would submit to the external operation. The custom of doing internal urethrotomy in the office, and allowing the patient to go home in a hack or on a car could not be too strongly condemned. It was an operation fraught with danger, and so we should guard against any mishap, giving the patient the best treatment possible. The operation should be done at home, and the patient kept in bed for at least five days, and it would be safer still to require a week's rest.

In closing the author emphasized the importance of urethral irrigation before surgical operations upon the urethral canal, whether it be only the passage of a sound or an internal urethrotomy. If this was done there would be fewer cases of urethral fever and less irritation and inflammation after using instruments. Within the past twelve months, he had used "hydrostatic irrigation" in the treatment of inflammatory conditions of the urethra and bladder, and considers it far superior to any other method.

Dr. E. R. ANTHONY, of Griffin, contributed a paper on the relations of the State Board of Medical Examiners to the profession of the State.

SECOND DAY—AFTERNOON SESSION.

Dr. LOUIS H. JONES, of Atlanta, read a paper entitled "Physical Signs in Diseases of the Lungs."

Dr. A. W. STIRLING, of Atlanta, followed with a contribution entitled

REMARKS ON CERTAIN OCULAR DISTURBANCES OF GENERAL INTEREST.

The author confined himself to one or two of those ocular lesions which are likely to be of general interest. Of conjunctival affections he mentioned one-sided hyperemia, which he said should always suggest a foreign body in the conjunctival sac or on the cornea. Few of the minor operations in surgery would better repay the practitioner than a dexterous manipulation of the eye in such cases, and one should not be hasty in excluding a foreign body.

Passing to the cornea, the speaker said that our chief inter-

east lies with ulcers and with foreign bodies. The latter were often difficult to find, and when found may be deeply embedded in the corneal tissue, and not always quite easy of removal. Even after the simplest abrasion by the foreign body, or by the instrument used in its removal, the protecting epithelium was destroyed, and not infrequently germs thereby gain access to the corneal tissue, and severe ulceration, with or without hypopyon results. Strict antiseptics was therefore advisable, frequently also a bandage for twenty-four hours, and sometimes atropin. Corneal abscesses and ulcers had a very varied etiology, and were often dependent upon general ill health. They usually demanded shade, atropin and antiseptic applications, but when near the periphery eserine might replace atropin in the absence of iritis. Should the ulcer perforate, there was then less likelihood of prolapse of the iris into the wound. Some of the severest forms of ulcer might be rapidly cutshort by certain destructive agents, notably the electric cautery, the sharp spoon, strong solutions of perchlorid of mercury, mercury in glycerin, or alcohol, and frequently very prompt treatment in them also is required to save the whole eye from destruction.

While cataract is looked upon as usually a purely local disturbance, except in the rare cases in which it is associated with certain diseases, as diabetes, there is one form of opacity in the lens which is believed to have important relationships to conditions of general health. This is called zonular or lamellar, and sometimes congenital cataract, and is by far the most frequent type of lenticular opacity met with in children. It affects a varying amount of the lens and the opacity produced by it may be so slight as to interfere but little with vision, or so great as to disqualify its owner for ordinary work.

The author then passed on to the consideration of iritis, saying that it was a fairly common disease, and one which, on account of circumstances, has frequently to be treated in great measure by the non-specialist. The likelihood of an attack proving destructive to vision depends to a great extent upon its early recognition and prompt and energetic treatment.

Dr. SAMUEL LLOYD, of New York, gave an excellent demonstration of Roentgen rays. He showed skiagraphs of a case of knock-knee, of congenital disappearance of the fingers and toes, and a case of scissor-legs, upon which he operated some weeks ago. The latter patient was a young girl whose thigh bones were crossed, thus preventing her from using the limbs. About nine weeks ago she was taken to the Post-Graduate Hospital of New York, when Dr. Lloyd performed the operation of osteotomy. Both thigh bones were fractured and placed in position for a normal reunion. The bones were subjected to a ten minute exposure of the ray, and by the use of the fluoroscope Dr. Lloyd was able to announce a perfect union of the bones. He related other experiments which were equally successful, which were made with fractured bones of the knee and elbow and with diseased bones of the hand. Dr. Lloyd also showed skiagraphs of a case of fracture of the forearm and one of osteoma of the clavicle.

THIRD DAY—MORNING SESSION.

Dr. R. M. HARBIN, of Rome, read a paper entitled

RAPID DILATATION OF THE UTERUS A CONSERVATIVE OPERATION.

His attention was recently called to an article in the *British Medical Journal* by Dr. Fournel, condemning rapid dilatation of the uterus as not being a conservative operation. So far as his observation goes, the dangers from the operation were very slight, where proper precautions have been taken. Divulsion of the uterus offers more relief in selected cases than the more complicated and dangerous operations, and should be done before advising the latter. The main indications for the operation are narrowness of the os and cervix of the uterus, flexions with dysmenorrhea and sterility, and the reflex symptoms arising from same. Personal observation leads the author to believe that many cases of obstinate nausea and vomiting of pregnancy could be relieved by rapid dilatation, shortly before an expected conception, as the practitioner often had to perform abortion in cases that conceived very soon afterward, rendering the operation again necessary. The cause of dysmenorrhea and sterility in a majority of cases was mechanical, and dilatation is usually followed by a relief of the symptoms, if not a cure of the sterility. The contraindications are pyosalpinx and acute peritonitis. In an aggravated case of chronic pelvic peritonitis rapid dilatation can be done with safety after a few weeks of general and local treatment. The operation should be done about a week before menstruation, and the technique was simple.

Dr. Wm. S. GOLDSMITH, of Atlanta, made some remarks on

FISTULA IN ANO.

The relative frequency of fistula in ano, as compared with other

rectal affections, induced the author to consider this subject. Some differences of opinion exist among authors as to the frequency of fistula. Allingham states that in a collection of 4,000 consecutive rectal cases in the Out-patient Department of St. Mark's Hospital, 1,057 were fistula in ano, 196 abscesses, 151 of which subsequently became fistula, and that for a period of several years, two-thirds of the cases operated on in this hospital were for fistula. The author believed that the incision of all fistulous tracts and sinuses, and the complete section of the sphincter muscles with the knife is the only method by which the surgeon can assure the patient that the operation will result in a rapid and successful cure. The author has yet to see a wound made in the area usually involved fail to promptly and satisfactorily granulate, provided it has had the benefit of a thorough eradication of all morbid tissues. To further elucidate this point, suppose all branches and pockets have been opened, should the operation be pronounced completed? Decidedly no. And just here, in the opinion of the author, Dr. Mathews executes a procedure that is rather tedious, in that he advises the excision of the whole bottom of the wound, using pinch forceps and curved scissors, and states that he is not satisfied with simply scraping out the sinuses. Dr. Goldsmith thinks the careful use of the Volkmann spoon, together with the application of peroxid of hydrogen, is far preferable. After incising the main tract and all sinuses, satisfying himself that the superior extremity of the original tract is reached, and making a rather prolonged search for pockets and hidden branches, he trims away the over-hanging edges of skin along the entire cut area, paying particular attention to the edges and vicinity of the original external apertures. This is followed by a thorough curettage of the bottom of the sinus, and the removal as far as possible of every particle of the so-called pyogenic membrane. The wound is irrigated and sponged as dry as circumstances will permit. The author now uses peroxid of hydrogen, full strength, applied in the form of a spray by an ordinary hand atomizer. This valuable agent has an excellent effect on the debris unavoidably retained in the wound. The hydrogen used in this manner penetrates into every minute pocket and cuts out particles of tissue that is impossible to remove, except by the total excision of the entire lining membrane. Having decided acid reaction, it is most valuable in checking the otherwise profuse oozing, accompanying the simple curetting or excision. The splendid results attained by the use of peroxid of hydrogen in the manner described, are obtainable in other lines of work where the same action is desired, and has been used by Dr. Westmoreland and the author most satisfactorily in the treatment of chronic osteomyelitis and all varieties of indolent ulcers.

Dr. HUNTER MCGUIRE of Richmond, Va., read a paper (by invitation) entitled

REMARKS ON APPENDICITIS

with a report of twenty-six cases operated on during the past twelve months. The author considered, at the outset, the importance of operating for appendicitis during an interval between attacks. All of the nineteen cases of chronic, or relapsing appendicitis embraced in the report recovered. In looking over his record book for previous years he finds that he has operated on 33 other cases with only one fatal result, thus making a total of 52 consecutive operations for this form of appendicitis with one death. One of the cases was operated on for him by Dr. Joseph Price. The results he has attained he says are no better than many other operators have had, and he attributes his success largely to the fact that, if possible, he operates during the quiescent stage, as originally suggested by Mr. Treves in 1886, when danger of sepsis has passed and inflammatory symptoms have disappeared. The danger is practically nothing if the surgery is clean.

Under the head of symptoms which determine the safety of postponing operative interference until the acute stage has passed, the author said when we remember that fully one-half of all the cases of appendicitis recover from the first attack; that spontaneous resolution takes place when peritonitis, exudation and sometimes even suppuration, have been present; and that a large number of cases which recover without an operation in the primary attack remain well and have no recurrence of the disease, the question of when to operate is a very nice, difficult and always an important one. Dr. McGuire agrees with Dr. Wyeth, that if we have a competent surgeon, one skilled in abdominal work, and the patient can be operated on within twelve hours of the first symptoms of the attack 99 per cent. will be cured. But we frequently see the cases after these twelve hours have expired and surgeons of experience in such work are not always within call. He is not in favor of an operation in all cases as soon as a positive diagnosis is made.

Value and limits of saline purgation.—In an ordinary case,

not a fulminating one, after a short time the pain abates, the fever lessens, the pulse gets slower, the abdomen less hard and tender, and all the urgent symptoms more or less subside, they do not disappear, but are less pronounced, and then there comes in a remedy which in his hands has been as certainly valuable for good as quinin in malaria or arsenic in neuralgia; that is, saline purgatives, given in frequent doses until the patient is freely and repeatedly purged.

Relative frequency of the disease in the two sexes.—From the reports of many surgeons we learn that appendicitis is much more common in males than in females, the proportion stated being one to four. This has not, however, been the author's experience. In his cases for the past year, thirteen were females and thirteen were males, and this has been about the proportion of all of his cases, amounting now to 155, the cases being nearly equally divided between the two sexes.

Dr. McGuire then dwelt on the differential diagnosis between appendicitis and disease of the ovaries and tubes.

With reference to the technique of operation, he has this to say: "In fulminating cases the abdomen should be opened by a long incision, the gangrenous appendix ligated and cut off, and the belly washed out with gallons of sterilized water. Six or eight strips of iodoform gauze should be carried through the incision to different parts of the cavity. The wound should not be sutured, but every facility afforded for easy drainage. If such a case is not seen until the bowels are distended with gas, and the patient prostrated or collapsed, it is useless to operate. I have never seen a case of fulminating appendicitis without premonitory symptoms. A careful inquiry into the past history will always show former attacks, which possibly at the time were not recognized. In cases where there is a deep-seated localized abscess it should be rendered accessible by a free abdominal incision. The abscess should be carefully walled off from adjacent tissues by pieces of gauze and then opened. The pus should be sponged out and the appendix carefully searched for and removed. The abscess wall should be dissected out and the bowels examined to see that they are intact. It is impossible to treat such cases extraperitoneally, and when you have exposed the cavity to the danger of infection there is no more excuse for doing incomplete work than in other forms of abdominal surgery."

In cases where the abscess has approached the anterior abdominal wall and become adherent to the peritoneum, he simply opens and drains it, and makes no effort to extract the appendix if not loose, or to remove the wall. To endanger the infection of the general cavity by too prolonged an attempt to find the appendix is not good surgery.

In cases of chronic or relapsing appendicitis, Dr. McGuire does not advise an operation until the patient has had two attacks. Sometimes the inflammation which attends the first attack renders the patient free from a second attack, because of some obliterating pathologic change in the appendix. He makes one exception to this rule. If, several weeks after the first attack he finds induration or tenderness, or both, over the region of the cecum, he advises the patient to have the operation done at once. The operation should always be done between the attacks. In every case all adhesions should be freed, and any portion of the omentum in contact with the appendix, which is suspected of being contaminated, should be removed.

THIRD DAY—AFTERNOON SESSION.

Dr. J. C. LEHARDY, of Savannah, read a paper in which he outlined an act to create a Commissioner of Health and Drainage for the State of Georgia.

Dr. J. D. CHASON of Iron City, read a paper entitled

PUERPERAL SEPTICEMIA; ITS CAUSE AND TREATMENT.

The author regards a patient with this disease in a position strikingly analogous to one bitten by a snake. A poison is introduced into the blood which causes minute changes in the tissues and also produces a decided shock to the nervous system. The patient may be prostrated by the primary depression. If this can be averted here, as in snake bite, the patient will recover, unless the diffuse changes have too deeply involved vital organs. In this disease we must stop the generation and absorption of poison, and if this can be done we need not fear the slight damage done by the poison already absorbed.

The indications for the treatment are threefold: 1, to stop the generation and absorption of the poison; 2, to neutralize the poison already absorbed by free stimulation; 3, to increase the action of the excretory organs with a view to the elimination of the poison already absorbed and to prevent further absorption.

Dr. R. R. KIME of Atlanta, followed with a paper on

THE PRESENT STATUS OF PUERPERAL INFECTION.

The author said that the keystone to success in puerperal

infection is elimination and drainage, counteracting absorbed toxins and germs, checking their further development, and sustaining the patient by such remedies and measures as will conserve the vital forces of patient the most. After more than ten years of practical demonstration of drainage, both uterine and alimentary, in puerperal infection, the author is more fully convinced than ever of its utility. Not only does it lessen suffering, relieve more cases of puerperal infection, and save more lives than any other means now at our command, but also prevents more pelvic complication, saves more uteri, tubes and ovaries from subsequent disease and leaves them in a condition to perform their normal functions, which can not be said of any other plan of treatment known to the profession of today. All cases of puerperal infection should be fed systematically liquid, easily digested food, and where they fail to take sufficient nourishment some of the prepared foods should be given. Of medicinal remedies, quinin given in 5 to 10 grain doses, every four to six hours, acts well in many cases, tending to check germ development and inflammation, incidentally helping to control temperature without detriment to the patient. Strychnia combined with bitter tonics, antiseptics or digestants, given every four hours with nourishment, is beneficial in most cases. In weak, debilitated cases some form of iron should be given. Hypnotics should be given if needed to procure rest or sleep. Stimulants in moderation, systematically given, will do good in very weak cases; yet strychnia, quinin and digitalis are more permanent and beneficial in their results.

Surgical measures are indicated when the infection becomes localized with pus formation, and some claim in general peritonitis. Pus accumulations in the broad ligaments, as a rule, should be drained through the vagina by Henrotin's method, whether they be due to cellulitis, peritubal inflammation or ruptured pus tubes. In pyosalpinx and ovarian abscess authorities differ as to whether the vaginal or abdominal route is best.

Hysterectomy is advocated in cases of thrombo-phlebitis, multiple abscesses in uterine wall, etc., but it is a very difficult matter to diagnose the condition requiring such a surgical procedure. Where the septic infection is so marked as to produce such serious lesions of the uterus, it has usually passed beyond the reach of hysterectomy before a differential diagnosis can be made demanding such an operation. While the infection is progressing the author doubts the utility of such a measure, but after the infection and inflammation have become localized in the uterus, tubes, or ovaries, then it is time to consider such operative measures as are best suited to the individual case.

Dr. J. L. HIERS of Savannah, read a paper entitled "Some Interesting Ophthalmological Cases" in which he reported 87 cases of phlyctenular and corneal ulcers treated with tincture of iodine, 74 cases requiring only one application, 9 cases two applications, 2 cases a third application, and 3 cases had to be cauterized by the actual cautery.

Dr. GEORGE HORNE of Americus, read a paper on "Lupus of the Nose, its Medical and Surgical Treatment." The author reported three cases of this disease which were successfully treated by the use of pyoktanin.

Dr. J. M. CRAWFORD of Atlanta, reported a successful rhinoplastic operation for the loss of the nose. He also reported a case in which he operated for removal of the drum membrane and necrosed bones in chronic suppurative aural catarrh.

Several papers were read by title and referred to the Committee on Publication.

The following officers were elected: President, Dr. J. B. Morgan of Augusta. First Vice-president, Dr. L. G. Hardman of Harmony Grove. Second Vice-president, Dr. J. L. Hiers of Savannah.

The next place of meeting to be Cumberland Island, on the third Wednesday in April, 1898.

Eczema in Cyst Fluids and their Diagnostic Significance.—Observation of a case of pancreatic cyst in which the fat-emulsifying action was very slight and irregular, induced Zehuisen to investigate the fermentative action in various fluids, transudations, exudations, ovarian cysts, etc. He found that diastatic fermentation was almost invariably present, while the tryptic and fat-emulsifying action was invariably absent. The results with urine were contradictory. The discovery of fat-emulsifying and tryptic action is therefore very important in diagnosing a pancreatic cyst, while diastatic fermentation has no significance in this respect.—*Wien. Klin. Rundschau*, March 14 from *Cbl. f. Inn. Med.*, No. 40, 1896.

Special Courses in Medicine and Surgery to be given in Philadelphia the Week Preceding and that Following the Meeting of the American Medical Association.

The course of instruction, which is free to members of the AMERICAN MEDICAL ASSOCIATION for the week preceding and that following the meeting of this ASSOCIATION in Philadelphia, includes a series of clinical lectures and demonstrations given by the Faculty of the teaching colleges of Philadelphia, and of laboratory, dispensary and ward demonstrations given by the staff of the various hospitals of the city and medical institutions.

The college courses are as follows:

COLLEGE COURSES.

WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA CLINICS.

- Monday, May 24, 12 m., Gynecology, Hannah T. Croasdale. 1 p.m., Obstetrics, Anna E. Broomall.
 Tuesday, May 25, 12 m., Pediatrics, Edward P. Davis. 1 p.m., Neurology, Charles K. Mills.
 Wednesday, May 26, 12 m., Medicine, Frederick P. Henry. 1 p.m., Ophthalmology, Amy S. Barton.
 Thursday, May 27, 12 m., Otolaryngology, Charles H. Burnett. 1 p.m., Dermatology, Henry W. Stelwagon.
 Friday, May 28, 12 m., Laryngology, Emma E. Musson. 1 p.m., Surgery, John B. Roberts.
 Saturday, May 29, 12 m., Medicine, Frederick P. Henry. 1 p.m., Orthopedics, James K. Young.
 Monday, May 31, 12 m., Gynecology, Anna M. Fullerton. 1 p.m., Obstetrics, Anna E. Broomall.
 Saturday, June 5, 12 m., Pediatrics, Edward P. Davis. 1 p.m., Neurology, Charles K. Mills.
 Monday, June 7, 12 m., Medicine, Frederick P. Henry. 1 p.m., Surgery, John B. Roberts.
 Tuesday, June 8, 12 m., Otolaryngology, Charles H. Burnett. 1 p.m., Dermatology, Henry W. Stelwagon.
 Wednesday, June 9, 12 m., Laryngology, Emma E. Musson. 1 p.m., Orthopedics, James K. Young.
 Thursday, June 10, 12 m., Otolaryngology, Charles H. Burnett. 1 p.m., Dermatology, Henry W. Stelwagon.
 Friday, June 11, 12 m., Laryngology, Emma E. Musson. 1 p.m., Ophthalmology, Amy S. Barton.
 Saturday, June 12, 12 m., Medicine, Frederick P. Henry.

PHILADELPHIA POLYCLINIC CLINICS.

- Monday, May 24, 12 m., Laryngology, W. J. Freeman. 1 p.m., Ophthalmology, S. D. Risley.
 Tuesday, May 25, 12 m., Medicine, P. C. Griffith. 1 p.m., Neurology, Charles K. Mills.
 Wednesday, May 26, 12 m., Otolaryngology, B. A. Randall. 1 p.m., Dermatology, Van Harlingen.
 Thursday, May 27, 12 m., Obstetrics, E. P. Davis. 1 p.m., Pediatrics, J. M. Taylor.
 Friday, May 28, 12 m., Surgery, J. B. Roberts. 1 p.m., Orthopedics, T. G. Merton.
 Saturday, May 29, 12 m., Genito-urinary, T. R. Neilson. 1 p.m., Gynecology, B. F. Baer.
 Monday, May 31, 12 m., Laryngology, A. W. Watson. 1 p.m., Ophthalmology, Edward Jackson.
 Saturday, June 5, 12 m., Medicine, S. Solis-Cohen. 1 p.m., Neurology, Charles K. Mills.
 Monday, June 7, 12 m., Otolaryngology, R. W. Seiss. 1 p.m., Dermatology, J. A. Cantrell.
 Tuesday, June 8, 12 m., Obstetrics, E. P. Davis. 1 p.m., Pediatrics, J. M. Taylor.
 Wednesday, June 9, 12 m., Surgery, L. W. Steinbach. 1 p.m., Orthopedics, H. A. Wilson.
 Thursday, June 10, 12 m., Genito-urinary, Edward Martin. 1 p.m., Gynecology, J. M. Baldy.
 Friday, June 11, 12 m., Laryngology, E. L. Vansant. 1 p.m., Ophthalmology, G. E. de Schweinitz.
 Saturday, June 12, 12 m., Medicine, A. A. Eshner. 1 p.m., Neurology, C. W. Burr.

MEDICO-CHIRURGICAL COLLEGE CLINICS.

- Monday, May 24, 12 m., Medicine, Wm. E. Hughes. 1 p.m., Pediatrics, W. C. Hallowpeter.
 Tuesday, May 25, 12 m., Dermatology, John V. Shoemaker. 1 p.m., Orthopedics, J. P. Mann.
 Wednesday, May 26, 12 m., Genito-urinary, J. V. Shoemaker. 1 p.m., Gynecology, W. E. Ashton.

- Thursday, May 27, 12 m., Surgery, Ernest Laplace. 1 p.m., Ophthalmology, L. Webster Fox.
 Friday, May 28, 12 m., Medicine, J. M. Anders. 1 p.m., Neurology, C. W. Burr.
 Saturday, May 29, 12 m., Laryngology, A. H. Cleveland. 1 p.m., Otolaryngology, E. B. Gleason.
 Monday, May 31, 12 m., Obstetrics, W. Frank Haehnlen. 1 p.m., Pediatrics, W. C. Hallowpeter.
 Saturday, June 5, 12 m., Gynecology, W. E. Ashton. 1 p.m., Orthopedics, J. P. Mann.
 Monday, June 7, 12 m., Surgery, Ernest Laplace. 1 p.m., Genito-urinary, J. V. Shoemaker.
 Tuesday, June 8, 12 m., Dermatology, John V. Shoemaker. 1 p.m., Ophthalmology, L. Webster Fox.
 Wednesday, June 9, 12 m., Medicine, J. M. Anders. 1 p.m., Neurology, C. W. Burr.
 Thursday, June 10, 12 m., Laryngology, A. H. Cleveland. 1 p.m., Otolaryngology, E. B. Gleason.
 Friday, June 12, 12 m., Medicine, J. M. Anders. 1 p.m., Pediatrics, W. C. Hallowpeter.
 Saturday, June 13, 12 m., Orthopedics, J. P. Mann. 1 p.m., Surgery, Ernest Laplace.

JEFFERSON MEDICAL COLLEGE CLINICS.

- Monday, May 24, 12 m., Medicine, H. A. Hare. 1 p.m., Neurology, F. X. Dercum.
 Tuesday, May 25, 12 m., Demonstration in Bacteriology, W. M. L. Coplin. 1 p.m., Dermatology, H. W. Stelwagon.
 Wednesday, May 26, 12 m., Laryngology, W. S. Jones. 1 p.m., Ophthalmology, H. F. Hansell.
 Thursday, May 27, 12 m., Orthopedics, H. W. Wilson. 1 p.m., Surgery, J. H. Brinton.
 Friday, May 28, 12 m., Genito-urinary, Orville Horwitz. 1 p.m., Gynecology, E. E. Montgomery.
 Saturday, May 29, 12 m., Obstetrics, Edward P. Davis. 1 p.m., Pediatrics, E. E. Graham.
 Monday, May 31, 12 m., Medicine, H. A. Hare. 1 p.m., Neurology, F. X. Dercum.
 Saturday, June 5, 12 m., Otolaryngology, S. MacC. Smith. 1 p.m., Medicine, J. C. Wilson.
 Monday, June 7, 12 m., Laryngology, D. Braden Kyle. 1 p.m., Ophthalmology, G. E. de Schweinitz.
 Tuesday, June 8, 12 m., Orthopedics, H. A. Wilson. 1 p.m., Surgery, W. W. Keen.
 Wednesday, June 9, 12 m., Genito-urinary, Orville Horwitz. 1 p.m., Gynecology, J. C. DaCosta.
 Thursday, June 10, 12 m., Obstetrics, Edward P. Davis. 1 p.m., Surgery, W. Joseph Hearn.
 Friday, June 11, 12 m., Surgery, J. M. Barton. 1 p.m., Gynecology, E. E. Montgomery.
 Saturday, June 12, 12 m., Surgery, J. Chalmers DaCosta.

UNIVERSITY OF PENNSYLVANIA CLINICS.

- Monday, May 24, 12 m., Surgery, John Ashhurst. 1 p.m., Orthopedic Surgery, De F. Willard.
 Tuesday, May 25, 12 m., Genito-urinary, Edward Martin. 1 p.m., Gynecology, C. B. Penrose.
 Wednesday, May 26, 12 m., Obstetrics, B. C. Hirst, Subject: Labor obstructed by a contracted pelvis and its management. 1 p.m., Pediatrics and Surgery, J. P. Coyne Griffiths, T. Wm. White.
 Thursday, May 27, 12 m., Medicine, Wm. Pepper. 1 p.m., Neurology, H. C. Wood.
 Friday, May 28, 12 m., Otolaryngology, B. Alex. Randall. 1 p.m., Dermatology, L. A. Duhring.
 Saturday, May 29, 12 m., Laryngology, C. P. Grayson. 1 p.m., Ophthalmology, W. F. Norris. (This one only).
 Monday, May 31, 12 m., Surgery, John Ashhurst. 1 p.m., Orthopedics, De F. Willard.
 Saturday, June 5, 12 m., Genito-urinary, Edward Martin. 1 p.m., Gynecology, C. B. Penrose.
 Monday, June 7, 12 m., Obstetrics, B. C. Hirst. 1 p.m., Pediatrics, J. P. C. Griffiths.
 Tuesday, June 8, 12 m., Medicine, James Tyson. 1 p.m., Neurology, H. C. Wood.
 Wednesday, June 9, 12 m., Otolaryngology, B. Alex. Randall. 1 p.m., Surgery, F. Wm. White.
 Thursday, June 10, 12 m., Laryngology, C. Grayson. 1 p.m., Medicine, John Musser.
 Friday, June 11, 12 m., Surgery, John Ashhurst. 1 p.m., Orthopedics, De F. Willard.
 Saturday, June 12, 12 m., Genito-urinary, Edward Martin. 1 p.m., Gynecology, C. B. Penrose.

LABORATORY WORK.

- Monday, May 24, 10 a.m., Philadelphia Board of Health, Practical Bacteriology (City Hall), A. C. Abbott.

Tuesday, May 25, 10 a.m., University Hospital, Skiagraphy (Pepper Laboratory), C. Lester Leonard.

Wednesday, May 26, 10 a.m., University of Pennsylvania, Skiagraphy (Department of Physics), A. W. Goodspeed.

Thursday, May 27, 10 a.m., University of Pennsylvania (Department of Hygiene) Pathogenic Bacteria, A. C. Abbott. 10 a.m., Medico-Chirurgical College, Skiagraphy, C. L. Furbush. 10 a.m., Woman's Medical College, Microscopic examination of urine, sputum and blood, A. A. Stevens.

Friday, May 28, 10 a.m., University of Pennsylvania (Department of Hygiene) Pathogenic Bacteria, A. C. Abbott. 10 a.m., Medico-Chirurgical Skiagraphy, C. L. Furbush. 10 a.m., Jefferson Medical College, Examination of urine, sputum and blood, H. F. Harris.

Monday, May 31, 10 a.m., Woman's Medical College, Examination of urine, sputum and blood, A. A. Stevens. 10 a.m., University of Pennsylvania (Pepper Laboratory), Practical Bacteriology, D. Reisman. 10 a.m., Jefferson Medical College, Pathogenic Bacteria, W. M. L. Coplin.

Monday, June 7, 10 a.m., Medico Chirurgical College, Demonstrations in rare Tumors, Joseph McFarland. 10 a.m., Polyclinic, Skiagraphy, Max J. Stern. 10 a.m., Jefferson Medical College, Surgical Disinfection, J. Chalmers DaCosta and T. L. Rhoads.

Tuesday, June 8, 10 a.m., Medico-Chirurgical, Demonstrations of rare Tumors, Joseph McFarland. 10 a.m., Polyclinic, Skiagraphy, Max J. Stern. 10 a.m., Jefferson, Practical Disinfection, W. M. L. Coplin.

Thursday, June 10, 10 a.m., University of Pennsylvania (Chemical Laboratory), Urinalysis, sugar, albumin, etc., John Marshall. 10 a.m., University of Pennsylvania (Pepper Laboratory), Practical Pathology, D. Reisman. 10 a.m., Jefferson Medical College, Autopsies (Methods), W. M. L. Coplin.

Friday, June 11, 10 a.m., University (Chemical Laboratory), Urinalysis, John Marshall. 10 a.m., Woman's Medical College, Bacterial Demonstration, B. Lewis.

Daily at the Pepper Laboratory from 3 to 5 in the afternoon, under the personal supervision of Dr. Alfred Stengel, Director, A. E. Taylor will demonstrate blood; S. S. Kneass, will show bacteria; W. G. Spiller and Joseph Sailer will exhibit pathologic specimens of the nervous system; C. Lester Leonard will carry on his work with the Roentgen rays; D. L. Edsall will show the modern methods of investigating diseases of the stomach; Samuel Hamill will examine sputum; G. S. Woodward will explain the methods of testing milk.

The Laboratories of Bacteriology, Pathology and Histology of the Jefferson Medical College will be open daily at 11 o'clock under the charge of Drs. D. Braden Kyle and W. M. L. Coplin.

SURGICAL COURSE—DAILY OUT-PATIENT DEPARTMENT.

8 a.m., Woman's Hospital: Drs. Kate W. Baldwin, Clara Reimel, Margaret Butler, Elizabeth Clark, Caroline Van Horn, Catherine Storm and Miriam Butt.

9 a.m., Hospital and Dispensary of the Alumnae of the Woman's Medical College of Pennsylvania: Mary R. Wilcox, Rachel Skidelsky.

9:30 a.m., West Philadelphia Hospital for Women: Linda M. Stewart, R. Anna Breed, Elizabeth Griscom, Mary Griscom, Anna Sharpless and Helena Goodwin.

10 a.m., St. Agnes Hospital: Ellwood R. Kirby.

10 a.m., Pennsylvania Hospital: Joseph M. Spellisey.

10 a.m., German Hospital: (Mondays, Wednesdays and Saturdays) George D. Ross and A. D. Whiting.

10 a.m., Methodist Episcopal Hospital: Jas. P. Hutchinson.

11 a.m., Howard Hospital: Henry Kiersted.

11 a.m., Children's Hospital: James P. Hutchinson and Robert G. LeConte.

11 a.m., Polyclinic: T. S. K. Morton and L. W. Steinbach.

12 m., Jefferson Medical College Hospital: J. Chalmers Da Costa.

12 m., Presbyterian Hospital: J. P. Tunis.

12 m., University Hospital: Charles H. Frazier.

12:30 p.m., St. Joseph's Hospital: Drs. McKee and Baker.

1 p.m., Medico-Chirurgical College Hospital: B. F. Shimwell.

5 p.m., Polyclinic Hospital: John B. Roberts and Max J. Stern.

6 p.m., West Philadelphia Hospital for Women: Esther L. Blair, Helen Murphy and Margaret Butler.

SURGERY—CLINICAL LECTURES AND WARD DEMONSTRATIONS.

Monday, May 24, 11 a.m., Polyclinic: T. S. K. Morton. 12 m., University of Pennsylvania: John Ashhurst, Jr. 1 p.m., Methodist Hospital: E. W. Holmes. 3 p.m., Presbyterian

Hospital: Henry R. Wharton. 5 p.m., Polyclinic: John Roberts.

Tuesday, May 25, 11 a.m., Polyclinic: L. W. Steinbach. 12 m., Pennsylvania Hospital: T. G. Morton. 1 p.m., Episcopal Hospital: T. R. Neilson. 3 p.m., St. Agnes Hospital: Edward Martin. 5 p.m., Polyclinic: Max J. Stern.

Wednesday, May 26, 11 a.m., Polyclinic: T. S. K. Morton. 11 a.m., Pennsylvania Hospital: John Ashhurst, Jr. 12 m., University of Pennsylvania: J. William White. 1 p.m., Methodist Hospital: E. W. Holmes. 3 p.m., Presbyterian Hospital: Henry R. Wharton. 5 p.m., Polyclinic: John B. Roberts.

Thursday, May 27, 11 a.m., Polyclinic: L. W. Steinbach. 12 m., Medico-Chirurgical: Ernest Laplace. 1 p.m., Jefferson: John H. Brinton. 3 p.m., Howard Hospital: Edward Martin. 5 p.m., Polyclinic: Max J. Stern.

Friday, May 28, 11 a.m., Polyclinic: T. S. K. Morton. 12 m., Polyclinic: John B. Roberts. 1 p.m., Episcopal Hospital: T. R. Neilson. 1 p.m., Woman's Medical College Hospital: John B. Roberts. 3 p.m., Presbyterian: H. R. Wharton. 5 p.m., Polyclinic: John B. Roberts.

Saturday, May 29, 11 a.m., Pennsylvania Hospital: Richard Harte. 11 a.m., Polyclinic: L. W. Steinbach. 12 m., Pennsylvania Hospital: T. G. Morton. 1 p.m., Philadelphia Hospital: Edward Martin. 3 p.m., Methodist Hospital: E. W. Holmes. 5 p.m., Polyclinic: Max J. Stern.

Monday, May 31, 11 a.m., Polyclinic: T. S. K. Morton. 12 m., University of Pennsylvania: John Ashhurst, Jr. 1 p.m., Presbyterian: H. R. Wharton. 3 p.m., St. Agnes Hospital: Edward Martin. 5 p.m., Polyclinic: John B. Roberts.

Saturday, June 5, 11 a.m., Pennsylvania Hospital: Richard Harte. 11 a.m., Polyclinic: L. W. Steinbach. 12 m., Medico-Chirurgical: Ernest Laplace. 1 p.m., Philadelphia: Edward Martin. 3 p.m., Children's Hospital: H. R. Wharton. 5 p.m., Polyclinic: Max J. Stern.

Monday, June 7, 11 a.m., Polyclinic: T. S. K. Morton. 12 m., Medico-Chirurgical Hospital: Ernest Laplace. 1 p.m., Woman's Medical College: John B. Roberts. 3 p.m., Children's Hospital: H. R. Wharton. 5 p.m., Polyclinic: John B. Roberts.

Tuesday, June 8, 11 a.m., Pennsylvania Hospital: John Ashhurst, Jr. 12 m., Episcopal Hospital: T. R. Neilson. 1 p.m., Jefferson Hospital: W. W. Keeo. 3 p.m., Howard Hospital: Edward Martin. 5 p.m., Polyclinic: Max J. Stern.

Wednesday, June 9, 11 a.m., Polyclinic: T. S. K. Morton. 12 m., Polyclinic: L. W. Steinbach. 1 p.m., University of Pennsylvania: J. William White. 3 p.m., Children's Hospital: H. R. Wharton. 5 p.m., Polyclinic: John Roberts.

Thursday, June 10, 11 a.m., Polyclinic: L. W. Steinbach. 12 m., Medico Chirurgical Hospital: Ernest Laplace. 1 p.m., Jefferson Hospital: Joseph Hearn. 2 p.m., Howard Hospital: Charles Frazier. 3 p.m., St. Agnes: Edward Martin. 5 p.m., Polyclinic: Max J. Stern.

Friday, June 11, 11 a.m., Polyclinic: T. S. K. Morton. 12 m., Episcopal Hospital: T. R. Neilson. 1 p.m., Woman's Medical College: John Roberts. 3 p.m., Presbyterian Hospital: H. R. Wharton. 5 p.m., Polyclinic: John B. Roberts.

Saturday, June 12, 11 a.m., Polyclinic: L. W. Steinbach. 12 m., Jefferson Medical College: J. Chalmers Da Costa. 1 p.m., Methodist Hospital: E. W. Holmes. 3 p.m., Philadelphia Hospital: Edward Martin. 5 p.m., Polyclinic: Max J. Stern.

Dr. Max J. Stern will give two cadaveric demonstrations of the technique of some modern surgical operations at dates to be later announced.

The following Out-patient Departments will be open for the treatment of medical cases at the hours named:

8 a.m., Woman's Medical College: Kate W. Baldwin, Clara Reimel, Margaret Butler, Elizabeth M. Clerk, Caroline Van Horne, Katherine L. Storm, Miriam M. Butt.

9:30 a.m., West Philadelphia Hospital for Women: Lida M. Stewart, R. Anna Breed, Esther L. Blair, Elizabeth W. Griscom, Mary W. Griscom, Helen Murphy, Anna P. Sharpless, A. Helena Goodwin, Margaret Butler.

9 a.m., Hospital and Dispensary of the Alumnae of the Woman's Medical College of Pennsylvania: Miriam M. Butt, Rebecca Fleisher, Rachel Williams.

10 a.m., Pennsylvania Hospital: Henry Fisher.

10 a.m., Episcopal Hospital: Clarence Lincoln and Cyrus Moore.

11 a.m., St. Joseph's Hospital: Washington Baker (Tuesday and Friday).

11 a.m., Howard Hospital: A. E. Roussel and Charles Wirgman.

12 m., St. Agnes Hospital: A. H. Strecker.

12 m., Jefferson Hospital: Julian L. Salinger and T. G. Ashton.

12 m., University Hospital: M. Howard Fussell.
 12 m., Medico-Chirurgical Hospital: G. W. Fromm.
 1 p.m., Orthopedic Hospital: S. Weir Mitchell, Wharton Sinkler, Morris J. Lewis.
 12 m., Presbyterian Hospital: Guy Hinsdale.
 2 p.m., Episcopal Hospital (Mondays and Thursdays): Harvey Shoemaker.
 4 p.m., St. Joseph's Hospital: Telt (Monday, Wednesday, Thursday and Saturday.)
 6 p.m., West Philadelphia Hospital for Women: Lida M. Stewart, R. Anna Breed, Esther L. Blair, Elizabeth Griscom, Helen Murphy, Anna P. Sharpless, A. Helena Goodwin, Margaret Butler.

MEDICINE.

CLINICAL LECTURES AND WARD DEMONSTRATIONS.

Daily—11 a.m., Presbyterian Hospital, Roland Curtin; 3 p.m., Presbyterian Hospital, John Musser; 4 p.m., Municipal Hospital (Infectious Diseases), Wm. M. Welch.
 Monday, May 24, 11 a.m., St. Agnes', B. Stahl; 12 m., Jefferson, Hobart A. Hare; 12 m., Medico-Chirurgical, William E. Hughes; 3 p.m., Philadelphia, Frederick A. Packard; 3 p.m., Polyclinic (Diseases of Chest), Judson Daland; 5 p.m., Polyclinic, A. A. Eshner.
 Tuesday, May 25, 11 a.m., St. Agnes', A. A. Stevens; 12 m., Polyclinic, Crozer Griffith; 1 p.m., Philadelphia Hospital, John Musser; 2 p.m., Polyclinic (Diseases of Stomach), D. D. Stewart; 3 p.m., University Hospital, Alfred E. Stengel; 3 p.m., Philadelphia Hospital, Frederick A. Packard; 3 p.m., Polyclinic (Diseases of Chest), Thos. J. Mays; 5 p.m., Polyclinic (Diseases of Chest), A. E. Tussey.
 Wednesday, May 26, 11 a.m., St. Agnes', B. Stahl; 12 m., Woman's Medical College, F. P. Henry; 12 m., Polyclinic, S. S. Cohen; 3 p.m., Philadelphia Hospital, W. E. Hughes and F. A. Packard; 3 p.m., Polyclinic (Diseases of Chest), Judson Daland; 5 p.m., Polyclinic, A. A. Eshner.
 Thursday, May 27, 11 a.m., St. Agnes', A. A. Stevens; 12 m., University, William Pepper; 1 p.m., Philadelphia, John Musser; 2 p.m., Polyclinic (Diseases of Stomach), D. D. Stewart; 3 p.m., Polyclinic (Diseases of Chest), Thos. J. Mays; 3 p.m., University Hospital, Alfred Stengel; 4:30 p.m., St. Joseph's Hospital, H. B. Allyn; 5 p.m., Polyclinic (Diseases of Chest), A. E. Tussey.
 Friday, May 28, 11 a.m., St. Agnes', B. Stahl; 12 m., Medico-Chirurgical, J. M. Anders; 3 p.m., Philadelphia Hospital, W. E. Hughes and Frederick Packard; 3 p.m., Polyclinic (Diseases of Chest), Judson Daland; 5 p.m., Polyclinic, A. A. Eshner.
 Saturday, May 29, 11 a.m., St. Agnes', A. A. Stevens; 12 m., Woman's, F. P. Henry; 1 p.m., Philadelphia, John Musser; 2 p.m., Polyclinic (Diseases of Stomach), D. D. Stewart; 3 p.m., University, A. E. Stengel; 3 p.m., Polyclinic (Diseases of Chest), T. J. Mays; 5 p.m., Polyclinic (Diseases of Chest), A. E. Tussey.
 Monday, May 31, 12 m., Jefferson, Hobart A. Hare; 1 p.m., University, A. E. Stengel; 3 p.m., Philadelphia Hospital, James Tyson; 3 p.m., Polyclinic (Diseases of Chest), Judson Daland; 4:30 p.m., St. Joseph's Hospital, L. Marshall; 5 p.m., St. Joseph's Hospital, A. A. Eshner.
 Saturday, June 5, 11 a.m., St. Agnes', A. A. Stevens; 12 m., Presbyterian, John Musser; 12 m., Polyclinic, J. P. Crozer Griffith; 2 p.m., Polyclinic (Diseases of Stomach), D. D. Stewart; 3 p.m., Polyclinic (Diseases of Chest), Thos. J. Mays; 3 p.m., Philadelphia Hospital, A. E. Stengel; 4:30 p.m., St. Joseph's Hospital, H. B. Allyn; 5 p.m., Polyclinic (Diseases of Chest), A. E. Tussey.
 Monday, June 7, 11 a.m., St. Agnes', B. Stahl; 12 m., Medico-Chirurgical, Wm. E. Hughes; 12 m., Woman's Medical College, F. P. Henry; 12 m., Polyclinic, S. S. Cohen; 3 p.m., Philadelphia Hospital, James Tyson; 3 p.m., Polyclinic (Diseases of Chest), Judson Daland; 5 p.m., Polyclinic, A. A. Eshner.
 Tuesday, June 8, 11 a.m., St. Agnes', A. A. Stevens; 12 m., University, James Tyson; 2 p.m., Polyclinic (Diseases of Stomach), D. D. Stewart; 3 p.m., Philadelphia Hospital, Alfred E. Stengel; 3 p.m., Polyclinic (Diseases of Chest), Thos. J. Mays; 5 p.m., Polyclinic (Diseases of Chest), A. E. Tussey.
 Wednesday, June 9, 11 a.m., St. Agnes', B. Stahl; 12 m., Medico-Chirurgical, J. M. Anders; 3 p.m., Philadelphia, James Tyson; 3 p.m., Polyclinic (Diseases of Chest), Judson Daland; 5 p.m., Polyclinic, A. A. Eshner.
 Thursday, June 10, 11 a.m., St. Agnes', A. A. Stevens; 12 m., Polyclinic, J. P. Crozer Griffith; 1 p.m., University, John Musser; 2 p.m., Polyclinic (Diseases of Stomach), D. D. Stewart; 3 p.m., Polyclinic (Diseases of Chest), Thos. J. Mays;

3 p.m., Philadelphia Hospital, A. E. Stengel; 4:30 p.m., St. Joseph's Hospital, L. Marshall; 5 p.m., Polyclinic (Diseases of Chest), A. E. Tussey.

Friday, June 11, 11 a.m., St. Agnes', B. Stahl; 12 m., Medico-Chirurgical, J. M. Anders; 3 p.m., Polyclinic (Diseases of Chest), Judson Daland; 3 p.m., Philadelphia Hospital, James Tyson; 5 p.m., Polyclinic, A. A. Eshner.

Saturday, June 12, 11 a.m., St. Agnes', A. A. Stevens; 12 m., Woman's Medical College, T. P. Henry; 2 p.m., Polyclinic (Diseases of Stomach), D. D. Stewart; 3 p.m., Polyclinic (Diseases of Chest), T. J. Mays; 3 p.m., Philadelphia Hospital, A. E. Stengel; 5 p.m., Polyclinic (Diseases of Chest), A. E. Tussey.

Alfred Stengel will give two demonstrations of the performance of autopsies at the German Hospital on date which will be announced later.

NEUROLOGY.

HOSPITAL SERVICES FOR MENTAL AND NERVOUS DISEASES.

The following neurologic services for outdoor patients are conducted daily:

Hospital of University of Pennsylvania, 12 to 1 p.m., H. C. Wood.

Hospital of the Jefferson Medical College, 12 to 1 p.m., F. X. Dercum.

Medico-Chirurgical Hospital, 1 to 2 p.m., C. W. Burr.
 Polyclinic Hospital, 3 to 4 p.m., Charles K. Mills and C. W. Burr.

Orthopedic Hospital and Infirmary for Nervous Diseases, 1 to 2 p.m. Physicians, S. Weir Mitchell, Wharton Sinkler and Morris Lewis; Assistant Physicians, J. M. Taylor, Guy Hinsdale and J. K. Mitchell; Electrician, J. H. W. Rhein.

The Neurologic Department of the Philadelphia Hospital, which includes beds for three hundred cases of organic nervous disease, and the Insane Department of the hospital, with more than eleven hundred patients, is visited at least three times a week by each member of the neurologic staff on duty, with whom arrangements can be made to visit the wards. The neurologists now on duty are James Hendrie Lloyd and C. W. Burr.

Dispensary services for nervous diseases are also held at the Howard Hospital, Broad and Catherine Streets, and at the Northern Dispensary, Sixth Street and Fairmount Avenue.

CLINICAL LECTURES AND WARD DEMONSTRATIONS.

Monday, May 24, 3 to 4 p.m., Philadelphia Polyclinic, Clinical Lecture, C. K. Mills. 4 to 5 p.m., Clinical Lecture, C. W. Burr.

Tuesday, May 25, 3 to 4 p.m., Infirmary for Nervous Diseases, Clinical Lecture, W. Sinkler. 4 to 5 p.m., Clinical Lecture, J. K. Mitchell.

Wednesday, May 26, 3 to 4 p.m., Philadelphia Polyclinic, Clinical Lecture, C. K. Mills. 4 to 5 p.m., Electrotherapeutics, J. W. McConnell.

Thursday, May 27, 3 to 4 p.m., Philadelphia Hospital, Clinical Lecture, J. H. Lloyd. 4 to 5 p.m., Pepper Laboratory, University Hospital, Clinico-pathologic Demonstrations, W. G. Spiller.

Friday, May 28, 3 to 4 p.m., Jefferson College Hospital, Clinical Lecture, F. X. Dercum. 4 to 5 p.m., Electrotherapeutics, M. H. Boechroch.

Saturday, May 29, 3 to 4 p.m., Philadelphia Polyclinic, Clinico-pathologic Demonstrations, A. O. J. Kelly. 4 to 5 p.m., Infirmary for Nervous Diseases, Electrotherapeutics, J. H. W. Rhein.

Monday, May 31, 3 to 4 p.m., Philadelphia Hospital, Clinical Lecture, C. W. Burr. 4 to 5 p.m., University Hospital, Electrotherapeutics, Charles S. Potts.

Saturday, June 5, 3 to 4 p.m., Jefferson College Hospital, Clinical Lecture, F. X. Dercum. 4 to 5 p.m., Infirmary for Nervous Diseases, Electrotherapeutics, J. H. W. Rhein.

Monday, June 7, 3 to 4 p.m., Philadelphia Hospital, Clinical Lecture, J. H. Lloyd. 4 to 5 p.m., Clinical Lecture, C. W. Burr.

Tuesday, June 8, 3 to 4 p.m., Infirmary for Nervous Diseases, Clinical Lecture, W. Sinkler. 4 to 5 p.m., Clinical Lecture, J. K. Mitchell.

Wednesday, June 9, 3 to 4 p.m., Philadelphia Polyclinic, Clinical Lecture, C. K. Mills. 4 to 5 p.m., Electrotherapeutics, J. W. McConnell.

Thursday, June 10, 3 to 4 p.m., Philadelphia Hospital, Clinical Lecture, J. H. Lloyd. 4 to 5 p.m., Pepper Laboratory, University Hospital, Clinico-pathologic Demonstrations, W. G. Spiller.

Friday, June 11, 3 to 4 p.m., Jefferson College Hospital, Clinical Lecture, F. X. Dercum. 4 to 5 p.m., Electrotherapeutics, M. H. Boechroch.

Saturday, June 12, 3 to 4 p.m., Philadelphia Polyclinic, Clinico-pathologic Demonstrations, A. O. J. Kelly. 4 to 5 p.m., University Hospital, Electrotherapeutics, Charles S. Potts.

GYNECOLOGY AND OBSTETRICS.

In the following Out-patient Departments the diseases of women will be treated daily at the hours stated.

8 a.m., Woman's Hospital: Marie K. Formad, Frances Hachette, Sarah Chapin, Caroline Purnell and Ruth Clement. 9:30 a.m. and 12:30 p.m., West Philadelphia Hospital for Women: Lydia M. Stewart, R. Anna Breed, Elizabeth Griscom, Mary Griscom, Anna Sharpless, Helena Goodwin.

12 m., Jefferson Medical College Hospital: John M. Fisher. 12 m., Medico-Chirurgical College: Walter B. Woods. 12 m., University of Pennsylvania: John H. Girvin and Lawrence S. Smith.

12 m., Howard Hospital: B. C. Hirst, John B. Shober. 12 m., Hospital and Dispensary of the Alumnae of the Woman's Medical College: Lucy M. Tappan, Mary E. Allen, Mary W. Griscom.

6 p.m., West Philadelphia Hospital for Women: Esther F. Blair, Helen Murphy and Margaret Butler.

West Philadelphia Hospital for Women: Tuesdays and Fridays are operating days, 2 p.m.

At the Polyclinic B. F. Baer will operate Mondays and Saturdays at 1 p.m.; J. M. Baldy will operate Tuesdays and Wednesdays at 10 a.m.; H. A. Slocum will operate Tuesdays and Fridays at 5 p.m.

OPERATIONS AND CLINICS—GYNECOLOGY AND OBSTETRICS.

Monday, May 24. 10 a.m., Howard Hospital: John B. Shober. 12 m., Woman's Hospital: Hannah T. Croasdale. 1 p.m., Woman's Hospital (Obstetrics): Anna Broomall. 3 p.m., Lying-in Charity: G. M. Boyd, O. Hopkinson or J. R. Wilson.

Tuesday, May 25. 10 a.m., Private Hospital: Joseph Price. 1 p.m., University Hospital: C. B. Penrose. 3 p.m., University Hospital (Obstetrics—ward visit): B. C. Hirst.

Wednesday, May 26. 10 a.m., St. Joseph's Hospital: E. E. Montgomery. 12 m., University Hospital (Obstetrics)—labor obstructed by a contracted Pelvis and its management: B. C. Hirst. 1 p.m., Medico-Chirurgical Hospital: W. E. Ashton. 3 p.m., Jefferson Maternity (Obstetrics): E. P. Davis.

Thursday, May 27. 10 a.m., Kensington Hospital for Women: C. P. Noble. 12 m., Jefferson (Obstetrics): E. P. Davis. 3 p.m., Jefferson Maternity (Obstetrics): E. P. Davis.

Friday, May 28. 10 a.m., Gynecian Hospital: J. M. Baldy. 1 p.m., Jefferson Hospital: E. E. Montgomery. 3 p.m., Lying-in Charity: G. M. Boyd, O. Hopkinson, W. R. Wilson.

Saturday, May 29. 9 a.m., Philadelphia Hospital: R. C. Norris. 10 a.m., Polyclinic: B. F. Baer. 12 m., Jefferson (Obstetrics): E. P. Davis. 3 p.m., University of Pennsylvania (Obstetrics): B. C. Hirst.

Monday, May 31. 10 a.m., Kensington Hospital for Women: C. P. Noble. 12 m., Medico-Chirurgical (Obstetrics): W. Frank Hashlen. 12 m., Woman's Medical College: Anna M. Fullerton. 3 p.m., Lying-in Charity: G. M. Boyd, O. Hopkinson, W. R. Wilson.

Saturday, June 5. 9 a.m., Philadelphia Hospital: R. C. Norris. 10 a.m., Private Hospital: Joseph Price. 12 m., Medico-Chirurgical: W. E. Ashton. 3 p.m., University Hospital (Obstetrics—ward visit) B. C. Hirst.

Monday, June 7. 10 a.m., Howard Hospital (Gynecology): B. C. Hirst. 12 m., University Hospital (Obstetrics): B. C. Hirst. 2 p.m., Lying-in Charity: G. M. Boyd, O. Hopkinson and W. R. Wilson.

Tuesday, June 8. 10 a.m., Polyclinic: B. F. Baer. 12 m., Polyclinic (Obstetrics): E. P. Davis. 3 p.m., University of Pennsylvania (Obstetrics): B. C. Hirst.

Wednesday, June 9. 10 a.m., St. Joseph's Hospital: E. E. Montgomery. 12 m., Jefferson Medical College: John C. Da Costa. 10 a.m., Jefferson Maternity (Obstetrics): E. P. Davis.

Thursday, June 10. 10 a.m., St. Agnes Hospital: W. H. Parish. 12 m., Polyclinic (Obstetrics): E. P. Davis. 1 p.m., Polyclinic: J. M. Baldy. 3 p.m., Jefferson Maternity (Obstetrics): E. P. Davis.

Friday, June 11. 10 a.m., Gynecian Hospital: J. M. Baldy. 1 p.m., Jefferson Hospital: E. E. Montgomery. 3 p.m., Lying-in Charity: G. M. Boyd, O. Hopkinson, W. R. Wilson.

Saturday, June 12. 9 a.m., Philadelphia Hospital: R. C. Norris. 10 a.m., Methodist Hospital: George E. Shoemaker. 1 p.m., University Hospital: C. B. Penrose. 3 p.m., University, (Obstetrics—ward visit): B. C. Hirst.

OPHTHALMOLOGY, OTOLOGY AND LARYNGOLOGY.

The following list contains the hours and hospitals at which the visiting physicians interested in ophthalmology, otology

and laryngology will find clinics and dispensary services, and where they may see the active work in these departments of medicine and surgery.

MONDAY, MAY 24.

Ophthalmology.—8 a.m., Gertrude A. Walker, Women's Medical College; 9 a.m., J. Thorington, Polyclinic; 12 m., W. Sweet, Polyclinic; 1 p.m., L. W. Fox, Medico-Chirurgical; 2 p.m., de Schweinitz or Veasey, Jefferson; 2 p.m., Norris or Mellor, University of Pennsylvania; 2 p.m., Norris, Harlan, Risley, McClure, Oliver, Wills; 2 p.m., Mary Getty, Dispensary of Alumnae of Women's Hospital, 1212 South 3rd Street; 3 p.m., Mary Getty, West Philadelphia Hospital for Women; 3 p.m., L. Ziegler, St. Joseph's; 3 p.m., A. G. Thomson, Children's; 4 p.m., T. B. Schneideman, Polyclinic; 4 p.m., G. E. de Schweinitz, Philadelphia.

Otology.—8 a.m., Eleanor Adamson, Women's Hospital College; 1 p.m., B. A. Randall, University of Pennsylvania; 1 p.m., E. B. Gleason, Medico-Chirurgical; 1 p.m., Ralph Seiss, Polyclinic; 1 p.m., Kate W. Baldwin, Dispensary of the Alumnae of the Women's Medical College; 2 p.m., A. H. Cleveland, Presbyterian; 3 p.m., S. MacCuen Smith, Jefferson.

Laryngology.—8 a.m., Eleanor Adamson, Women's Hospital; 11 a.m., E. L. Vansant, Polyclinic; 12 m., C. P. Grayson, University of Pennsylvania; 12 m., W. S. Jones, Jefferson; 12 m., A. H. Cleveland, Medico-Chirurgical; 1:30 p.m., W. Freeman, Children's; 2 p.m., A. Watson, Polyclinic; 4 p.m., G. M. Marshall, Philadelphia.

TUESDAY, MAY 25.

Ophthalmology.—8 a.m., Elizabeth Snyder, Women's Medical College; 9 a.m., Jackson, Polyclinic; 12 m., H. F. Hansell, Polyclinic; 1 p.m., Chas. S. Turnbull, German; 1 p.m., L. W. Fox, Medico-Chirurgical; 1 p.m., Amy S. Barton, Women's Medical College; 2 p.m., Marie W. Haydon, Hospital and Dispensary of the Alumnae of the Women's Medical College; 2 p.m., de Schweinitz or Veasey; Jefferson; 2 p.m., Norris or Mellor, University of Pennsylvania; 2 p.m., W. Thomson, Fisher, Berens, Jackson, Wills; 2 p.m., F. M. Perkins, Presbyterian; 2 p.m., E. H. Rehffuss, St. Agnes; 2 p.m., Harlan and Schwenk, Pennsylvania; 2 p.m., W. C. Posey, Howard; 2 p.m., G. O. Ring, Episcopal; 2 p.m., Gertrude A. Walker, Dispensary of Alumnae of Women's Hospital, 1212 S. 3rd St.; 3 p.m., L. F. Love, St. Mary's; 4 p.m., G. E. de Schweinitz, Polyclinic.

Otology.—8 a.m., Ida E. Gaston and Clara Dercum, Women's Medical College; 12 m., S. MacCuen Smith, Jefferson; 12:30 p.m., J. M. Brown, University of Pennsylvania; 1 p.m., E. B. Gleason, Medico-Chirurgical; 1 p.m., Ada H. Audenried, Dispensary of Alumnae of Women's Medical College; 2:30 p.m., B. A. Randall, Children's; 3 p.m., G. M. Marshall, St. Joseph's; 3 p.m., Randall, Children's.

Laryngology.—9 a.m., Ida E. Gaston, Clara Dercum, Women's Medical College; 11 a.m., J. S. Gibb, Polyclinic; 12 m., D. Braden Kyle, Jefferson; 12 m., A. H. Cleveland, Medico-Chirurgical; 2 p.m., W. Hoch, Methodist; 2 p.m., D. B. Kyle, St. Agnes; 2 p.m., W. Freeman, Polyclinic; 2 p.m., A. W. MacCoy, Pennsylvania; 2 p.m., L. P. Smock, St. Agnes; 2 p.m., G. Hudson Makuen, Polyclinic; 3 p.m., G. M. Marshall, St. Joseph's.

WEDNESDAY, MAY 26.

Ophthalmology.—8 a.m., G. A. Walker, Women's; 9 a.m., J. Thorington, Polyclinic; 12 m., W. Sweet, Polyclinic; 1 p.m., L. W. Fox, Medico-Chirurgical; 3 p.m., de Schweinitz or Veasey, Jefferson; 2 p.m., Norris, Harlan, Risley, Oliver, McClure, Wills; 2 p.m., Norris or Mellor, University of Pennsylvania; 2 p.m., Mary Getty, Dispensary of Alumnae of Women's Hospital, 1212 S. 3rd St.; 3 p.m., Mary Getty, West Philadelphia Hospital for Women; 4 p.m., T. B. Schneideman, Polyclinic; 4 p.m., G. E. de Schweinitz, Philadelphia.

Otology.—8 a.m., Sarah F. Tyson, Women's Medical College; 12 m., S. MacCuen Smith, Jefferson; 12 m., Randall, Polyclinic; 1 p.m., Randall or Brown, University; 1 p.m., E. B. Gleason, Medico-Chirurgical; 1 p.m., Ralph Seiss, Polyclinic; 2 p.m., A. H. Cleveland, Presbyterian.

Laryngology.—8 a.m., Sarah F. Tyson, Women's Medical College; 11 a.m., A. Watson, Howard; 11 a.m., E. L. Vansant, Polyclinic; 12 m., D. Braden Kyle, Jefferson; 12 m., C. P. Grayson, University of Pennsylvania; 12 m., A. H. Cleveland, Medico-Chirurgical; 1 p.m., Kate W. Baldwin, Dispensary of Alumnae of Women's Medical College; 2 p.m., A. Watson, Polyclinic.

THURSDAY, MAY 27.

Ophthalmology.—8 a.m., E. Snyder, Women's; 9 a.m., J. Thorington, Polyclinic; 12 m., H. F. Hansell, Polyclinic; 1 p.m., L. W. Fox, Medico-Chirurgical; 2 p.m., G. E. de Schweinitz, Jefferson; 2 p.m., Norris or Mellor, University of

Pennsylvania; 2 p.m., Jackson, Thompson, Fisher, Berens, Wills; 2 p.m., F. M. Perkins, Presbyterian; 2 p.m., W. C. Posey; Howard; 2 p.m., P. N. K. Schwenk, Pennsylvania; 2 p.m., E. H. Rehffuss, St. Agnes; 2 p.m., Frances Janney, Dispensary of Alumnae of Women's Hospital, 1212 South Third Street; 3 p.m., L. F. Love, St. Mary's; 4 p.m., S. D. Risley, Polyclinic.

Otology.—12 m., Charles H. Burnett, Women's Medical; 12 m., S. MacCuen Smith, Jefferson; 12:30 p.m., J. M. Brown, University of Pennsylvania; 1 p.m., B. A. Randall, Polyclinic; 1 p.m., E. B. Gleason, Medico-Chirurgical; 1 p.m., Ada H. Audenried, Dispensary of Alumnae of Women's Medical; 3 p.m., B. A. Randall, Children's.

Laryngology.—8 a.m., Eleanor Adamson, Women's Medical College; 11 a.m., J. S. Gibb, Polyclinic; 12 m., W. S. Jones, Jefferson; 12 m., A. H. Cleveland, Medico-Chirurgical; 2 p.m., W. Hoch, Methodist; 2 p.m., D. B. Kyle, St. Agnes; 2 p.m., W. J. Freeman, Polyclinic; 2 p.m., A. W. MacCoy, Pennsylvania; 2 p.m., L. P. Smock, St. Agnes; 2 p.m., G. Hudson Mahnen, Polyclinic.

FRIDAY, MAY 28.

Ophthalmology.—8 a.m., G. A. Walker, Women's; 9 a.m., E. Jackson, Polyclinic; 12 m., W. Sweet, Polyclinic; 1 p.m., L. W. Fox, Medico-Chirurgical; 1 p.m., C. S. Turnbull, German; 2 p.m., de Schweinitz or Veasey, Jefferson; 2 p.m., Norris or Mellor, University of Pennsylvania; 2 p.m., Risley, Harlan, Oliver, Norris, McClure, Wills; 2 p.m., G. O. Ring, Episcopal; 2 p.m., Gertrude A. Walker, Dispensary of Alumnae of Women's Hospital, 1212 South Third Street; 3 p.m., Mary Getty, W. Philadelphia Hospital for Women; 3 p.m., L. W. Ziegler, St. Joseph's; 3 p.m., A. G. Thomson, Children's; 4 p.m., T. B. Schneideman, Polyclinic; 4 p.m., G. E. de Schweinitz, Philadelphia.

Otology.—9 a.m., Musson, Women's Medical College; 12 m., S. MacCuen Smith, Jefferson; 12 m., Randall, University of Pennsylvania; 1 p.m., Randall or Brown, University of Pennsylvania; 1 p.m., Ralph Seiss, Polyclinic; 1 p.m., E. B. Gleason, Medico-Chirurgical; 2 p.m., A. H. Cleveland, Presbyterian.

Laryngology.—11 a.m., E. L. Vansant, Polyclinic; 12 m., D. B. Kyle, Jefferson; 12 m., A. H. Cleveland, Medico-Chirurgical; 12 m., Emma E. Musson, Women's Medical College; 1 p.m., Kate W. Baldwin, Dispensary of Alumnae of Women's Medical College; 1:30 p.m., W. Freeman, Children's; 2 p.m., A. Watson, Polyclinic; 3 p.m., Kyle and Jones alternating, Jefferson; 4 p.m., G. M. Marshall, Philadelphia.

SATURDAY, MAY 29.

Ophthalmology.—8 a.m., E. Snyder, Women's Medical College; 9 a.m., J. Thorington, Polyclinic; 12 m., H. F. Hansell, Polyclinic; 1 p.m., L. W. Fox, Medico-Chirurgical; 2 p.m., de Schweinitz or Veasey, Jefferson; 2 p.m., Mellor, University of Pennsylvania; 2 p.m., Thompson, Fisher, Jackson, Berens, Wills; 2 p.m., E. H. Rehffuss, St. Agnes; 2 p.m., Harlan and Schwenk, Pennsylvania; 2 p.m., F. Janney, Dispensary of Alumnae of Women's Hospital 1212 South Third Street; W. C. Posey, Howard; 3 p.m., L. F. Love, St. Mary's; 4 p.m., G. E. de Schweinitz, Polyclinic.

Otology.—8 a.m., Sarah F. Tyson, Women's Medical College; 12 m., S. MacCuen Smith, Jefferson; 12:30 p.m., J. M. Brown, University of Pennsylvania; 1 p.m., B. A. Randall, Polyclinic; 1 p.m., E. B. Gleason, Medico-Chirurgical; 1 p.m., Ada H. Audenried, Dispensary of Alumnae of Women's Medical College; 3 p.m., B. A. Randall, Children's; 3 p.m., G. M. Marshall, St. Joseph's.

Laryngology.—8 a.m., Sarah F. Tyson, Women's Medical College; 11 a.m., J. S. Gibb, Polyclinic; 11 a.m., A. Watson, Howard; 12 m., W. S. Jones, Jefferson; 12 m., A. H. Cleveland, Medico-Chirurgical; 12 m., D. B. Kyle, St. Agnes; 2 p.m., A. W. MacCoy, Pennsylvania; 2 p.m., L. P. Smock, St. Agnes; 2 p.m., G. Hudson Mahnen, Polyclinic; 3 p.m., G. M. Marshall, St. Joseph's.

MONDAY, MAY 31.

Ophthalmology.—8 a.m., G. A. Walker, Woman's Medical College; 9 a.m., J. Thorington, Polyclinic; 12 m., W. Sweet, Polyclinic; 1 p.m., L. W. Fox, Medico-Chirurgical; 2 p.m., de Schweinitz or Veasey, Jefferson; 2 p.m., Norris or Mellor, University of Pennsylvania; 2 p.m., Norris, Harlan, Risley, McClure, Oliver, Wills; 2 p.m., M. Getty, Dispensary of Alumnae of Women's Hospital, 1312 S. 3d Street; 3 p.m., M. Getty, West Philadelphia Hospital for Women; 3 p.m., L. Ziegler, St. Joseph's; 3 p.m., A. G. Thompson, Children's; 4 p.m., T. B. Schneidemann, Polyclinic; 4 p.m., G. E. de Schweinitz, Philadelphia.

Otology.—8 a.m., Eleanor Adamson, Women's Medical College; 1 p.m., B. A. Randall, University of Pennsylvania; 1 p.m.,

E. B. Gleason, Medico-Chirurgical; 1 p.m., Ralph Seiss, Polyclinic; 2 p.m., A. H. Cleveland, Presbyterian; 3 p.m., S. MacCuen Smith, Jefferson.

Laryngology.—11 a.m., E. L. Vansant, Polyclinic; 12 m., C. P. Grayson, University of Pennsylvania; 12 m., W. S. Jones, Jefferson; 12 m., A. H. Cleveland, Medico-Chirurgical; 1 p.m., Kate W. Baldwin, Dispensary of the Alumnae of the Women's Medical College; 1:30 p.m., W. Freeman, Children's; 2 p.m., A. Watson, Polyclinic; 4 p.m., G. M. Marshall, Philadelphia.

SATURDAY, JUNE 5.

Ophthalmology.—8 a.m., E. Snyder, Women's Medical College; 9 a.m., J. Thorington, Polyclinic; 12 m., H. F. Hansell, Polyclinic; 1 p.m., L. Webster Fox, Medico-Chirurgical; 2 p.m., de Schweinitz or Veasey, Jefferson; 2 p.m., Mellor, University of Pennsylvania; 2 p.m., Thompson, Fisher, Jackson, Berens, Wills; 2 p.m., E. H. Rehffuss, St. Agnes; 2 p.m., W. C. Posey, Howard; 2 p.m., Harlan and Schwenk, Pennsylvania; 2 p.m., F. Janney, Dispensary of Alumnae Woman's Hospital, 1212 S. 3d Street; 3 p.m., L. F. Love, St. Mary's; 4 p.m., G. E. de Schweinitz, Polyclinic.

Otology.—8 p.m., Sarah F. Tyson, Women's Medical College; 12 m., S. MacCuen Smith, Jefferson; 1 p.m., B. A. Randall, Polyclinic; 1 p.m., E. B. Gleason, Medico-Chirurgical; 1 p.m., Ada H. Audenried, Dispensary of Alumnae of Women's Medical College; 1 p.m., Brown, University of Pennsylvania; 3 p.m., B. A. Randall, Children's; 3 p.m., G. M. Marshall, St. Joseph's.

Laryngology.—8 a.m., Sarah F. Tyson, Women's Medical College; 11 a.m., J. S. Gibb, Polyclinic; 11 a.m., A. Watson, Howard; 12 m., W. S. Jones, Jefferson; 12 m., A. H. Cleveland, Medico-Chirurgical; 2 p.m., D. B. Kyle, St. Agnes; 2 p.m., A. W. MacCoy, Pennsylvania; 2 p.m., L. P. Smock, St. Agnes; 2 p.m., Hudson MacCuen, Polyclinic; 3 p.m., G. M. Marshall, St. Joseph's.

MONDAY, JUNE 7.

Ophthalmology.—9 a.m., J. Thorington, Polyclinic; 9 a.m., G. A. Walker, Women's Medical College; 12 m., W. Sweet, Polyclinic; 1 p.m., L. W. Fox, Medico-Chirurgical; 2 p.m., de Schweinitz or Veasey, Jefferson; 2 p.m., Norris or Mellor, University of Pennsylvania; 2 p.m., Norris, Harlan, Risley, McClure, Oliver, Wills; 2 p.m., M. Getty, Dispensary of Alumnae of Woman's Hospital; 3 p.m., M. Getty, West Philadelphia Hospital for Women; 3 p.m., L. Ziegler, St. Joseph's; 3 p.m., A. G. Thompson, Children's; 4 p.m., T. B. Schneidemann, Polyclinic; 4 p.m., G. E. de Schweinitz, Philadelphia.

Otology.—8 a.m., Eleanor Adamson, Women's Medical College; 12 m., Ralph Seiss, Polyclinic; 1 p.m., B. A. Randall, University of Pennsylvania; 1 p.m., E. B. Gleason, Medico-Chirurgical; 2 p.m., A. H. Cleveland, Presbyterian; 3 p.m., S. MacCuen Smith, Jefferson.

Laryngology.—11 a.m., E. L. Vansant, Polyclinic; 12 m., C. P. Grayson, University of Pennsylvania; 12 m., W. S. Jones, Jefferson; 12 m., A. H. Cleveland, Medico-Chirurgical; 1 p.m., Kate W. Baldwin, Hospital and Dispensary of Alumnae of the Woman's Medical College; 1:30 p.m., W. Freeman, Children's; 2 p.m., A. Watson, Polyclinic; 4 p.m., G. M. Marshall, Philadelphia.

TUESDAY, JUNE 8.

Ophthalmology.—8 a.m., E. Snyder, Women's Medical College; 9 a.m., Jackson, Polyclinic; 12 m., H. F. Hansell, Polyclinic; 1 p.m., C. S. Turnbull, German; 1 p.m., L. W. Fox, Medico-Chirurgical; 2 p.m., de Schweinitz or Veasey, Jefferson; 2 p.m., Norris or Mellor, University of Pennsylvania; 2 p.m., Thompson, Fisher, Berens, Jackson, Wills; 2 p.m., F. M. Perkins, Presbyterian; 2 p.m., E. H. Rehffuss, St. Agnes; 2 p.m., Harlan and Schwenk, Pennsylvania; 2 p.m., Mary W. Hayden, Hospital of Alumnae of Women's Medical College, 2 p.m., W. C. Posey, Howard; 2 p.m., G. O. Ring, Episcopal; 2 p.m., G. A. Walker, Dispensary of Alumnae of Woman's Hospital; 3 p.m., L. F. Love, St. Mary's; 4 p.m., G. E. de Schweinitz, Polyclinic.

Otology.—12 m., Charles H. Burnett, Woman's Medical College; 12 m., S. McCuen Smith, Jefferson; 12:30 p.m., J. M. Brown, University of Pennsylvania; 1 p.m., E. B. Gleason, Medico-Chirurgical; 1 p.m., B. A. Randall, Polyclinic; 1 p.m., Ada H. Audenried, Dispensary of Alumnae of Woman's Medical College; 3 p.m., B. A. Randall, Children's; 3 p.m., G. M. Marshall, St. Joseph's.

Laryngology.—9 a.m., Ida E. Gasten and Clara Dercum, Women's Medical College; 11 a.m., J. S. Gibb, Polyclinic; 12 m., D. Braden Kyle, Jefferson; 12 m., A. H. Cleveland, Medico-Chirurgical; 2 p.m., W. Hoch, Methodist; 2 p.m., D. B. Kyle, St. Agnes; 2 p.m., W. Freeman, Polyclinic; 2 p.m., A. W. McCoy, Pennsylvania; 2 p.m., L. P. Smock, St. Agnes; 2 p.m., G. Hudson Makuen, Polyclinic; 3 p.m., G. M. Marshall, St. Joseph's.

WEDNESDAY, JUNE 9.

Ophthalmology.—8 a.m., Gertrude A. Walker, Woman's Medical College; 9 a.m., J. Thorington, Polyclinic; 12 m., W. Sweet, Polyclinic; 12 m., Emma E. Musson, Woman's Medical College; 1 p.m., L. W. Fox, Medico-Chirurgical; 2 p.m., de Schweinitz or Dr. Veasey, Jefferson; 2 p.m., Drs. Norris, Harlan, Risley, Cliver and McClure, Wills; 2 p.m., Dr. Norris or Dr. Mellor, University of Pennsylvania; 2 p.m., Mary Getty, Dispensary of Alumnae of Women's Hospital, 1212 S. 3d St.; 3 p.m., Mary Getty, West Philadelphia Hospital for Women; 4 p.m., T. B. Schneidemann, Polyclinic; 4 p.m., G. E. de Schweinitz, Philadelphia.

Otology.—8 a.m., Sarah F. Tyson, Women's Medical College; 12 m., S. McCuen Smith, Jefferson; 12 m., Dr. Randall, University of Pennsylvania; 1 p.m., Dr. Randall or Dr. Brown, University; 1 p.m., E. B. Gleason, Medico-Chirurgical; 1 p.m., Ralph Seiss, Polyclinic; 2 p.m., A. H. Cleveland, Presbyterian.

Laryngology.—8 a.m., Sarah F. Tyson, Women's Medical College; 11 a.m., A. Watson, Howard; 11 a.m., E. L. Vansant, Polyclinic; 12 m., D. Braden Kyle, Jefferson; 12 m., C. P. Grayson, University of Pennsylvania; 12 m., A. H. Cleveland, Medico-Chirurgical; 1 p.m., Kate W. Baldwin, Dispensary of Alumnae Women's Medical College; 2 p.m., A. Watson, Polyclinic.

THURSDAY, JUNE 10.

Ophthalmology.—8 a.m., E. Snyder, Women's Medical College; 9 a.m., J. Thorington, Polyclinic; 12 m., H. F. Hansell, Polyclinic; 1 p.m., L. W. Fox, Medico-Chirurgical; 2 p.m., G. E. de Schweinitz, Jefferson; 2 p.m., Dr. Norris or Dr. Mellor, University of Pennsylvania; 2 p.m., Drs. Jackson, Thomson, Fisher and Berens, Wills; 2 p.m., F. M. Perkins, Presbyterian; 2 p.m., W. C. Posey, Howard; 2 p.m., P. N. K. Schwenk, Pennsylvania; 2 p.m., E. H. Rehfuss, St. Agnes; 2 p.m., Frances Janney, Dispensary of Alumnae of Women's Hospital, 1212 S. 3d St.; 3 p.m., L. F. Love, St. Mary's; 4 p.m., S. D. Risley, Polyclinic.

Otology.—12 m., Charles L. Burnett, Women's Medical College; 12 m., S. McCuen Smith, Jefferson; 12:30 p.m., J. M. Brown, University of Pennsylvania; 1 p.m., B. A. Randall, Polyclinic; 1 p.m., E. B. Gleason, Medico-Chirurgical; 1 p.m., Ada N. Andenried, Dispensary of the Alumnae of Women's Medical College; 3 p.m., B. A. Randall, Children's.

Laryngology.—8 a.m., Eleanor Adamson, Women's Medical College; 11 a.m., J. S. Gibb, Polyclinic; 12 m., W. S. Jones, Jefferson; 12 m., A. H. Cleveland, Medico-Chirurgical; 2 p.m., W. Hoch, Methodist; 2 p.m., D. B. Kyle, St. Agnes; 2 p.m., W. J. Freeman, Polyclinic; 2 p.m., A. W. MacCoy, Pennsylvania; 2 p.m., L. P. Smock, St. Agnes; 2 p.m., G. Hudson Makuen, Polyclinic.

FRIDAY, JUNE 11.

Ophthalmology.—8 a.m., G. A. Walker, Women's Medical College; 9 a.m., E. Jackson, Polyclinic; 12 m., W. Sweet, Polyclinic; 1 p.m., Amy L. Barton, Women's Medical College; 1 p.m., D. W. Fox, Medico-Chirurgical; 1 p.m., C. S. Turnbull, German; 2 p.m., Dr. de Schweinitz or Dr. Veasey, Jefferson; 2 p.m., Dr. Norris or Dr. Mellor, University of Pennsylvania; 2 p.m., Drs. Risley, Harlan, Oliver, Norris, McClure, Wills; 2 p.m., G. O. Ring, Episcopal; 2 p.m., Gertrude A. Walker, Dispensary of Alumnae of Women's Hospital, 1212 S. 3d St.; 3 p.m., Mary Getty, West Philadelphia Hospital for Women; 3 p.m., L. W. Ziegler, St. Joseph; 3 p.m., A. G. Thomson, Children's; 4 p.m., T. B. Schneidemann, Polyclinic; 4 p.m., G. E. de Schweinitz, Philadelphia.

Otology.—8 a.m., Ida E. Gaston and Clara Dercum, Women's Medical College; 12 m., S. McCuen Smith, Jefferson; 1 p.m., Dr. Randall or Dr. Brown, University of Pennsylvania; 1 p.m., Ralph Seiss, Polyclinic; 1 p.m., Kate W. Baldwin, Dispensary of Alumnae of Women's Medical College; 1 p.m., E. B. Gleason, Medico-Chirurgical; 2 p.m., A. H. Cleveland, Presbyterian.

Laryngology.—8 a.m., Ida E. Gaston and Clara Dercum, Women's Medical College; 11 a.m., E. L. Vansant, Polyclinic; 12 m., D. B. Kyle, Jefferson; 12 m., A. H. Cleveland, Medico-Chirurgical; 12 m., Emma E. Musson, Women's Medical College; 1:30 p.m., W. Freeman, Children's; 2 p.m., A. Watson, Polyclinic; 3 p.m., Kyle and Jones alternating, Jefferson; 4 p.m., G. M. Marshall, Philadelphia.

SATURDAY, JUNE 12.

Ophthalmology.—8 a.m., E. Snyder, Women's Medical College; 9 a.m., J. Thorington, Polyclinic; 12 m., H. F. Hansell, Polyclinic; 1 p.m., L. W. Fox, Medico-Chirurgical; 2 p.m., de Schweinitz or Veasey, Jefferson; 2 p.m., Mellor, University of Pennsylvania; 2 p.m., Thomson, Fisher, Jackson, Berens, Wills; 2 p.m., E. H. Rehfuss, St. Agnes; 2 p.m., W. C. Posey,

Howard; 2 p.m., Harlan and Schwenk, Pennsylvania; 2 p.m., F. Janney, Dispensary of Alumnae of Women's Hospital, 1212 S. 3rd St.; 3 p.m., L. F. Love, St. Mary's; 4 p.m., G. E. de Schweinitz, Polyclinic.

Otology.—8 a.m., Sarah F. Tyson, Women's Medical College; 12 m., S. McCuen Smith, Jefferson; 12:30 p.m., J. M. Brown, University of Pennsylvania; 1 p.m., B. A. Randall, Polyclinic; 1 p.m., E. B. Gleason, Medico-Chirurgical; 3 p.m., B. A. Randall, Children's; 3 p.m., G. M. Marshall, St. Joseph's.

Laryngology.—8 a.m., Sarah F. Tyson, Women's Medical College; 11 a.m., J. S. Gibb, Polyclinic; 11 a.m., A. Watson, Howard; 12 m., W. S. Jones, Jefferson; 12 m., A. H. Cleveland, Medico-Chirurgical; 12 m., D. B. Kyle, St. Agnes; 1 p.m., Ada H. Andenried, Dispensary of Alumnae of Women's Medical College; 2 p.m., A. W. MacCoy, Pennsylvania; 2 p.m., L. P. Smock, St. Agnes; G. Hudson Makuen, Polyclinic; 3 p.m., G. M. Marshall, St. Joseph's.

GENITO-URINARY DISEASES.

The following Out-patient Departments are open daily for the treatment of ambulant cases suffering from genito-urinary diseases:

12 m., University of Pennsylvania, Henry M. Christian.
12 m., Medico-Chirurgical College, W. Newbold Watson.
12 m., Jefferson Medical College, H. R. Loux.
12 m., Methodist (Mondays, Wednesdays, Fridays), D. E. Kucher.

4 p.m., Polyclinic, T. R. Neilson and H. M. Christian.
7:30 p.m., Mondays, Wednesdays and Fridays, demonstrations in cystoscopy and vesical explorations, Edward Martin and James Hutchinson.

Clinical lectures and ward demonstrations by John V. Shoemaker at the Medico-Chirurgical College, Orville Horwitz at the Jefferson College, H. M. Christian and T. R. Neilson at the Polyclinic, and Edward Martin at the University, are scheduled in the college courses.

PEDIATRICS.

The following Out-patient Departments will be open for the study of children's diseases:

8 a.m., Woman's Hospital, Kate Baldwin, E. C. Jones, Margaret Butler.
11 a.m., Medico-Chirurgical, Alexander Ramsey.
12 m., Jefferson, H. M. Shriver.
12 m., University, W. H. Price.
10 a.m., Polyclinic, J. M. Taylor and J. H. McKee.
3 p.m., Hospital and Dispensary of the Alumnae of the Woman's Medical College, Eleanor Jones, Clara Revell, Emma Weeks.

11 a.m., Children's Hospital.
3 p.m., Children's Hospital, J. P. Crozer Griffith.
Clinical lectures on children's diseases by J. P. Crozer Griffith at the University, E. E. Graham at the Jefferson, W. C. Hollopeter at the Medico-Chirurgical, Edward P. Davis at the Woman's Medical, and J. W. Taylor at the Polyclinic, are scheduled in the college courses.

DERMATOLOGY.

The following Out-patient Departments will be open for the study of skin diseases at the hours named:

12 m., Howard Hospital, Henry W. Stelwagon and C. N. Davis.
12 m., Jefferson, E. J. Stout.
1 p.m., University, M. B. Hartzell and C. N. Davis.
11 a.m., Medico-Chirurgical, E. S. Gans.
11 a.m., Fred Douglas Memorial Hospital (Mondays and Fridays), J. A. Cantrell.
10 a.m., St. Agnes' (Mondays, Wednesdays and Fridays), C. S. Mears.
12 m., Polyclinic, J. A. Cantrell.

Clinical lectures on dermatology by Louis A. Duhring at the University, H. W. Stelwagon at the Jefferson, J. V. Shoemaker at the Medico-Chirurgical and J. A. Cantrell at the Polyclinic are scheduled in the college courses.

Dr. Cantrell will have ward demonstrations at the Philadelphia Hospital on Mondays, Wednesdays and Fridays, at 3:30 p.m.

Intestinal Pneumatoma.—Orland describes a case of occlusion and fatal peritonitis caused by the formation of several walnut-sized, gas-filled tumors near the ileo-cecal valve. The protruding mucous membrane subsided to the level after puncture and the escape of the gas, with no evidences of degeneration. Bacilli obtained from the wall of the tumors proved virulent in experiments, but developed no gas. He ascribes their action in the case to alterations in the tissues that transformed them from saprophytes to gas-forming agents.—*Cbl. f. Chir.*, April 3.

ASSOCIATION NEWS.

The Philadelphia Meeting of the American Medical Association.

It may interest the members of the ASSOCIATION to know of the very great interest which is being taken in the coming meeting by physicians in all portions of the United States. Every mail brings to me a large number of letters in which the writers promise to be present at the meeting and express great enthusiasm as to the possibilities which it offers to themselves and to the ASSOCIATION itself. Already we have been informed of three special trains from various portions of the West which will bring a large number of delegates to the hospitable doors of Philadelphia, and arrangements are already so far completed that the ASSOCIATION might meet here within a week and find everything in readiness for its complete entertainment both scientifically and socially.

You have already received from the hands of Dr. Martin, the Chairman of the Committee on Hospital Demonstrations, a complete and exhaustive roster¹ which informs visitors of the possibilities offered them for clinical observation in the large teaching institutions and hospitals of Philadelphia. It is believed that this course has been arranged in such a way as to provide visiting physicians with the largest possible amount of practical information which can be obtained either by the bedside or in laboratory work within the short period of a few days or weeks. It will be noted that in this roster hospital and other facilities are offered to visitors for the week before and the week following the meeting. To those physicians who desire to stay longer I may announce that special spring and summer courses have been arranged by those in charge of the laboratories connected with Jefferson Medical College Hospital and the Pepper Laboratory of the University of Pennsylvania, so that those who desire to remain over a period longer than that covered by the roster prepared by Dr. Martin's committee can continue such courses of instruction as they desire. All these courses have been arranged, as I have said, in such a way as to present to the physician the practical advantages he would naturally seek as aids in his daily work.

The appended information in regard to the various meeting places will also, I think, be read with interest by those who have any knowledge of the situation of the various meeting places. To those who do not know them, as has already been stated in the editorial in the JOURNAL of April 24, these meeting places are included in one entire block on both sides of Broad Street and are within a stone's throw of all the large hotels.

PLACES OF MEETING.

The general meetings will be held in the main auditorium of the Academy of Music, Broad and Locust Streets.

Headquarters, Hotel Walton, Broad and Spruce Streets.

Registration Office will be in the lower corridor of Horticultural Hall, Broad Street below Locust.

Postoffice will be in the outer vestibule of Horticultural Hall.

SECTIONS.

The Section on Practice of Medicine will meet in the Broad Street Theater.

The Section on Surgery and Anatomy will meet in the lower hall of Horticultural Hall.

The Section on Obstetrics and Diseases of Women will meet in the main auditorium of Beth-Eden church, Corner of Broad and Spruce Streets.

The Section on Neurology and Medical Jurisprudence will meet in the upper room of Beth-Eden church, entrance on Spruce Street.

The Section on Laryngology and Otology will meet in the central room, tenth floor, Hotel Walton.

The Section on Materia Medica and Pharmacy will meet in the Blue Room of the Academy of Music.

The Section on Diseases of Children will meet in the foyer of the Academy of Music.

The Section on State Medicine will meet in the Red Room of the Academy of Music.

The Section on Dermatology and Syphilography will meet in the foyer of Horticultural Hall.

The Section on Physiology and Dietetics will meet in the banquet hall of the Hotel Stenton, Broad and Spruce Streets.

The Section on Dental and Oral Surgery will meet in Parlor D, Hotel Walton.

COMMITTEE ROOMS.

The Executive or Business Committee will meet in Parlor C, Hotel Walton.

The Judicial Council will meet in the Lower Ladies' Parlor of the Academy of Music.

The Trustees will meet in the Upper Ladies' Parlor of the Academy of Music.

The Nominating Committee will meet in the Green Room of the Academy of Music.

It is hoped by the officers of the ASSOCIATION and by the members of the Committee of Arrangements that every member of the ASSOCIATION will not only make an effort to be present, but that he will if detained send a substitute and urge all his medical friends to accompany him to this meeting, which promises to be the most successful one in our history.

In order to facilitate the business of the meeting I append a list of the chairmen of the various sub-committees to whom gentlemen wishing information in regard to matters falling within their jurisdiction should write direct.

Committee on Ways and Means, including Transportation.—Dr. E. E. Montgomery, 1715 Walnut Street.

Committee on Exhibition.—Dr. Edward Jackson, 1633 Locust Street.

Committee on Reception and Accommodation.—Dr. G. E. de Schweinitz, 1401 Locust Street.

Committee on Registration.—Dr. John Marshall, 1409 Spruce Street.

Committee on Entertainment.—Dr. L. Webster Fox, 1304 Walnut Street.

Committee on Hospital Facilities.—Dr. Edward Martin, 415 South Fifteenth Street.

Committee on Anniversary Exercises.—Dr. John B. Roberts, 1627 Walnut Street.

Committee on General Information.—Dr. H. A. Hare, 222 S. 15th Street.

Committee on Section Dinners.—Dr. Edward Jackson, 1633 Locust Street.

If the readers of the JOURNAL will remember that by a little individual effort they can persuade a friend or friends to add his or their names to the membership of the ASSOCIATION and thereby greatly increase its usefulness they will confer a lasting benefit upon our organization. Yours truly,

H. A. HARE, M.D.,

Chairman of the Committee of Arrangements.

Section on Laryngology and Otology.—Program.

TUESDAY, JUNE 1ST—AFTERNOON SESSION.

1. Address of Chairman. W. E. Casselberry, Chicago, Ill.
2. The So-called Bleeding Polyp of the Septum. Norval H. Pierce, Chicago, Ill.
3. Some Notes Concerning the Influence of Sexual Excitement upon Intra-nasal Disease. Charles P. Grayson, Philadelphia, Pa.
4. Nasal and Laryngeal Affections Traceable to Diseases of the Genital Organs. A. B. Kirkpatrick, Philadelphia, Pa.
5. Two Cases of Asthma due to Intra-nasal Obstruction. Wilbur W. Bulette, Pueblo, Colo.
6. Something on the Amusing Side of Nasal Reflexes. Arthur G. Hobbs, Atlanta, Ga.
7. Spasmodic Closure of the Glottis in an Adult. Hamilton Stillson, Seattle, Wash.
8. Salivary Calculi. W. Freudenthal, New York, N. Y.
9. An Unusual Case of Blood-Cyst of the Posterior Nares. John N. Mackenzie, Baltimore, Md.
10. A Clinical and Experimental Study of Atrophic Disease of the Upper Air Passages. J. L. Goodale, Boston, Mass.
11. Some Remarks on Cases of Atrophic Naso-pharyngitis. Edward F. Parker, Charleston, S. C.
12. Treatment of Acute Rhinitis. A. R. Solenberger, Chicago, Ill.
13. The Treatment of Chronic Catarrhal Diseases of the Throat in General Practice. J. M. G. Carter, Waukegan, Ill.
14. Fluoroscopy in Certain Forms of the Diseases of the Throat, Nose, Lungs, etc. J. Mount Bleyer, New York, N. Y.
15. Non-specific Perforation of the Nasal Septum, with Report of Cases. J. R. Straw, Ashland, Wis.

¹ See page 886 et seq.

16. Practical vs. Theoretical Tonsillotomy. J. Homer Coulter, Chicago, Ill.

WEDNESDAY, JUNE 2D—MORNING SESSION.

17. A Case of Chronic Abscess of the Base of the Tongue. C. W. Richardson, Washington, D. C.

18. A Case of Polypus involving the Antrum of Highmore. A. E. Prince, Springfield, Ill.

19. A Case of Recurrent Headaches which Continued until Relieved by the Spontaneous Discharge of a Watery Fluid from the Nostrils; the Successive Opening of the Frontal and Maxillary Sinuses and Ethmoidal Cells without Relief of the Recurrent Headaches. W. Scheppegrell, New Orleans, La.

20. Suppurative Ethmoiditis. Robert W. Haynes, Los Angeles, Cal.

21. Studies of the Nasal Fossa and Maxillary Sinus, with their relations. M. H. Cryer, Philadelphia, Pa.

22. Discussion—The Treatment of Empyema of the Frontal Sinus. Opened by J. H. Bryan, Washington, D. C.

23. A Contribution to the Surgery of the Accessory Cavities of the Nose. Max Thorner, Cincinnati, Ohio.

24. Meniere's Disease, with Report of a Case. James M. Brown and Judson Daland, Philadelphia, Pa.

25. Diseases of the Conjunctiva in Relation to Diseases of the Nasal Passages. Robert N. Keely, Philadelphia, Pa.

Discussion opened by J. F. Fulton, St. Paul, Minn.

26. Irruption of Teeth into the Antral Cavities. Alexander W. MacCoy, Philadelphia, Pa.

27. Exhibition of Anatomic Sections of the Ear and Accessory Nasal Cavities. C. R. Holmes, Cincinnati, Ohio.

WEDNESDAY, JUNE 2D—AFTERNOON SESSION.

28. Report of Two Cases of Abscess of the Mastoid Region. J. H. Bryan, Washington, D. C.

29. Mastoid Empyema without Objective Symptoms, with Presentation of Patients. S. MacCuen Smith, Philadelphia, Pa.

30. An Historical Sketch of the Operation of Opening the Mastoid for Suppurative Middle Ear Disease. Laurence Turnbull, Philadelphia, Pa.

Discussion opened by D. B. St. John Roosa, New York, N. Y.

31. Phenomena Observed in Twelve Cases at various stages of the Operation of Tenotomy of the Stapedius and Section of the Incudo-stapedial Articulation in Chronic Catarrh of the Middle Ear; Improvement in the Hearing for Low Tones following Wolfe's Operation; Exhibition of Case. E. B. Gleason, Philadelphia, Pa.

32. The Clinical History of Three Cases of Otitis Media Presenting Serious Constitutional Symptoms, with Special Reference to the Vital Indications for Mastoid Operation. Hiram Woods, Baltimore, Md.

33. Caries and Necrosis of the Roof of the External Auditory Canal. Seth Scott Bishop, Chicago, Ill.

Discussion opened by Walter J. Freeman, Philadelphia, Pa.

34. A Case of Rhino-pharyngeal Fibroma, with Projections Extending Through the Two Nasal Cavities to the Anterior Nares. Hanau W. Loeb, St. Louis, Mo.

Discussion opened by E. F. Ingals, Chicago, Ill.

35. Contribution to Our Knowledge of the Diseases of the Naso-pharynx. Emma E. Munson, Philadelphia, Pa.

36. Question Regarding the Etiology of Adenoid Vegetations, as Found in the Naso-pharynx, with Suggestions as to Treatment. Also a Serrated Curette-syringe, New, for the Purpose of Freeing the Vault of Detritus after Operation. M. C. O'Toole, San Francisco, Cal.

37. Adenoids in the Naso-pharynx, with Operative Treatment of the Same. W. M. Roads, Cincinnati, Ohio.

THURSDAY, JUNE 3D—MORNING SESSION.

38. General and Local Anesthesia in Rhinology and Laryngology. Joseph S. Gibb, Philadelphia, Pa.

39. Tonsil and Adenoid Operations under Anesthesia by Nitrous Oxid, and Nitrous Oxid with Hydrogen; a Preliminary Report. W. E. Casselberry and F. Menge, Chicago, Ill. (Paper prepared and read by Dr. Menge.)

Discussion opened by J. O. Roe, Rochester, N. Y.

40. Cocain and Eucin: A Comparison. T. H. Shastid, Galesburg, Ill.

41. Cocain, Its Uses and Abuses in Laryngology. Ledru P. Smock, Philadelphia, Pa.

42. Certain Conditions of the Tonsils which Limit the Usefulness of the Tonsillotomy. Arthur A. Bliss, Philadelphia, Pa.

Discussion opened by Charles H. Knight, New York, N. Y.

43. Fracture of the Nasal Bones. Frederick C. Cobb, Boston, Mass.

44. The Treatment of Chronic Inflammation of the Tonsils. J. A. Ellegood, Wilmington, Del.

45. Peritonitis, Its Etiology and Treatment. Kate W. Baldwin, Philadelphia, Pa.

46. Contribution to the Study of Prophylaxis in Diphtheria of the Upper Respiratory Tractus. Henry L. Wagner, San Francisco, Cal.

47. Municipal Control of Diphtheria. W. K. Jaques, Chicago, Ill.

THURSDAY, JUNE 3D—AFTERNOON SESSION.

48. Three Obscure Cases of Laryngeal Disease: Tuberculosis—Syphilis—Epithelioma. Charles H. Knight, New York, N. Y.

49. Malignant Growths of the Larynx, with Report of Cases. Presentation of a Specimen from a Case of Fatal Extirpation. Robert C. Myles, New York, N. Y.

Discussion opened by J. Solis-Cohen, Philadelphia, Pa.

50. Some Defects of Speech: Their Cause and Treatment with Exhibition of Cases. G. Hudson Makuon, Philadelphia Pa.

51. Esophagotomy for the Removal of a Tooth Plate Impacted Five Days in the Upper Third of the Esophagus. John O. Roe, Rochester, N. Y.

52. Stenosis of the Larynx. W. S. Jones, Camden, N. J.

53. A Case of Bilateral Gummata with Dangerous Stenosis of Larynx. S. K. Merrick, Baltimore, Md.

54. Tubercular Laryngitis. Ellet Orrin Sisson, Keokuk, Iowa.

55. Tuberculous Tumor of the Larynx. Louis Jurist, Philadelphia, Pa.

56. Sand Burrs in the Larynx. D. Emmett Welsh, Grand Rapids, Mich.

FRIDAY, JUNE 4TH—MORNING SESSION.

57. Otitic Pachymeningitis Externa. Joseph A. Andrews, New York, N. Y.

58. Acute Myringitis. Ralph W. Seiss, Philadelphia, Pa.

59. The Treatment of Tinnitus Aurium. G. Sterling Ryerson, Toronto, Ont.

60. Discussion: Tinnitus in its Relation to Nasal and Aural Affections. Opened by B. Alexander Randall, Philadelphia, Pa.

61. The Treatment of Acute Otitis Media—Acute Earache. J. Hubert Claiborne, New York, N. Y.

62. Acute and Chronic Caries of the Mastoid; Pachymeningitis Externa; Epidural Abscess; Circumscribed Leptomeningitis. Herman Knapp, New York, N. Y.

63. What can be Accomplished by Treatment of the Eustachian Tube. George Morley Marshall, Philadelphia, Pa.

64. Natural Gas and Acute Inflammation of the Eustachian Tube. John Johnson Kyle, Marion, Ind.

65. Eustachian Deafness. A. J. Erwin, Mansfield, Ohio.

66. A Novel Method of the Use of Dry Heat in Middle Ear Diseases, Otagia, etc. E. L. Vansant, Philadelphia, Pa.

67. Non-surgical Diseases of the Ear. E. L. Klopp, Philadelphia, Pa.

68. Surgical Treatment of Acute Inflammations of the Middle Ear. E. B. Dench, New York, N. Y.

FRIDAY, JUNE 4TH—AFTERNOON SESSION.

69. Larvæ Complicating Middle Ear Disease, Minneapolis, Minn.

70. The Double Current Eustachian Canula in the Treatment of Middle Ear Catarrh. James E. Willitts, Pittsburg, Pa.

71. Intra-tympanic Surgical Treatment of Chronic Purulent Otorrhea. C. H. Burnett, Philadelphia, Pa.

72. Ossiculotomy in Chronic Otitis Media. G. A. Stucky, Lexington, Ky.

73. The Venous Channels of the Aural Region; Illustrated with Stereopticon. B. Alexander Randall, Philadelphia, Pa.

Discussion opened by W. E. Casselberry, Chicago, Ill.

74. Catheterization of the Eustachian Tubes through the Mouth. D. Braden Kyle and W. H. King, Philadelphia, Pa. (Paper read by W. H. King.)

75. The Relation Existing between Bright's Disease and Certain Ear Symptoms. Francis Dowling, Cincinnati, Ohio.

76. Some Further Results in Treating Ears by Massage Methods. Louis J. Lautenbach, Philadelphia, Pa.

Section on Diseases of Children.—Program:

TUESDAY, JUNE 1ST—AFTERNOON SESSION.

1. Address of Chairman. J. A. Larrabee, Louisville, Ky.

2. The Physiologic Treatment of Diphtheria. Elmer Lee, Chicago, Ill.

3. The Antiseptic versus the Antitoxic Treatment of Diphtheria. C. W. Braymer, Camden, N. J.

4. The Successful Treatment of Diphtheria as Compared with Antitoxin; Exhibition of a Croup Kettle. John H. Coughlin, New York, N. Y.

5. The Past and Present Status of our Knowledge of the

Etiology, Pathology and Treatment of Diphtheria; What we have Accomplished. C. G. Slagle, Minneapolis, Minn.

6. The Serum Therapy of Diphtheria, an Answer to Dr. Lee. Prof. Edwin Klebs, Chicago, Ill.

7. The Specific Use of Diphtheria Antitoxin in Laryngeal Diphtheria. Edwin Rosenthal, Philadelphia, Pa.

8. The Therapeutics of Diphtheria with Special Reference to Antitoxin. W. W. Gray, Bridgeport, Conn. Discussion opened by Frederick A. Packard, Philadelphia, Pa., S. G. Dabney, Louisville, Ky.

Section Dinner on the Evening of the First Day.

WEDNESDAY, JUNE 2D—MORNING SESSION.

9. Intubation. T. C. Evans, Louisville, Ky.

10. The Technique of Extubation. Robert H. M. Dawbarn, New York, N. Y. Discussion opened by Floyd M. Crandall, New York, N. Y.

11. Tests to be Applied to Every Case of so-called Maternal Impressions. Marcus P. Hatfield, Chicago, Ill. Discussion opened by S. W. Kelly, Cleveland, Ohio.

12. Some Causes of Congenital Deformities. Ella E. Barnes, Birmingham, Ala. Discussion opened by Bedford Brown, Alexandria, Va.

13. Tubercular Meningitis. Annie S. Daniel, New York, N. Y.

14. Meningitis a Complication of Measles. Thomas W. Harvey, Orange, N. J.

15. The Clinical Importance of the Eye Symptoms in Arriving at a Diagnosis of Meningitis in Children, with Cases. A. E. Davis, New York, N. Y. Discussion opened by Harold N. Moyer, Chicago, Ill.

16. Hysterical Contractures in Children. Chas. W. Burr, Philadelphia, Pa.

WEDNESDAY, JUNE 2D—AFTERNOON SESSION.

17. Some Fundamental Principles to be Observed in Infant Feeding. L. Emmet Holt, New York, N. Y.

18. The Use of Artificial Foods Largely a Fashion, not a Necessity in Country Practice. W. A. Dixon, Ripley, Ohio.

19. Infant Feeding with Reference to Examination of the Feces. Louis Fischer, New York, N. Y.

20. Condensed Milk as a Food for Infants, its Uses and Limitations. Chas. G. Kerley, New York, N. Y. Discussion opened by J. P. Crozer Griffith, Philadelphia, Pa.

21. The Relation of the Liver to Digestive Diseases of Children. J. M. G. Carter, Waukegan, Ill.

22. Typhoid Fever in Infancy and Childhood. Henry A. Fairbairn, Brooklyn, N. Y.

23. Cases Illustrating Typhoid Fever in Children. J. P. Crozer Griffith, Philadelphia, Pa. Discussion opened by William P. Northrup, New York, N. Y.

24. Some Points in the Treatment of Wasting Diseases of Children. J. P. Cooke, New York, N. Y.

25. How Best to Care for Syphilitic Children. C. Travis Drennen, Hot Springs, Ark.

THURSDAY, JUNE 3D—MORNING SESSION.

26. The Study of the Etiologic Factors of Difficult Defecation in Children and Mechanical Means for its Relief. Thos. Chas. Martin, Cleveland, Ohio.

27. Infantile Constipation. J. W. Byers, Charlotte, N. C. Discussion opened by Floyd M. Crandall, New York, N. Y.

28. The Treatment of Rickets and Rickety Deformities. John Ridlon, Chicago, Ill.

29. The Ambulatory Treatment of Fractures of the Leg in Children. James P. Fiske, New York, N. Y.

30. Van Arsdale's Triangular Splint for Fractures of the Femur in Children, with Remarks on the Use of Cardboard as Splint Material. A. Ernest Gallant, New York, N. Y. Discussion opened by John Woodbury, New York, N. Y.

31. The Treatment of Hernia in Infancy and Childhood. William B. Coley, New York, N. Y. Discussion opened by William L. Rodman, Louisville, Ky.

32. The Operative Relief of Intussusception. C. L. Gibson, New York, N. Y. Discussion opened by Robert H. M. Dawbarn, New York, N. Y.

33. New Methods of Resuscitating Still Born and Feeble Born Children. Bedford Brown, Alexandria, Va.

THURSDAY, JUNE 3D—AFTERNOON SESSION.

34. The Influence of Our Present School System on the Health and Development of the Child. E. Stuver, Rawlins, Wyoming. Discussion opened from the Standpoint of the Physician by Harriet E. Garrison, Dixon, Ill.; and from the Standpoint of the Surgeon by Prof. J. Henry Bartlett, Philadelphia, Pa.

35. The Training and Home Life of Neurotic Children. Ella M. Patton, Quincy, Ill.

36. The Early Recognition and Treatment of Defective Development of Children. Louis F. Bishop, New York, N. Y.

37. Infant Bathing. A. Campbell White, New York, N. Y.

38. Malignant Scarlet Fever. L. S. Baker, Erie, Pa.

39. The Belladonna Treatment of Pertussis. Harriet E. Garrison, Dixon, Ill. Discussion opened by Chas. G. Kerley, New York, N. Y.

40. The Signs and Symptoms of Enlarged Bronchial Glands of Children. Frederick A. Packard, Philadelphia, Pa.

41. Abnormal Respiration in Infants from Obstruction in the Upper Air Passages. Jas. J. Concannon, New York, N. Y.

42. Ventilation as a Prophylactic and Curative Measure. A. J. Work, Elkhart, Ind.

FRIDAY, JUNE 4TH—MORNING SESSION.

43. The Prevention of Tuberculosis in the Predisposed by Appropriate Treatment in Childhood and Youth. John A. Robison, Chicago, Ill.

44. The Management of Children with Inherited Tubercular Diathesis. Jos. Wm. Stickler, Orange, N. J. Discussion opened by Paul Paquin, St. Louis, Mo.

45. Skin Granulomata in Children. Jas. S. Johnston, New York, N. Y.

46. Noma. Thomas Darlington, Kingsbridge, N. Y.

47. The Bullous Eruptions in Infancy and Childhood. C. W. Allen, New York, N. Y. Discussion opened by L. Duncan Bulkley, New York, N. Y., I. N. Bloom, Louisville, Ky.

48. A Plea for the More Common Sense Treatment of Sick Children. A. H. P. Leuf, Philadelphia, Pa.

49. Teething, Its Pathology and Treatment. G. M. Blech, Louisville, Ky.

50. Seed Sown in Childhood and the Harvest Therefrom. Florus F. Lawrence, Columbus, Ohio.

51. The Care of the Baby's Eyes in the Perambulator. Mary E. Baldwin, Newport, R. I.

Section on Physiology and Dietetics.—Program:

1. Address of the Chairman. Augustus P. Clarke, Cambridge, Mass.

2. Diet as a Remedy in Disease. Charles H. Shepard, Brooklyn, N. Y.

3. The Value of Therapeutic Fasting in the Treatment of Acute Fevers. Elmer Lee, Chicago, Ill.

4. Problems in Feeding School Children. Horace P. Makeclune, Somerville, Mass.

5. What are the Characteristics of a True Cardiac Tonic, and what the Physiologic Differences between a Tonic and a Stimulant? N. S. Davis, Chicago, Ill.

6. Diet in Diseases of the Stomach. J. M. G. Carter, Waukegan, Ill.

7. Diet in Diseases of Mexico. Frederick Semeleder, Cordova, Mexico.

8. The Physiologic Combustion of the Animal Oils. J. Wellington Byers, Charlotte, N. C.

9. Some Points in the Physiology and the Congenital Criminal. James Wier, Jr., Owensboro, Ky.

10. The Mechanism of the Activity of Glands. G. Walter Barr, Quincy, Ill.

11. Dietetics—The Pathology and Therapeutics in Diseases of the Stomach. Fenton B. Turck, Chicago, Ill.

12. The Physical Development of Woman. Harriet E. Garrison, Dixon, Ill.

13. Feeding of Surgical Patients. Albert H. Tuttle, Cambridge, Mass.

14. Artificial Respiration in Relation to Physiologic Principles. Edward D. McDaniel, Mobile, Ala.

15. Increasing Consumption of Acidulous Foods and Drinks. Wm. T. English, Pittsburg, Pa.

16. The Relation of Food, Air and Exercise to Healthy Growths and Development. E. Stuver, Rawlins, Wyo.

17. Recent Advances in Mental Physiology. E. P. Hurd, Newburyport, Mass.

18. Physiology of the Sigmoid Flexure of the Colon and Rectum. J. G. Carpenter, Stanford, Ky.

19. The Psychology and Physiology of Hypnotism. Randall Hunt, Shreveport, La.

20. Intestinal Tuberculosis Due to Certain Articles of Food. R. J. Nunn, Savannah, Ga.

21. Pulmonary Tuberculosis with Special Reference to Diet. H. W. Mitchell, New York, N. Y.

22. Alcoholic Beverages. S. S. Herrick, San Francisco, Cal.

23. A Few Remarks on the Diet and General Care of Consumptives in Southern California. Geo. L. Cole, Los Angeles, Cal.

24. Diet of the Insane. Hugh Hagan, Atlanta, Ga.

25. Maranta Arundinacea: its Medical Properties and Dietetic Uses. A. Thomas Cuzner, Gilmore, Florida.

26. The Therapy of Tuberculosis and the Diet for Acute Diseases. John Ashburton Cutter, New York, N. Y.
27. The Hygiene and Dietetics of Chronic Nephritis. Asa F. Pattee, Boston, Mass.
28. Monologue on the Voice of a Larynxless Man. J. Solis-Cohen, Philadelphia, Pa.
29. The Metabolism in the Human Organism and the Potential Energy of Food. W. W. Grube, Toledo, Ohio.
30. Comparison of the Anatomy and Functions of the Cerebrum and the Cerebellum. William Fuller, Grand Rapids, Mich.
31. Hair-Cells of the Crista Acustica on the Ampullæ of Aural Areas (Illustrated). B. Alexander Randall, Philadelphia, Pa.
32. Some Important Features in Dietetics: The Effect of Heat on Food; the Uses of Atmospheric Nitrogen; the Ferments in the Human Organism; the Morphologic Development of Cells in Effete Products (Illustrated). Ephraim Cutter, New York, N. Y.
33. Dietetic Treatment for Fatty Degeneration. William F. Holcombe, New York, N. Y.
34. Physiology of the Live Human Heart in Situ Naturali. Alex. Hugh Ferguson, Chicago, Ill.
35. A Neglected Factor in the Economy of Digestion. H. S. Drayton, New York, N. Y.
36. Diet in the Chronic Catarrh of the Gastro-intestinal Tract. Boardman Reed, Philadelphia, Pa.
37. Food and the Agencies of Digestion. Robert W. Hastings, Brookline, Mass.

Section on State Medicine.—Program:

TUESDAY, JUNE 1.

1. Chairman's Address—History of the Section on State Medicine. Elmer Lee, Chicago, Ill.
2. The Abuse of Medical Charities. Landon Carter Gray, New York, N. Y.
3. Flannels and Personal Sanitation—Sweltering and Smothering the Skin contrary to the Nature of the Animal Organism, and therefore Inimical to Health. Charles E. Page, Boston, Mass.
4. The Present Medical Science Education not in Harmony with the Nature of Things. W. H. Dunham, Keene, N. H.
5. Rest. C. F. Ulrich, Wheeling, W. Va.
6. The Progress of the Individual Cup Movement. H. S. Anders, Philadelphia.
7. A National Medical School. Albert Ashmead, New York, N. Y.
8. A Plea for Less Hobby-riding and More Science in State Medicine. Eugene C. Bardwell, Emporium, Pa.
9. The Germ Theory Disproved. Thomas Powell, Los Angeles, Cal.
10. The Physical and Hygienic Care of Children. Randolph Faries, Philadelphia, Pa.
11. Air, its Use and Abuse. James Cokenower, Des Moines, Iowa.

WEDNESDAY, JUNE 2.

12. Quarantine in the United States. Walter Wyman, Washington, D. C.
13. The Advantages of Castration in the Defective. Everett Flood, Baldwinville, Mass.
14. Some Features Respecting the Drainage of Larger Municipalities. Augustus P. Clarke, Cambridge, Mass.
15. Credulity and Skepticism in Medicine. W. G. McFadden, Shelbyville, Ind.
16. Turkish Baths in Hydrophobia. Charles H. Shepard, Brooklyn, N. Y.
17. State Medicine to the Present Time. Franklin Staples, Winona, Minn.
18. More Physicians and Fewer Lawyers in Congress. Ephraim Cutter, New York, N. Y.
19. Some Considerations of the Import of the Occurrence of Pathogenic Spirilla in the Water of the Delaware and Schuylkill Rivers at Philadelphia. D. H. Bergley, Philadelphia, Pa.
20. The Successful Treatment of Snake Bites. J. G. Tuten, Jessup, Ga.
21. The Frequency of Apoplexy among the Higher Classes with Recommendations for Prevention of the Condition and Escape from Fatality. Elmer Lee, Chicago, Ill.
22. An Alcove Dormitory for the Epileptic. Everett Flood, Baldwinville, Mass.
23. Relation of Railway Companies to State Boards of Health. G. P. Conn, Concord, N. H.

THURSDAY, JUNE 3.

24. Tuberculosis Prophylaxis. Raley H. Bell, Atlanta, Ga.
25. A Study of the Blood in Tuberculosis. A. M. Holmes, Denver, Colorado.

26. Bovine Tuberculosis and its Relations to Public Health, with suggestions for Prevention of Transmission—Specimens. Howard Carter, St. Louis, Mo.
27. On the Principles of Prophylaxis for Limiting the Prevalence of Pulmonary Tuberculosis. N. S. Davis, Chicago, Ill.
28. The Contagiousness of Consumption. J. M. Anders, Philadelphia, Pa.
29. The Use of Normal (Horse) Serum in the Treatment of Tuberculosis. Wm. Thornton Parker, Groveland, Mass.
30. Tuberculosis in the Southern Negro, Pointing out the Difficulties of Prophylaxis and the Impossibility of Satisfactory Treatment. J. F. Jordan, Montgomery, Ala.
31. Prevention of Tuberculosis. J. M. Emmett, Atlantic, Iowa.
32. The Present Status of Preventive Means against the Spread of Tuberculosis in the Various States of the Union, Critically Reviewed. S. A. Knopf, New York, N. Y.
33. Present Attitude of Sanitariums and Boards of Health toward Pulmonary Consumption. Benjamin Lee, Philadelphia, Pa.

FRIDAY, JUNE 4.

34. The Necessity of Fixed Criteria in the Study of the Therapeutics of Tuberculosis. Louis Faugères Bishop, New York, N. Y.
35. Alcohol in Modern Medicine; a Collective Study. I. N. Quimby, Jersey City, N. J.
36. Alcoholic Sore Throat. H. S. Drayton, New York City.
37. The So called Stimulant Action of Alcohol. J. M. French, Milford, Mass.
38. Is Alcohol a Food or Stimulant? W. V. R. Blighton, Buffalo, N. Y.
39. The Therapeutics of Alcohol in Disease. F. B. Garber, Dunkirk, Ind.
40. Alcohol versus Chemical Poisons. C. H. Shepard, Brooklyn, N. Y.
41. Non-Alcoholic Treatment in Diphtheria. L. Frissell, Springfield, Mass.
42. Concealed Alcohols in Drugs. T. D. Crothers, Hartford, Conn.

SELECTIONS.

Malarial Fever in the Goose.—Dr. Osler states that he first had his attention called to the malarial infection of birds in 1886 (*Johns Hopkins Hospital Bulletin* for March). In that year a goose was sent by Dr. MacCallum of Dunnville, Ont., to the Toronto Biological Laboratory with a diagnosis of malaria. Dr. Osler was extremely skeptical about it, as at that time, ten years ago, very little was known about the parasitism of birds, but very much to his astonishment he found large numbers of the pigmented intracellular organisms or hemocytzoa. Since that time he has been interested in the subject as having a more or less direct bearing upon the life history of the malarial parasite in man, since it is quite possible that there may come to us very important clues as to the outside evolutions of that parasite by a study of the forms in the aviariums. As has been remarked by Dr. Barker and others, our research may not with profit be confined to clinical methods; microscopic sections after death yield important information both as to blood and tissue phenomena. We get a very one sided and incomplete view of the structure of these parasites of malaria and of their attacks upon the cells if we scrutinize them only in fresh blood or in smear coverglass preparations, even when dried and stained. In tissues which have been hardened in alcohol it is very easy in sections stained with hematoxylin and eosin or with methylene blue, to make out within the half-grown and full-grown tertian parasites of human malaria a relatively large spherical area which stains feebly, though sometimes very distinctly in nuclear dyes. Peripheral to this mass is a thin superficial layer which does not stain at all in ordinary nuclear dyes. In this peripheral non-basophile layer of the parasite is situated the malarial pigment when it is present. The internal stainable mass may be centrally placed, though it is more usual to see it situated somewhat excentrally, so that the peripheral layer of non-stainable substance may vary in thickness in different parts of the organism. The

internal mass, which is entirely free from pigment, may stain somewhat unevenly, and occasionally it is possible to make out in it an intensely stained nodule which was thought to correspond to what has been described in stained smear preparations as the nucleus. It would seem more rational to look upon it as the nucleolus or as an aggregation of the chromatin within the nucleus, though for the decision of this point we must wait for further investigations. We need to know more about the macronuclei or micronuclei in malarial parasites, such as have formed the basis of so much interesting research of late years in the infusoria. It is indeed to be hoped that the large size of the malarial parasites in birds will permit of the unraveling of the finer structure of these curious organisms. In studying specimens of the spleens of infected birds, we are well nigh bewildered by the enormous masses of malarial parasites to be seen there. At first it seemed almost improbable that the huge brownish masses could consist of malarial parasites. It seemed more likely that they could be explained as forms of blood pigment, but careful study with the oil immersion lens will convince any one that they are in reality aggregations of altered malarial organisms. There is a distinct possibility that in very malarial districts man may harbor the parasites without showing special manifestations. We know that in certain regions all dogs have filaria in the blood, and in many parts of Africa the filaria are present in the natives without causing much trouble. It is quite possible, too, that there may be a minor grade of malarial infection in which the organisms are not present in sufficient numbers to cause fever or the characteristic paroxysms. Dr. Thayer stated that recent observations appear to show that the parasites of birds and human beings are not identical; they are, however, so similar that it is not improbable that the form in which they exist outside of the body and their method of entrance to the body are likewise not unlike the corresponding phases in the life history of the parasite of human beings. There are many more points to be studied with regard to the morphologic and biologic characteristics of the avian hematozoa. In these present observations, for instance, no idea has been formed with regard to the length of the cycle of existence of the parasites. Danilevsky believes that he has been able to distinguish an acute and a chronic form, while Celli divided the parasites of birds into three forms with cycles of existence corresponding to the quartan, tertian and restivo-autumnal parasites. Here, however, there has as yet been nothing to point out the exact length of the cycle of existence of each generation of parasites. Further, it would be advisable to make careful measurements and observations of the temperature in infected birds, observations which, to be sure, have been made by other authors, but with regard to which there is as yet a lack of agreement. It is also, I think, very important that the intimate structure of the parasites of birds' blood should be carefully followed out; this can be done with much greater facility than in the human being, inasmuch as specimens of tissues can be instantly obtained at any time desired. But really the most important point, it seems to me, as Bignami has emphasized in a recent paper, is to determine, if possible, the manner in which the parasite exists outside of the body, or more particularly its manner and portal of entry. It may well be possible that careful and continued observations of this sort may bring us nearer the solution of the greatest questions in connection with malarial infection. With regard to the remark of Professor Osler concerning the possibility that a human being may harbor the malarial parasites in an active condition for a considerable time without showing distinct clinical symptoms, I must say that the more of the disease one sees the more reasonable seems the possibility that this condition may exist with relative frequency. In many cases of tertian fever after insufficient doses of quinin, or during attempts at spontaneous recovery, a few parasites may be found in the blood for very considerable periods of time with-

out marked symptomatology. The parasite has been found in the blood of illy-defined cases, such as present no paroxysms, but only vague symptoms; in such patients it is fair to assume that the parasites have not accumulated in sufficient number to produce a chill. If now in a certain number of instances a single tertian paroxysm may be followed without treatment by so extensive a destruction of the organisms that fever does not recur for a week or ten days (a not very infrequent occurrence), theoretically there would seem to be no reason why in certain instances a similar destruction might not occur in groups which have not as yet reached a size sufficient to produce actual manifestations; thus there would result an indefinite prolongation of what one might call the incubation period of the infection.

The Antitoxin in Country Practice.—Dr. Herman of Sansdale, Pa., reports four cases from his note-book of diphtheria, in which the results of the use of antitoxin were most satisfactory. He feels confident that with that remedy the type of diphtheria that is encountered by him can be cured, and that no sequelæ or untoward complications need be feared. This declaration is made independently of any statement relative to the day on which the initial dose is or should be given. He agrees with the foremost authorities that the early employment of the serum is always most desirable, and also states that the severity and prognosis of a case is not dependent, *per se*, upon the number of hours which may have elapsed since the appearance of the first symptoms, but upon the quantity and virulence of the toxins absorbed into the system, and the cell destruction of the vital organs caused by them. The wide difference between individual cases of the same epidemic of diphtheria and between cases of different outbreaks is thus explained. The best rule for treatment is to give the initial dose of antitoxin immediately after the diagnosis of diphtheria is made. In all doubtful cases it is best to administer it even if a positive diagnosis can not at the time be reached. Prof. H. C. Woods states: "There is no reason at present for believing that antitoxin in moderate quantities does any harm when the child has not diphtheria. When, therefore, any case presents the clinical aspect of diphtheria, antitoxin should be used at once. One point I wish to make prominent here is that carbolic acid, which is but feebly antiseptic except in strong solutions, is a powerful toxic agent in the human system. It is too irritant a drug to use in the preservation of antitoxin. I believe the failure to recognize this fact has resulted in deaths which were falsely charged, in part or wholly, against the antitoxin treatment. Trikresol, which is but feebly toxic, does not irritate the kidney, while it is such a valuable antiseptic that but five-tenths of 1 per cent. is required to positively prevent contamination of the serum. All zymotic diseases necessarily have a most dire effect upon the vital organs; these need sustaining treatment, and it is as important to husband the patient's strength as it is to combat the disease. He had several cases in one family, but only one of them was sufficiently severe to require antitoxin. The disease in this patient only assumed a most malignant aspect, the throat being literally full of the exudate. One thousand units of concentrated antitoxin was injected and the doses repeated on the following day. The effect was again equally favorable. At the same time, a brother physician had a patient, an only child in a neighboring family, who was suffering from a most virulent attack of the disease. Encouraged by the foregoing results the physician borrowed my syringe, and with two doses of 1000 units each, successfully treated his case. The dread that he had always entertained of having this monster, diphtheria, invade his own home and community, has absolutely left him, as he is convinced that in antitoxin he has a remedy that is worthy of complete confidence."—*Medical News*, February 20.

PRACTICAL NOTES.

Oxyuris Vermicularis.—Comby administers in the morning fasting for three days, one of the following powders; Santonin 5 centigrams; calomel 10 centigrams. Apply locally at night as the child retires, for three days, the following salve inside the anus: Glycerite of starch, 20 grams; Neapolitan unguent 10 grams.—*Presse Méd.*, March 27.

Prophylaxis of Tumefaction of the Cervical Ganglia Consecutive to Eczema of the Scalp in Infants.—Antiseptic cleanliness and relief from the pruritus are the requisites, and Steinhardt recommends for the purpose, washing the child's hands and cleaning his nails every two hours, washing his playthings at the same time and changing the clothes and bed linen frequently. The eczematous regions should be moistened for an hour with fresh Goulard's lead water, and then the following salve applied: Salicylic acid 0.50 gram; menthol 1 gram; linseed oil and lime water ññ 50 grams. Externally.—*Semaine Méd.* March 31.

To Preserve Steel Instruments from Rusting.—Dr. Maréchal in 1893 placed several perfectly new steel instruments, including bistouries, Pravaz' needles, a nickel watch (open), etc., in the following solutions: 1, an aqueous 2 per cent. solution of sodium bicarbonate; 2, ditto sodium carbonate; 3, ditto sodium borate; 4, ditto sodium benzoate; 5, alcoholic 2 per cent. solution of sodium benzoate; 6, alcohol, 95 per cent., 5 grams to 1 gram sodium borate; 7, alcohol 95 per cent.; 8, water. In 1895, two years later, the instruments in the first six solutions were found absolutely intact, without a trace of rust, even when tested with potassium sulfo-cyanid. But those in the 7th and 8th were completely covered with rust. He therefore recommends keeping steel instruments in one of the first six solutions to preserve them from tarnish and rust.—*Gaz. Med. de Liège*, April 1.

Influence of Tobacco on the Nervous System.—Buccelli concludes from his investigations of 200 patients with nerve and brain troubles, and others, that tobacco affects the *normal* nervous system to a comparatively trifling extent, but as soon as the condition of perfect integrity is impaired, its effect is extremely and progressively pernicious. The subcortical and bulbar nerve centers suffer particularly then from the toxic effect of tobacco.—*Riv. di patol. nerv.*, 1896, page 327.

Traumatism of the Biliary Passages.—Terrier and Auvray assert in the *Revue de Chir.*, No. 1, that no case of injury to the biliary passages has recovered without puncture or incision, and that better results follow prompt and adequate laparotomy than mere puncture which has often to be repeated. They state the indications for operative treatment as follows: In case of laceration of the gall bladder, suture or ablation, according to the extent of the injury. Ligate an injured ductus cysticus, and conclude with cholecystectomy. Temporary drainage of injured ductus hepaticus, and suture of an injured ductus choledochus, or cholecyst-enterostomy after double ligatures. Although these indications are still partially theoretic, they should be borne in mind in cases of the kind. They report twelve recoveries in twenty-one cases of injury to the biliary passages treated by puncture; four recoveries in seven cases treated with tardy laparotomy, and recovery in both of the two cases treated with prompt laparotomy.

Hoffa's Method of Treating Congenital Luxation of the Hip Joint.—Professor Hoffa (Würzburg) has been in Paris recently, and many were interested in witnessing his operation as he performed it at one of the hospitals. Since Lorenz emphasized the importance of retaining the muscles, he opens up the articulation with a front, lengthwise incision at the edge of the greater trochanter, opens into the capsule in the direction of the neck of the femur, and by twisting the femur outward, reaches the acetabulum, which he hollows out to the required shape, and replaces the head in it, which completes the opera-

tion. The wound is tamponed with sterilized gauze, without suturing, and a plaster cast applied. Six deaths occurred in his first 190 cases, but only one in his last 100. Absolute asepsis is the indispensable requisite of success; massage and gymnastics are also important factors. If suppuration occurs, there is imminent danger of ankylosis. He has had no relapses in his last 44 cases of bilateral luxation with pronounced lordosis. Almost normal position and abduction of the extremities was secured. The best age for the operation is between 3 and 4. It is difficult to reduce the femur in older subjects, and Kirrmisson's sub-trochanteric osteotomy is to be preferred, or for bilateral luxations Hoffa's "pseudo-arthritis," which consists in sawing off the head of the femur and fixing the end to the pelvis. He exhibited at the Acad. de Méd., a six-year-old child successfully operated by this method.—*Bulletin*, March 16, and *Therap. Woch.*, March 28.

Antitoxins in the Blood After Recovery from Streptococcus Infection.—Neufeld concludes his report of experimental investigation in this line with the statement that all results were negative, and hence the outlook does not seem very favorable that we shall be able to secure artificially in animals what Nature herself is unable to accomplish in human beings recovering from streptococcus infection, namely, an accumulation of anti-toxins in the blood.—*Deutsche Med. Woch.*, March 11.

Rectal Injections in Diabetes with Threatening Coma.—The obstinate constipation in diabetes is due to the more or less paralyzed condition of the bowels, unaffected by purgatives taken into the stomach, or else the violent evacuation induced may lead to serious accidents. Dr. P. A. Teschemacher recommends an injection of 10 to 40 grams of glycerin three or four times a week, retained half an hour in the dorsal decubitus, if possible. He also rests the stomach by administering alimentary injections four times a day, composed of 50 grams of wine, the same quantity of bouillon, to which somatose has been added, two eggs and a pinch of salt. At this time nothing should be taken into the stomach but a few swallows of wine or brandy, a little beef tea, and pounded ice to quench thirst.—*Semaine Méd.*, March 20.

Tests in Cases of Apparent Death.—Icard suggests that certainty can be attained in doubtful cases by the subcutaneous injection of some stain, soluble in water, non-toxic, non-caustic, and containing a substance not found normally nor accidentally in the organism. If the stain is then found in the blood or some remote part of the body, it must have been absorbed, and there is still life remaining, as absorption ceases absolutely with life. He recommends fluorescein for the purpose, as 1-1000 gram will discolor perceptibly forty-five liters of water. Half a gram injected subcutaneously, will stain in a few minutes the skin, eyes, mouth, urine and serum a brilliant green, if there is still life. The iodids are also effective; 25 centigrams will be found by the starch test in the urine and saliva in a few minutes, if it is absorbed. Three grams of potassium or sodium ferrocyanid can be injected and can be readily distinguished in the urine by testing it with perchlorid of iron, which forms Russian blue with it. Another way is to pass a thread through a fold of the skin. It is thus moistened with the serum, and turns bright blue after dipping it into weak hydrochloric acid, and then into perchlorid of iron, if the injected salt has been absorbed. He also states that aromatic substances are eliminated by the bronchi to such an extent that they are easily detected if they have been absorbed. These tests should reassure those who are haunted by the fear of being buried alive.—*Journal des Sc. Méd. de Lille*, April 3.

Injections of Artificial Serum in Uremis.—Richardière in *Union Médical*, December 5, has used large injections of artificial serum in two cases with good results. His practice is to bleed to 300 to 400 grams, and immediately inject slowly into the cellular tissue 800 grams of serum at the temperature of

the body. The serum is made after Hayem's formula, and is used aseptically. His first case presented intense dyspnea, numerous mucous and subcrepitant rales all over the chest, and nearly all the subjective symptoms of Bright's disease, with extensive edema. Under ordinary treatment the patient got worse, respirations rising to 48 per minute with Cheyne-Stokes character, and suffered from hallucinations, so that six days after admission he was comatose, and dyspnea was still increasing. Bleeding to 300 grams, with injections immediately after, was followed by a fall of pulse rate from 140 to 120; the temperature rose from 37.8 to 37.9 C., and the respiration became slower and regular. During the next few days the urine increased in amount, then fell again, when Cheyne-Stokes breathing reappeared and the state became alarming. The patient was bled again 250 grams, and injected 800 grams; a second injection was given six hours afterward. Temperature rose 35.8 to 37 C., and no further trouble occurred, although the edema persisted; respirations remaining regular, and he remained free from somnolence, passing about one liter of urine in twenty-four hours. The second case presented signs of grave uremia; injection was followed by improvement, which failed again in twenty hours. A second injection was followed by profuse diarrhea, and caused permanent amelioration of the condition. He quotes other cases, and points out that the injection is harmless though painful; it raises the temperature, slows the pulse and steadies breathing previously irregular and of a Cheyne-Stokes character, lessening the rate at the same time. It also increases the amount of urine and seems to have a tendency to produce diarrhea, which he looks on as favorable.

Aid to Diagnosis of Fractures.—It is often difficult to decide after an accident whether a limb is fractured or only bruised. Schröter has been able to decide the matter at once by simply placing the palms of his hands on each extremity of the bone in question and exerting a firm, increasing pressure on it, longitudinally to its axis. If the bone is not fractured, the pressure is not at all painful, and the patient can be reassured at once. But if it is fractured even the first feeble pressure elicits a cry of pain, and the patient is convinced immediately of the necessity of fracture treatment. He suggests the name "bipolar counter pressure" for the test, which he states is probably practised by others, but of which there is no mention in the text books.—*Cbl. f. Chir.*, April 3.

Tuberculous Arthritis in Early Infancy.—Rovsing has observed seven cases of a special tuberculous joint affection, which differs in several respects from the generally accepted picture of tuberculous arthritis. It resembles more a pyarthrum tuberc. acutum and is distinguished by its especially favorable prognosis, even quoad functionem, and the property it shares with tuberculous peritonitis, that it is cured by simple incision, arthrotomy. It commences suddenly with fever, sensitiveness and tumefaction in the joint, and microscopic and bacteriologic tests disclose the presence of the tubercle bacilli. In five cases the knee joint alone was affected, in three several were involved. The necessity of asepsis to prevent mixed infection is evident.—*Cbl. f. Chir.*, April 3.

Intolerance Toward Antipyrin.—Among the discussions that have been going on at the Therapeutical Society of Paris recently, an important one was that which dealt with intolerance of certain drugs displayed by some patients, in particular as regards antipyrin. M. Lyon, M. Dalché, and M. Duclenne reported cases of stomatitis, pemphigus and various rashes produced by antipyrin. M. Blondel related a case where the use of antipyrin produced buccal lesions in a woman exactly like mucous plaques and also a rash resembling syphilitic roseola, so that the diagnosis from syphilis was rendered very difficult. The majority of patients with this idiosyncrasy had no albuminuria, so that it did not seem to depend upon faulty

elimination, but rather on some particular predisposition of the subject. It was possible that in many cases the digestion was at fault, for, on the one hand, these accidents more rarely followed the use of antipyrin in solution than as a powder, and on the other hand, the drug was much better tolerated if given with bicarbonate of soda or some intestinal antiseptic.

Suppurations in the Adipose Tissue Surrounding the Kidneys.—Niebergall states that apparently insignificant trauma may lead to this condition; a false step, digging or stamping with the foot, lifting or carrying heavy weights, riding in a jolting vehicle or on horseback. These may occasion some trifling hemorrhage in the pararenal tissues, followed later by suppuration. Pain is felt in the renal region, and a swelling is noticed apt to be ascribed to a periostatic abscess of the os innominatum. The fever is not characteristic, but there is usually obstinate constipation. Motion is painful, with radiating pains. There is usually a more or less characteristic flexion contracture of the thigh. Prompt evacuation will alone prevent the most serious consequences. He prefers a retro-lumbar incision, with ample provision for the evacuation of the pus out of all the pockets. Secondary tuberculous lesions of the kind may require nephrectomy. The abscesses take a long while to heal even with complete drainage, and the cicatrix is liable to impair efficiency for military service. He reports three cases and reviews seven others, in the *Deut. Mil. Zeitschrift.*, August and September, 1896.—*Cbl. f. Chir.*, February 17.

Glioma of the Brain.—Devic and Courmont (*Revue de Médecine*, April 10, 1897, p. 268) have reported the case of a man, 46 years old, presenting narrowing of the mitral orifice of the heart, who was seized with headache, apparently due to an abscess of the brain seated in the right frontal region. Domestic difficulties were followed by an aggravation of the headache and the development of mental symptoms, with alterations in memory, apathy, suicidal ideas and attacks of sopor. In the course of six months manifestations of ambulatory automatism were superadded. In the further progress of the case the headache increased in severity, insomnia set in, the remaining symptoms progressed and left hemiplegia developed, with bilateral papillary edema. Finally, trephining was undertaken and a glioma removed from the right frontal region. The headache and the edema of the optic papillæ soon disappeared and the hemiplegia became less marked. Improvement continued, though interrupted temporarily by an attack of migratory erysipelas of the face, after which, however, the general condition was satisfactory. Some four months after the operation left hemiplegia followed a mild apoplectic attack, but without the development of the earlier symptoms. Death took place, and postmortem examination disclosed a thrombus at the origin of the right Sylvian artery, with a focus of encephalitis, but without any sign of recurrence of the glioma. From a study of this case the conclusion is reached that certain cerebral tumors may be attended with pronounced mental symptoms, appearing in advance of sensory and motor manifestations. Ambulatory automatism is a rare form of the psychic disorders of this kind. The tumors that occasion mental symptoms are seated most often in the frontal lobes. They exert this influence either by massive destruction of cerebral substance or by causing degeneration of tangential fibers or by simple compression or by reason of their mere presence. Trephining with ablation of the tumor, may be followed by disappearance of the edema of the optic papillæ within forty eight hours, and also by recovery from the hemiplegia and the mental disorder. Cerebral compression is the principal factor in the development of these phenomena. Recovery following extirpation of the tumor, while extremely rare in the case of glioma, may however be complete and may persist if there be no local operative complication, as encephalitis, thrombosis, etc. This fact ought to encourage surgical intervention in the majority of cases.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, In Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the Association living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, MAY 8, 1897.

THE PHYSICIAN AND THE HOSPITAL.

A subject which at present seems to provoke considerable discussion in medical associations and in medical journals, is the so-called "Dispensary and Hospital Abuse" question. It is by no means a new one, but probably it is being looked at from a different point of view. The profession of medicine, like that of theology, has seldom been considered in a commercial sense. Doctors are supposed to be poor business men and are usually judged by other methods than those which hold in the laws of trade.

The medical guilds and societies which have existed since the earliest times have been concerned more with the advancement of learning and the forwarding of the science of medicine than with any pecuniary betterment of its members. Guilds in the trades have held out for shorter hours of work, more pay, recognition of members of the union, etc. Doctors of Medicine, however, have usually been their own masters. The tools necessary for the profession were owned by themselves individually. Just as in the earlier days of industry, when each shoemaker, each carpenter, each weaver and potter was his own employer and rendered his services direct to the consumer.

In industry things are changed; the factory has come into vogue and a few persons own the tools and the machinery, while the mass of workers are merely "hands," whose product belongs to the factory owner,

who gives in return sufficient only to keep the "hands" alive.

In the medical profession a similar state of affairs is beginning to exist. In the large cities there are no huge factories to employ medical men, but there are huge hospitals which occupy the same relative position. When machinery was introduced the poor individual artisan whose livelihood it took away was very bitter in his opposition. In England the factories were burnt and the machinery for woolen manufacture destroyed by the weavers whom it displaced; but machinery triumphed, concentration of capital increased, the factory system like some great juggernaut swept everything before it, crushing out the lives of the skilled trades and doing away with the individual shoemaker and weaver. Of course, when disinterestedly we take a calm retrospective view of the situation, we feel that this evolution in industry is as important and essential as the change from stage coach to steam locomotive in transportation and not in the least to be regretted.

The medical hospital and institution is in a position to treat the sick with such appliances and with such measures as no individual practitioner can command. There are no great machines required in the art of healing, but the serious surgical operations which demand special care, the BRAND method of handling enteric fever, the MITCHELL rest cure are measures which one can hardly deny are better employed in a hospital than in the home. Then there is specialization. The dispensaries as manned at present are in no position to give accurate or careful treatment to those who make use of them; but what might not an institution, having in its employ paid specialists and demanding a moderate fee for its services, do to systematizing and making thorough the treatment of those who come to it for relief? The patient would meet the registrar, he would then be sent to the ophthalmologist, aurist, laryngologist and other "ists." His urine, sputum and blood would be examined and then the reports of the examinations would come to the head physician or surgeon, who would be in the best position to know what to prescribe. The medicine would be compounded by intelligent and capable pharmacists and the whole institution would be under the strictest scientific management. This is the next advance that will probably come in institutionalism. The first steps have already been taken, but the commercial and eleemosynary sides have been made the most prominent. Organizations of physicians, mutual or coöperative, may be obliged to institute such dispensaries and hospitals in order that they should become all that is demanded of them.

In the city of Philadelphia there are over a thousand positions in dispensaries and hospitals occupied by physicians who receive no pay for their work. Thus nearly one-half of the physicians in practice in that

city are connected with medical relief institutions. Not only do these men and women serve without pay, but by treating patients who are able to pay they prevent other physicians from obtaining such fees which otherwise would come to them. Some would advise that the physician run a dispensary in his own office in opposition to the hospital dispensary. This is not a remedy, and any one who tries it will soon find out that it does not pay. Others advise organization on business principles and we understand such a new medical society has been started in New York city.

The trade unionists fought machinery and were defeated. They preached organization, and organization gave them as weapons only the boycott and the strike, and these failed them because of machinery. The hospital is the *machine*, specialism is a part of it and against these the doctor will find it useless to fight. He must recognize the trend of affairs, the natural evolution which goes from the general to the more particular and again to the organization of particulars into a complete whole. If he be wise he will strive to adapt himself, he will make use of the machinery about him and he will associate himself with others for coöperation.

The doctor through organizations has been able to accomplish much for his own good and that of medicine in general. By legislation, he has raised the standard of requirements for entering on the study of medicine, thus limiting the number who engage in the profession. He has succeeded in controlling the work of medical schools. He has been able to educate the community to respect regular physicians somewhat as the trades unions have been striving to do with their labels. And the medical society's boycott is a very strong one. But something more than legislation is required to meet the newer combinations. Laws will not prove effective in fighting hospitals and dispensaries, either in suppressing those already in existence or preventing their spread.

The doctor as a private physician working for himself will more and more find his position disappearing. There will be general practitioners in out-of-way places as there are now; there will be men of rare talent and ability who will attract by their personality and who will remain individualistic in their work.

But the great mass of town physicians may be obliged to adapt themselves to other conditions, and either become salaried employes of State and private institutions or form mutual and coöperative hospitals and dispensaries, thereby employing themselves; which plan or plans will soonest find adoption the future alone will tell; but the general physician will probably not remain as he is, and sooner or later he will be obliged to choose between the old and new paths.

CEREBRAL HEMORRHAGE FOLLOWING DIPHThERIA.

That diphtheria, apart from the mechanical interference with respiration to which it gives rise when the larynx is involved, exerts its baneful influence through the activity of poisons generated as a result of the disease-process may be accepted as a fact. Some of the toxic complications and sequelæ are attributable to the presence of the diphtheria-bacilli, others to secondary infection. In either event these possibilities must be constantly borne in mind and be as carefully guarded against as possible. Early administration of the antitoxin is capable of averting in a large degree many of the toxic manifestations, as well as the unpleasant and dangerous results of interference with the respiration through obstruction of the larynx. There is reason to believe further that judicious employ of antistreptococcic serum will serve to mitigate the severity of many attacks of diphtheria, especially when secondary infection exists.

The poisons circulating in the blood as a result of the pernicious activity of the diphtheria-bacilli and other microorganisms exert their toxic influence especially, though not exclusively, upon the parenchyma of manifold tissues and organs. Liver and kidneys are especially prone to suffer and the nervous system scarcely less so. Probably the most common nervous lesion is neuritis, as manifested more particularly by paralysis of the soft palate (with regurgitation of liquids through the nares), cycloplegia (with paralysis of accommodation), foot-drop, abolition of knee-jerks and motor disability. In a much smaller proportion of cases the brain suffers, directly or indirectly. Cerebritis and meningitis would seem to be of rare occurrence. As the result of the action of the poison or poisons of diphtheria upon the blood and the blood vessels hemorrhage into the brain may take place; or from the detachment of endocardial vegetations secondary to inflammation of the lining membrane of the heart, embolism of a cerebral artery may result; or finally by reason of weakness or irregularity of action of the heart in consequence of toxic influences upon the vagus or the intra-cardiac ganglia or upon the heart-muscle itself, cerebral thrombosis may develop. Of a case of the last kind LEVI (*Archiv für Kinderheilkunde*, B. XXII, H. 1, 2, p. 11) has made an interesting report, to which he appends an analysis of the small number of cases previously recorded.

A girl, 6 years old, came under observation at the close of the first week of a severe attack of diphtheria of gangrenous type. Under treatment with antitoxin and repeated irrigation of the nares improvement gradually set in. At the close of the second week, however, speech began to be nasal and in a short while paralysis of the soft palate was evident, with regurgitation of fluids through the nares. The power of accommodation also became diminished. In the

third week there appeared at the site of the last (fifth) injection of antitoxin an urticaria-like eruption, which spread in a short time over the entire body, excepting the face. This was accompanied by renewed febrile movement, marked prostration, increased presence of albumin in the urine and for the first time also of hyaline and granular tube-casts. Edema of the face and extremities developed and the action of the heart became irregular. Finally symptoms of endocarditis also appeared. At the end of a month right-sided otitis developed as a further complication. Several days later the patient was suddenly seized with an apoplectic attack, followed by paralysis of the left side of the face and of the left lower and upper extremities. From this considerable amelioration took place in the course of a few hours, but two days later a second attack occurred in which the same parts were affected though now in more pronounced degree. The facial palsy gradually diminished, while that of the extremities persisted. After another interval of nine days the child manifested evidences of weakness of the trunk and neck. Sensibility and reflex activity remained unaffected. Slow improvement followed, although stiffness and weakness remained. Diphtheria-bacilli were demonstrated in the discharges and in the membrane from the throat and nose for a period of six weeks, together with streptococci and other microorganisms. The case is viewed as one of cerebral thrombosis, largely on account of the enfeeblement and irregularity of action of the heart, in conjunction with increased plasticity of the blood, but principally on account of the situation of the lesion on the right side of the brain and the transient and incomplete character of the symptoms.

LEVI has succeeded in collecting from the literature thirty-four cases of cerebral hemiplegia in the sequence of diphtheria, in addition to his own, so that it will be seen that the frequency of this complication is not at all great. The rarity becomes accentuated when compared with the frequency (25 per cent., GOWERS) of other forms of paralysis complicating diphtheria. In the thirty-four collected cases embolism was given as the lesion in fourteen cases and hemorrhage in seven; while in the remaining thirteen the diagnosis was not clear. Reports of necropsies were made in only six cases, in one of which hemorrhage was found and in the remainder embolism. Of the total number of thirty-four cases complete recovery is stated to have taken place in four and death in seven, while the remainder entered upon the chronic stage of cerebral paralysis.

THE BRITISH DOCTOR AND HIS SOCIAL RANK.

Dr. MALCOLM MORRIS, in the April issue of his magazine, *The Practitioner*, takes exception to the statements in an editorial in the *JOURNAL* some months ago in regard to the estimation of the medical

profession by British royalty, and its social standing generally in Great Britain. He claims that it misrepresented the facts, that there was "a daring fatuity" in its statements, and that far from being ill-treated by royalty, no profession has been more honored than has that of medicine.

Of course much depends upon the point of view, and what Dr. MORRIS may consider as special consideration may not be so self-evident to cis-Atlantic eyes, but if any injustice has been done to Her Imperial Majesty, the present fountain of honor in the British dominions, our apologies are hereby tendered. It seems hardly necessary, however, to consider that any such are due to the ex-commander-in-chief whose insulting address to an army medical officer was quoted from an English journal in the aforesaid editorial. It is a weak defense to say that this behavior was due to his special ideas in regard to military discipline. As far as that special relative of the royal family is concerned, certainly no very serious injustice has been done.

In spite of Dr. MORRIS's expressed opinion there still remains a doubt as to whether the medical profession has received the consideration that ought to be its recognized due. The personal confidence and friendship of royalty given to its individual members does not necessarily elevate the profession socially, for the same is given to menial attendants. Neither does the making of a few medical baronets or the late elevation to the peerage of a distinguished surgeon, who is not made any more illustrious by the bestowal, give it really any higher social rank as a body, nor do away with the fact that it is the only one of the three learned professions that has, as such, no place in the sixty or more grades of precedence that appear to be still a part of the social law in the British islands. Dr. MORRIS himself admits that the social position of doctors in England is perhaps not what it ought to be, and that is the important question, not what the Queen's intentions may have been.

To an American, the grades which the English medical profession itself makes amongst its members would seem to have a tendency to degrade it as a whole. The controversies that are carried on in British medical journals as to the right to use the title of doctor on a doorplate or a card, are not particularly elevating in themselves; the public recognizes the fact that professional ability is not to be gauged by the title, and, if one is not mistaken, is inclined to grant it to all respectable general practitioners: The fact that it may possibly be given to unworthy individuals does not necessitate the distinctions that are made, when the public does not practically recognize them. It is only in a certain limited social way that they have any value, and that is to the advantage of only a part, and to the disadvantage of the remainder. If they even represented any really important differ-

ences in qualifications, professional or otherwise, that time is now past, for many of the brightest lights of British medicine, among them apparently Dr. MORRIS himself, do not carry the title of M.D., and they are not necessarily inferior in general education or culture to those that do have it. If a man has a university degree let him append it also to his name if he wishes to, and as is done by many; there is no good reason why it should be included in his medical appellations to make a professional distinction, to the disadvantage of his equally qualified and worthy, though perhaps less fortunate, medical brethren.

It is commonly said that science recognizes no national frontiers, and it is on this ground that whatever effects our profession elsewhere is of interest to us here. America and England are the two most closely related nations, with largely the same laws, the same general characteristics, and to some extent the same institutions. Fortunately, however, we have in this country escaped some of the social incubi that still bear down upon our English confrères, and it is to be hoped that British common sense and justice will before long overcome British conservatism in doing away with certain usages and social laws which, as applied to a scientific profession, are irrational and ridiculous.

We have in this country our own troubles, and some of them in the military and naval medical services are occasionally suggestive of those abroad, but such flagrant outrages as that in the BRIGGS case, not long since discussed in English medical and lay journals, could never occur under our institutions. Such an incident shows the actual injustice and hardship that is possible with the system of social distinctions like that existing in Great Britain and its dependencies, and which no amount of philosophy can render easily endurable.

CONGENITAL CEREBRAL DIPLEGIA FOLLOWING EXTRA-UTERINE PREGNANCY.

In a considerable number of cases presenting spastic conditions from birth a history of difficult labor or of instrumental delivery can be secured. There remains, however, not a small number in which such a history is wanting and one is at a loss to account for the manifestations. While the possibility of intra-uterine disease of the fetus, traumatic or infective, can not under these circumstances be denied, there is little actual evidence in support of such a view. This possibility is given strength and may be said to be raised to the dignity of a probability by the report of a case by GROSZ (*Deutsches Archiv für Kinderheilkunde*, B. xxii, H. 1, 2, p. 1) in which spastic manifestations were present in a child born by abdominal section after an extra-uterine pregnancy, examination after death disclosing gross organic changes in the brain sufficient

to account for the symptoms observed during life. When examined, ten days after birth, the child, a female, presented a dolichocephalic head, with a distinct depression upon the left side, which was attributed to the pressure exerted by the adjacent uterus. There was, besides, paresis of the right side of the face and rigidity of the upper and lower extremities upon the right side of the body. Increase of the knee-jerks could not be made out. The head was deflected toward the right shoulder.

On account of the poor state of the mother the child was nourished with sterilized milk, which it appeared to bear well, although it developed slowly. In a short while athetoid movements appeared in the right hand, while some degree of motility returned in the arm. The rigidity in the right lower extremity also diminished somewhat. At the same time loss of power set in in the left upper extremity, together with rigidity and athetoid movements in the fingers. The patellar and the tendo-Achillis reflexes became exaggerated. No derangement of sensibility could be made out. The general condition of the child gradually failed and death took place at the age of four months.

Upon postmortem examination the left cerebral hemisphere, on its convexity as well as at its base, was found covered with a pseudo-membrane, throughout which numerous small hemorrhages were distributed. Both hemispheres displayed evidences of flattening, the left in particular, in conjunction with defects in development and secondary degeneration of cortico-muscular tracts. The right pyramidal tract of the spinal cord was degenerated and the whole of the right half of the cord was less well developed than the left.

This case would seem to show conclusively that cerebral lesions and spastic states may develop in prenatal life; and what is possible under the conditions attending extra-uterine pregnancy seems scarcely less possible under those attending ordinary uncomplicated intra-uterine gestation. Probably few women pass through pregnancy without traumatism, concussion or shock of some sort or some infectious disease or other, influence capable of causing a cerebral lesion, with its developmental imperfections and attendant manifestations. It may easily be that to these groups of causes are due a considerable number of cases of idiocy, spastic paralysis and allied conditions dating from birth.

EUROPEAN STEAMSHIP MEDICAL OFFICERS.

It has been alleged from time to time that anything but care is used in the selection of the surgeons of the various European steamship lines crossing between America and Europe. That there is some basis for this complaint is shown by the results of a criminal trial just concluded in a French court. The correc-

tional tribunal at Marseilles has condemned to two years imprisonment and a fine of 1,000 francs an individual named GOUNEAU, who had found means to get appointed surgeon on board the liner *Les Andes*, although he had never studied medicine. For two years the sham doctor occupied his position and even amputated a leg and performed other operations without serious results to the patient. This case which is but one of a number reported from time to time, indicates that some sort of supervision should be exercised over the medical officers of European steamships. While actions for malpractice by passengers would undoubtedly lie against the steamship companies for improper selection of their medical officers, still this is rather a round-about method and would fall far short of producing immediate benefit.

AN OSTEOPATHY CONSPIRACY.

It is now absolutely certain that the "osteopaths," whoever they are, have an organized conspiracy to have their diplomas recognized, and themselves placed above the regular profession in the eye of the law, in every State in the Union, as the Osteopathy Bills identical in words have been introduced in various legislatures. In most of the States an attempt has been made to sneak the bills through the Legislature without comment, and, as might be expected, with the least possible publicity.

Who is paying for all this energetic action on the part of the legislative Solons in the different States, has not yet been made apparent, but a certain advertising quack in Chicago admitted within the hearing of the writer of this article, that he himself had "put up," and was therefore sure of the passage of this bill. He said it would be the means of breaking down the present laws enacted against quackery and advertising generally.

By reference to another column it will be seen that the bill was railroaded through the Michigan Legislature at a speed that puts legitimate measures to the blush. [See page 910.]

THE JOURNAL SPECIAL TRAIN.

Medical gentlemen from Illinois and vicinity, the Pacific Coast and the Northwest, who intend to be present at the great jubilee meeting of the ASSOCIATION, are invited to go by the JOURNAL SPECIAL, which will go by the Pennsylvania Railway without change from Chicago to Philadelphia. See their advertisement in another column.

CORRESPONDENCE.

Teaching *Materia Medica*.

PITTSBURG, PA., May 3, 1897.

To the Editor:—So many physiologic actions are accredited to each agent in the text books on *materia medica* that the average student does not know the difference between the

important or leading actions and those of minor importance. If you ask a recent graduate from any medical school to name the five most important physiologic actions of the common drug, opium, he will probably be unable to correctly answer in a majority of cases. Personal observation, rather than rumor, justifies this statement.

The lack of this essential knowledge of the important drugs is to be deplored; and its remedy should engage the attention of all medical teachers. The great majority of medical graduates know little of pharmacy and less of *materia medica*. They enter practice and waste their lives writing original package prescriptions.

In teaching this important branch too many agents are studied and too few, if any, are mastered. If from the more than a thousand preparations in the U. S. P. fifty leading ones were thoroughly taught, and the student had *enough* of pharmacy to enable him to prescribe or compound prescriptions scientifically, the golden dawn in medicine would be hastened.

Original investigation deserves commendation, but the medical student ought first to follow well-beaten paths, until he has had actual practice. The prescriber who knows a few drugs thoroughly and has mastered the principal physiologic actions of each, is less liable to order agents not needed by his patient.

There has been a noticeable improvement in medical teaching in the last ten years, but much remains to be done. While graduates are sent out from many medical schools after a four years' course, who can not give the principal actions of common drugs like morphin, strychnin, digitalis and quinin, it is time to further revise the methods of instruction.

E. B. BORLAND, M.D.

Requirements for Membership.

GRANDVIEW, IND., May 3, 1897.

To the Editor:—Will you please state to me the requirements for membership in the AMERICAN MEDICAL ASSOCIATION.

Respectfully, W. C. FINCH, M.D.

ANSWER: "The delegates shall receive their appointment from permanently organized State medical societies, and such county and district societies as are recognized by representation in their respective State societies, and from the medical departments of the Army and Navy and the Marine-Hospital Service of the United States.

"Each State, county and district medical society entitled to representation shall have the privilege of sending to the ASSOCIATION one delegate for every ten of its regular resident members, and one for every additional fraction of more than half that number; provided, however, that the number of delegates for any particular State, Territory, county, city or town shall not exceed the ratio of one in ten of the resident physicians who may have signed the Code of Ethics of the ASSOCIATION.

"*Members by Application*.—Members by application shall consist of such members of the State, county, and district medical societies entitled to representation in this ASSOCIATION as shall make application in writing to the treasurer, and accompany said application with a certificate of good standing, signed by the president and secretary of the society of which they are members, and the amount of the annual subscription fee, \$5. They shall have their names upon the roll, and have all the rights and privileges accorded to permanent members, and shall retain their membership upon the same terms."

"Medical Instruction of the Laity in the Lay Press."

WILLETS POINT, NEW YORK HARBOR, April 30, 1897.

To the Editor:—Dr. Shastid's suggestions on the above named subject on page 808 of your issue of April 24, strike one as being very good. Something has already been done in this

direction by Dr. Cyrus A. Edson and others (though Edson signed his articles); and in the leading lay newspapers, particularly the *New York Tribune* and *Times*, short unsigned articles are not infrequently seen which must have been written by physicians.

Dr. Shastid evidently takes the broad view that medicine should no longer be a mere occasionally useful mystery to the laity, but a living, continuously applied help to a higher civilization.

Public instruction will be of great benefit to the masses provided it is conservative, non-dogmatic, free from great detail, and be imparted in popular, but dignified and serious language.

The proposed system is in the line of preventive medicine which has, leaving out surgical matters, already helped the world vastly more than curative.

Reacting, this instruction will tend to beget among the laity more respect for physicians in the everyday affairs of life, and will do much toward blotting out the only too common opinion that, while they are well posted in technical knowledges, they can not be trusted in positions where executive ability is needed. Witness the charter of Greater New York requiring that the president of the board of health shall not be a physician.

Likewise it will add impetus to the movement for the creation of a Department of Public Health, the mile-post that most of us hope to see passed in our time—for we do not doubt that we are on the road to it.

Finally, the system, if carefully carried out, will redound to the credit of the AMERICAN MEDICAL ASSOCIATION, and serve to draw its members into a closer union, and to attract new members.

J. D. POINDEXTER,
Captain, Med. Dept. U. S. Army.

PUBLIC HEALTH.

A Study of the Ocular Refraction in School Children.—As the result of a study of the refraction of the eyes of 1,000 school children, with particular reference to astigmatism as shown by the ophthalmometer, Carhart (*New York Medical Journal*, April 17, 1897, p. 520) expresses the opinion that changes in ocular refraction during childhood and adolescence are due to slow distension of the eyeball, caused either by strain of accommodation in an otherwise healthy eye, or by physiologic use of an eye weakened by local or constitutional disease or dyscrasia. Poor light in crowded school rooms is particularly productive of accommodative strain. Such distention of the eyeball results not only in progressive lengthening of the optic axis, but also in alterations of the curve of the cornea. In a considerable proportion of cases, hypermetropic astigmatism is probably congenital, but in much the larger proportion and in all cases myopic and mixed astigmatism are caused by the same process as results in lengthening of the optic axis from the congenital high degree of hypermetropia of infancy to the high degree of myopia seen typically in German universities, and occasionally in our schools. This process of distension is more easily arrested in its earlier stages, and therefore prompt and exact correction of the refractive error, and particularly of low grades of astigmatism, is indicated in all cases to prevent an extension of the process. In cases of compound myopic astigmatism correction of the astigmatic element is of equal, if not of greater importance than correction of the myopic element of the refraction.

Prophylaxis of Yellow Fever in Brazil.—The disease was kept under control and stamped out in Buenos Ayres by the immediate removal of every case as it appeared to the floating hospital, while all the other inmates of the house were taken at the same time to the island quarantine station, where they remained until all danger was past. The house was submitted to a vigorous disinfection during the entire time of their absence, and as a final

measure, all the walls were whitewashed or calcimined. The physician first called to the case was also quarantined in his own house for the same length of time, and the premises disinfected. By these means the disease was restricted to a few isolated cases in the early spring. Dr. A. Simoes proclaims in the *Rev. Med. Chir.* of Brazil the success of inoculations with attenuated cultures of the yellow fever microbe, the micrococcus xanthogenicus discovered by Freire in 1880. Since he was authorized in 1883 by the government to administer them, 11,881 persons have been inoculated, and he states that the mortality among them has been only 0.5 per cent., while among the rest of the population it has averaged 30 per cent. The yellow fever hospital had a mortality of 78 per cent. until the inoculations were introduced, when it fell to 30 per cent. He adds that if all strangers recently arrived, and all persons exposed to contagion, would have themselves inoculated, epidemics would cease and there would only be a few sporadic cases, while vigorous hygienic and disinfecting measures in addition would exterminate the pest altogether.—*Cronica Medica*, October 15.

The Influence of Smallpox Hospitals upon Adjacent Territory.—A recent number of *Public Health* (London) contains an interesting abstract by Dr. Meredith Young of the Local Government Board Report, 1894-5: Dr. Young, in dealing with the question of smallpox, points out that though the thesis of the aerial connection of this disease is regarded by the "bulk of authorities" as a settled question there are many still unconvinced, and he draws attention to the experience of Hastings in 1894, where the facts observed form yet another illustration of the danger of placing these hospitals near to human habitations. It was found in that instance that out of thirty-six cases which occurred within 500 yards of the Hastings Smallpox Pavilion the percentages of smallpox attacks to population varied as follows:

	Attacks. Per cent. of population.
Within 100 yards circle,	4.2
Within 100 to 200 yards zone	2.7
Within 200 to 300 yards zone	1.9
Within 300 to 400 yards zone	0.9
Within 400 to 500 yards zone	0.2
Total within 500 yards circle	1.3

Dr. Young adds that the diffusion of smallpox occurred apart altogether from any communication of contagion by infected persons or things, as a most painstaking inquiry showed.

Necessary Police Powers Over Water-sheds.—There is only one correct time for the protection of the water supplies of cities, and that is as early as possible in the formation of the plant. If this protection is put off, or is made to depend upon special legislation, the result is only too apt to become a failure; or if not a failure, it is often the source of inordinate expense. The State board of health of North Carolina has laid before itself the very commendable task of trying to reduce the death rate by typhoid fever, and laws are being framed to begin the work of protecting all the public water-supplies of the State. According to a writer in the *Bulletin* of that board for March, the supplies are peculiarly liable to pollution and the State pays a heavy tax in lives by reason of that fact. How heavy the tax is, the following computation by Dr. R. H. Lewis, Secretary, has been drawn up for the information of the law makers:

"Of all the preventable diseases, consumption alone excepted, typhoid fever is by far the most deadly in our State. In the year 1896 there occurred in eleven cities and towns of the State, having an aggregate population of 105,501, which certified to the accuracy of their mortuary statistics, 107 deaths from typhoid, or 1 in every 967 of the population. Estimating at this ratio for the whole State on a basis of 1,800,000 population, the number of deaths from typhoid fever in North Carolina during the past year was 1,861. Taking the death-rate given by one of the highest authorities in a similar calculation, 10 per cent., there were, during the same time, 16,740 persons

sick of the disease who recovered. Let us see what this meant to the State in dollars and cents, leaving out of consideration entirely the anxiety and sorrow entailed. Valuing each life at \$2,000, time lost by those who recovered on an average of forty-five days of sickness per case at 80 cents per day, nursing, medicines, and doctors' bills at \$25, and funeral expenses of those who died at \$25 each, the statement of the matter in tabular form is as follows:

1,861 deaths at \$2,000 each	\$3,722,000
1,861 funerals at \$25 each	46,525
Wages of 16,740 convalescents, during forty-five days, at 80 cents	360,103
Nursing, medicines and doctors' bills for 18,610 cases, at \$25 each	465,250

Total tax levied in 1896 by typhoid fever upon the State \$1,593,878

"Deducting 33 $\frac{1}{3}$ per cent. for every possible inaccuracy or over-estimate, typhoid fever cost the State last year, in round numbers, \$3,000,000.

"Typhoid fever is a preventable disease. It is caused almost invariably by drinking water which has been contaminated with the bowel discharges of another case. To prevent the entrance of the germs into water in the first instance is for the direct benefit of the 125,000 of our people living in fourteen of our largest and most progressive cities and towns. One case of typhoid fever or cholera on a water-shed without proper sanitary oversight, would be liable to poison the whole city, or at any rate all of the inhabitants who use the public water-supply, to spread sickness and death wholesale. Most of the water-supplies in the State are from small, short streams whose water-sheds are thickly populated, and therefore peculiarly dangerous.

"It is the duty of the State to protect the lives of its citizens. Water companies are corporations organized for the purpose of making money. Their object is to declare dividends. A tender regard for the lives and health of individuals does not characterize them any more than other corporations. It is a proverb that corporations are soulless. An annual expenditure on their part of three or four hundred dollars would be required, but it would be more than re-imbursed by the larger consumption which would result from the greater confidence in the purity and safety of the water, that the presence of this law on the statute books would give. It would remove the suspicion and distrust that now exists—and with reason—in the minds of many. Seriously, the bill could be justly entitled 'An Act to Promote the Business Interests of Water Companies.' In a word, its passage would materially promote the public health, and not only not injure but positively benefit the water companies.

"The extension of the police powers of the cities and towns to their water sheds, for the purpose of carrying out the provisions of this act alone is extremely important, because it would provide what is now lacking, the practical machinery which would insure protection."

Since the above was written three water companies, namely, Raleigh, Henderson and Durham, have expressed their approval of the bill and their desire for its passage.

New Jersey Epidemic and Quarantine Law.—*Be it enacted, by the Senate and General Assembly of the State of New Jersey:*

1. No vessel having on board any person or persons affected by yellow fever, cholera, typhus or ship fever, bubonic plague, smallpox, scarlet fever, diphtheria, measles, relapsing fever, or any other dangerous disease of a contagious, infectious or pestilential nature, and no vessel infected by any of these diseases, and no infected baggage, dunnage, rags or hides, shall be brought to any wharf in the State of New Jersey, and no person, persons or property shall be landed in this State from any such vessel without a permit shall have first been issued by the health officer of the port, if there be such officer, and if there be no such officer, then by the local board of health having jurisdiction in the locality.

2. The master of every vessel from a foreign or domestic port which shall pass the quarantine station located at City Island or elsewhere in Long Island sound or the quarantine station at Port Wadsworth or elsewhere in New York bay, and which vessel is allowed by written permit, issued by the proper officer at either of the said quarantine stations, to proceed to any port or place in the State of New Jersey, shall, within twenty-four hours after the said permit is received by him, exhibit said permit and deposit the same at the office of the local board of health of the said port or place of destination, and he shall be entitled, subject to the rules and regulations hereinafter provided for, to receive from the said local board of health, or health officer

of the port, if there be such officer, a permit to land passengers, baggage and cargo.

3. The health officer of the port, if there be such officer, and if there is no such officer then the local board of health of every sanitary district in this State is hereby authorized and empowered to order, whenever in the judgment of said officer or board the public health requires such action, that any vessel which is within the jurisdiction of said officer or board may be removed to the quarantine grounds or to some other place of safety, and may require all of the persons, baggage, merchandise and articles which have been landed from such vessel to be seized, returned on board thereof or removed to quarantine grounds or to other place of safety; if the master, owner or consignee of such vessel can not be found, or shall neglect or refuse to obey any such order of removal, such health officer or board of health may employ such assistance as may be necessary to effect such removal, and all expenses incurred in such removal shall be paid for by the master, owner or consignee of such vessel; such vessel shall not return within the limits of the jurisdiction of said board or officer, nor come to anchor, nor land at any wharf within said limits, without the written permission of the said board of health or officer of the port; any person employed to remove any such vessel, persons, merchandise or articles pursuant to this section shall have a lien on such vessel, its tackle, apparel and furniture for his services and expenses in effecting such removal.

4. The masters of vessels arriving at any port or harbor in the State of New Jersey shall pay to the health officer of the port, if there be such officer, and if there be no such officer, then to the local board of health, the following fees: For inspection of any vessel from a foreign port, five dollars; for inspection of every vessel from a domestic port south of Cape Henlopen, between May first and November first in each year, steamers, three dollars, other vessels one dollar; for medical inspection of every one hundred, or fraction of one hundred, steerage passengers upon transatlantic steamers, two dollars; for each permit issued for the discharge of cargo or baggage brought as freight, twenty-five cents; for sanitary inspection of every vessel after the discharge of cargo or ballast, ten dollars; for disinfection of every vessel from an infected port, or of such vessels as shall require disinfection by reason of exposure to infection or contagion, fifty dollars; for vaccination of persons on vessels on board of which smallpox has developed during the voyage, each twenty-five cents; the health officer of the port, if there be such officer, and if there be no such officer, then the local board of health having jurisdiction in each port and harbor, shall report in writing to the board of health of the State of New Jersey on the first day of October of each year; said report shall state the number of vessels inspected during the preceding year; the number of passengers examined; the number of permits issued; the amount of fees received from each vessel and the total amount of fees received, and said report shall also include answers to all inquiries which may have been addressed by said State board to the said health officer or local board of health.

5. The board of health of the State of New Jersey is hereby empowered to make and alter rules and regulations to prevent the introduction into this State of infected persons and property, and to prevent the spread of any dangerous infectious disease which may have been so introduced; the expenses incurred and the services rendered by any local or State health officer, or by any of their employes, in the discharge of any duty imposed by said rules and regulations in relation to vessels, merchandise, baggage or persons, shall be paid by the master or owner of the vessel in which such persons, baggage or merchandise shall have arrived, and all such expenses, services and charges shall be a lien on the vessels, merchandise or other property in relation to which they shall have been made, incurred or rendered, and if such master, owner or consignee shall omit to pay the same within three days after the presentation of such account, the local or State board of health may proceed to enforce such lien in the manner provided by law; any person or persons who shall violate any of the provisions contained in any rule or regulation made by the said State board of health under the authority contained in this section, shall be punished by a fine of two hundred and fifty dollars, or by imprisonment for a period not exceeding six months, or by both fine and imprisonment.

6. Any person or persons who shall obstruct any duly authorized health officer in the enforcement of any of the provisions of this act, or who shall violate any of the provisions of sections one, two, three and four of this act, shall be guilty of a misdemeanor, and shall be punished by a fine not exceeding three thousand dollars, or by imprisonment in the State prison for a period not exceeding one year, or by both fine and imprisonment.

Approved April 9, 1897.

BOOK NOTICES.

Clinical Lessons on Nervous Diseases.—By S. WEIR MITCHELL, M.D., LL.D., Edin. Pp. 305. Philadelphia and New York: Lee Bros. & Co. 1897.

This is a book by a master and if we mistake not it will prove a very popular one. The book treats of hysteria, recurrent melancholia, disorders of sleep, choreic movements, false sensations of cold, ataxia, hemiplegic pain, treatment of sciatica erythromelalgia, reflex ocular neurosis, hysteric contractions, rotary movements in the feeble minded, etc. Few can speak with more authority than the author.

Lectures on Renal and Urinary Diseases. By ROBERT SAUNDRY, M.D., Edin., Fellow of Royal College of Physicians, London, etc. Pp. 434; \$2.50, Philadelphia: W. B. Saunders. 1897. For sale by W. T. Keener, 95 Washington Street, Chicago.

These lectures have some of them been printed before and were very well received, the author's long service in the Birmingham General Hospital having given him exceptional opportunities. They have now been revised and republished in this single volume. A fourth section has been added on miscellaneous affections of the kidneys, which makes the book more complete as a work of reference. The volume is well worthy a place in the library of the progressive physician.

A Clinical, Pathological and Experimental Study of Fracture of the Lower End of the Radius, with displacement of the carpal fragment toward the flexor or anterior. By JOHN B. ROBERTS, A.M., M.D., Professor of Anatomy and Surgery, etc. With 33 illustrations; pp. 76. Price \$1. Philadelphia: P. Blakiston Sons & Co. 1897.

This book is a verbatim reproduction from the transactions of the American Surgical Association for 1896. The paper is a valuable one. The author has wisely concluded to publish it as a separate volume.

La Spedallta Infantile in Italia. By ALPHONSO MANDELLI, Presidente dell'Ospedale dei Bambini di Cremona, etc. Pp. 648. Milan: Ulrico Hoepli. 1897.

This is a report of the Children's Hospitals in Italy. The work is illustrated with a number of cuts and colored plates, beautifully printed, and they set forth in detail the equipments of the various hospitals devoted to children in Italy and the treatment pursued. It also has the elevations from block plans of most of the institutions. A perusal of the volume will speedily convince the reader that the Italians in practical medicine are fast regaining their ancient prestige.

California of the South. By WALTER LINDLEY, M.D., and J. P. WIDNEY, A.M., M.D., LL.D. Third edition; pp. 335. New York: D. Appleton & Co. 1896.

This work, which is well illustrated, gives in detail the climatic and other conditions of Southern California, and it may be depended upon as a truthful account. There is a map of California in the volume, which has been drawn with the skill which characterizes all the work of the Messrs. Appleton. The book is full of information regarding California and few can read it without a desire to visit the wonderful land, of which after all that has been written only part has been told. The medical reader will find it very helpful to him in the selection of climate for his cases.

Diphtheria and Antitoxia. By Dr. NESTOR TIRARD, F.R.C.P. Pp. 141. London, New York and Bombay: Longmans, Green & Co. 1897.

This little book has its origin in sundry papers read before meetings of the British Medical Association in recent years. It summarizes the result of the antitoxin treatment and free use has been made of the reports of the medical superintendents of the metropolitan asylums and the data brought in the report of the American Pediatric Society, with which report the author is in entire harmony. He regards antitoxin as having robbed diphtheria of most of its terrors. To convince others of that fact seems to be the purpose of the book.

Atlas and Essentials of Gynecology. By Dr. OSCAR SCHAEFFER, privat docent in obstetrics, etc., at the University of Heidelberg. Pp. 288. New York: Wm. Wood & Co. 1897.

This Atlas of Dr. Schaeffer is very valuable and its careful reproduction with its accompanying text gives the reader the concrete advantage of the great gynecologic clinics of Munich. Not only will the book prove an excellent one for students but as well for the general practitioner in any emergency pertaining to the art.

The Diseases of the Stomach. By Dr. C. A. EWALD, Extraordinary Professor of Medicine at the University of Berlin, etc. Translated and edited by MORRIS MANGES, A.M., M.D. Second edition; pp. 602. New York: D. Appleton & Co., 1897.

The name of Dr. Ewald is as familiar as a household word on this side of the Atlantic, and to all who pretend to be acquainted with the literature of the diseases of the stomach Dr. Ewald stands as one of the highest authorities.

This is the second American edition and the great progress which has been made since the appearance of the first edition in 1892 has rendered its revision necessary. We observe with pleasure that in prescription writing the translator has retained the metric system of dosage, although for the benefit of those whose knowledge of metric system is yet limited, he has also translated in the old British system of weights and measures.

Lectures on Appendicitis and Notes on Other Subjects.—By ROBERT T. MORRIS, A.M., M.D. Second edition; pp. 173. New York and London: G. P. Putnam's Sons. 1897.

This is the second edition of the book of Dr. Morris, and as it has been carefully revised and brought up to date, leaves little to be said on the subject and little to criticise. The typography is excellent and the paper is good. Although still a young man Dr. Morris may be classed as one of the pioneers on this subject and therefore speaks with an *ex cathedra* utterance. The book is of high order and compares very favorably with the other recent works on this subject.

Warner's Pocket Medical Dictionary of today, comprising pronunciation and definition of 10,000 essential words and terms used in medicine and associated sciences, by WILLIAM R. WARNER.

This is an excellent little dictionary and will be found very useful to students and others.

NECROLOGY.

DILANEY L. WASHBURN, M.D., of Louisville, an alumnus and prosector of the University of Louisville is the subject of a warm tribute in the *American Practitioner and News*, April 3. He was born in Jefferson County, near Louisville, in 1855. He received his literary education in the public schools of that city. In 1880 he began the study of medicine under Prof. H. A. Cottell. As a student his progress was exceptionally rapid, and at the time of his graduation his rank was far above the average. He immediately found employment as assistant in the clinics of the University and teacher in the sub-department. He served as assistant to Prof. John A. Ouchterlony in the medical clinic till 1886, when he was appointed prosector to the chair of anatomy and quiz master under Prof. J. M. Bodine. Here his proficiency, learning and energy found full scope and profitable exercise. He was a thorough anatomist, an expert dissector, and a teacher of unusual clearness and power. He was faithful and true in every obligation of life, the soul of honor, and the personification of industry and singleness of purpose. To this he added a kindness of heart and a cheerfulness of manner which caused him to be loved by all who knew him. He dies in the plenitude of ardent manhood, just as time had given him through study and experience that professional repose which insures the largest usefulness. The loss to friends, colleagues, students, and clientèle is irreparable; but in consolation, if not in compensation, he leaves behind him the priceless legacy of a stainless character, and a life devoted to science and the good of man.

Dr. JACQUES MAISONNEUVE, the most eminent Parisian surgeon of his day, has died at the age of 87. His death took place at his chateau of Missillac, where he had lived in retirement since 1890. Born at Nantes in 1810, Jacques Gilles Maisonneuve became resident medical officer at a Paris hospital, and afterward prosector at Clamart. In 1840, after a brilliant concours, Maisonneuve was nominated surgeon to the Cochin Hospital. Thence he transferred his services to the Pitié, and finally to the Hôtel Dieu. He soon became noted as the most skillful surgeon of his time, being particularly well known for the number of surgical instruments which he invented, and some of which, for instance the urethrotome, are still in use under his name. Maisonneuve was the first surgeon to perform the operation of resection of the hip-joint, while his conservative surgery was as sensational as his operative. In 1862 he showed before the Academy of Medicine the case of a young engineer whose leg he had preserved by the practical application of the physiologic theories of Flourens as to the reproduction of bone by the periosteum. In this case he removed the fractured tibia, retaining the periosteum, out of which a new tibia was formed. Since 1875 he had retired from the practice of his profession so entirely that many even in his own country thought him to be dead.

PROFESSOR STOUKOVENKOFF, Chair of Dermato-syphilography at Kiew. His sudden death in the midst of his inaugural address at the first meeting of the local physico-medical society which he had just founded, created a profound impression, at home and abroad. He was assiduous in his attendance at International Congresses and was always in the van of progress. His works on the treatment of syphilis with benzoate of mercury, etc., have made his name prominent.

LEONCIO ROS, M.D., a Cuban by birth and the youngest son of Salvador Ros, died in New York city, April 30, not quite a day after receiving burns caused by the explosion of an alcohol jar in the Woman's Hospital, while he and the apothecary were engaged in the sterilization of catgut ligatures. He was a Senior Assistant Surgeon on the House Staff.

W. C. PIPINO, M.D.—The following resolutions were adopted at a meeting of the Western Ophthalmological, Otological, Laryngological and Rhinological Association:

WHEREAS, We have heard with profound regret of the untimely death of our late confrère Dr. W. C. Pipino at his home at Des Moines, Iowa, last summer; therefore be it

Resolved, That our society, realizing the great loss we have sustained, desire to express in appropriate manner our appreciation of his worth as a member of our profession and society.

Resolved, That these resolutions be engrossed upon our society records and a copy furnished the medical journals representing our society, for publication.

NEW INSTRUMENTS.

NEW MECHANICAL SAW FOR SEPTAL OPERATIONS.

W. SHEPPEGRELL, A.M., M.D.

VICE-PRESIDENT OF THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY, ETC.
NEW ORLEANS, LA.

In order to obviate the difficulty and fatigue of operating the nasal saw by hand, and to do this mechanically, by some mechanism which will enable us to use the saw not only with less exertion, but also with greater rapidity and precision, a number of mechanical saws have been devised. These saws are practically all operated by the electric dental motor.

For over a year I have endeavored to devise a saw for nasal operations which would combine simplicity, effectiveness, ease in application, facility of control, and would enable the operator to clearly follow the progress of the operation within the nasal cavity. After changing the model many times so that the last bears scarcely any resemblance to the first, I have at last devised a saw which combines the important features enumerated above, and which has done me excellent service. This saw may be attached to any of the dental motors now sold by dealers.

In this mechanical saw the handle, instead of being at right angles with the direction of the saw, is at an obtuse angle, thus giving it the shape which has been found the most convenient in the ordinary nasal saws, and which prevents the hand which holds the saw from coming too near the face of the patient. In order to permit this position, the driving wheels used in the other mechanical saws, which have been described, can not be used, and the backward and forward movement of the saw is obtained by means of a ball revolving at an eccentric (D). The flexible shaft is attached within the handle (A) and the obtuse angle also prevents the excessive bending of the flexible shaft and the friction which would result from this position.

The second advantage of this instrument is that the saw is at a higher plane than the transforming mechanism, so that it enables the operator to see more fully the work which is

The Scheppegrell Mechanical Saw. (Reduced one-half.)

being done by the saw within the nasal cavity. The third advantage is that the arrangement by which the saw blades are held in position enables the saw to be used not only upward and downward as in the mechanical saws which have been described, but also at any required angle. The fourth, and not least important feature, is, that the movement of the saw may be instantly started or stopped by the movement of a sliding thumbpiece (E) in the handle, and that its movement may likewise be increased from zero to a one-eighth inch stroke without arresting the movement of the motor.

In this saw the whole mechanism is made of steel so as to combine strength with lightness. The handle is of brass, the central part being hollow for lightness and for the admission of the handle of the flexible shaft, and the whole instrument is nickel plated. The movement of the saw is obtained by means of a steel ball which is attached to a shaft at an eccentric. This I believe is the first attempt to apply this principle to an instrument of this kind. The ball revolves within an oblong slot so arranged that it gives a backward and forward movement to the saw-holder, to which the saw is attached by means of a binding screw below the saw-holder and out of the line of vision. This mechanism is covered by a thin metallic

sheet which slides over the upper part of the instrument and is fixed by means of two small screws, thus protecting the mechanism from dust, etc.

At the upper part of the handle there is a sliding thumbpiece attached to a sleeve (*E*) which raises or lowers the ball in or out of the slot (*D*), thus giving complete control over the movement of the saw and enabling the operator to stop or start it instantly.

The same mechanism which starts and stops the saw may be used to regulate the range of movement from zero to one-eighth inch, the full stroke of the saw. This is effected by gradually raising the thumbpiece, and the action of the saw commences as soon as the upper part of the ball enters the slot, and the full stroke is obtained when the ball is fully within it. At the upper and lower portion of the slot (*E*) respectively, there is a lateral extension by means of which the movement of the instrument may be continued without pressure of the thumb in the upper position, and may be prevented from starting automatically in the lower position.

The instrument is provided with two saws, one long and the other short (*B*). As these saws are reversible on the horizontal axis, they may be used either upward, downward or otherwise.

This instrument may also be used effectively for massage work. The opening into which the saw is inserted will fit an ordinary Buck's applicator, and the mechanism is carried on in the same manner as for the saw. The applicator (*C*) is armed at the end with a pledget of cotton well attached and flattened at its extremity. It is then dipped into the solution which is to be used, and the massage may then be commenced, the strength of the stroke being adjusted by means of the thumbpiece, which also enables the operator to stop or start the movements at will.

AN EFFICIENT AND INEXPENSIVE INSTRUMENT FOR THE REMOVAL OF EAR WAX.

BY ALFRED HINDE, M.D.
CHICAGO, ILL.

Many years ago from a piece of iron wire heated at one end, flattened, and then twisted half a revolution, cooled quickly, and sharpened near its point, I hastily constructed a most efficient ear wax remover. It still continues to be the most suitable instrument for the rapid removal of inspissated cerumen with which I am acquainted. After repeated requests of the students of Rush Medical College I have had Messrs. Sharp &

Smith copy my old instrument—a cut of which is herewith presented and its dimensions given. They have made one instrument blunt-pointed for the removal of softened wax, and one with a cutting edge of three millimeters length at the inner lip or edge of the instrument. This is used where the wax is of greater density and the plug is readily tunneled and removed piecemeal or extracted in one lump if too hard to be broken down.

Handle, length 5.5 centimeters; drain 4 millimeters. *Shaft*, length 8 centimeters; drain, 2 millimeters. *Twisted extremity* length 18 millimeters. This end consists of a half twist or revolution of a circle whose diameter is 5 millimeters. The end is thinned out and rounded so that it will more readily engage the wax and as already stated, one of the instruments has a cutting inner lip.

MISCELLANY.

Physico-Chemic Prizes.—An English scientist has presented the Académie des Sciences with an endowment representing an income of 4,000 francs, to be awarded each year for the encouragement of new investigations in the physico-chemic sciences. The competition is international and may be retrospective. It will be known by the name of the donor, M. H. Wilde.

Moscow International Congress.—The *Progrès Méd.* announces that a special train with dining and sleeping cars will start from Moscow immediately after the Congress for a free excursion to the Caucasus, for regularly inscribed members of the

Congress. The incidentals of the trip will not be over 150 francs per person.

Increase of Cancer.—Commenting on the recent statements of English statisticians that the deaths from cancer have increased from 177 per million inhabitants to 713 in the last 50 years, or 1 death from cancer in every 23, the French state that in Paris there is 1 death from cancer in every 19 or 20, according to the latest statistics published (1894).—*Nouv. Remèdes*, April 8.

College Exercises.—The annual commencement of the College of Physicians and Surgeons, Chicago, now a part of the University of Illinois, was held April 20. Eighty-three students were graduated.—The annual commencement of the College of Physicians and Surgeons, Baltimore, Md., was held April 15. There were eighty-three graduates.—The commencement exercises of the Beaumont Medical College were held April 15. There were thirty graduates.

Sale of Adulterated Whisky Violates Pure Drug Law.—The supreme court of Ohio says, in *State v. Hutchinson*, Feb. 2, 1897, that the United States Pharmacopeia is adopted by the statute of that State against the adulteration of food and drugs as an authoritative compilation, comprising accepted and known articles of drugs, with a description of their characteristics and qualities, and an approved standard of their strength and purity. Whisky is recognized by that name in the pharmacopeia, where its proper standard of purity and strength is laid down, and, therefore, the court holds, is a drug, within the meaning of the pure food and drug statute. Moreover, it maintains that the provisions of the statute relating to the sale of drugs are not limited in their application to sales by druggists and pharmacists, nor to sales for medicinal or pharmaceutical use; but they extend to all persons, without regard to their vocation, and make no distinction on account of the use intended to be made of the article. This renders the sale of whisky which is adulterated, within the meaning of the statute, an offense against its provisions, though it be sold as a beverage or commercial commodity, and by one who is neither a druggist nor pharmacist. And while the statute referred to is mainly designed for the better preservation and promotion of the public health, the court holds that it is also directed against frauds resulting from the sale of inferior articles for prices which entitle the purchaser to those that are of the required standard.

Congenital Obliteration of the Esophagus, with other Malformations. Bowes (*British Medical Journal*, March 6, 1897, p. 586) has reported the case of a female child, born at term, after a normal labor, the fingers of whose hands pointed upward toward the elbows. The thumbs and both radii were wanting. At rest the outer side of the hand (that is the index finger and its metacarpal bone) rested against the forearm; but by manipulation the hands could be brought down at right angles with the forearm, but no further, and there was great resistance to supination. The ulna in each arm was a little curved and seemed shorter than normal. On the third day when the mother's breasts had filled with milk, it was noticed that the milk sucked by the child in nursing returned through the nares. No cause for this could be seen in the child's mouth and the progressive wasting led to a suspicion of esophageal obstruction. The use of the bougie was abstained from on account of frequent attacks of cyanosis with much choking, from which the child suffered. The child eventually died on the thirteenth day, and on postmortem examination the upper part of the esophagus was found to consist of a mere cul-de-sac extending about three-fourths inch below the level of the larynx, while the lower part, communicating with the stomach, opened into the trachea close to its bifurcation. The cardiac interventricular septum was deficient in its upper part.

Uric Acid a Factor in Hay Fever.—Dr. Norton L. Wilson of Elizabeth, N. J. (*N. Y. Medical Journal*), believes that in the production of hay asthma there are three important factors: 1, the predisposing constitutional condition; 2, an external irritant; 3, a pathologic condition of the nasal mucous membrane. He asks, a neurosis being present, may not the condition be

due to uric acid irritation, since neurasthenia and lithemia go hand in hand? External irritants, such as the emanation from certain plants, dust, odors, pollen or any other mechanical irritant may be superadded disturbers, so also polypi, spurs or hypertrophies may constitute the third factor. During the attack he concludes that it is better to free the blood from uric acid by the administration of an acid. "Aromatic sulphuric acid or phosphoric acid acts very well. After freeing the blood, gradually extract the uric acid from the tissues by two or three grain doses of sodium salicylate (given three times a day), cut off the acid-producing foods, such as meat, beer, wine, cider, lemonade, etc." Look after hygienic measures, polypi, etc. Begin the crusade against uric acid six weeks or two months before the attack. For local relief Dr. Wilson advises menthol and camphor in liquid albolene sprayed into the nostrils. Where this method is intolerable he would use a 6 or 10 per cent. solution of cocain and then coat the turbinate region with a thin film of flexible collodion. For the itching of the conjunctiva he would use hot water or yellow ointment. He claims, however, to have hinted rather than given any definite plan of treatment. As regards the asthmatic symptoms three of his patients have suffered quite as much as in former years, but in the next season he shall begin earlier and hopes thereby at least to mitigate their symptoms.

Experts May be Cross-examined from Books.—Although the contents of scientific books can not be read to a jury for the purpose of proving the facts or establishing the deductions stated in them, the appellate division of the supreme court of New York holds, in *Egan v. Dry Dock, E. B. & B. R. Co.*, Dec. 1, 1896, that whenever a person holds himself out as an expert witness, and undertakes to give his opinion upon any scientific matter, it is not only proper to examine him as to the ground of his opinion, but his qualifications as an expert may be tested upon cross-examination in any way which will enable the jury, who are to pass upon the weight to be given to his testimony, to judge intelligently about it. For that purpose, the court says that it is perfectly proper to ask him whether or not the opinion he has expressed agrees with the opinion of other people who are conceded to be learned upon the same subject, because, if an expert witness admitted that the opinion which he expressed was contrary to the opinion which was held upon the same subject by other men who were acquainted with the same science, it might, unless the reasons which he gave for his opinion were satisfactory, tend strongly to detract from the weight which that opinion would otherwise receive. For the same reason, if the witness admitted that text writers of acknowledged authority had expressed opinions contrary to that one which he gave in regard to the matter under examination, that might go to detract from the weight to be given to such testimony. Therefore it has been the custom, at least in the State of New York, to call the attention of expert witnesses, upon cross-examination, to books upon the subject, and ask whether or not authors whom he admitted to be good authority had not expressed opinions different from that which was given by him upon the stand. The reference to books in such cases is not made for the purpose of making the statements in the books evidence before a jury, but solely for the purpose of ascertaining the weight to be given to the testimony of the witness. The extent to which such examinations may go is very largely at the discretion of the court.

The Alleged Origin of Life Insurance.—Under the title of "How Life Insurance was Suggested," the *Insurance Post* publishes the following: A game of cards suggested the system of life insurance. More than two hundred years ago a Flemish nobleman attempted to divide equitably the money staked upon an interrupted game of chance. He was assisted in the task by a Jesuit priest, one of the most accomplished mathematicians of any age. Pascal solved the problem, and in doing so enunciated the "doctrine of probabilities," or laws governing insurance of all kinds. The theory is illustrated by the throwing of dice. When a single die is thrown the chance of throwing up an ace is precisely one out of six, or one out of the total number of sides or faces. In a large number of

throws the chances are in the same proportion. From this Pascal laid down the proposition that results which have happened in any given number of observed cases will again happen under similar circumstances, provided the number be sufficient for the proper working of the law of average. The life of a single individual is one of the greatest uncertainties, but the duration, or rate of mortality, of a large number of individuals may be depicted with great accuracy by comparison with the observed results among a sufficiently large number of persons of similar ages and occupations, and similar to climatic influences.

Election of Officers.—At a recent meeting of the Western Ophthalmological, Otological, Laryngological and Rhinological Association the following officers were elected: President, B. E. Fryer, Kansas City, Mo.; first vice-president, J. Elliott Colburn, Chicago, Ill.; second vice-president, F. M. Rumbold, St. Louis, Mo.; third vice-president, A. E. Bulson, Jr., Ft. Wayne, Ind.; secretary, Hal Foster, Kansas City, Mo.; treasurer, W. L. Dayton, Lincoln, Neb. The next annual meeting will be held in Chicago, Ill., on April 7 and 8, 1898.

A Rare Variety of Congenital Occlusion of Duodenum and Rectum.—Hess (*Deutsche medicinische Wochenschrift*, April 1, 1897, p. 218) has reported the case of male child, born three or four weeks before term, without an anal orifice and unable to pass urine. The prepuce of the penis was represented by a thin, tense, discolored membrane covering the orifice of the urethra and on rupture of which urine escaped. The bladder was apparently enlarged. At the insertion of the scrotum into the perineum the skin was thrown into the slight stellate folds suggestive of a rudimentary anus. Vomiting occurred and the child was unable to take food. In the hope of establishing an outlet from the bowel the pelvic tissues were divided through the perineum but the rectum could not be reached in this way. The establishment of an artificial anus was deferred until the following day, but hemorrhage took place from the wound already made and amid signs of exhaustion death took place. On postmortem examination the stomach was found to be practically normal, with a well-defined pylorus. Continuous with the latter was a large blind sac almost equal in size to the stomach, but evidently the first part of the duodenum. Into this emptied the common bile-duct. There was, however, no communication with the remainder of the intestine. In the situation where the duodenum normally passes beneath the mesentery the continuation of the bowel was found, being attached to the peritoneum by numerous adhesions. The bowel at this point was of smaller caliber than farther on and into it emptied the pancreatic duct. The remainder of the small intestine exhibited no peculiarity. The large intestine was somewhat dilated and terminated in a fibrous band at the level of the bladder, to which it was attached. This portion of the bowel contained meconium, in which the presence of biliary matters could be demonstrated. The walls of the bladder were thickened and adherent to the anterior abdominal wall. In explanation of the malformations present in this case the occlusion of the rectum is attributed to a not uncommon defect in development, while that of the duodenum is attributed to twisting of the bowel at this point and consequent separation of the parts on either side of the constriction.

New York.

THE AMBULANCE SYSTEM IN THE GREAT PARADE—The formal surrender to the city on April 27, of the mausoleum by the Grant Memorial Fund Committee was a successful procedure. The day was cold, cloudy and marked by the prevalence of very high winds. Only a few trivial accidents occurred and they were mostly due to horses frightened by applause or flying hats and programs. The estimate that the procession mustered 60,000 men is at least approximately correct, but the ambulance system was so perfect in detail that it could afford relief in three minutes to an individual dropping from the ranks or in half an hour could extricate a crowd from a collapsed stand. It is well to add that the spectators were, as is usual in American cities, in the best of humor and the police, fire, military and public parks departments were in harmony as well as under the best discipline.

Detroit.

AT A REGULAR MEETING of the Wayne County Medical Society, held on Thursday evening, April 29, Dr. S. O. Kulick read a paper on the subject of "Antitoxin in Diphtheria." The author of the paper stated that his first treatment of diphtheria by antitoxin was begun somewhat experimentally when he was called to see a pair of twins suffering from the disease. These babies, the author stated, were as near alike as any two children could be, so he determined to use the antitoxin on one case and give iron and potassium chlorate to the other without using antitoxin. Accordingly he injected 1000 units hypodermically in Case No. 1, and prescribed for No. 2 a mixture of iron and chlorate of potash. The result was that case No. 1 was decidedly better on the third day, while case No. 2 did not show any decided improvement until the thirteenth day. This was a strong argument to the author in favor of antitoxin and he accordingly determined to use it thereafter. He has done so, with the following results: Out of fifty-four cases treated three died. Two of these died within three hours after his first visit, from laryngeal croup. Intubation had been advised but had not been accepted. The third death was that of a child who had been sick three days when the doctor was called. The patient had been treated by another physician with calomel and was salivated. The case was malignant. Fifteen hundred units of antitoxin were injected and the iron mixture was administered *per os*. Peroxid and other antiseptic treatment was given the nasal passages. On the fifth day the membranes were shrunken and black and the nose bled freely. He died on the ninth day. Antitoxin had been used about every sixteen hours for several days. In this case it failed to benefit. The author of the paper related the history of another case, that of a girl 5 years old who had been about three weeks sick with measles before he was called. The nose and pharynx were filled with pseudo-membrane. Fifteen hundred units were injected, repeated again in twelve hours and again on third day. On the fourth day stenosis of larynx was so great that the patient became suffocated. The doctor having nothing else at hand, inserted a catheter into the larynx and was gratified to see the patient begin to revive. In forty minutes the child became conscious and began vomiting. He removed the catheter, when she immediately vomited up a large mass of membrane. She went on to complete recovery. In none of his cases did he find any untoward effect from the use of the antitoxin, and in all but the few cases mentioned the injection was followed by a very noticeable change for the better in a few hours. The doctor uses the iron mixture in all cases as adjunct to the antitoxin and washes out the nares. Dr. Gordon gave the history of a case of puerperal eclampsia after childbirth. He had been called hastily to see the case and found a doctor (?) in attendance, who he afterward learned belonged to the school of Christian science healers. The woman was in convulsions, which had been so severe that the right arm had been dislocated at the shoulder. The Christian science gentleman sat there looking at his patient quite unconcernedly without making any other attempt than that possibly of silent prayer to relieve the spasms. Dr. Gordon immediately used chloroform, morphin and veratrum viride. As soon as possible he reduced the dislocation. The woman made a good recovery.

THE DETROIT MEDICAL AND LIBRARY ASSOCIATION at its regular meeting Monday, April 26, listened to an interesting paper by Dr. F. L. Newman, entitled, "Incontinence of Urine in an Adult, with Report of a Case." In presenting his paper the doctor lamented the fact that for the last ten years there had only been one or two papers on this important subject in all of the leading medical journals of our country. He touched particularly upon incontinence of urine in young girls, commenting upon the treatment, taking in electrolysis, hygiene, massage and the treatment with different drugs. In speaking of the surgical treatment he noted the stretching of the urethra and the different operations upon the clitoris. He cited different cases which had been under treatment for one year and longer by the different methods. The electrolysis had been carried out with great thoroughness, locally in contact with the urethra or per vaginal route. He described one case, as a typical example of several cases he had seen and told of what treatment had been used, the whole line of medical and some surgical procedures. In conclusion, the author, while not offering any line of treatment himself, said that the profession at large was not able to cope successfully with this difficulty: that most cases of nocturnal incontinence are due to the hypertonicity of the urethra muscle, and in the variety where there is an atonic condition the treatment is least promising.

THE STATE OF MICHIGAN now has another law added to its list of "medical" laws. The "osteopathy" bill was introduced by Senator Barnum of Grand Rapids, Feb. 24, 1897, taken up March 18, referred to the committee on public health, reported by the committee March 19 and has become a law, being signed by the Governor the day after it passed the House of Representatives. In the Senate the bill passed by almost a unanimous vote. In the House the vote was 73 in favor, 0 against. The text of the bill is as follows:

A Bill regulating and licensing the practice of osteopathy in the State of Michigan.

SECTION 1.—The People of the State of Michigan enact, That any person having a diploma regularly issued by the American school of osteopathy of Kirksville, Mo., or any other legally chartered and regularly conducted school of osteopathy, who shall have been in personal attendance as student in such school for at least four terms of not less than five months each before graduation, shall be authorized to treat diseases of the human body according to such system without the use of medicine or surgery, after having filed such diplomas for record with the clerk of the county in which such person proposes to practice, and having filed with such clerk an affidavit that the diploma is genuine, and that he or she is the person to whom the same was issued, and that all provisions of this act were fully complied with before the issuing of such diploma; whereupon the clerk shall record such diploma in a book to be provided by him for that purpose, and shall indorse upon such diploma the date of filing and recording the same, for which he shall receive from such person a fee of one dollar. SECTION 2. Any person who shall practice or pretend or attempt to practice the system, method or science of osteopathy in treating diseases of the human body within this State without having complied with the provisions of this act shall be deemed guilty of a misdemeanor, and upon conviction thereof, shall be fined in a sum of not less than fifty nor more than one hundred dollars for each offense: *Provided*, That nothing in this act shall be construed as prohibiting any legally authorized practitioner of medicine or surgery or any other person in this State from curing or relieving disease with or without drugs, or by any manipulation by which any disease may be cured or alleviated.

THE PUBLIC SERVICE.

Army Changes. Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from April 24 to 30, 1897.

Capt. Frank R. Keefer, Asst. Surgeon, U. S. A. (Washington Bks., D. C.), is granted leave of absence for four months and fifteen days, to take effect on or about May 27, 1897, with permission to go beyond sea.

Change of Address.

Anderson, B. C., from Galesburg to 502 Seventh St., Rockford, Ill.
Bennett, Alice, from Thomaville, Ga., to Wrentham, Mass.
Bean, W. B., from Latour to LaGrange, Ark.
Current, O. E., from Albany to Farmland, Ind.
Cool, R. H., from Oakland to 300 Stockton St., San Francisco, Cal.
Cook, J. F. D., from Chicago, Ill., to Doland, S. Dak.
Crawford, S. K., from 471 S. Paulina St. to 440 S. Hermitage Av., Chicago, Ill.
Dental Review, from 66 Madison St. to 96 State St., Chicago, Ill.
De Long, W. H., from Emporia, Fla., to Emporium, Pa.
Elmer, E. O., from 61 Francis Av. to 641 Park St., Hartford, Conn.
Ferdenthal, W., from 943 to 1003 Madison Av., New York, N. Y.
Gerhard, G. S., from Phoenix, Ariz., to Ardmore, Pa.
Gapen, Clarke, from Kankakee to 641 Boulevard Pl., Chicago, Ill.
Krausgrill, D., from Terre Haute to Chesterton, Ind.
May, L. R., from 235 State St. to 6605 Stewart Av., Chicago, Ill.
Pry, E. T., from Douglas to Pine Bluff, Ark.
Perkins, D. S., from 711 Genesee Av. to 1273 Euclid Av., Cleveland, Ohio.
Potts, C. N., from Colorado Springs to Silverton, Colo.
Scates, D. W., from Waco to Waxahachie, Texas.
Todd, F. Walton, from Camp Capitola to Occidental Hotel, San Francisco, Cal.
Watson, F. W., from Tiptonville to Union City, Tenn.

The Journal of the American Medical Association

VOL. XXVIII.

CHICAGO, ILL., MAY 15, 1897.

No. 20.

ADDRESSES.

TENDENCIES IN MEDICINE.

The President's Address to the Association of American Physicians,
delivered at Washington, D. C., May 4, 1897.

BY J. M. DA COSTA, M.D., LL.D.

PHILADELPHIA.

It is expected of the President of your Association that he offer some remarks as introductory to the scientific papers that are to occupy your attention, and every presiding officer has done so, expressing himself on subjects for some time in his mind or to which he has been recently giving heed. Thus, diversified and excellent addresses have been made, some treating of medicine and its aims in a broad philosophical spirit; some reviewing its achievements; others giving most erudite and valuable historical information. In my turn I ask that you will indulge me if I present a few thoughts on what seem to me in our science the best tendencies of the day, as well as on certain causes that, with all the wonderful work being done, and with the immense energy and industry of the devoted laborers in four continents, retard its still broader and steadier development.

The greatest advance of our time—it seems trite to mention it to such an assembly—is the ardent study of the causation of disease. Students have speculated in all ages on the causes of disease; but these have been, for the most part, half-hearted speculations, made so by the feeling of impossibility of reaching a conclusion, or dogmatic assertions that, believed in for a time, soon became of interest only to the curious searchers for fragments on the shelving beach of science. Now, the recognition of minute organisms, their study, their artificial culture and modes of growth, their secretions, their chemical characters, their likes, their antagonisms, have let us into the secrets of another world and are showing us the way in which infective maladies originate and the laws they obey. We are looking for infection in every disease; we are often keenly pursuing it where it probably does not exist; at all events, not in the shape of bacteria, which in our day we accept as a term almost synonymous with infection. A sense of causation, formerly deficient, has been replaced by a most acute sense, and by a desire for unrelenting search. What is still greatly needed is, I think, an appreciation of how infection may light up slow processes and lead to structural complications, such as are found, for instance, in the exanthemata. We have also much to learn of bacteria that exist normally becoming abnormal in certain perverted conditions, either in manifold growth, as happens with the bacillus coli communis, or in character. What we consider the cause may thus be only the consequence of disease. The soil and its forces, too, are to be studied and critically examined.

But the power of this little, invisible world is

mighty. It is told of Napoleon that he could never understand the fame of Cuvier. He spoke of him, with something like contempt, as only occupied with small things. Yet smaller things conquered even him, the great conquerer. It was the plague bacillus, not Sir Sidney Smith, that compelled him finally to leave Syria and give up his dream of subduing the East like another Alexander.

Other than mere bacteriologic work forms a most valuable part of the contribution of the laboratory to the investigation of disease, and in the last decade has placed this investigation on a much higher plane. The microscopic and chemic examinations of the secretions and excretions and of the blood have become our daily duty. The chemic examinations, which, dealing, as they may be made to do, with the constantly varying problems of life in disease, have been temporarily overshadowed by the ardor of bacteriologic research, will, with widening fields, resume their former prominence. The time is indeed at hand in which, without the ready access to a laboratory manned by experts in all these lines, or the association with a trained laboratory assistant, no physician can do his patients, himself, or his science justice.

Closely connected with the laboratory investigation of disease, especially with its chemic investigation, is the study of the effects of the products generated by decomposition of albuminous matter, producing, when developed in the dead body, the substances known as ptomaines, when in the living body as leukomains. The recognition of these agents, so frequently poisonous, is explaining many obscure processes, is leading to new and close scrutiny of others and to search after means of neutralizing their toxic influence. It is with pride that this Association can view the history of this branch of research, for the fruits it has yielded have been largely gathered by the efforts of some of its own members.

Another of the best results of the achievements of our time is seen in the effacement of the strict division between medicine and surgery, or rather in the recognition that there are no lines separating them, but lines becoming continuous, on which joint action proceeds. We see this in the whole clinical history of appendicitis and its progressive unfolding; the more the medical part is studied and rendered precise, the more exact become the indications for operation and the appreciation of the chances of this. The same may be said of abscess and of tubercle of the kidney; of the investigations of the character of effusions into pleural, or pericardial, or peritoneal cavity; and of many other well-known conditions that surgeons and physicians are now studying together. This new tendency is sure to counteract not only the excessive specialism of our day, but to give us once more broader physicians and surgeons, taking the keenest interest in each other's work.

One of the greatest improvements in our generation

is in the much better appreciation and larger use of hygienic means, of systematic exercise, of baths, of regulated rest, of out-door life. Then, too, when medicines are given they are much more generally used singly, with a view to their direct effect, and not in excessive combination. Moreover, the substitution of extracts and of active principles for many of the nauseous drugs has taken away the terror and disgust with which medicines were regarded. It is, from a pharmaceutical point of view, at least, no longer a punishment to be ill. The satire of Molière is lost to the playgoers of our generation. The highly appreciated answer of the Bachelor of Medicine, when examined for his doctor's degree, that the remedies are always "Clysterium donare, postea seignare, ensuite purgare," would fall at present on totally unsympathetic ears; for now there are delightful capsules and triturates, and pills of esthetic colors—"dear little pink pills," as I have heard them called, though the dear little pills happened to contain strychnin. And the boy of the period is not tempted to view an open window as the only means of getting rid of the hated bottle; he may, indeed, want to take too much of it, because with all its potency, it is sweet and pleasant.

The tendency of our time is to endeavor to overcome disease, and not merely to observe and palliate its ravages. We are going back to the doctrines of our forefathers, abandoned for a time because, with an expanding knowledge from the study of pathology, the means they possessed were found to be, for the most part, totally inadequate. Thus there was a period of nihilism and expectancy in therapeutics. But so-called rational expectancy is but a confession of impotency. Now the tendency is once more aggressive. We are trying directly to choke or to subvert morbid action, and doing this partly through the old transmitted remedies of former generations, but employed with a better understanding of their real qualities, partly by new agents furnished by chemistry and by constant research in other fields. Of the former, the freer and more scientific administration of digitalis may be taken as an illustration; and the use of mercury, though in a different manner, is infinitely more prevalent than it was some years ago. To bleeding, too, I, for one, believe that we shall return; only it will not be the mere abstraction of blood perverted by disease, but there will be, with this, immediate attempts at the reconstruction of the blood by supplying it with the proper saline fluid and other ingredients. In the second class, the bromids, chloral, the nitrites and nitroglycerin are prominent, as is a whole group of antiseptic agents. Many of these—it is especially true of the nitrites—have come to us from the physiologic laboratory. One of the most interesting attempts at radical therapeutics is the endeavor to counteract the bacteria of disease by substances that form in the body which neutralize their toxic products. This antoxin treatment is brilliant and hopeful, and is being tried in many affections, preëminently in diphtheria, in tetanus and in erysipelas. It can not be said that as yet it has led to any great results, though the evidence is decidedly in its favor in diphtheria. It seems scarcely worth while to push it in erysipelas—at least in erysipelas that the physician sees—for the mortality in this is, under any treatment, but very slight. How valuable the antitoxins will prove as preventives remains also to be solved. More productive thus far has been the use of attenuated virus, as, for instance, in Pasteur's

treatment of hydrophobia; the influence in cholera, in yellow fever, in bubonic plague, is now under keen observation. The effects on tuberculosis must be taken thus far as the expression of hope rather than of fact. The next decade will prove whether the X-rays, which are making such wonderful additions to diagnosis, will also have their therapeutic triumphs. In it, too, we may look for some striking developments of suggestion, not only as explaining mental and morbid processes—what more extraordinary and thought-starting, for instance, than the recently tested production of special cutaneous affections by it?—but as a harnessed therapeutic force. All this is in the line of present investigation, and there will be much disappointment and wasted labor in particular points, but it is not too sanguine to believe that there will be also a solid outcome which will immensely advance scientific medicine.

There are, with all these tendencies of our day that work for good, some which, whether growing out of them or whether the exaggeration of old hindrances, have to be, in the interest of true science, strenuously guarded against. One that is very evident is the tendency to immediate generalization. The discovery of every new bacterium is supposed to instantly revolutionize the science of medicine and is announced with all the air of the unexpectedness of genius. Fortunately or unfortunately, one may be discovered every day, and a man may thus find himself with three hundred and sixty-five opinions on the tenets of his art in the course of the year; but this would not daunt the enthusiasm of the insatiate generalizer:

"Ten thousand great ideas filled his mind,

But with the clouds they fled, and left no trace behind."

Fixity of opinion in medicine is a virtue, if the mind remain open to proof and be in sympathy with advance; and it is this freshness of mind, joined to good judgment, through which is best estimated the true value of the many facts constantly discovered in an advancing science like ours. Clinical medicine, indeed, must continue to be the final court of appeal for the purposes of the practitioner of medicine. Before the court will come and be listened to with sympathetic interest, as eloquent advocates, those who are presenting the claims of special studies. But these must be well supported and judged in their bearing on the whole before new laws are laid down. And we see that the more we investigate and the more we know the more will old questions assume different aspect, the more they will have to be retested; there is no finality—there can be none—in medicine. When the last word is spoken we shall have a perfect science; until then there must remain for us a certain amount of empiricism, especially in treatment.

There is no doubt that, considering the amount of work done and recorded, medicine—especially clinical medicine—would be much more advanced if the records were differently made, and were not so vague as they often are. What is more provoking than to see constantly such loose statements as this: "The examination was negative." Negative as to what? If applied to the action of an organ, as to what part of its action? If to secretions, to what part of their constituents? How much easier to say, even if it have been an incomplete examination, for what exactly they were investigated, and how much more certain to be of use for comparison in similar cases. Worse still is it with the records of treatment. This is an ever-recurring expression: "The usual treatment was

employed." I saw this in a recent volume of *Transactions* with reference to the congestion of the lungs in typhoid fever. What is meant? Is there such a thing as a fixed treatment for it the world over? It might mean dry cups to some; ammonia, turpentine, digitalis, or yet different things to others. Then the utter absence of mention of doses makes it impossible to say whether any remedy was fully tested, or to compare its action when given in small or in large quantities. For very many purposes records, as published, are valueless; in truth, they impede progress, and a little care would make it otherwise.

Then there are records which, made even to the full limit of industrious exhaustion, are so badly and confusedly presented that they bury themselves from the start. A little more time spent on their expression might make them absolute and convincing. It would be, indeed, well if in all our professional literature there were something more of the learning of the scholar and the clearness of the literary artist; men who followed the master, Harvey, in other points besides profound and productive research. A few more Watsons and Pagets, Trousseaus and Hyrtls would make knowledge easier to obtain, more constantly with us, forming much more a part of our daily life and application. It is true that if, in our science, we must choose between profound inquiry and its clear enunciation, we shall choose the former. It is a pity, and it is unnecessary, that there should be any occasion for a choice. The French, with their lucidness in scientific matters, set all other nations an example. The countrymen of Goethe, foremost in investigation, following his avowed contemptuous indifference to style, are the great sinners against clearness and vivid expression. They evidently believe in the reverse of the thought with which Johnson excused the inaccuracies in Goldsmith's "Animated Nature," that, if he once began to make experiments, life would be too short for him to get his book written.

One more tendency of the day let me notice, which is not for good, and undoubtedly retards progress. It is the excessive publication of half-knowledge, of doubtful fact and of loose inquiry. The propensity for authorship is an old disease, but it has assumed a development commensurate with the prodigious development of everything else in the age in which we live. It is harmless in journalism, less so in literature, but positively dangerous in science; for it fills this with immature or false observation, and takes the time of others to remove the obstructions placed in the stream of knowledge. With some, want of sufficient training leads to it and absence of inquiry into what has been already ascertained; in others, in proceeds from a girl-like genius that, in place of letter-writing, pours itself out in medical periodicals, fascinated by penning sentences full of pseudo-scientific commonplace. It is far from being a disease only of the untried or ignorant; famed workers, too, may succumb to it, listening, perhaps, to the entreaties of friendly and sleepless editors. Who knows that it is not, after all, a physiologic function, giving full play to brain-centers in very rare use—centers situated in what Oliver Wendell Holmes has called the idiotic area of the brain.

But whatever the retarding influences, they are not to any extent checking the onward course of medicine. The numerous inquiries, the keen experimentation and close research, the general thoughtfulness,

are developing a resistless scientific method; resistless because it is true. Medicine is no longer an art founded only upon empirical observation, no longer a purely deductive science; it is becoming also an inductive one. The great body of the community is touched with friendly interest in watching its growth. With the advance of the scientific method special systems are crumbling; future ones are impossible. There can be no more pathies; the general intelligence will prevent it; for educated men are recognizing the broad base on which medicine is resting, and that truth is sought in it by the same means that are used in physics and in the highest development of other sciences. In our midst with all this, conviction is becoming clearer, purpose waxing more resolute. We see, without pang, castles which have crowned rocks being turned into dismantled memories, because we know that something stronger, that will defy all time, will stand ultimately on the old commanding sites. Everyone of us must work until he discovers in his work his true self, and then aid with what he finds he can do best in helping all. With every one of us there is a mission to assist the general advance.

THE ANTISEPTIC TREATMENT AND THE LIMITATION OF CLIMATIC TREAT- MENT OF PULMONARY TUBERCULOSIS.

President's Address Delivered at the Meeting of the American Climatological Association, WASHINGTON, D. C., May 4, 1897.

BY E. FLETCHER INGALS, M.D.

CHICAGO.

Gentlemen of the American Climatological Association:—In assuming the duties of your presiding officer, I again thank you for the high honor which you have conferred upon me and wish to congratulate you upon the status of this Association. From the origin of this Association to the present time it has steadily increased in numbers and grown in influence until at present its members are scattered throughout the length and breadth of this land and exert an untold influence for the advancement of science, the alleviation of suffering and the prolongation of human life. In 1884 this Association numbered forty-two members. Since that time we have had enrolled, all told, 191 names. Of these, ten have been dropped, thirty-five have resigned and thirty-two have finished their work. During the year just passed we have been called upon to mourn the loss of one of our fellows, Dr. Jacob Reed, of Colorado Springs. Dr. Reed had lived in Colorado Springs over twenty years and was much respected and beloved by his acquaintances. He was a man of strong individuality and an active, earnest physician who will be greatly missed. Today we number 114 active members and the council will present several new names for your consideration.

When this Association was first organized the climatological possibilities of the United States were almost unknown; since then the industry and enthusiasm of our members, aided much by the accurate data obtained by the United States Weather Bureau, has demonstrated the fact that within our borders may be found every variety of climate possessed of value in the healing or prevention of disease. Twenty-five years ago there were a few more or less noted health resorts in the country, where invalids repaired of their

own volition, or were occasionally sent by the few physicians familiar with the locality; but numerous places where invalids may now obtain satisfactory accommodations in the best atmospheric conditions were unknown. That the members of our Association have done much in searching out the more valuable resorts and in securing suitable accommodations for patients can not be gainsaid, and that we have correspondingly added our share to the great work of prolonging human life and mitigating suffering, no one can doubt, but that very much is yet to be learned, that the deductions from our observations are still in many instances crude, and that we have often been too enthusiastic in our hopes for individual localities, can not be denied; yet, as a rule, our members have been reasonably conservative in their estimates of the value of climate and have patiently and conscientiously studied and labored for the advancement of science and the benefit of their patients.

Over-estimation of the value of climate, as well as of drugs, often occurs through inexperience or over-enthusiasm of the physician, and usually the most laudatory articles are from the pens of those having comparatively little information. We all grow more conservative as the years go by and most of us learn that the deductions from some, even of our own, earlier observations are erroneous; therefore, it not infrequently happens that the careful physician finds himself unable to accept the conclusions even of one who may have been painstaking and conscientious in his work. The physician must needs wait two or three years for any climate or any medicine to be tested before he can form a fair estimate of its value. It must be remembered that the varying conditions affecting limited observations may necessarily militate much against the conclusions drawn from them and, therefore, one who is slow to accept new hypotheses should not at once be put down among ancient geologic specimens.

The purpose of this paper is not to build up new theories nor yet as an iconoclast to tear down where we are unable to replace, but to draw the attention of this Association and of those who may read our proceedings, to a few important facts which seem established by experience.

In the title of this paper I have referred to the antiseptic treatment of pulmonary tuberculosis which, in the light of our present knowledge of the origin of the disease, seems to me to have a specific tendency to check its progress, though I would in no way minimize the importance of tonic and supporting treatment and of good hygienic surroundings.

Since the Koch bacillus was recognized as the ultimate cause, that under favorable conditions, produces tuberculosis, there have been unceasing experimentation and careful clinical observation to find some agent or agents that would destroy the microbes without injury to the tissues upon which they rest or within which they may be imbedded. Contemplating this long line of experiments and scrutinizing the vast array of statistics, we are forced to admit that it has not been demonstrated that any remedy, or any class of remedies, has the power to destroy this bacillus when ensconced in the human body, with any degree of certainty; yet when we carefully analyze the various methods of treatment that have been more or less successful in checking the progress of the disease, we nearly always find that they have been of a distinctly antiseptic character.

We must remember that, although the bacillus is the ultimate cause of tuberculosis, it is innocuous excepting under favorable conditions, and therefore those supporting measures that enable the tissues to pen up or to bar out this pestilential microbe must receive a large part of the credit for the successful management of any case. The late Austin Flint, in his work on phthisis, stated that very many of the phthisical patients that had recovered were those who had refused or neglected all treatment. This must not be taken as advice to those suffering from tuberculosis to rely upon mental influences and reject the assistance of science, for it is reasonable to suppose that the majority of those who have recovered without any assistance have done so from the sheer resisting force of their vital processes, and that many of those who did not recover relied too long upon the *vis medicatrix nature*, only to find that it failed at the end, while judicious treatment might have saved their lives.

The fact referred to by Austin Flint reminds us that we must be extremely cautious in attributing to any particular remedy the benefit that may occur in any individual patient, or in any series of patients, with consumption; yet typical cases that have been cured, and have remained well under conditions where the majority of patients would have steadily grown worse and died, may justify us in believing that the remedies used were of some value and that a more perfect application of the same may ultimately lead to even better results. I know, and I wish that the general profession could realize as it should, that no case of consumption can be classed among the cured in eighteen or twenty months and that even many who live for years can never properly be called cured. Nevertheless, I hope to show by a few briefly reported cases that betterment sufficient to commonly be termed a cure may often be obtained from antiseptic treatment. From my own experience I fully believe that aside from tonic and nutritive agents, antiseptics are the only medicines that have any power in checking the progress of tuberculosis, and I as firmly believe that when they are thoroughly used so as to bring the system as nearly as possible to a point of saturation they are of great value in a large percentage of cases, if used in the early stage of the disease.

The first case to which I wish to call attention was treated by the Shurly method and reported, with a series of others, to this Association several years ago, but it has acquired additional interest from the time that has elapsed since that treatment, and from the good health the patient now enjoys, though he remains in the same surroundings as when the disease was contracted. In this instance the patient greatly improved under the use of iodine and, later, oil of cloves, with the occasional use of the extract of hyoscyamus, nux vomica and quinin for cough, appetite and digestion. The chief benefit appeared to come from the antiseptics.

Case 1.—V. W. J., aged 29, clerk, came to me in February, 1891, complaining of cough and expectoration of three or four weeks' duration, and stating that he had not been well for four or five months. He was able to attend to business, had not lost much flesh, but the pulse was 96 and the temperature 99. He was raising at the time about two ounces of muco-pus daily and had had two moderate hemorrhages in the past few months. There was not hereditary predisposition to phthisis. Physical examination showed diminished motion with high-pitched respiratory sounds over the left apex as low as the second rib, and indistinct subcrepitant rales. The microscope revealed many tubercle bacilli in the sputum. I instituted the

Shurly treatment, injecting from seven to fifteen of the solution of iodine every two or three days. I gave also a bitter tonic. The injections were continued in this way for about four weeks and subsequently once a week for six or eight weeks longer. At the end of eight weeks it was noted that he was doing well, the weight was normal and there was very little expectoration. Subsequently the patient was seen at intervals varying from one or two weeks to three or four months, or a year or more, at times when he had taken cold, or had some special cause of debility, but he was not kept upon any continuous treatment. Two years after he first began treatment, on account of a renewed cold with increased cough, he was given strychnia, with other bitter tonics, and the oil of cloves as an antiseptic. He took the oil of cloves in twenty-five drop doses for about three months, beginning it at a time when he went South for a vacation of five or six weeks and continuing it six weeks after his return, by which time he had gained fifteen pounds and felt so well that he discontinued all treatment. On two other occasions, when he became run down and the disease seemed to be lighting up afresh, he took the oil of cloves with the result, as he believes, of speedily checking the trouble.

Other remedies consisted of tonics, digestive agents and occasionally hyoscyamus as needed. He was out of the city on two or three occasions, but only for a short time. In January, 1897, when he returned to me on account of a slight cold, he was looking very well, and had had no symptom of tuberculosis for a long time.

Case 2.—The following case was also reported at the meeting just referred to, and as the patient is still in very good health a brief résumé of the history is of interest as it apparently shows good results from the antiseptic use of iodine, although the improvement has been mainly due to climate. I first saw Mrs. W. B. N. in April, 1888, when it was found that consolidation of the left apex extended as low as the third rib; subcrepitan râles extending considerably lower, with a few subcrepitan râles over the upper part of the right apex. She was given tonics and supporting treatment together with inhalations of iodine, under which she steadily improved until the latter part of gestation in the spring of the following year. Shortly afterward she began to decline and steadily failed until in August of the same year when the signs of phthisis had much increased and there was a large vomica in the left lung. She was extremely weak and anemic and her life was despaired of. She was so ill that it seemed impossible to obtain benefit by change of climate, but her friends insisted upon it and took her to California to an elevation of 2,500 feet. During most of her illness she had suffered much from disturbance of the digestive organs, and after arriving in California had what appeared to be an attack of tubercular meningitis; however, she gradually recovered and subsequently went for a few months to an altitude of 3,500 feet, in Texas, and later on to Las Vegas where she remained for a couple of months. At the time she went to Las Vegas I was using iodine according to Shurly's method and at my suggestion her physicians there placed her upon it. During about two months that she remained under the treatment she gained very rapidly and the expectoration greatly diminished. She then went to Colorado Springs where she is still living in comfortable health, though fibrosis has extended well through the left lung. When I first examined the sputum in 1895, it contained many tubercle bacilli. In this case climate undoubtedly should be given the credit for nearly all of the improvement, but although life was saved under the most unpromising circumstances by the antiseptic air of a good climate, yet two periods of especially marked improvement were coincident with the use of iodine, and the improvement was so great that I feel justified in believing that it was aided much by the antiseptic.

Case 3.—In the following case no other treatment was employed than the oil of cloves, which appeared to cause great improvement, but I saw the patient only twice and am unable to ascertain the subsequent history. Mrs. X., about 35 years of age, came to me about two years ago with well marked symptoms and signs of the early stage of phthisis. I ordered for her the oil of cloves in doses ranging from five to twenty-five drops five times daily, and I did not see her again for three or four months. She then returned having lost all of the symptoms of tuberculosis and many of the physical signs. She said she felt perfectly well. The improvement in this instance seemed entirely due to the antiseptic treatment, and the result might safely be called a cure if she still maintains the condition in which I last saw her.

Case 4.—The following case had the benefit of both internal antiseptics and of an antiseptic atmosphere.

Dr. G. C. A., aged 26, had been in good health previous to consulting me on August 18, 1894. He had lost one brother

and two uncles from tuberculosis. Two months before seeing me he had a hemorrhage from the lungs and his temperature ran up to 103. At the time he consulted me his appetite and digestion were good but he had lost twenty pounds of flesh and was having a daily temperature of 100.5 to 103 F. He was coughing considerably and expectorating about one and one-half ounces of muco-pus daily. I found slight dulness at the left apex, low as second rib, with feeble respiration and subcrepitan râles extending down to the fourth rib. Microscopic examination showed many tubercle bacilli in the sputum. Antiseptics were ordered but when I saw him a few weeks later he looked so much worse that I was not at all surprised in a few months to hear the report of his death. However, the report proved untrue, for in November of the same year he had gone to Montana to an altitude of about four thousand feet, where he rapidly improved, gaining fifteen pounds within two months; but when the weather became bad he caught cold and began to fail. Shortly after he went to New Mexico where he again improved. During all this time he had been using guaiacol applied to the surface, and creosote internally. Soon after he arrived in Las Vegas, January, 1896, his cough disappeared and with it the pains which he had formerly suffered in the chest. He soon found that his respiratory capacity was increasing and ere long the difference in the circumference of the chest between inspiration and expiration amounted to five inches and he had gained thirty-one pounds since going to a high altitude. He continued the guaiacol and creosote and also took cod liver oil alternating at times with syrup of the hypophosphites.

This patient is now living in Denver in good health. In this case the almost continuous use of antiseptics was combined with the benefits of a high altitude and dry atmosphere, but the patient attributes much of the benefit to the antiseptics, and I have no doubt he is correct.

Case 5.—In the following case the improvement was apparently due to tonics and alcoholic stimulants. Mrs. D. K. M., aged 25, came to me on Nov. 15, 1895, complaining of pain in the left lung of three months' duration, cough, afternoon fever, dyspnea and loss of strength. She had lost ten pounds in weight in three months. She expectorated a small quantity of thick whitish sputum and about a month previously had raised nearly half an ounce of blood. The pulse when I first took her was 88, temperature normal. There was dulness at the left apex as low as the first rib. Subcrepitan râles numerous at the apex in ordinary respiration and heard all over the left lung on deep breathing. Respiratory sounds were diminished in intensity over the upper half of the lung. Many tubercle bacilli were found in the sputum. She was given moderate doses of nux vomica, hyoscyamus, quinin and carbonate of guaiacol in capsules. She continued these remedies for a year, but it does not appear to me that the doses of guaiacol were large enough to in any way account for her improvement. During this time she took a small glass of whisky before each meal and at bed time, and probably from this cause gained fifteen pounds. A year later, February, 1897, she had gained a few pounds more, was much stronger, being able to walk several blocks a day, coughed very little indeed and that only to clear the throat. Her pulse was reported to be from 84 to 88, but the temperature record I could not obtain. She had a splendid appetite and appeared practically well. This patient went to Manitou, Colo., for ten weeks shortly after she began the treatment and subsequently spent a few weeks in Kansas City, but she was steadily improving before she made these trips. She still takes the whisky occasionally.

Case 6.—The following case was uniformly benefited by antiseptic medicines although he also had the advantage of a good climate part of the time. Mr. A. G. A., aged 39, came to me first in September, 1891, complaining of hacking and clearing of the throat for the last three years and hoarseness for the last three weeks and some pain on swallowing. He had lost weight and strength and had experienced five or six hemorrhages from the lungs four months previously amounting to eight or twelve ounces each, as nearly as he could ascertain. He had a poor appetite, and had lost about ten pounds in weight and had suffered from dyspnea upon exertion. His pulse was 72 and temperature normal when I first saw him. The epiglottis and arytenoids were swollen 30 per cent., and the vocal cords considerably congested. There were no distinct sounds over the lungs upon percussion, but there was broncho-vesicular breathing with a few subcrepitan râles extending as low as the second rib in front and to the seventh rib behind. Microscopic examination showed a large number of tubercle bacilli in the sputum. I ordered for him the chlorid of calcium and maltine with hypophosphites, with small doses of cannabis indica and hyoscyamus to relieve cough and nux vomica and quinin to improve the appetite. He went to Colorado where he remained for five months. During

this time and until a month later he continued to take the medicines first ordered. He then called at my office and reported that he had not gained much in weight but had a good appetite and was very well. At this time I ordered for him the oil of cloves in doses of from five to fifteen minims to be taken five times daily. He returned to his home in Northern Wisconsin, where he remained until the following December. He then went again to Colorado for four months and from there returned to his home where he has remained ever since. I first gave him the oil of cloves May 21, 1892, and he took it for sixteen months, half of the time in doses of forty-five drops a day and the remainder of the time in doses of seventy-five drops daily. During this time he had gained about twenty pounds in weight, which he retained until the latter part of August, 1896, when he had another hemorrhage followed by severe gastric disturbance which continued for many weeks. During this attack he lost twenty pounds. In January, 1896, I ordered for him the carbonate of creasote which he took for about sixty days and then went back to the oil of cloves, which he continued to the first of March, 1897, since which time he has taken nothing. He has since then had an attack that he calls grippé and has lost ten pounds more. His appetite is not very good, but his pulse is only 84, temperature normal and he says he feels in fair general health and strength, and has at present very little cough and expectoration. He tells me that he has always improved when taking the oil of cloves, and he attributes most of the benefit that he has received to that remedy.

Case 7.—In the following case the improvement may be attributed to alcoholic stimulants alone. Mr. D. W., aged 47, came to me November, 1894, complaining of having taken cold and having expectorated about five or six ounces of blood in the last few days. He had been feeling poorly for about two weeks. There was a hereditary history of consumption on both sides of the family and he had lost two brothers and two sisters with the disease. His weight was normal, pulse 132, temperature 99.6. Physical examination showed consolidation of the left apex with not very well defined broncho-vesicular breathing and a number of subcrepitant râles. Many tubercle bacilli were found in the sputum. The oil of cloves was ordered for the patient, together with nux vomica, quinin and carbonate of guaiacol, but he appears to have discontinued all treatment after a week or two excepting three to five good drinks of whisky daily. Two years later when I saw him he had gained twenty pounds, the pulse was 102, the temperature normal and there were very slight physical signs of disease. He told me that he felt as well as he ever had in his life. In this instance I am inclined to attribute the improvement to the nutritive and antiseptic properties of the alcohol contained in the whisky. In health the bactericidal properties of the blood are able to destroy the bacilli with which we are constantly being infected; but in the depressed state accompanying actual pulmonary tuberculosis these elements are more or less deficient. If in this condition some antiseptic be introduced in small or larger quantity, according to the condition of the blood, we should be able to make up for this deficiency. If there is any ground for this belief, alcohol is exhaled so freely that it does not seem unreasonable to attribute to it an antiseptic influence in phthisis. The patient did not go out of the city and indeed made no change whatever in his residence or business excepting that he was obliged to take more rest because of great weakness.

Case 8.—The following history illustrates the fortunate outcome of a case of tuberculosis without the aid of either antiseptic remedies or antiseptic atmosphere. Although it appeared most unpromising in the beginning, it is introduced with the hope of rendering the reader more conservative in estimating the value of remedies and climates. Mrs. L. B. J., aged 31, came to me in February, 1891, complaining of trouble with the lungs of three years' duration, though she had been worse during the preceding six weeks. There had been consumption on her father's side of the family and she had suffered from inflammatory rheumatism five different winters several years ago. She had a very troublesome cough, especially in the morning, and expectorated about five drams of muco-pus during the day, containing some blood at times. She weighed 147, having lost about five pounds. The pulse was 88 and regular, the temperature 100. She had a good appetite but poor digestion. Physical examination revealed dulness over the upper part of the left lung with subcrepitant râles as low as the seventh interspace and the microscope showed many tubercle bacilli in the sputum. She was then ordered moderate doses of cannabis indica and hyoscyamus to relieve cough, nux vomica for her appetite, creasote in small doses and papain for the digestion. She was given also a few injections of the chlorid of gold and soda and of iodine according to Shurly's method, but she objected to it on account of the pain. She

continued internal remedies similar to those first ordered much of the time for about three months and subsequently I only saw her at irregular intervals of several months or a year or more. Four years after she first visited me there were still a great many tubercle bacilli in the scanty sputum, but she had gained flesh and to external appearance was in perfect health. Subcrepitant râles, which at times had been very numerous over the chest, had disappeared. I have not seen her for a couple of years, but my associate saw her upon the street in March of this year and reported that she appeared in excellent condition. After the first three months of treatment she took no remedies regularly, and she has not been out of Chicago for any length of time.

It is unnecessary to cite cases that have been relieved or cured by climatic treatment, because every one who has had much experience in the treatment of pulmonary tuberculosis must have observed many patients who were undoubtedly benefited by change of climate, yet in a large percentage of such cases it is impossible to estimate accurately the real cause of improvement. I have no doubt that in many instances the change of food, of scene and of other surroundings which might stimulate the process of nutrition, has as much to do with the favorable progress of a case as continued residence in a pure atmosphere. This was illustrated in the case of a gentleman who was for several years under my care in the latter part of the eighties suffering from pulmonary tuberculosis, but who without any change of climate maintained a good degree of health that allowed him to attend to business with only now and then a few days' confinement to the house; but at the end of three or four years he began to have hectic fever, to emaciate rapidly and to cough excessively. There were present also numerous pulmonary signs indicating rapid progress of the disease in the lungs. At the time his financial condition was such that he felt unable to go to a different climate, but he obtained the opportunity of making a short trip of only about three weeks to Dakota, from which he returned very much improved. The improvement steadily continued, and in the course of a few weeks more he was as well as he had been for a long time. Subsequently he continued at his business for about four years, then again began to decline and went to the southwest into a dry atmosphere and high altitude, where he again improved for a time, but at the end of a few months he died suddenly from hemorrhage. In this instance certainly very little could be attributed to the pure atmosphere, and we have every reason to believe that the improvement was like that of many other persons whom we every year see gain greatly in mental and physical vigor from short vacations.

If we concede that certain cases may be benefited by a simple change to agreeable scenes and surroundings, we must also admit that certain other cases, when placed in the best climate away from home and friends and under various depressing conditions, speedily grow worse and rapidly decline and die; whereas they might have lived for months, or possibly years, if they had remained at home. Another difficulty in estimating the value of climatic influences arises from the fact that some patients, when they go away from home, continue the same treatment which had been used previously, and therefore it would be unjust to ascribe all improvement to the climatic conditions. Many physicians in favored climates are accustomed to tell patients as soon as they arrive in the pure atmosphere to discontinue all previous treatment; but at the same time some physicians endeavor to impress upon the patient's mind the necessity of yielding

themselves to the climatic influences, with the aid of such remedies only as the exigencies of the physician may demand. I believe that in many cases such advice is most untimely, for if we admit that remedies do any good in unfavorable climates, we must also admit that the same remedies should aid in the restoration to health much more when the patient was placed amid favorable surroundings. I have known not a few who were doing comparatively well at home go to a favorable climate with the result of becoming immediately worse and rapidly declining to death. Some of these I fully believe might have lived much longer if they had not made the trip, and some of them I think might have continued to improve even more rapidly with the trip, if they had continued former remedies.

As I have elsewhere stated, I believe that, all told, about 33 per cent. of patients with pulmonary tuberculosis recover under ordinary conditions, and I think that patients sent early to a high altitude and dry atmosphere have their chances increased fully 50 per cent. This belief is based upon the well-known fact that the records of autopsies show that in 25 per cent. of bodies dying from other diseases than pulmonary tuberculosis, the previous existence of this disease is demonstrated in the apices of the lungs; also upon the oft-repeated statement that a large percentage of those sent early to a good climate recover; and further, upon my personal observation of many cases. After consolidation of the apex of the lung has extended below the third rib, by which time the second stage is generally fully established, I feel that I have ample reason for believing that from 15 to 30 per cent. may be greatly benefited by climate, although life is seldom prolonged more than five or six years. Even after breaking down of the lung tissue has begun, a few may have their lives considerably prolonged by suitable climate. I have no doubt, however, that in the latter part of the disease the fatal result is generally hastened by the fatigue and the mental and physical distress incident to the journey. The physician should carefully study not only the physical, but the social and financial conditions of his patient before recommending a change, and while it is not necessary to say it to the members of this Association, I wish to impress upon others that it is neither scientific nor kind to send patients with consumption indiscriminately to places from which we have simply heard favorable reports. As a rule, in the first stage a warm climate is most salutary, but it is not so important, providing an abundance of sunshine and a dry atmosphere are obtained, although many phthisical patients are better in a southern latitude in winter. It will be found that patients who feel best in winter are likely to be benefited by a comparatively cool climate, the others in a warmer temperature. In the first stages it is desirable, when there are no contraindications, that patients go to an altitude of from six to seven thousand feet, but this is not suitable for persons who are nervous to a marked degree or who have a high temperature, or who have pronounced cardiac disease, emphysema, or laryngeal complications. Laryngeal tuberculosis is generally markedly aggravated by high altitudes. Hemoptysis is not, as is often supposed, a contraindication to a sojourn in a high altitude. On the contrary, bleeding is often promptly checked by this change, and those who seldom or never have hemorrhages in a high altitude frequently experience them quickly upon return to a lower level. In the second

stage of the disease a high altitude is often beneficial, but we can not feel so certain of its results, therefore it is best to send the patient to an altitude of not more than two or three thousand feet, and if they do well, subsequently advise the higher level. A warm, moist atmosphere seldom seems to have any useful effect in prolonging the life of consumptive patients, though it undoubtedly adds to their comfort in certain instances by relieving the irritability of the bronchial mucous membrane. The majority of patients who are unable to take care of themselves seldom receive much benefit from a change of climate, but as a few of them do, the experiment is constantly made, more often, I think, by the friends than by the physician. Wherever practicable, even in the best cases, it would be desirable for friends to accompany the invalid, because we must not forget the necessity of maintaining the nutrition, not only by suitable food, but by cheerful environment foreign to those who, sick and lonesome, find themselves the prey of nostalgia. Before recommending a patient to change climate, we should inquire as carefully as practicable as to his disposition and social and financial condition. If he is unable to obtain the comforts and some of the luxuries of life away from home, it is generally unkind to recommend any change of climate, because the chances are greatly that it would do more harm than good. If he is despondent he should have a cheerful companion. If he is in constant terror from the bacilli floating in the atmosphere, or is depressed by the sight of sickness in others, he should be removed as far as possible from other invalids suffering from tuberculosis. Indeed, this would be a good rule in many cases, but it is hardly ever practicable, because as soon as a locality obtains a reputation in the cure of tuberculosis, many invalids are attracted thither. The physician must remember that he has a duty to others as well as to the patient, and that he must sometimes consider the healthy friends, or more particularly the widow and helpless children soon to be thrown upon the world. Hard-hearted as it may appear, the physician must then answer to his conscience whether it is right to advise the friends to make great sacrifices with the hope of prolonging the invalid's life for a few weeks or months. As a general rule, our duty is to the patient only, but this, like other general rules, is subject to many exceptions. Unhappily, it is only in the minority of cases that experts in the Eastern or Middle States are consulted as to the wisdom of a change of climate by the patients who come under their observation. The greater number come with their minds already made up to go somewhere, so that we can only guide them to the least objectionable place. This explains the fact often observed at health resorts, that the majority of patients sent away might better have been kept at home.

In conclusion, in addition to tonic, supporting and anodyne remedies various antiseptics appear to possess great value in the treatment of pulmonary tuberculosis, but in order to get good effects it is imperative that the system be as nearly saturated with them as possible. They should be given at first in small doses, but the amount should be steadily increased until the maximum dose is obtained, care being always taken not to disturb the digestive organs. For example, with the oil of cloves we may begin with five drops to be given in capsule from three to five times daily after each meal and in the middle of the forenoon and of the afternoon, the medicine always to be

followed by a glass of milk. The second day the dose should be six drops, the third seven drops, and so on, until a dose of twenty-five or thirty drops is given each time.

Creasote can seldom be given in sufficient quantity to have any material effect, because of the disturbance of the digestive organs which it is liable to cause and because of its coagulating effect upon all albuminoids. The same may be said of carbolic acid.

Carbonate of creasote is much more bland and may be given in doses of from five to sixty drops after each meal with great benefit.

Guaiacol may be given in much the same way as the oil of cloves, though in somewhat smaller doses, but it is usually less easily borne than the carbonate of creasote or oil of cloves and often can not be tolerated in sufficient quantity. The carbonate of guaiacol may be used in much the same way as guaiacol itself, but most patients seem unable to take it in sufficient doses.

Oil of cloves and carbonate of creasote are the most satisfactory antiseptics for internal use. Iodin may be used as recommended by Shurly with undoubted benefit, but it causes considerable pain and is open to the objection that it necessitates too constant attendance of the physician; it may also be used advantageously as an inhalant.

Patients should not be sent from home unless their financial and social condition is such as to render the journey and sojourn easy and agreeable.

In the first stage of the disease patients should as a rule go to a high altitude where the atmosphere is dry and as warm as practicable. In the second stage they should be sent to a medium altitude and in the advanced stage, if sent anywhere, it should be to a low altitude.

Patients who have been improving on any course of medication should not discontinue it upon going to a different climate, but, however valuable any remedy may appear, it should not be continued if it becomes clear that it is deranging the digestion.

When sojourning in a favorable climate the patient should be out of doors as much as practicable during the pleasant portion of the day, should avoid excessive heat, excessive cold and unusual fatigue.

Of anodynes to check cough hyoscyamus, camphor, cannabis indica, stramonium and conium are of the most value, because they can generally be taken in sufficient quantities without disturbing the digestion, whereas opiates are usually deleterious in whatever form they may be employed.

The majority of patients sent from home in the latter stages of pulmonary tuberculosis are injured by the journey and their lives correspondingly shortened, though in a small percentage very great benefit is obtained in a warm and very dry climate.

Sciatica Treated by Compression of the Sciatic Nerve.—Arullani has improved upon the digital compression practiced by Negro by substituting a double pad apparatus for the fingers. He has applied it to 40 patients: 2 were improved, 6 proved rebellious, but all the rest, 32, were cured. He recommends compression of the popliteal cavity besides the point where the sciatic nerve emerges in the thigh. The general condition of the patient and the location of the pain are better criteria for the success of the measure than electric tests or the duration of the trouble. For details of the Negro method, see the JOURNAL, Oct. 3, 1896, page 765.—*Gaz. d. Osp. e d. Clin.*, February 23.

THE MEDICO-LEGAL ASPECT OF FLOATING KIDNEY.

Read at the Third Annual Meeting of the American Academy of Railway Surgeons, held at Chicago, Ill., Sept. 23, 24, 25, 1896.

BY R. HARVEY REED, M.D.

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY AND CLINICAL SURGERY, OHIO MEDICAL UNIVERSITY; SURGEON TO PROTESTANT AND UNIVERSITY HOSPITALS; CHIEF SURGEON
C. S. & H. R.R. CO.
COLUMBUS, OHIO.

The rarity of a condition makes it all the more important from a medico-legal standpoint. Cases of frequent occurrence give greater opportunity for their study and consideration. Rare cases offer few precedents and afford but occasional opportunities for observation.

Less than a year ago, I was called to testify as an expert witness in one of these rare cases, which, so far as I am able to learn, has never had a precedent, but its importance impressed me so profoundly that I feel that I owe it to the medical as well as the legal profession to briefly consider it on this occasion. Without referring to names, dates or places, I shall simply state the facts in the case and then proceed to study them from a medico-legal standpoint.

A gentleman of middle age was injured in a railroad wreck which he claimed caused a floating kidney on his right side. Beyond this his personal injuries were comparatively slight. He presented his claim to the company, which did not deny its liability as to the cause of the accident in which he claimed to have been injured, but disclaimed the responsibility of having caused the existence of a floating kidney. The company's defense was based on the fact that the gentleman had, to their positive knowledge, been affected with a floating kidney for years prior to the accident. He had consulted eminent members of the medical profession, who confirmed this diagnosis. Surgeons of high repute were called to examine him after the accident, who found him unquestionably affected with the disease in question.

The claimant admitted having had a floating or movable kidney prior to the accident, but alleged that with the use of bandages and the palliative treatment he had received, he had fully recovered and at the time of the accident was perfectly well, and that although the floating or movable kidney was the same organ that was displaced before, again loosened and was in an abnormal condition as the direct result of the accident.

It will be observed that in a trial of a case of this kind, the prosecution and the defense must depend largely on the medical evidence as to whether the claimant is entitled to damages at all and if so, to what extent. The company admitted its negligence, it acknowledged that he was injured and that he had a floating or movable kidney, but it denied being responsible for the existence of the abnormal condition; hence, it lay with the medical witnesses to show from a clinical standpoint whether it was probable for a patient to make a spontaneous recovery after having had a floating kidney for years, and if so, whether he would be as sound after such recovery, as if the floating or movable kidney had never existed. In the study of this case it becomes necessary to briefly consider the clinical features of a floating or movable kidney.

1. Its frequency. 2. Its tendency to spontaneous repair. 3. Palliative treatment for its relief.

Its frequency.—In this connection, I have been unable to obtain any reliable statistics except that a floating kidney occurs much more frequently in the female than in the male, and that in a large majority of cases, the right kidney is the one effected. For years I have been particularly interested in this subject and during that time have made hundreds of examinations for various diseases common to the abdominal cavity, and with few exceptions have I failed to examine the patient, carefully, for a displaced movable or floating kidney. I have rarely found the left kidney floating, but I have found the right kidney floating or movable in female patients very frequently, so much so that I am inclined to believe that it is much more common than it is generally supposed to be. In all the examinations I have made, I can only recall some two or three cases in which I have found a floating or movable kidney in the male. It seems to be an exceedingly rare occurrence in this sex, so much so that I feel that we are justified in saying that it is only in exceptional cases that we find it existing in the male at all.

Its tendency to spontaneous repair.—There is not a case of movable or floating kidney that has come under my observation in the male or female that has made a spontaneous recovery. In conversation with medical friends who have had experience in this class of disorders, I have thus far failed to find a single case in which there was reason to believe spontaneous recovery had taken place. In fact, if we study the pathology of floating kidney, we can not reasonably expect spontaneous recovery, for the reason that in the true floating kidney, the organ is surrounded with a meso-nephron, and hangs by a pedicle, free to move within the abdominal cavity in any direction. The anatomic relations of the kidney with the peritoneum are such that when it has a meso-nephron, the peritoneum has been displaced to such an extent as to form a capsule, which even the most expert operator is unable to replace. This, being the fact, it is unreasonable and impractical to expect spontaneous recovery.

A movable kidney is distinguished from a floating kidney from the fact that it does not have a meso-nephron, but is free to move underneath the peritoneum, which it dissects from the lumbar muscles, and when once loosened, permits the kidney to move to and fro underneath it like a shuttle.

A displaced kidney may be congenital or post-natal. I recall a case of displaced kidney which I observed a few days ago in an abdominal operation. In this case the kidney was very much distorted and located just over the promontory of the sacrum. The patient had never complained of any pain or trouble with the kidney and had it not been for an operation for the removal of the ovaries and uterus it is quite probable that no one would have been the wiser. In considering a displaced kidney, we shall not include those of a congenital origin, but simply, where it has by some external force been displaced and lodged in another part of the abdominal cavity and anchored there by inflammatory adhesions. The tendency to spontaneous recovery in cases of this kind is not very flattering, and I am frank to say that in my experience I have never had the pleasure of seeing a case in which such displacement existed and spontaneous recovery took place. From these few observations I am led to believe that any one of these conditions may be tolerated by the patient, and the kidney and the surround-

ing structures may so accommodate themselves to their new environments as to relieve the patient from pain to such an extent that he may apparently recover his normal health; as a rule I do not believe that this is true but, on the contrary, I have found in these cases a general tendency on the part of the majority of patients, at least, to get worse. If not troubled with actual pain, they become nervous; their digestive system is disturbed as well as the functions of the kidney itself, which, of necessity, sooner or later lead to grave systemic complications.

Palliative treatment for its relief.—The palliative treatment which has been recommended for years in our text-books for the relief of floating or movable kidney is in my judgment worse than useless. I am not insensible to the fact that our best writers recommend the use of bandages and compresses for the treatment of this disorder, but why they should recommend such treatment is beyond my comprehension, except that somebody who wrote a book sometime before had recommended such a thing and like the traditions of old, it has been handed down from one generation to the next. Certainly there is no logical reason for the use of bandages and compresses in the treatment of floating kidney. If you stop a minute and study the anatomy of the human body you will readily see that no bandage can be placed over the abdomen with safety to the adjacent structures that will have the slightest influence in holding the kidney in its place. It is only necessary for you to cut a cadaver in two, crosswise on a line with the kidney, and you will see at once that the kidney is not *only* protected by the ribs posteriorly, laterally and even anteriorly, but it is also guarded by the vertebræ, which in the majority of cases project beyond the level of the kidney so that if it were practical to bandage a patient so tight that the bandage would rest on the anterior portion of the spinal vertebræ it would not be sufficiently tight to hold the kidney in its normal position. It is only necessary to examine an articulated skeleton to demonstrate this for yourself, when it will be evident how utterly absurd it is to expect beneficial results from this method of treatment. But I imagine I hear some one say that this can be overcome by compresses. Admitting that you can make a compress that will fit down between the ribs and spinal vertebræ so as to make pressure on the kidney, I defy you to hold the kidney in place with any such compress, without injury to the adjacent structures as well as the kidney itself. Worthy Fellows of the Academy, in summing up these observations, I want to call your attention to the fact that a movable or floating kidney in the male is quite an unusual occurrence; that the tendency to spontaneous repair is exceedingly rare; that the palliative methods heretofore advised and used for the treatment of this condition are anatomically and physiologically impractical.

Legal aspects.—To properly consider the legal aspects of a movable or floating kidney it is necessary for us to consider, as we have already done, the clinical conditions which exist in these cases. The legal responsibility depends largely on circumstances, and circumstances are usually the offspring of facts. In studying this part of the subject we shall divide it into three divisions. 1. In acute diseases. 2. In chronic cases. 3. In alleged spontaneous recoveries.

The legal aspects in acute cases.—The legal aspects in acute cases of movable or floating kidney depend entirely upon the legal responsibility of the company.

If a claimant has, without any fault of his own, been the victim of an accident, which accident had been entirely the fault of the company and as such has resulted in an acute case of movable or floating kidney it would only be necessary to show that these were the facts in order to establish a claim against the company. The defense would not be justified in setting up the claim that the party may have had a predisposition by reason of general disability, to a displacement of the kidney, because it is presumed it will use every reasonable precaution against injuring any of its patrons whether they be in enfeebled or of robust health.

The legal aspects in chronic cases of floating or movable kidney.—While the company may be responsible to a claimant for injury by reason of an accident, such responsibility is not lessened so far as the company is liable for negligence, but it is lessened by reason of the fact that a diseased condition existed prior to the accident and may have been exaggerated by the accident; but not in fact a primary result of said accident, hence the company should not be held responsible in a case of this kind to the same extent it would be held responsible in a case where no such chronic condition existed.

Allow me to illustrate. A few months ago I was called as an expert witness in a case that was being tried before the United States court, in which it was shown beyond dispute that the claimant had suffered from tuberculosis of the hip joint in childhood and had been treated for the same for years, finally recovering sufficiently from the disease to do a certain class of manual labor but leaving him a confirmed cripple. Outside of this crippled condition his general health appeared to be normal. He was riding in a sleeping car on one of the trunk lines of Ohio when a very trivial accident occurred causing a sudden stoppage of the train, but being in the sleeping car riding with his head toward the engine, he suffered no visible injury whatever, did not know what happened until he got out of the train and made inquiry, after which he went back into the car, went home, and some days afterward complained of his old trouble; was taken down a few weeks later with suppurative morbus coxarius in which there was multiple infection. The abscess was opened by a competent surgeon but the patient died of pyemia and the company was sued for \$10,000 damages. In the trial it was shown that there was a head-end collision, which, of itself, held the company without any further evidence of negligence. It also developed that the claimant had suffered from hip-joint disease long before the injury, and although he had for the time being apparently recovered, yet he was predisposed to its return. The expert witnesses for both the prosecution and the defense confined themselves to scientific and clinical facts rather than taking sides in the case. The attorneys for both plaintiff and defendant, who were among the most able counsel in the State of Ohio, showed a remarkable disposition to get at the real facts and place them fairly and squarely before the jury, which was one of more than ordinary intelligence.

In summing up the evidence brought out in the trial, it showed that a party who had suffered from hip-joint disease prior to any accident had a predisposition to the return of the disease, and hence, a very slight injury that would not affect a healthy person in the least, might result in the return of the tubercular trouble and to that extent the defendant was not liable for damages.

As a legitimate result the jury rendered a verdict accordingly, giving the administrator a few hundred dollars instead of several thousand.

From this I observe that it is only fair and reasonable to assume that where a floating kidney existed prior to an accident, that the defendant in an action for damages is not responsible for its existence, although it may have exaggerated its condition, and hence should only be held liable for such injury as is clearly shown to be the direct result of the accident.

Legal aspects in alleged spontaneous recovery.—If a claimant has suffered from a floating or movable kidney and alleged to have recovered from such abnormal condition, received an injury in which he assumes to have had a return of his former trouble, and on account of return of said condition claims damages, it becomes necessary for him to show, beyond a question, that he had fully recovered from his former diseased condition and to show that his present abnormal condition was wholly due to negligence on the part of the defendant and in no wise the result of the former diseased condition before he is entitled to damages for the same.

In conclusion, it has been my experience that the disposition to spontaneous recovery with or without palliative treatment, in cases of floating or movable kidney, is not warranted by clinical observations. This being the fact a jury is not warranted in awarding the same damages to a claimant as if the whole injury had been caused by the accident, although he may allege to have recovered from his former abnormal condition prior to the accident, but they may award such damages as the evidence shows was the direct result of the accident.

68 Buttles Avenue.

DISCUSSION.

Dr. GALBRAITH—Mr. President and Gentlemen of the Academy: I desire to compliment the Doctor upon his courage in selecting so unique and unsatisfactory a subject for a paper. In the first place the difficulty in making a diagnosis of a floating or loose kidney is readily understood by every member of this Academy. Again, the subject being so unusual that in the doctor's description he has not cited or brought to our notice a case of a loose or floating kidney either so as to speak of idiopathic or traumatic case but has confined entirely those conditions to females. We can readily and in a measure understand that the exciting cause of floating kidney in females is the result of tight lacing, and as the doctor mentioned it is invariably confined to the right side; in connection with crowded and depressed viscera you do occasionally find this condition in a female from this cause. That we should select or bring up a case for discussion of so unusual occurrence struck me as of little benefit either for ourselves or for our companies. I am afraid we are running too much into peculiarities, idiosyncrasies and unique ideas that will not only cause comment from our superior officers but from the public at large. In nearly all the railway meetings of the last two or three years I have attended there have been something new as the result of alleged traumatism. Now as regards the medico-legal aspect and treatment of floating kidney, I doubt if we would be justified to the extent of the heroic and mutilating methods that are advised. In the first place the Doctor has not cited, as trauma or the results, a case that has been approved. I failed to note anything of that kind in his paper. Now we have the palliative treatment; our text books say we will apply a bandage and compress, and in the case of a loose kidney as the result of trauma we have a dozen or more text books stating positively that to apply a compress and bandage is the principal thing. In this the Doctor takes exception to the authori-

ties. Now then are we justified in proceeding to perform an operation that the Doctor has very well and satisfactorily demonstrated? Is that protecting our company, or do we as individuals assume the responsibility of so heroic surgical interference?

Dr. E. WYLLYS ANDREWS—I would like to ask Dr. Reed whether it is not true that perhaps the majority of our cases of floating kidney are accompanied by disease of the organ, of course producing an enlargement, hypertrophied condition or dilatation; that the bandage with an exceedingly large kidney is of use? While it is anatomically true that no force can be exerted on a normal sized kidney, may it not be true that a movable large kidney can be restored and the pain somewhat diminished by a soft compress?

Dr. LEMEN—I would state that my experience with the bandage has certainly given more or less relief in floating kidney, as Dr. Andrews says allowing for an enlarged kidney but especially in a relaxed abdomen; anything that will give support to the abdomen will more or less support the contents therein, and I have had several cases that had a great deal of relief by simple abdominal support. It did not cure the trouble, but acted as a simple palliative measure to relieve the distress as a truss.

Dr. OWENS—I beg to differ with my friend (Dr. Galbraith) in reference to the importance of the subject. The gist of the paper is this: That given a case of floating kidney, or a kidney that is capable of being displaced, and a railroad accident where it could be afterward shown that a displaced kidney existed, and then the evidence comes in that displacement of the kidney once existed and offered in evidence—may be shown from professional standpoint that such displacement did exist but that it had been cured by a bandage and that the jar or shock had displaced it—the question comes, is it possible to cure a floating kidney or displaced kidney by a bandage? I must say I am in full accord with the paper. The kidney may have general support by means of the bandage and it will be helpful and comfortable more or less, but in no sense is it cured. And we ought to be able to show sooner or later that it is not possible to cure a floating kidney and hold it there till it remains fixed in a healthy state by means of the bandage. I did not see anything in the paper that urged an operation, but the plain question is whether we can cure a displaced or floating kidney by means of the bandage, and if we can not we ought to be able to show that such is the fact. I have one case in mind on the Northwestern in which a girl was injured and she had complained of various ill-defined symptoms; she passed through the hands of one or two and finally an expert diagnosed a floating kidney and operated, and it was claimed she was entitled to damages. I think from a medico-legal standpoint the position taken by the writer of the paper is very correct and will be sooner or later recognized.

Dr. RANKIN—It seems to me the most important question is, are we forced to admit that trauma can produce floating kidney? There is such close sympathy between all these organs—they have a common peritoneal covering with the entire viscera—and these organs, with the kidneys, vary so much that it seems to me that we have not sufficient proof that trauma is the cause of floating kidney at all. It is certainly very difficult for me to understand how it could; anything that would displace the kidney would bring on inflammatory reaction around the kidney, which would have the reverse action—make it stick instead of float. Can we under our present state of knowledge admit that trauma can produce floating kidney at all? I doubt it very much.

Dr. HARNDEN—One well authenticated case came under my notice. A woman had been treated for some years for floating kidney by compresses; she was better in health and it was claimed she had been cured. She was taken sick something like a year after the supposed cure had taken place and her

case was diagnosed then as an aneurysm, and she went from bad to worse till she was in a hopeless condition. I was called in consultation to see her and I pronounced it floating kidney. She died something like two weeks after that time; an autopsy was made and it was found it was floating kidney and there was no indication of cure in the case; the kidney, like a shuttle, passed about in every direction, and it seems to me the limited description of the kidney and its attachments would bear out the idea that it could not be cured by any such means. It seems to me, an application made through the abdominal tissues and surrounding tissues would be utterly futile in holding in position the kidney. And furthermore I think it is about on a par with the treatment of hernia; when the kidney has lost its attachment, the pedicle has become elongated. I do not believe there is anything that will cure it but shortening the pedicle and tying it up.

Dr. HAWES—I have known a great many cases of floating kidney that were alleged to be very much improved by bandages and trusses and quacks, and for all that, notwithstanding the testimony that has been adduced in their favor I am strongly inclined to the opinion it was not in a majority of the cases a disease of the kidneys so much as a disease of the imagination. There is a large per cent. of the cases where floating kidney is alleged to be found, as we know, in hysteric women, and if we were able to make an exact diagnosis and able to see the exact results of our treatment without being able to give any reasons except such as had been satisfactory to me and the result of observation in the past, I should feel strongly inclined to believe the very respectable per cent. of such cases was discomfort arising from the imagination rather than from the kidney.

Dr. GALBRAITH—Before closing, permit me to say, if memory serves me right upon the literature of this subject, it fully concurs with the evidence we have had here as regards it being almost invariably found in women. I further doubt, as already stated, that there is in this Academy or in this city a case of floating kidney which can be positively proved beyond doubt due to trauma. If that were the case—that such conditions could result from trauma—stop and think, nearly 200 men are injured on the railroad to one woman, and I fail to discover, either from the evidence here or from the text books I can think of, a case where this condition has been alleged and damage proceedings brought against the railroad for this condition in men. Now then we do perform operations successfully for the anchoring of the kidney, but in alleged floating kidney the results of an injury to an employe or a passenger upon a railroad, are we justified in resorting to those methods which the Doctor has described and the text books describe, to cure the condition? I doubt it. I doubt if we would be using proper judgment in resorting to anything of an operative character. As to the medico-legal aspect of assuming responsibility of these cases I am not prepared to remark, but in my judgment we would be to a greater or less extent responsible for the direct result of this operation. In reviewing this subject I find that the text books merely mention the fact that it may be the result of trauma—that is very unsatisfactory (laughter), it is like a great many other subjects in our text books, very unsatisfactory indeed.

Dr. LEMEN—Why would you [Dr. Galbraith] hesitate to operate on a floating kidney that was the result of trauma, any more than on hernia that was the result of trauma?

Dr. GALBRAITH—I think I have made that very plain, that the moment we perform the operation for traumatic floating kidney we are confronted, as the author of the paper says, by a dozen or more text-books stating that the bandage, compress and various appliances are recommended.

Dr. REED—I am very sorry our distinguished friend, Dr. Galbraith, "got off the eggs on to the straw." My paper did not consider the question of anchoring the kidney, did not consider it

as coming in this discussion at all; and furthermore, I did not say in the paper that there was such a thing as traumatic displacement of the kidneys; the question is asked whether I ever knew of one—I think I can cite several cases which I have every reason to believe were traumatic. One case of a young girl in this city, lifting a bucket of coal, and as she said, something gave away in her right side, she felt sick and faint, was placed in bed and was an invalid—that was not imagination. Having been a citizen of Columbus she came home, and was brought to me by her family physician; an examination was made and I could very easily, as she was a thin, spare girl, move that kidney from the bottom of the pelvis under the edge of the ribs, a distance of three or four inches, as plain as anything. I made an operation for anchoring the kidney. Two years ago the lady was brought to me with an ovarian tumor and I made another operation—thought I, this is my time to examine the kidney and see whether it is fast or not; because we had a distinguished member of the profession who said the kidney was loose again, and I was more than interested because my operation was challenged. I made that examination, and the kidney was fixed in its normal place. That was a case where lifting occasioned the injury, a floating kidney was found, it was operated on, it got well, and it seems to me that is conclusive that we have such a thing as traumatic floating kidney. In another case a young man playing ball was struck in the abdomen, was taken with severe pain immediately afterward, and from that day to this has never been well, though he was the strongest young man in that section of the country. But on examination you can find the lump in the right side, that can be slipped up and down a distance of two or three inches, and I believe is a floating kidney, the result of traumatism. I can not prove this matter any clearer, but however, let that be as it will, it does not enter into this discussion of the medico-legal aspect of the paper, because here comes a man who was injured on the railway; he admits having a floating kidney, but claims to have been cured of this and now comes up to the company and gets \$12,000 damages, and gentlemen, dare we stand and ignore these facts, if they are facts? Twelve thousand dollars is pretty rare; I would not want to pay it, nor have my company pay it unjustly. The fact is that these cases come to us, we must study them and, as I said in the beginning of the paper, because they are rare, it catches us unprepared, and when this case was tried there was very little testimony that could be gotten at. Further than that, we find the text-book, as I have already said, is absolutely useless because it is false—I do not believe he ever was cured and I do not believe he was entitled to damages. That is the reason I bring this out, and it seems to me it is fair and just and reasonable. Dr. Andrews' suggestion with reference to an enlarged kidney; of course, in an acute displacement of the kidneys in case of congestion we may have hydronephrosis, but generally there is no enlargement in the cases that I have examined; I could not detect any enlargement, but I could move the kidney several inches. But if enlarged I admit the use of the bandage, but I deny that it cured them, and that is the point in law, because the law says they must have been absolutely cured to receive any damage. I want to reiterate, you can not by this treatment cure these cases, and hence, if you can not cure them, they have not a right to damages. The same argument that I have just given you I think obtains as to the matter of imagination. I admit we may have an imaginary tumor and other things in the abdominal cavity, but I do think there is a question in the world but what we have floating kidneys, and if we have floating kidneys from any cause whatever, then my paper holds good, and the case as brought before the company holds good as a possibility.

Dr. COLE—In those cases occurring suddenly what is the history with reference to the acute constitutional disease?

Dr. REED—The history is prostration, faintness; they speak

of it as an all-gone feeling, whatever that is like; they feel as if something dropped away from them, and if they stoop it gives them pain; on lifting they feel a dragging pain in the right side; I believe I never saw but two on the left side. One case passed bloody urine after the accident, another I did not observe and could not say.

Dr. GALBRAITH—I think my colleagues will fully concur that what I say is the fact, that the great difficulty in making a differential diagnosis between floating kidney and diseased conditions of other parts of the viscera of the abdominal cavity, and I wish to cite one case where my colleague and the author of this paper, with other very able gentlemen, was called in consultation by me to examine a case of abdominal tumor beyond any question of doubt; they were satisfied, as well as myself, that we had a floating kidney—the floating kidney proved on examination under anesthesia to be gallstones. I removed seventy or eighty gallstones from the gall-bladder.

ON THE TREATMENT OF DIABETES MELLITUS BY A DIET FROM WHICH ALL CARBOHYDRATES HAVE BEEN EXCLUDED.

BY EDWARD L. MUNSON, M.A., M.D.

ASSISTANT SURGEON, U. S. ARMY, FORT ASSINNIBOINE, MONTANA.

Since diet has always played such a prominent and supposedly essential part in the treatment of diabetes mellitus a general discussion of this subject may be of interest, the more especially as there has apparently been of late an under-current of thought to the effect that possibly the complete exclusion of carbohydrates from the diet might not be an unalloyed blessing to the diabetic. The writer hopes to show in this paper, both from careful personal observation of a typical case of diabetes as well as the quoted experience of others upon the salient points, that a diabetic should be placed under no different conditions of diet than are granted the healthy individual and that a rigid exclusion of carbohydrates from the diet is productive of abnormal metabolic changes which result in not only progressive emaciation and weakness, but also in the production of various toxic bodies to which the severe cerebral symptoms of this disease are to be attributed.

I. SUGAR IS ALWAYS PRESENT IN THE BLOOD.

Physiologically.—"Glucose is always present in the blood in quantities varying from 0.1 to 0.15 per cent." (Landois, "Lehrbuch der Physiologie des Menschen," p. 59). "The normal proportion of sugar in the blood does not, as a rule, go up as high as 1 per cent., although it may vary in different individuals" (Cohnheim, "Vorlesungen ueber allgemeine Pathologie," p. 97). "Sugar is a normal extractive of the blood" (Foster, "Text-book of Physiology," p. 50). "The amount of blood sugar remains about the same even during starvation" (Abeles, *Wiener med. Jahrberrichte*, 1875, No. 3).

The following tables of Seegen (*Archiv f. d. ges. Physiol.*, 37, 348-369) show that sugar is always present in the blood irrespective of various diets or fasting.

	Carotid Blood. percentage.	Portal Blood. percentage.	Blood in Liver Veins. percentage.
Fasting (8 exp.) . . .	0.157	0.147	0.260
Starch Diet (9 exp.) . .	0.150	0.144	0.261
Sugar Diet (6 exp.) . .	0.165	0.186	0.265
Dextrin Diet (4 exp.) .	0.176	0.256	0.320

In Diabetes.—"Diabetes is an abnormal increase in the blood sugar" (Cohnheim, *op. cit.* p. 97). "The elimination of sugar in diabetes does go down considerably in diabetes during a prolonged fast but is

always present in appreciable quantity" (Mering, *Tageblatt der 49 Naturforscherversammlung in Hamburg.*) "In diabetes there is a large increase in the blood sugar" (Landois, "Physiologie des Menschen," p. 73). Quantitative determinations have been made upon this point by Kütz (Archiv f. exp. Path. u. Pharm. vi, p. 140); Mering (*Zeitschrift f. prak. Med.* 18 and 20, 1873), Kratschmer (Voit's "Stoffwechsel Physiologie," p. 230) and many others. It is evident, since the presence of sugar is so diagnostic of diabetes, that further discussion of this point is unnecessary. The occurrence of sugar as a constant constituent of the blood in health and disease has been repeatedly demonstrated.

II. THE ELIMINATION OF CARBOHYDRATES FROM THE DIET DOES NOT CAUSE A DISAPPEARANCE OF THE BLOOD SUGAR.

Physiologically.—"The quantity of blood sugar remains the same even if a diet free from carbohydrates is taken" (Cohnheim, "Vorles. ü. allgem. Path." p. 93). Bödeker (Landois' "Physiologie," p. 458) found glucose in the urine of healthy individuals on placing them on a diet composed exclusively of meat and chondrin. "Experiments on animals have shown that if an exclusive meat diet or proteid diet, as fibrin, be administered over a considerable length of time, a certain quantity of sugar and glycogen can always be detected in the liver, muscles and blood" (Foster, "Text-book of Physiology," p. 717). "If animals are subjected to a long course of starvation there is a decrease but no disappearance of the blood sugar, the animal invariably dying before such a result can be brought about" (Foster, *loc. cit.*). "During prolonged fasting sugar does not disappear from the blood." (Landois, "Physiologie des Menschen," p. 322). "The quantity of sugar after long starvation remains the same, although the liver glycogen disappears" (Cohnheim, "Vorles. ü. allgem. Path." p. 95). Mering (*Cent. f. d. Med. Wissensch.* No. 53, 1887) has also found that if a dog be starved his blood still contains sugar although the liver and muscles yielded no glycogen.

In diabetes.—In the case experimented on by the writer a strict proteid diet maintained during a period of several months never caused the disappearance of sugar from the urine but the sugar excretion for many months was constant at about 6 per cent. Mering (*Zeitschrift f. prak. Med.* Nos. 18 and 40, 1887) found 39.8 gm. of sugar in the urine of a diabetic who had lived on proteids only for fourteen days. Kütz also found that a diabetic, following the ingestion of 300 gm. of casein, free from fat and sugar, excreted under this diet an average of 81 gm. of sugar (*Arch. f. exp. Path. u. Pharm.* vi, 140). It was also found by Kratschmer (*Sitzungsberichte d. k. Wien. Akad.* Bd. 66, 1872) in a large number of experiments that the sugar excretion was still maintained even on a strictly proteid diet, some patients excreting 112 gm. or more during the twenty-four hours. The same writer (Voit's "Stoffwechsel Physiologie," p. 230) records an instance in which a diabetic excreted 62 gm. of sugar without taking food of any sort for thirty-six hours. Voit and Pottenkofer (*Zeitschrift für Biologie*, III, 398) also report a case of diabetes in which there was a sugar excretion of 52 gm. although no food of any kind had been allowed for thirty-six hours. Sugar appears in the urine of rabbits and dogs in starvation following the administration of phloridzin. The above instances, like the prac-

tice of nearly every physician, show that in advanced cases of diabetes neither the exclusion of carbohydrates nor even abstinence from all foods whatever can cause the disappearance of or greatly reduce the sugar excretion. It is evident, then, that the source of the excreted sugar must be sought for elsewhere than in the carbohydrates ingested.

III. SUGAR IS PRODUCED FROM THE INGESTED AND SYSTEMIC ALBUMIN.

In health.—"Sugar is probably produced from proteid decomposition in some part" (Foster, "Text-book of Physiology," p. 724). "The organism has the property of forming sugar out of albumin, probably by the splitting up of the latter into glycogen, which is then converted into sugar" (Cohnheim, "Vorles. ü. allgem. Path." p. 106). "The manufacture of sugar is merely a product of healthy metabolism" (Voit, "Handbuch der Phys. des gesamt. Stoffwech." p. 228). "A source of sugar is found in the fats and albuminoids" (Landois, "Physiologie des Mensch." p. 324). "The largest part of the animal diet is converted into sugar. At least two-thirds of each part of albumin consists of carbohydrates, that is, yields carbohydrates" (Seegen, Landois' "Physiologie," p. 324). "Proteid material in giving rise to urea throws off somewhere in the body a large quantity of a carbon containing radical in some combination, since the proteid contains far more carbon than is needed to unite with the nitrogen to form urea. This carbon has a tendency to appear in the form of fats, but it may be supposed that it might, as a preliminary process, take on the form of sugar. It may further be supposed that the sugar is formed from proteids not in the liver but in some other tissue, as muscle. In such a case the hepatic glycogen may be formed by a dehydration of the sugar manufactured elsewhere and brought to the liver by the portal blood" (Foster, "Text-book of Physiology," p. 724). That sugar is formed from the systemic albumin is shown by previous references in which it is seen that the sugar did not disappear from the blood even on prolonged starvation. It is evident that in such cases the sugar excreted must have been a product of the decomposition of the tissue albumin.

In diabetes.—The fact that sugar is produced from albumin in diabetes is abundantly proven by the many cases already quoted in which the sugar excreted could have had no carbohydrate source. It is a notorious fact that many cases of diabetes, from the diet of which all carbohydrates have been carefully excluded, still continue to excrete considerable quantities of sugar. In the case studied by the writer, under a rigorous proteid diet, there was never an entire disappearance of the sugar from the urine.

SUGAR COMES FROM INGESTED ALBUMIN.

"There are some cases of diabetes which continue to excrete large amounts of sugar even if kept on an exclusive albumin diet (Mering, *Zeitschrift f. prak. Med.* 36, 1872). Kütz (*Arch. f. exp. Path. u. Pharm.* vi, 140) finds, according to the following tables, that the increased ingestion of albumin causes an increased secretion of sugar. He gave as diet casein free from fat and sugar.

EXP. I.		
Casein.	Urine Excretion.	Sugar Excretion.
200 gm.	4.180 c.c.	79 gm.
240 gm.	4.100 c.c.	70 gm.
300 gm.	4.950 c.c.	87 gm.
300 gm.	6.420 c.c.	137.1 gm.

EXP. II.		
Casein.	Urine Excretion.	Sugar Excretion.
200 gm.	4.460 c.c.	66 gm.
240 gm.	6.140 c.c.	65.7 gm.
300 gm.	6.620 c.c.	96.7 gm.
500 gm.	7.210 c.c.	126.9 gm.
240 gm.	5.250 c.c.	86.6 gm.

"A diabetic who lived on an exclusive meat diet for fourteen days and then fasted thirty-six hours, eliminated during the last twenty-four hours sugar amounting to 34.15 gm. During the next twenty-four hours the patient ingested 300 gm. of casein, free from fat and sugar, and also one liter of meat broth. The sugar excretion for that twenty-four hours amounted to 61 gm. The patient had therefore manufactured 26.85 gm. from the ingested albumin. . . . In another case, in which the sugar excretion was considerably diminished after a fast of thirty-six hours, a marked increase was at once noticed upon the ingestion of coagulated egg albumin" (Mering, *Zeitschrift f. prak. Med.* 40, 1873).

SUGAR IS ALSO PRODUCED FROM THE SYSTEMIC ALBUMINS.

"A diabetic patient kept without food of any kind for thirty-six hours was found to excrete 34.15 gm. glucose" (Mering, *loc. cit.*). "Sugar does not disappear from the urine on fasting" (Block, *Deutsch. Arch. f. klin. Med.* 25, 1880, 470). "The elimination of sugar is often considerably decreased during prolonged fasting, but is always present in certain quantity" (Mering, *Tageblatt der 42 Naturforscherversammlung in Hamburg*). "On fasting thirty-six hours a diabetic excretes 52.1 gm. of sugar" (Voit and Pettenkofer, *Zeitschrift für Biologie*, 3, 383).

From the above observations it is seen that blood sugar is produced from albumin, both ingested and systemic, in health and diabetes. In diabetes there is an excess of the production beyond the consumption and the unoxidized portion is eliminated in the urine. Fats, ingested or systemic, can not be considered as the source, since even the most emaciated diabetic, restricted to a diet of albumin or even fasting, will still excrete a certain amount of sugar. This excessive production of sugar from the systemic albumin by metabolic changes can have but one result—more nitrogen is eliminated as urea than is taken in as nitrogenous foods and a progressive loss of body weight is consequent.

IV. THE EXCESSIVE ALBUMIN DECOMPOSITION, DUE TO THE RIGID ENFORCEMENT OF A NITROGENOUS DIET, INDUCES AN INCREASED METABOLISM AND LOSS OF BODY WEIGHT.

In health.—"A man is not able to keep up the equilibrium of his metabolism with pure meat. If obliged to do so he very soon dies. The reason is easily seen. In beef the proportions of the nitrogenous to the non-nitrogenous food-stuffs is as one to one and seven-tenths. A healthy man gives off in the CO₂ of expiration, feces and urine about 280 gm. of carbon daily. If he should take these 280 gm. of carbon out of the carbon of a purely meat diet, he would be obliged to digest and assimilate during each twenty-four hours over two kilos of meat. To accomplish this task the digestive organs of the man are by no means competent. The man would then, under these conditions, be forced to ingest less meat, but this would necessarily mean a supply of the needed carbon from his own bodily tissues, at first from the fats and then from the albuminoids. A purely albu-

minous or proteid diet would act in the same way" (Landois, "Physiologie des Menschen," p. 457). It has recently been shown by Lusk ("Ueber den Einfluss der Kohlehydrate auf den Eiweisszerfall," 1891) that a healthy individual, subsisting upon a purely nitrogenous diet, excretes more nitrogen in the form of urea than is taken in as food, which nitrogenous food, if mixed with carbohydrates, was entirely able to maintain the normal weight. Such an abnormal excretion of nitrogen must, of course, be the result of excessive decomposition of the tissue albumin, and must cause a progressive loss of body weight. Lusk comes to the conclusion that carbohydrates prevent a certain amount of albumin decomposition. If the metabolic equilibrium is destroyed by excluding carbohydrates from the diet the decomposition of the tissue albumin runs in excess of its formation. Voit (*Zeitschrift für Biologie*, 140, 144) has shown by the following experiment that if a certain amount of carbohydrates be supplied, whether albumin be withheld or allowed, a considerable decomposition of the systemic albumin is avoided. In a dog, which needed 850 gm. of meat to support his system, when under a rigid proteid diet, it was found that 500 gm. were sufficient, if small amounts of carbohydrates were supplied, thus saving a decomposition of 350 gm. of meats.

The following table, taken from Lotze ("Allgemeine Path. u. Ther.") shows the great increase of metabolism induced by a purely nitrogenous diet as compared with the metabolism under either a non-nitrogenous or a mixed diet. It gives the urine constituents in health, under various diets, for twenty-four hours.

	I. Non-nitrogenous Diet.	II. Mixed Diet.	III. Nitrogenous Diet.
Total solids . . .	41,680 gm.	67,820 gm.	87,440 gm.
Urea	15,408 gm.	32,498 gm.	53,198 gm.
Uric acid	0.735 gm.	1.183 gm.	1.478 gm.
Lactic acid	5.276 gm.	2.625 gm.	2.167 gm.
Extractives	11.894 gm.	10,508 gm.	5.145 gm.
Sod. phosph	—	3,673 gm.	5,421 gm.
Earthy phosph . . .	—	1,097 gm.	3,562 gm.
Alkal. sulph	—	7,026 gm.	10,399 gm.

In this experiment animal diet in III consisted entirely of egg albumin, which contained daily 30.16 gm. of nitrogen, of which an average of 25.623 gm. were again excreted as urea. This table shows that an increase in the ingestion of albumin, rendered necessary if the carbohydrate source of carbon is cut off, results in an increased metabolism in which nitrogen is produced in far greater quantities than the system can utilize, the excess of which must be excreted as a waste product.

In diabetes.—In the case experimented on by the writer, a removal of all carbohydrates from the diet immediately induced an enormously increased appetite, while, on a return to a mixed diet, there was a diminution of the appetite; showing that the patient craved and decomposed more food while on a proteid diet than when allowed carbohydrates in moderation. As to body weight, this patient lost sixteen pounds between the time when a polyuria appeared and the restriction of the diet to proteids, a period of about six months. During the first four weeks following the restriction to proteids, this patient lost fourteen pounds, and there was a constant decrease in weight as long as the treatment with proteids was maintained. Further, on a return to a mixed diet, there was an immediate gain in weight, and in three weeks there was an increase of eight pounds. The patient was steadily gaining in weight until his death.

Cohnheim ("Vorlesungen ueber allgemeine Pathologie," p. 110) finds that "the quantity of urea excreted by a diabetic is enormous, often going as high as 150 gm. in the twenty-four hours. This may be explained by the large amount of meat which the diabetic usually ingests. The body in this way is able to keep up itself to the necessary carbon and albumin; but the progressive emaciation of diabetes shows that he is only able to keep this up for a certain time."

According to Voit and Pettenkofer (*Zeitschrift für Biologie*, 3, p. 419) "large amounts of meats and fats (in diabetes) were not sufficient to keep up the body, since the body weight decreased," etc. In a series of experiments made by the same authorities, large amounts of albumin were given with very little carbohydrates, only in milk and beer. The food contained 1590 gm. meat and 168 gm. fat. Of this large amount of meat 1364 gm. were taken into the blood. Of this quantity 1287 gm. were decomposed and excreted and only 48 gm. were stored up. The body weight decreased 201 gm. and the urine contained 397 gm. of sugar. The tables given in the same reference (p. 388-398 and 392-394) also corroborate the above.

All authorities agree with the above quotations, which show that the more albumin is ingested, the more urea is excreted from which it follows that an excessive ingestion of albumin induces increased metabolism. It is also shown that in spite of this increased ingestion of albumin the larger part is excreted unused, the patient constantly decreases in body weight and only a relatively small proportion of the nitrogen ingested is stored up in the system. Since the patient is unable to absorb sufficient albumin he abstracts it from his own body.

V. THE ADMINISTRATION OF CARBOHYDRATES RETARDS ALBUMIN DECOMPOSITION.

It has been shown by Hirschler (*Jahrsberichte der gesamm. Med.*, 1889) that proteids allowed to putrefy and decompose in the presence of a carbohydrate or a carbonate do not yield as many or as much of putrefactive and decomposition products as when decomposing alone. He therefore recommends carbohydrates to retard excessive intestinal decomposition and systemic metabolism. The results arrived at by Voit (*Zeitschrift für Biologie*, 3, 140-144) and Lusk ("Ueber den Einfluss der Kohlenhydrate auf den Eiweisszerfall," 1891), which have been already quoted in this article, seem to confirm this theory of Hirschler's, with regard to the power of carbohydrates in retarding metabolism. According to Landois ("Phys. des Mensch.," p. 459), "while on a purely meat diet, to maintain the body an enormous amount is necessary, while a much smaller portion is sufficient on the addition of fats or carbohydrates. For 100 parts of fat which are added to the meat 245 of dry meat can be saved. If, instead of fat, carbohydrates are used, 100 parts of fat are equal to 230-250 of the carbohydrates. On an insufficient supply of dry meat the addition of fats or carbohydrates still causes a diminished decomposition of the bodily material, and if very large amounts of meats are ingested with carbohydrates the body weight is still more increased than without the latter. The body, in this last condition, takes on more fat than flesh." Ephraim ("Diss.," Breslau, 1885) found that an acetonuria accompanied by an increased metabolism follows the exclusion of carbohydrates from the diet of healthy persons. This acetonuria with its increased metabo-

lism disappears if carbohydrates are again administered. The tables of Lötze, already quoted, also show that the exclusion of carbohydrates from the diet induces an increased metabolism. Duprè (*Practitioner*, 1871) found that in a certain case of diabetes, if considerable amounts of honey were added to the usual diet of the patient, the quantity of urea was greatly diminished. The diet of this patient was gluten bread and meats. It has been found by Voit and Pettenkofer (*Zeitschrift für Biologie*, iii, 398), that the urea excretion of a diabetic in hunger is much greater than when carbohydrates are allowed, showing that under the administration of carbohydrates a lessened breaking down of the systemic albumin takes place. Their results are as follows:

	Fasting.	Carbohydrate diet.	Mixed diet.	Albumin diet.
Urea	28.5	19.4	48	62.4
Sugar	52	429	464	149

Ebstein (*Schmid's Jahrbücher*, 1884, Bd. 204, S. 65) always found the ferric chlorid reaction associated with an increased metabolism as shown by the excretion of urea. He also found if a certain amount of carbohydrates be administered that a certain amount of metabolism is avoided and the ferric chlorid reaction disappears. It was found by Rossbach (*Corresp. d. allgem. ärztl. Ver. f. Thüringen*, 1887) that on placing a diabetic on a meat diet there is a lessened sugar excretion but a much greater metabolism. If this patient is now placed on a mixed or carbohydrate diet a great diminution of the metabolism occurs. In the same way, if a patient be given no food at all for a certain length of time and then be given carbohydrates, it is found that the metabolism is very greatly decreased upon the administration of the latter. If a diabetic has not entirely lost the power of oxidizing sugar, as will be shown in this paper, it is evident that a certain amount of glucose can still be used in the system. If such a quantity of sugar be supplied to the organism in some carbohydrate form it is evident that the amount of albumin decomposition, by which this quantity of sugar, which is so essential to the maintenance of health, can be manufactured is wholly unnecessary and may in this way be avoided. Sugar appears in the urine not because the system has entirely lost the power of oxidizing it but because the pathologic decomposition of albumin in which it is produced does not run exactly even and parallel with the capacity of the system to burn it. In the case experimented on by the writer a return to mixed diet caused a lessened appetite and an increased body weight. Several other cases of diabetes which have come under the notice of the writer and which have been given a mixed diet have maintained relatively good health and became by no means greatly emaciated. The writer is strongly inclined to the belief that the progressive emaciation which is so often seen in diabetes is not so much due to the disease itself as to the unnatural conditions of diet under which the patient has been so frequently placed.

VI. THE DIABETIC HAS AN ESPECIAL PREDISPOSITION TOWARD METABOLISM.

It is a characteristic symptom of diabetes that during the later and severe stages a great emaciation and loss of body weight occurs. The patient observed by the writer lost about forty-five pounds or 30 per cent. of his body weight during the eleven months through which the disease continued, while his excretions of urea rose as high as 75-80 grams in the twenty-four

hours. Many observers have shown that a diabetic is subject to a more rapid metabolism than is a healthy individual. Gachtgen ("Ueber Stoffwechsel beim Diabetes vergleichen mit einem Gesunden," Diss. Dorpat, 1872) showed that a diabetic and a healthy individual of the same weight and ingesting the same amounts of a mixed diet differed greatly in their nitrogenous decomposition, the diabetic excreting far more urea than the healthy individual. This result he confirmed by repeated observations. "A diabetic on fasting excreted much more urea than a healthy individual under the same conditions" (Kratzschmer, *Sitzungsber. d. Wien. Akad.*, iii, 66, 1872). It was found by Külz (Ueber Harnauscheidung im Diab.," Diss. Marburg, 1872) that a young diabetic girl on the same diet and under the same conditions as a strong, healthy man, excreted 50 grams of urea more than the latter during the twenty-four hours. Cohnheim says ("Vorles. ü. allgem. Path., p. 110) that "there is an increased metabolism going on in diabetes as is shown by the increased amount of urea excreted. The quantity excreted may go up as high as 150 grams in the twenty-four hours. . . . The increased appetite is simply due to the attempt of the system to make good the excessive albumin decomposition." According to Voit ("Physiologie d. Stoffwechsels," p. 227). "It has been supposed that the increased amounts of urea in diabetes was caused by the large amounts of albumin ingested, but it very soon became evident that the diabetic is obliged to eat so much because the loss and consumption in his body is so enormous." It has been shown by Voit and Pettenkofer (quoted by Lusk, "Ueber den Einfluss d. Kohlenhyd. auf d. Eiweisszerfall," 1891) that a mixed diet which was sufficient to keep a strong, healthy workingman, weighing 71 kilos, in good condition was not sufficient for the needs of a diabetic, weighing 54 kilos, and that the latter lost fat and albumin from his own body.

VII. THE DIABETIC POSSESSES SOME POWER OF BURNING INGESTED SUGAR, SINCE THE INGESTION BEARS NO PROPORTION TO THE EXCRETION.

It has been shown by Külz (Marburg, Elwert, 1874, viii, 222) in a series of experiments carried on upon six diabetics, four of whom had the mild form and two the severe form, as he says, that a diabetic has by no means lost all power of oxidizing ingested glucose. In his first experiment, made upon a mild form of the disease, a certain amount of nitrogenous food was allowed each day, to it being added a daily allowance of 100 grams of dextrose in watery solution, which the patient drank in thirty to forty-five minutes. The patient previous to this experiment was placed on a meat diet until all sugar had disappeared from the urine.

Experiment.	Twenty-four hours' urine.	C.c.	Sugar excretion. Gm.
1	1273		0.946
2	1527		2.994
3	2144		1.526
4	1622		1.950
5	1653		1.710
6	1353		3.996
7	1278		3.510
8	1344		5.898
9	966		4.536
10	1226		4.914
11	1299		5.220
12	1454		2.319

By this table, therefore, it is seen that this patient only excreted about 3 per cent. of the ingested sugar

unoxidized and had utilized the remaining 97 per cent. The second experiment was made on a patient suffering from the severe form of the disease. This patient while under a strictly proteid diet had a daily sugar excretion of 47 grams. To the same diet was now added 100 grams of glucose in watery solution which was drunk early in the day.

	Twenty-four hours' urine.	C.c.	Sugar excretion. Gm.
1	2496		79.8
2	2763		90
3	2444		71.6
4	1905		85.1

From these results the average daily excretion of 47 grams must be deducted. On this treatment the sugar excretion only increased from 38 to 47 per cent., showing that in a severe diabetes the patient still retains the power of burning considerable sugar. Seegen says (quoted by Külz, *loc. cit.*) that "in many instances a certain tolerance of starchy diet exists and that it is only when the quantity of carbohydrates is excessive that sugar appears." He then mentions a patient who excreted 4 grams of glucose following the ingestion of 30 grams. The assumption that 26 grams was the maximum quantity which the patient was able to utilize would be erroneous since in further experiments upon the same patient it was found that the administration of 60 grams of glucose was followed by an excretion of only 5.58 grams, and that only 13.13 grams were eliminated after ingesting 90 grams. In a second case the same investigator found an excretion of 5.998 grams after the ingestion of 50 grams of sugar, while the ingestion of 100 grams of sugar was followed by the elimination of only 8.924 grams. Had the organism only been able to oxidize the 45 grams which were not excreted in the first place, the administration of an additional 30 grams should have resulted in a sugar output of 55 grams. On the contrary there was only an increase of about 3 grams. Külz states that he has many times confirmed these results of Seegen. He states that "the assumption that the ingestion of a quantity of sugar, in excess of what appears to be the amount which can be oxidized in the system, will result in the excretion of this amount unchanged in the urine must therefore be considered to be wholly untrue." In the case treated by the writer the sugar excretion, while on a mixed diet, after a slight fluctuation remained for about four weeks—until the death of the patient—at about the same point at which it was constant while no carbohydrates whatever were allowed. While under a mixed diet the patient took fairly large amounts of carbohydrates in the form of bread, oatmeal, rice and hominy, in addition to his other food. This ingestion did not result in any permanent increase in the sugar output and the patient must therefore have utilized a large proportion of the sugar so ingested—while the allowance of carbohydrates was followed by a most marked and rapid physical and mental improvement on the part of the patient.

VIII. THE ABNORMAL METABOLISM WHICH IS ESPECIALLY PRODUCED BY A PROTEID DIET RESULTS IN THE EXCESSIVE PRODUCTION OF TOXIC BODIES.

Leva says (*Deutsch. Arch. f. klin. Med.*, May, 1891): "We found that on the usual diet with high sugar excretion the ferric chlorid reaction was weak and often absent. On proteid diet, however, where the sugar excretion was smaller, the reaction was very strong indeed. In one case, as long as the patient

excreted considerable sugar on the normal diet, no ferric chlorid test was present, but it appeared very markedly as soon as the patient maintained a proteid diet, disappeared again on a return to a mixed diet, and so continued coming and going according to the foods ingested." It was found by Janike (*Schmidt's Jahrbücher*, 1884, 204, 63) in two cases that a pure meat diet originated this reaction and that, if a mixed diet was afterward given, the ferric chlorid reaction disappeared in twenty-four to forty-eight hours.

Rossbach (*Corresp. d. allgem. ärztl. Ver. f. Thüringen*, 1887) placed a diabetic on an exclusive meat and fat diet. During the entire continuance of this treatment strong tests for acetone and diacetic acid could be obtained from the urine. Upon adding carbohydrates to the diet the sugar excretion rose somewhat, but the acetonuria and diaceturia entirely disappeared. Hugounenq (*Am. Jour. Med. Sci.*, October, 1887) has found the production and excretion of oxybutyric acid to be greatly favored, if not actually produced, by an exclusive meat diet. He does not appear to find this acid in urines which have been passed while on a mixed diet.

That this condition holds good in health as well as disease has been shown by Ephraim (Diss. Breslau, 1885). He found by a number of experiments made upon healthy persons, that a diet of pure albumin is followed by the appearance of acetone in the urine. He observed also that if carbohydrates are administered even with large quantities of albumin, no acetone can be detected in the urine. Clarke and Skelton (*Am. Jour. of Obstetrics*, February, 1897) state that "it (acetone) is found in urine and blood, in small quantities normally, and in large quantities in those suffering from abnormal decomposition of organized proteids. During the first twenty-four hours of starvation the amount of acetone increased forty-eight times in the case of Cetti, the starvation artist."

In the case observed by the writer, it was noticed that no ferric chlorid reaction was given by the urine previous to the institution of treatment, but that it at once appeared upon placing the patient upon a diet from which all carbohydrates had been excluded. It was further noted that, on again permitting carbohydrates to be eaten, this reaction was greatly diminished in intensity; that, on temporarily excluding carbohydrates from the diet, this reaction returned with almost its former intensity, and that this reaction was least in urines passed at mealtimes, and reached its greatest intensity in urines passed several hours after the ingestion of large quantities of meats. From the above observations he concludes that acetone, diacetic and oxybutyric acids are products rather of an albumin decomposition than an oxidation of sugar, and that their production is favored, and even directly induced, by the exclusion of carbohydrates from the diet. The production of these substances is probably accomplished in two ways, first, by the direct decomposition of the ingested albumin; and secondly, by abnormal splitting up of the systemic tissues—both caused by the elimination of carbohydrates from the diet.

IX. DIABETES IS DUE TO A DEPRESSED NERVOUS CONDITION, WHICH MUST ESPECIALLY FAVOR THE ACTION OF TOXIC BODIES.

Strämpell believes ("Specielle Pathologie und Therapie") that diabetes is due to a depressed and atonic condition of the nervous system, which may be

either inherited or acquired. This decreased nervous condition causes a predisposition not only for diabetes, but for various neuroses and psychoses also. Schmitz (*Brit. Med. Jour.*, 1883) gives an analysis of 600 cases of diabetes, in which 248 were hereditary. Ninety-six came of neuropathic or psychopathic families; in 183 the exciting cause was acute neurotic disorder. In one-third of a large series of cases reported by Ord (*N. Y. Med. Record*, 1884, p. 230), there was a history of mental anxiety or overwork, and in one-third a history of alcoholism. Quite recently Schmitz (*Berliner klinische Wochenschrift*, July 6, 1891), in an analysis of over 2,500 cases of diabetes, was able to find an hereditary neurotic taint in about 75 per cent. of all cases, in 15 per cent. he could get no history, and in the remaining 10 per cent. the results were negative. "Severe psychoses and melancholia which led to suicide were found in 428 families which had several cases of diabetes in each. In the families of 263 diabetics in which there was only one case there were many instances of insanity, especially of melancholia which induced suicide. I have also found that the evils which most resemble insanity—the morphin habit, alcoholism and onanism—are accustomed to occur frequently in diabetic families." He believes that there must be always a predisposition to induce the occurrence of this disease. There is then a condition of the nervous system in diabetes which is especially depressed and atonic, and it is evident that any toxic bodies acting on the nervous centers, as the oxy-acids are supposed to do, will be resisted to a far less degree than in health. For this reason, therefore, the occurrence of diacetic and oxybutyric acids in diabetes is of most dangerous import. In this connection it may be well to call to mind the neuroses and psychoses to which the diabetic is so liable, the neuralgia, headache, melancholia, vertigo, loss of memory, etc. Are these affections to be considered as the direct result of the disease itself, or as in great part due to the artificial conditions of diet under which, for the past hundred years, it has been customary to place diabetics? The writer is strongly of the impression that if the actual origination of these affections is not due to the rigorous maintenance of a proteid diet, at least it is directly responsible for the aggravation of any such conditions.

X. THE PRODUCTION OF TOXIC BODIES IS PREVENTED OR RETARDED BY THE ADMINISTRATION OF CARBOHYDRATES.

Since it has been shown in this article that the production of toxic bodies is the result of an abnormal albumin decomposition, and as it has also been demonstrated that the administration of carbohydrates retards and prevents this excessive metabolism, it is evident that no elaborate discussion is necessary to prove the truth of the above hypothesis. Suffice it to say that the experience of the writer, as well as the previously quoted observations of others, agree that acetone, diacetic acid and oxybutyric acid are greatly diminished in quantity or entirely disappear if carbohydrates are given. Prevent excessive metabolism, therefore, and toxemia is prevented.

CONCLUSIONS.

The conclusions arrived at in this article can best be shown by a recapitulation of the hypotheses demonstrated. They are as follows:

1. Sugar is always present in the blood.
2. The absence of carbohydrates from the diet does

not cause a disappearance of the blood sugar. Hence sugar must have some other source than the carbohydrates ingested.

3. This other source of sugar is the ingested and systemic albumin through a process of decomposition.

4. An increased albumin decomposition due to the rigid enforcement of a purely nitrogenous diet, means an increased metabolism and consequent loss of body weight. Hence the cutting off of carbohydrates from the diet directly produces an increased metabolism.

5. *Vice versa*, the administration of carbohydrates retards metabolism.

6. The diabetic has an especial predisposition toward metabolism.

7. The diabetic has by no means lost the power of burning sugar, therefore: *Sugar must, even more than in health, be allowed in order to prevent loss of weight and muscular weakness, which may ultimate in one of the natural endings of diabetes, death by asthenia.*

8. The abnormal albumin metabolism, which is especially produced by a rigid proteid diet, results in the production of toxic bodies.

9. The depressed nervous condition of the diabetic is especially favorable for the action of these bodies.

10. The production of toxic bodies is prevented or retarded by the administration of carbohydrates. Hence: *Carbohydrates should be administered to the diabetic to prevent the formation of certain toxic bodies and the severe and often fatal nervous and cerebral symptoms which they induce.*

That sugar is an important factor in the maintenance of health has long been recognized. Its presence in the blood under all conditions has repeatedly been demonstrated and by its oxidation it is believed to supply heat and energy to the organism. In the system, as is well known, the ingested carbohydrates are converted into glycogen and stored up as such, chiefly in the liver, for future consumption. This reservoir of heat and energy is called upon from time to time according to the needs of the system; a portion of the glycogen is reconverted into sugar, enters the blood current and is oxidized in the ultimate production of water and carbon dioxide. Ordinarily, then, the system receives its sugar in an easily assimilated form and, without any violent chemical changes, it is passed on into the blood current and there oxidized. Should this natural source be now removed by unnatural conditions of diet its manufacture is at once begun from an albumin source by the organism, which, continued over a considerable period, results in a progressive loss of weight due to the increased katabolism caused by production of the necessary sugar. In health this production this manufacture of sugar keeps within the capacity of the system to completely oxidize it. In diabetes, however, this relationship is lost, the production of sugar runs far in excess of its consumption and the portion of sugar which is in excess of what the system is able to oxidize is excreted unburned.

The accepted treatment of diabetes has essentially consisted in placing the patient upon a diet from which all carbohydrates are excluded. This treatment has the sole object of causing the disappearance of sugar from the urine at any cost and is based upon the false hypothesis that if this can be accomplished the disease is cured and that the presence of sugar in the urine constitutes the affection. It can not be too strongly urged that sugar in the urine does not con-

stitute the disease nor is its presence responsible for any pathologic changes or abnormal symptoms. By itself it is merely a symptom and a result of the more morbid processes through which the occurrence of such excessive quantities of sugar in the blood is rendered possible. To treat the sugar excretion can not cure the diabetes. To attempt to treat a constitutional affection like diabetes from a purely symptomatic standpoint would be analogous to attempting the cure of phthisis by treatment directed toward its accompanying cough. The treatment in both should be directed toward the constitutional changes which cause the excretion of sugar in the one case and the cough in the other. The sugar excretion, however, may in one way be pathognomonic since its presence or absence, while on a mixed diet, shows the presence or absence of the diabetes and if, under such a diet, sugar is no longer excreted a cure may be said to have taken place—not because the sugar had simply disappeared from the urine but because the morbid processes, by which the sugar was produced or by which its oxidation was rendered less complete, had ceased to act. It has already been shown that a healthy individual can not maintain a normal systemic condition upon a proteid diet, that a diabetic is especially liable to an excessive metabolism and still it has been the custom to sentence a diabetic, the victim of a disease due to nervous depression, to conditions of diet which directly tend to lower his vitality, to decrease his powers of resistance to the diabetes or to an intercurrent affection and to directly hasten his death by anasthenia or coma. It must be urged that in true diabetes the diminution of the sugar excretion by means of a proteid diet means simply the decrease of a symptom at the expense of an essential disease. It was recently said by Dr. Liebmann (*Boston Med. and Surg. Jour.*, Sept. 3, 1896): "I myself am a sufferer from this disease (diabetes). I can get along very well without potatoes or pastry but I must have bread and if I do not get bread I become so weak that I can not work. I would rather have 3 per cent. of sugar in my urine and for the time being feel strong than have only 1 per cent. or none and feel otherwise."

But, it may be urged, "Why give more sugar since the system is already unable to utilize what is excreted unoxidized?" A detailed explanation of this point will be given in the following paper. Suffice it here to say that the carbohydrate ingestion does not proportionately effect the sugar excretion. If a diabetic be given carbohydrates up to a certain amount it is found that an excess of this quantity does not cause a corresponding increase in the sugar elimination and it is evident that the diabetic still possesses the power of utilizing ordinary dextrose which he has lost to a greater or less degree with regard to sugar produced by the splitting of albumin. The ingestion of carbohydrates can therefore do no harm, but is rather beneficial in that it supplies an easily assimilated sugar to the organism. Are the extremely dangerous cerebral symptoms, the great body waste and consequent emaciation resulting from the enforcement of a proteid diet, are they to be considered as of less importance than the excretion of a few grams of unburned sugar which, it must be reiterated, has but little pathologic and no prognostic significance? A true diabetes can be influenced only unfavorably by the exclusion of carbohydrates from the diet although a simple glycosuria may disappear during or consequent to such treatment. In conclusion, why restrict a patient with dia-

betes to a purely proteid diet? The progress of the disease is not favorably influenced in this way and abnormal conditions are thus produced under which even the healthy individual finds it impossible to maintain his normal systemic condition. A fever patient is carefully nourished and all supporting measures are employed, and yet the processes in diabetes are in one sense similar. Let the diabetic, therefore, live upon a diet which it has been ascertained in his case keeps katabolism at the minimum. Let all depressing measures be avoided and let the treatment be directed not toward the symptomatic sugar excretion, but rather attack its source in those morbid processes by which its excretion in the urine, unoxidized, is brought about.

No means are at present known by which a cure of true diabetes can be rendered certain or even probable and it will probably be as difficult a matter to find a specific for this disease as to find one for chorea or melancholia. The treatment then must be prophylactic; to prevent coma and prolong life by a maintenance of the systemic strength and condition by a retarded metabolism. The writer has endeavored in this article to demonstrate that the employment of an exclusive meat or proteid diet is directly inimical to the accomplishment of these results.

A FECAL FISTULA THROUGH THE APPENDIX RESULTING FROM A PERFORATING APPENDICITIS.

BY J. B. EAGLESON, M.D.

A. A. SURGEON, U. S. MARINE HOSPITAL-SERVICE, ATTENDING SURGEON TO THE SEATTLE GENERAL HOSPITAL, CONSULTING SURGEON TO THE EVERETT HOSPITAL, EVERETT, WASH.
SEATTLE, WASH.

The patient, Captain J. A. O'B., aged 46 years, a native of Ireland, has been well known among steamboat and shipping men on the Pacific Coast for many years. He had a slight attack of pain in the bowels in February, 1894, for which he was treated in the hospital for two days. It was thought to have been a "bilious attack." In April, 1896, he took his steamer to Cook's Inlet, Alaska, with a party of miners and shortly before his arrival he was seized with a severe pain in the right side of the abdomen, and as soon as the steamer reached her destination he placed himself in the care of Dr. B. W. Rodgers of Oakland, Cal., who happened to be at the Inlet, as surgeon for a party of prospectors. He continued to grow worse and, on April 19, Dr. Rodgers operated, with the assistance of a dentist, who gave the anesthetic. The operation was performed in a little shack on the beach while the thermometer stood 9 degrees below zero. A large abscess was opened and the sac removed. It was thought to have been an abscess between the large intestine and the abdominal wall above the appendix. The cavity was drained and packed with iodoform gauze. As soon as the patient was able to bear transportation he was brought to Seattle, where he was placed in the hospital June 5, 1896. He regained his strength rapidly and after a few weeks the wound had all closed but a small sinus through which pus and occasionally fecal matter exuded. Thinking this would close spontaneously, I discharged him from the hospital, June 25, 1896, and in a few days he was able to resume his duties on board his vessel. The fistula was treated by irrigations of bichlorid solution and peroxid of hydrogen, but it refused to close completely, and at times

became quite painful. Hot poultices applied over the wound always relieved the pain and soreness. The discharge was purulent most of the time but occasionally become fecal. His general health remained good and he almost regained his usual strength and weight.

About Jan. 15, 1897, the pains in his abdomen and side became so severe that he was compelled to leave his vessel and go to his home. He had a chill, followed by a high temperature for a few days, and was sent to the hospital for treatment Jan. 22, 1897. The abdominal wall around the fistula was red, swollen and very tender. The pain and soreness were soon relieved by rest in bed and hot fomentations. It was decided to give an anesthetic and dilate the fistula for a more thorough examination, and, if possible to pack it with gauze down to the intestinal opening, and thus endeavor to get it to close. He was operated on January 26, under chloroform anesthesia. At this time a probe introduced into the fistula appeared to enter a small sinus in the abdominal wall in a downward, backward and slightly inward direction for a distance of about four inches, when it entered a free cavity which was evidently the lumen of the intestine. An attempt was made to dilate the external end of the fistula by introducing a pair of hemostatic forceps closed, and then forcibly open them, when, somewhat

1, the fistula through abdominal wall. 2, the appendix, with perforated tip, continuous with fistula. 3, cecum.

to our surprise, the median wall of the sinus gave way and the forceps blade opened into the abdominal cavity when but little force had been applied. A transverse incision was now made to the outer side of the fistula and the finger introduced into the abdomen, when it was discovered that the long sinus traced by the probe was the appendix with its tip adherent to the abdominal wall and perforated. The probe had passed directly through the wall and through the entire length of the appendix into the cecum. The appendix was loosened from the abdominal wall, and, after ligating its mesentery, was tied off with silk and the stump thoroughly cauterized with carbolic acid. The cecum was bound down so that it could not be brought into the wound for a thorough technique of the stump. The wound in the abdominal wall was partially closed with silkworm gut sutures and packed with iodoform gauze. It healed readily and the patient has since been free from pain and tenderness in that side, and is quite strong and robust. There is some tendency to the formation of a hernia through the scar of the first operation. The appendix removed was two and one-quarter inches long and free from adhesions except at the tip where it was attached to the abdominal wall. It contained two fecal concretions about the size and shape of date seeds, which were probably accountable for the pains and the inter-

mittent discharge of fecal matter from the sinus. There was no doubt a perforation at the tip, at the time of the attack of appendicitis, which had become adherent to and formed an abscess cavity on the abdominal wall. The cavity having been opened and drained, finally closed down to a sinus which was kept pervious by the intermittent discharge of fecal matter through the appendix. The accompanying rough sketch will assist in giving a better conception of the position of the fistula and appendix.

PEDERASTY VS. PROSTITUTION; A FEW HISTORIC NOTES.

BY WILLIAM LEE HOWARD, M.D.

BALTIMORE, MD.

In an article written by Dr. Allen, published in the *JOURNAL* March 13, 1897, reference is made to some historic facts regarding the lives, habits and laws governing the hetairæ during the height of Grecian glory and the subsequent decadent Roman Empire. From reading Dr. Allen's citations of the laws controlling prostitution, one would conclude that the curse of the Grecian warriors and Roman Emperors were women. The truth is that as long as the women were allowed to exhibit their charms and passions the morals of the ancients were only those of all strong nations whose youths were developed in the manly sports and whose occupation was warfare. The presence and freedom of women among the men undoubtedly was the cause of great excessive normal sexual intercourse, but when the hetairæ were suppressed sexual perversion prevailed to a shameful extent, and was the cause of the rapid disintegration of the Roman Empire. One principal reason for this is to be found in the fact that the courtesans of that period represented the education, wit and wealth of their sex. *Aperte mala cum est mulier, tum demum est bona.* We find in ancient times, at all periods and among all people, the love of men for men was prevalent in proportion as the social condition of women was inferior. We see according to Herodotus how strong was the normal sexual instinct among the Scythians when they met the Amazons, who enjoyed equal rights with the opposite sex. Among the ancient Jews women enjoyed a certain amount of liberty and respect, and this race stigmatized the love of men for men as immoral and criminal. This race regarded a numerous progeny as the principal aim in life. Moses said that the Children of Israel were to multiply like the sands of the sea. According to Flavius Josephus abortion was punished with death. Among the ancient Greeks, who looked upon their women as inferior beings, abortion was allowed (Ploss). It was also permitted in Rome. We have only to recall the word sodomy to appreciate the practices which prevailed in the ancient city of Sodom. The habits of the citizens of this city even extended to animals (*immissio penis in anum*). Was not Queen Semaramis accused of having intercourse with her horse? In antiquity, as well as today, Asia must be considered the cradle of pederasty; although one need not go out of Italy to have a boy offered to him for a consideration. Homo-sexual love is by no means an unknown practice in America.¹ Tarnowsky² states that pederasty was introduced into the Orient from Armenia.

The relation between Ganymede and Jupiter was

regarded by the ancient Greeks as an example of love of boys. Xenophon says in his symposium that Jupiter raped Ganymede on account of his soul. Plato in his *Phædo* gives us more explicit information and speaks more plainly on the subject. He also alludes to practices among men and boys in the gymnasia. The relations between Hercules and Hylas, Achilles and Patroclus, were those of sexual love. Æschines attributes to Homer the intention of speaking of these personages in an erotic sense. I might continue along mythologic lines, but these cited cases are sufficient for my purpose.

The laws of Solon recognized pederasty to a limited extent, although the practice was under certain restrictions, which applied generally to slaves, leaving the free Athenians all possible latitude. The erotic discourses which constitute an important part of Ancient Greek literature, deal largely with pederasty. In Athens there were many temples erected to Eros, protector of homo-sexual love. Athenians tell us that Charmas, lover of Hippias, erected an altar at the entrance to the Academy. The barber shops and baths were the principal meeting places of male lovers, who here practiced pederasty. But it was principally at the gymnasia porticos that masculine love was predominant, being accompanied by coquetry, mincing manners, jealousy and abominable passions (Arnold Hug). Many authors, among them Aristophanes, Plato in his laws, and Plutarch in his erotics, explicitly state the condition of affairs at the gymnasia. There can be no elision of facts, no maladroit euphemism in attempting to explain their statements that pederasty was openly practiced in these public places. Even a personage of the rank and dignity of Callias was made the subject of a comedy of Eupoles, the Antolykos; he was again ridiculed by Aristophanes in his "Birds and Frogs." Callias was the lover of Antolykos. Lysias, the celebrated orator, mentions the prevalence of homo-sexual love in Athens, as does Plutarch. The practice reached its height in the time of Themistocles. To those of my readers who wish further explicit information on this subject I refer to the Symposium and *Phædo* of Plato, and the Symposium of Xenophon. These latter authors evidently wrote these works with the intention of acquitting or excusing Socrates of the reproach of his loving boys in the carnal sense. Dr. Allen speaks of Socrates listening to the lectures of Aspasia, the celebrated courtesan. Socrates and Alcibiades were victims of homo-sexual love and passions. Any student would rightly construe the language of Alcibiades when speaking of Socrates. Who does not recall all the flatteries, importunities, all the artifices in dress and manner Alcibiades used to seduce Socrates? We know that Alcibiades had numerous lovers. One author, Cornelius Nepos, says that he was greatly loved in the Greek manner (*penis immissio*). Socrates weakly explains his Eros by his desire to exercise influence over youth. Haller passes a very severe judgment on Socrates.³ According to him, Socrates was a debauched philosopher who ever had on his lips the word virtue, and that in reality practiced pederasty. It was the well-known hetaira mentioned by Dr. Allen that instigated Socrates to love Alcibiades in the carnal sense. Pausanias, in his zeal to give pederasty an elevated character, said that those who do not love with the Eros of Urania, that is, those

¹ See Author's paper, *Allenist and Neurologist*, January, 1896; April, 1897.

² Die Krankhaften Erscheinungen des Geschlechtsinnes, Berlin, 1886.

³ Die Rede des Sokrates in Platons Symposium und das Problem der Erotik; M. Koch, Berlin, 1886.

who do not love men but women, think only of satisfying a vulgar desire.

The noble traits of the Spartans even extended to their laws relating to sexual acts. With them homosexual love was forbidden and punished, although it was undoubtedly practiced secretly to a certain extent. Men who had sexual intercourse with each other were considered incapable of good and noble actions. In Bœotia pederasty was considered a state of matrimony. The same conditions prevailed in Elis and Thebes, and the famous sacred legion of three hundred Thebans was composed of warriors and their lovers. The barbarians condemned the practice and punished severely those addicted to the vice.

What I have said concerning the interpretations of the writing of the ancient authors, only refer to the historians. If we search further and read the poets, even the laymen must admit that the songs of these writers are honeycombed with perverted sexual senses. As an example let us take Anacreon's portrait of his friend Batyttus: "His hair is black and shining, his throat is like ivory and his hips are as beautiful as those of Pollux. Between his slender thighs, his thighs full of joy, I accomplished with modesty an immodest act, which really aspires to love." This ode is teeming with such perverted ideas, and is only excelled in its lupanar incidents by the works of Theocritus. If, as Lessing says, a poet should only feel what he writes, we can only draw one conclusion concerning the habits of the ancient poets.

In closing these cursory historic notes it is only just to make some compensatory statements: Pederasty and respect for women appear to have been in inverse ratio. At the time of which we write women enjoyed but little esteem. Undoubtedly the rigorous separation of the sexes accounts somewhat for pederasty. Female modesty was strictly respected. The Greeks were not indifferent to the propagation of the species, and celibacy, in spite of pederasty, was forbidden. The laws of Lycurgus imposed humiliating punishment on celibates, and in Corinth and Athens celibates were denied decent burial.

We find that pederasty was not prevalent in Rome until after the first period of the Roman Republic, but began to flourish after the Punic wars. The practice was brought to Rome from the Carthaginians. We have, however, evidence enough that it existed under the rule of the Cæsars. Even before this event Titus Veturius, a slave of C. Plautius, was punished by his master for having refused him his favors (Dionysius, Valerius Maximus). According to Polybius a boy could be bought for a talent in Rome. It is a noticeable fact that during the rule of the Cæsars celibacy existed to a great extent, while pederasty was the almost universal practice, although forbidden by laws. Suetonius says that Cæsar was often accused of pederasty. He certainly took along on his campaign a large number of gaily decorated goats for himself and favored officers. During his wars in Asia it is stated that he prostituted himself to Nicodemus. So well known was this that Curio gave him the name of Lupanar; others the Queen of Bithnia. Cicero also states that he sacrificed the flower of his youth to Nicodemus. But Cæsar was not indifferent to the opposite sex and was generally known as the husband of all wives and the wife of all husbands. In most respects Cæsar was effeminate. He did everything possible to attract his own sex by his personal appearance. He had himself carefully

dressed and his face smoothly shaved. He had his body depilated in order to give his skin an effeminate appearance to the touch. Octavius, the first Emperor of Rome, labored under the same accusation as Cæsar. Mark Antony says that he had intercourse with Cæsar, which was the price of his adoption. Of the excesses of Tiberius it is scarcely necessary to speak. He debauched the youths wholesale. Caligula did not pay much attention to the courtesans. Valerius Catullus openly said that Caligula had made him ill by his excesses. Mantegazza says that the following verses refer to Caligula:

"Tres uno in lectu. Stuprum duo perpetiuntur,
Et duo committunt; quatuor esse reor.
Falleris, extremis da singula crimina, et illum
Bis numeres medium, qui facit et patitur."

"There are three in one bed; two are passive in debauchery and two are active. I think there are four. You are in error. Impute one crime to those outside, but the man in the middle, who is both active and passive, you must count twice." This passage is clear enough to enable us to understand the vices attributed to Caligula. The son-in-law of Claudius, Pompey, was stabbed because he was found in the arms of a boy that Claudius himself loved. Nero had the young boy Sporus metamorphosed as far as possible into a woman and publicly married him, exacting for him all the honors due to the wife of a Cæsar. Some wag of the day remarked what a pity it was that Nero's father had not had the habits of his son. (I am indebted to Dr. Moll's *Contrare Sexualemfundung* for many of the historic facts given.)

Prostitution as it existed among the ancients was a sad condition of morals. When it flourished in Egypt and Rome with all its license, wealth and social recognition, there was moral palsy but mental activity. When the hetairæ were suppressed, their magnificent and harmonious banquets neglected, their songs unsung, sexual perversion and inversion became prevalent and mental and physical degeneration was the precipitate left. One was a condition of excessive normal sexual impulsion; the other abnormal sexual propulsion. Of two evils choose the lesser. The proper regulation of prostitution is necessary in our present social condition. History shows this to be a logical sequitur. Nothing but mental obtuseness, obscuration of physical facts and incoherence of a former adolescence can be the excuse for arguing otherwise.

ADVICE TO THE PROSPECTIVE MOTHER ASSISTANCE DURING HER CONFINEMENT AND CARE FOR A FEW DAYS FOLLOWING.

BY J. O. MALSBERY, M.D.
PERU, IND.

Our advice to the prospective mother must necessarily be ineffective, owing to her inherent tendencies and conformity to custom. The advice to have been effective, should have been given and more or less closely observed by her progenitor mother. This advice not having been followed, if given, has led to a change in her anatomy and lessening of her vital and physical forces. Then does it look plausible that we can supplant those inherent defects, if such there be, by advice and rules of habit to be followed during gestation or just prior to confinement, and make her delivery as of yore?

I answer, no. We can do much, however, by hints and suggestions suited to each patient, to lead the prospective mother up to her time of confinement in the best possible manner, considering her heritage, inborn customs and acquired habits of dress, providing, however, that our enjoinders be observed, which will rarely be the case. In what way, then, can we be of most actual service to our patients in this now, but not formerly, critical period? I answer by mechanical art and skill. Some "old-timer" may say: "I have practiced medicine forty years and have only had occasion to use 'this mechanical art and skill' some three or four times during that period." I would suggest that the inference would be that even in these few cases mechanics only was used, devoid of the art and skill.

The question occurs to me: What kind of wives does the popular mind, more especially, perhaps, the middle and what is termed the upper classes, demand? Is it the straight-waisted, square-hipped and heavy-muscled woman of serfdom, with the old-time doctor of "give nature a chance" and the easy birth; or, is it the more symmetrical woman with slim waist, shapely hips and rounded muscles, with the skilled physician who is capable of and knows when and how to apply mechanics with art and skill? Regardless of what the popular mind prefers, we have for our patients, in the classes mentioned, those who do or are at least striving to conform to the second class described. And at least one of woman's great aims in life is nice appearance, and to be consistent with the fancies and demands of man for the beautiful. So we are face to face with a painful and difficult labor, which to be sure, as is claimed by the old-time faddist of "wait and give nature a chance," with a wise and grave look, will terminate at some time and in some way, as a rule, if given time enough. How often we know or hear of a physician sitting, lying or sleeping, usually the latter, about a woman in labor for twenty-four, thirty-six; yea, even seventy-two or more hours, with an occasional injunction, and as he may suppose consolation, "there is nothing to do but to wait and allow nature to have her course."

The contempt of the suffering woman for such a physician should impel her to have him thrown into the street for thus allowing her to unnecessarily suffer, beside imperiling her life, together with that of her child. And, too, for such an insulting remark to mechanical science, art and skill, he should be relegated to the accouchement of *squaws*. I will pass abnormal presentations with the hint that they are many times responsible for the delay and unnecessary suffering, which are finally righted in a measure and delivery accomplished without their having been recognized by the accoucheur who is over-dependent upon nature. There are a few cases, however, of such presentations and other abnormalities, in which nature throws up her hands, and mechanical assistance must be had, or the life of the mother or child or both will be sacrificed. Now these are the cases we are taught by the old-time faddist that mechanical interference will be admissible, hands to be preferred of course, though with a wise but grave look he reluctantly admits that forceps may be resorted to, even though an engine of torture they be.

How often we hear the remarks, "forceps are to be used only when absolutely necessary," "remember that forceps are to be used only to save life," etc.; the humane side of the matter being entirely lost sight

of. It is appalling to know the wide-spread mutilation of the perineum of child-bearing women. It is so common, indeed, that we scarcely find a normal perineum after childbirth. Not the complete destruction of the pelvic floor, to be sure, but enough mutilation to destroy the esthetic effect, which is no small affair.

Now, what is the cause of all this? Not forceps, since they have always been relegated to the background. I answer that it is due to the unskilful, inattentive and careless accoucheur, who is not up in this particular art. Note, if you please, the stride and advancement made in surgery, pathology and other branches of our art in the past few years, while obstetrics is still astride the same old hobbies of "wait and allow nature to have her course," "only use forceps as a last resort," etc. Properly constructed forceps, skilfully applied and carefully manipulated is the same boon to this branch of our art as asepsis has been to surgery and the microscope to pathology. What can be more grateful to the parturient woman than to have her suffering cut short, more beneficial at this period than to have her store of strength and vitality preserved, and of more lasting benefit than to have her perineum unutilated? A few whiffs of chloroform, the skilful use of a properly constructed pair of forceps, at the proper time and in a gentle manner, will accomplish all that is to be desired.

This does not mean that forceps are to be used regardless of circumstances; but that circumstances will nearly always warrant their usage. I have only a word of direction as to how and when to apply the forceps, skilfully and as soon as you can be of any assistance to your patient. Adapt yourself to the convenience of your patient and not she to your convenience. This bugaboo of squaring your patient across the bed, with feet on chairs and you seated between her limbs, is all uncalled for. You should take your patient as you find her, and without any flurry slip the forceps on by the sense of touch, allow them to gently lock, if not at once the first pain will usually lock them; gentle traction in the direction according as the presenting parts advance during contractions, the other hand to be the sentinel to guard the perineum and direct the movements of the presenting parts; the head delivered, now rests on the hand, and with a reasonable amount of care the shoulder will glide over the perineum and the task is over.

The placenta—the old-time faddist is not satisfied to have allowed his patient to fight her own battle thus far unassisted, but he would have her lay in the muck, exhausted as she is, yet another hour or two to allow the uterus, as he says, to regain itself sufficiently to loosen and expel the placenta. An old hobby conceived in ignorance, born of superstition and nurtured in tradition. The fact of the matter is, the placenta is usually loosened by the last expulsive contraction which empties the uterus of the child. Hence there is no occasion for any delay. The fingers of the convenient hand wound up in the cord close to the placenta, with the other hand grasping the fundus of the uterus through the abdominal wall, now gentle traction with firm compression like unto the squeezing of a sponge over the fundus, is all that is required to remove the placenta, and at the same time this firm hold on the uterus, crowding it over to the one side, will rid it of all clots as the placenta is expelled, and continual pressure and kneading for a short time will prevent relaxations and the subsequent

formation of clots, and thereby rid our patient of the annoying "after-pains."

Our patients, as a rule, are not kept in bed long enough after confinement, while their diet is too strenuously restricted during this period. The mother now has a rapidly developing child to nourish (instead of a slow and by a different process as before delivery), together with her own strength, to maintain, nurture, shield and protect. She should therefore be allowed a liberal diet of nourishing food. She should be confined absolutely to bed during the first three weeks after her delivery. The next three weeks she may divide her time between being up and about the house and resting on the couch, while the next three weeks should be spent in gradually resuming her household duties.

Regarding the use of the douche following delivery, there should be no fixed rule, but each case should be conducted according to indications and symptoms. The rise of temperature and a fetid discharge will be indicative of the douche, which should always be used with the patient in the recumbent posture, sterilized warm water probably being as effectual as any antiseptic combination. Sore nipples and suppurating breasts are in all cases preventable. The moisture and smegma conveyed to the nipple by the child's mouth and allowed to remain is a very prolific cause of trouble with the nipples. This, added to the traumatism sometimes caused by nursing, and we have the secret of sore nipples, and their manner of prevention indicated—cleanliness and protection from traumatism. Suppuration is usually due to damage done the nipples, use of the breast-pump and pressure on the milk ducts due to the dragging down of the breasts.

To prove this statement we have only to remember that the hardness, soreness and redness always begin about the nipples, or the outer and under side, or the lower and under side of the breasts, owing to the position the breasts are allowed to assume while the patient is in bed or while she is up and about. The preventive is a wide band about the body in such a manner as to support the breasts well up on the chest and prevent their dragging down to the sides while in bed, and more especially the first few days or week while the breasts are heavy. A support may be needed to prevent their dragging downward after the patient is up and about. The breast-pump should never be resorted to; it most often results in harm and can always be dispensed with.

To remove an excessive amount of secretion from the breasts, limit the amount of fluid taken by the patient, produce free catharsis and apply a firm bandage to the breasts; this will accomplish all that is desired. When the secretion is to be curtailed entirely, for any cause, a persistence in the above for a few days, limiting the catharsis somewhat, will be effective and complete; whereas the use of the breast-pump will only be transitory. I realize there is argument on the other side of this question; there is likewise on the old side of surgery.

QUID AVARUS? STULTUS ET INSANUS.

BY ALBERT S. ASHMEAD, M.D.

NEW YORK.

I lived for eighteen months with James Henry Paine, the miser. He occupied a garret room at 177 Bleecker Street, New York; the little house belonged

to the Oothout estate. He was apparently 70 or 75 years old, tall, slim-built, with pointed chin; had a sharp, beak-like, rather red nose, whose point turned in to the upper lip; his mouth firm set; his eyes keen, furtive; his forehead high, retreating; bald on the top of the head, and he bore his head carried forward, bent from his shoulders; his walk was a shuffling of one foot in front of the other, about six inches to a step. His face was bearded. He dressed shabbily, or worse; no stockings, shoes tied together with pieces of twine.

It was his habit to go out every morning, at 9 o'clock, and return about the same hour at night or later. When he returned he usually had a bundle of newspapers under his arm. His garret room was littered with dailies. The climbing the stairs at night, to reach his room, would take him a long time. He burned a lamp, or a candle. When he had reached his room, he used to strip stark naked, and go to bed. He washed himself every morning from head to foot; he was the cleanest man bodily that I ever saw, though his clothing was ragged and dirty. He was an educated man; he said that he had an annuity of \$375 to live on. If you offered him food, he would eat it ravenously and talk of the current topics of the day with sound sense. He had no infirmity of speech, sight or hearing.

This man, in crossing Broadway one day, was knocked down and received a fracture of the hip. He was carried to his room, where he died (Dec. 23, 1885). After his death, a lawyer presented a paper to the surrogate of New York for probate as the man's last will and testament. It was dated Aug. 15, 1885. It contained only a few lines, by which he gave all he died possessed of to the lawyer. When notice of probate had been published, Mr. Charles F. Chickering, the piano manufacturer, brought to court an old brown-paper parcel, with contents; Mr. Paine, said he, had left that in his trust, seventeen years before. He had put it in his safe, had never opened it and did not know its contents. It was opened in court and found to contain nearly \$400,000 of currency and securities, \$14,400 in State bank bills, which should have been redeemed in 1863, \$40,000 in certificates of deposit which had been lying dormant in the Metropolitan Bank for seven years, and \$342,000 in national bank bills. "At simple interest," said Attorney-General Russell, "these sums, so lying useless, would have swelled to \$800,000, while the owner went shirtless and stockingless, ate broken crusts and rotten vegetables and slept naked in a stifling garret."

A trial of the case resulted to test the validity of the will, three nephews and a niece appearing as heirs. I was the medical expert in the case. I testified that at the time I knew him, Mr. Paine was incompetent to make a will. Hon. Leslie W. Russell, ex-Attorney-General of the State of New York, appeared for the contestants; ex-Governor Chamberlain of South Carolina for the legatee.

On cross-examination I was asked whether, in my opinion, a miser was a sane or an insane man? I answered that any man who neglected his duty to himself, to relatives, neighbors and to his God, in the possession of great wealth, was insane. This man, if he remembered that he possessed this wealth, failed in these duties. If he did not remember that he possessed it, this might be an evidence of mental incapacity.

Mr. Paine was born on the 10th of April, 1805, in

Boston. He was a shrewd man of business, had received an inheritance of \$40,000, and in 1856, when he left Boston to come to New York, he had increased it to \$250,000. He had a strong will, and was very obstinate. Only after he came to New York, did he dress poorly and live meanly. While in Boston, he had had no eccentricities of habit or conduct. He left the latter city under a cloud, being suspected of misappropriating funds belonging to the Lobdell estate. In 1860, his brother came to New York, and after much difficulty found him. From this time forward, believing that his brother had lost his fortune, Robert Treat Paine sent him an allowance. In 1862, he was arrested and caused to disgorge the misappropriated funds, \$75,000. He declared, "pulling his hair out by the roots," that he was being robbed, blackmailed, victimized. That is the way the thing appeared to his mind. After that, his eccentricities grew on him; yet there is evidence to show that he was quite able to take care of his fortune, though he concealed it from his brother and his friends. In one transaction in 1868, he agreed to furnish \$20,000 to be doubled in Wall Street. He required of this partner, before advancing the money, a power of attorney not only to control the \$20,000, but to manage all the other's affairs. So closely did he follow his partner that after two or three weeks the latter preferred to forego the contemplated profits and to return Paine his money. The profits in this short time had amounted to \$8,000. Instead of giving the partner \$4,000, he gave him only \$400, under the plea that he had not fulfilled his contract.

From this time on, nothing is known of him, but a life of abject want and beggary. His friend, John H. Wardwell, the claimant, writes to his brother, Robert Treat Paine, Jan. 3, 1883, as follows: "He will not listen to reason, and has become so miserly in spirit, he is thoroughly devoted to a life of abstinence and penury. A gentleman from California has been with us for some time. He has noticed your brother. He says he is precisely in the condition of Mr. Lick of San Francisco, a rich old miser, who was starving himself to death. He was finally put under guardianship by the court (this gentleman being one of them) and was compelled to take care of himself, as a man ought to who was worth his millions." When he was injured on Broadway, Dec. 15, 1885, there were found on his rags \$125 in money. He was found dead in bed.

The following facts were distinctly shown by the evidence at the trial: This man allowed nearly \$400,000 to lie useless for nearly twenty years, and that he did not, like other misers, enjoy the presence and handling of his treasures, but apparently forgot all about it. He used to steal napkins, food, newspapers and other articles of little value. He would borrow small sums of money, when he had hundreds of dollars in his pocket. He bought sometimes bread, and paid only part of the price, saying that he had lost some money. He denied himself the necessaries of life, thus showing an utter disregard or ignorance of every obligation not only to others, but to himself. He had delusions too, believing that he had a claim against the Chicago Land Company, there being not the slightest ground for such an opinion. He believed his brother to be unfriendly to him, while he was shamelessly living on his bounty. He required 10 per cent. interest on a loan of \$10,000 to Mr. Chickering while \$400,000 of his money was lying in the latter's safe without bearing interest.

The evidences of mental incapacity in the case of this miser, for he was a miser, whether he remembered the \$400,000 stowed away in another's safe, or not, are to be found in the following facts: partial paralysis of the limbs, evidently due to some degeneration of the spinal cord; progressive debility due to chronic diarrhoea; lack of memory; filthy habits; disregard of his bodily wants; delusions; the hoarding of such a large sum of money, without specific aim; and the making of a will in vague terms, in a few words, giving it to a man who had no claim on him of any kind. It is possible that, had he not died from weakness of the heart consequent on the shock caused by his accident, he would have fallen within a few months into senile dementia.

The question is, are all misers insane? If so, Johns Hopkins of Baltimore, James Lick of California, were insane, and their wills should not stand, although their wealth did such good work after their death. All men have an element of insanity born with them—*un grain de folie*. In law there is one standard of sanity; in medicine there is another. From the medical standpoint all misers are insane, but the law discriminates. In medicine a man is declared insane on physical as well as mental pleas. The law recognizes in every individual an individual who, as long as he remains faithful to his once known nature, however whimsical, eccentric, absurd that may be, is a sane man. If a man has always been a fool, he is legally sane; he is insane only when the folly crops out suddenly, in sharp contrast with his previous manners and ways. Medicine recognizes alcoholic insanity; law does not. Should a man, while drunk, commit a murder, no expert could prove to the satisfaction of the law the irresponsibility of the patient. Yet medicine affirms that the drunkard is insane, consequently innocent. Drunkenness is the state of a diseased brain. Mr. Paine, up to the time when he left that money in Mr. Chickering's charge, was possibly sane. From that moment his keen desire for the acquisition of wealth began to deteriorate, although it revived in some degree from time to time, like a flickering flame about to be extinguished. As his paralysis increased, there must certainly have been some deterioration of his brain.

Inability to adapt oneself to a changed environment is evidence of insanity. But the opposite, that is, a change of nature without a preceding and corresponding change of environment justifies, perhaps, a similar deduction. There was no cause, no reason, why the life of this man should have been different in New York from what it was in Boston, yet it was utterly different, and had become suddenly so.

Leaving out of the question the moral responsibility of the possession of so much wealth, medicine finds sufficient grounds in this case for the definition of mental incapacity from the facts stated above.

Paine's will was set aside by the surrogate, so that law and medicine together affirmed the insanity of the man.

Definition of Insane Delusion.—The supreme court of errors of Connecticut holds, in the Appeal of Kimberly, Dec. 22, 1896, that the charge of a trial judge is as accurate as, in the nature of things and of language, could reasonably be expected or justly required, when he says that an insane delusion is a false belief, for which there is no reasonable foundation, and which would be incredible under the given circumstances to the same person if of sound mind, and concerning which his mind is not open to permanent correction, through evidence or arguments; and that it is only where false beliefs are such as a reasonable man would not entertain, that they become insane delusions.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

CHAPTER V.—SURGICAL INSTRUCTION AND LITERATURE.

(Continued from page 881.)

In the first half of the century the physicians wrote more in *Latin than in German*. At the expense of the substance, they sought with anxious care for classic purity and beauty of diction and guarded themselves, in their Latin, against errors. "*Donatschnitzer*," the usual expression at that time for grammatical errors. (From the writings of Donatus, a Roman grammarian of about 355 A.D., a system of Latin language was compiled, which served in the middle ages as a guide. Later, a Latin grammar was usually called a *Donat*.) The national self-consciousness was so weak that for a long time Germans contended as to which language they should write. The one party thought German books did more harm than good, bred quacks and incompetents, and increased the sufferings of nervous people, because every layman could understand the books; therefore it was not well to expound medicine in the mother tongue. They considered it too poor to express everything they desired, it made one ridiculous to use newly-coined words. They wished that all physicians would write in Latin, which would lighten study, since then one need not learn to use so many newer languages. "German is an affront," said the satirist Rabener, in 1751. "I know men who would gladly give half their faculties if they were not German, but might have been born in Rome under the consulate of Cicero. To them nothing is so amusing as the care necessary in the German language to avoid *Donatschnitzer*. Whoever took the pains to write elegant and grammatical German could not in their opinion feel greatly abused if they called him a German ignoramus (*deutscher Michel*)." The other party occupied the position held by the French, English and Italians, who wrote in their mother tongue and made merry over us because we learned so many foreign languages. It is safe to say we would be held in greater respect by other nations if we had written German; certainly the Latin writers were guilty of great error and folly. Only later in the second half of the century did it become the general custom to write in German, excepting for doctor's dissertations and academic programs, although in 1778 in Baldinger's new magazine for physicians, German and Latin articles alternated. In 1800, Bernstein appended to his practical handbook for physicians, a Greek, French and German index, and supplied the Latin words with long and short signs, that he might not offend a grammatical ear. The German of the second-class surgeons was thoroughly bad, and their descriptions of interesting cases so diffuse and tedious that today it is a punishment to read them. And also the style of the better surgeons left very much to be wished for, even the Surgeon-General Bilguer uses the word "*Arschbacken*." The first surgeon who wrote in choice German, and even in classic style, was A. G. Richter. He desired an elegant diction and correct expression in order to win the respect of the public. The French, as A. Paré, wrote almost everything in their mother tongue, for the simple reason that they seldom learned foreign

languages. Besides their many orthographical inaccuracies, they often stumbled over the names of foreigners in a very laughable way. It was not unusual for them to make authors' names out of the names of cities, and baptismal names were quoted instead of the family name. The surgeon David, in Paris (1757), in a dissertation on the extraction of cataracts, spoke often of the renowned Gottfried, who was no other than the German anatomist, Gottfried Zinn. In the translation of English they made frequent blunders. The words, "By an unknown," which stood on the title-page of an anonymous English work, were rendered, "Monsieur Unknown," and when Pott published his "*Farther Remarks upon a Method of Curing the Palsy of the Lower Extremities*," M. Duchanoy, in Paris, noticed this work with the following words: "*Monsieur Farther vient de publier en Anglaise*, etc.

German literature made a new departure in the second half of the century, when translations and extracts from the best works of the English and French were imported. There was an especial need in Germany of surgeons who could work independently, so that good original articles very seldom appeared. One of the evils of that time was the fact that our countrymen rarely made their unsuccessful cases public, and did not admit that the publishing of important unsuccessful cases was often far more instructive than collections of entirely successful cures. The praiseworthy undertaking to import foreign wares had also its reverse side; it lay in the blind esteem for everything foreign and the disregard of everything that did not come from London, Edinburgh or Paris. "People of good taste do not read German books," said Zimmermann. Whence developed a formal anglomania, which retarded the growth of national powers. It is not without interest to observe how belles lettres also suffered from this anglomania from 1750 to 1770. Young's "*Night Thoughts*," the romances of Richardson, and others, with their verbose, pathetic, sentimental elements have exercised through a long succession of years the greatest influence on the spirit of literary publications in Germany. They indiscriminately translated the most miserable, insignificant pamphlets, so that of the English medical literature appearing in the course of a year about three-fourths was good. The mania for translations was such that of about two hundred and eighty medical works appearing in Germany in 1784, seventy-seven were translations. Pott's work on injuries of the head was translated three times, by Murr, Rumpelt, and Spohr; likewise, his work on hydrocele. Each complained continually of the false rendering and bad German of the others. A few conducted the business *en gros*. Such was the principal product of Dr. Spohr, in Seesen, the father of our celebrated violinist, who within seven years (1786-1792) issued thirty-six translations of large works. Likewise, Dr. Michaelis, in Leipzig, who launched forty-eight translations in ten years, and probably more later. They both published, for the most part, English works, with a few French and Italian books, but, according to the fashion at that time, did not print their names on the title page. "Do not ask my name, since I do not think to make myself a great name through translations," he says in a preface. Regard for everything foreign was carried to such an extent by us that foreigners came to Germany, not only as physicians-ordinary, but even as teachers in the universities. In 1729 the French Astruc, Professor of Medicine in

Toulouse, went to Dresden as the Saxon physician-in-ordinary, but he soon returned to France. The Dane, Callisen, in 1787, after the death of Voitus, received a call to the Berlin Collegium Medicum Chirurgicum, but he declined it. When, after Baldinger's departure, the chair of medicine at Göttingen was vacant, they called Dr. Duncan from Edinburgh, offering a salary of £200 sterling. He declined this, as he earned very much more from his practice. At this time J. C. Rougemont became surgeon-in-ordinary to the Kurprince of Cologne, and soon after professor of anatomy and surgery in Bonn. He was born in St. Domingo, had studied in Dijon and Paris and had been, under Desault, demonstrator of anatomy and surgery. He knew no German, but he learned it in a very short time. Erfurt also enjoyed the honor of having a French surgeon, Dr. A. Alix, as professor of anatomy. Apparently convinced that surgery was nowhere in the world so advanced as in France he was proudly triumphant if he could discover an Erfurt village barber in some piece of stupidity. Dr. Alix was insolent enough to assert that in the largest cities of France there were not so many fools to be found as in the smallest villages in Germany; from which one can conclude how it was in German villages. French courtesy he certainly had never known, else he could not have become so inflamed over the ignorance of a surgeon who overlooked the venereal cause of phimosi, that he called him a beast. He belonged to those men who throw dirt if one does not take off his hat to them. The worst consequences of this mania for translations and undue esteem for everything foreign, were that the worth of the national writers was entirely overlooked and that the works of our best surgeons in Germany was much less known than that of foreigners.

The growing interest in natural science early resulted in the introduction of periodicals and magazines. Among the first was the *Hamburgische Magazin*, or "Gesammelte Schriften zum Unterricht und Vergnügen aus der Naturforschung und den angenehmen Wissenschaften überhaupt." The first volume appeared (monthly) in 1747.

Of the magazines which had sprung up with the impetus of the times, many had fallen by the wayside, but those in Hanover survived; and to fill the gap occasioned by those which had suspended, a new journal was established in Berlin, in 1765, under the title, *Gesammelte Schriften und Nachrichten für die Liebhaber der Arzneiwissenschaft, Naturgeschichte und der angenehmen Wissenschaften überhaupt*. It contained, like the one in Hamburg, translations, extracts, news from new books and journals. The following were among the most important medical and surgical periodicals:

S. Schaarschmidt. Med. und chir. Berlinische wöchentl. Nachrichten. 6 Bde. 1739-48.—Sammlung der Schriften vom Ursprunge der Wundarzneikunst. Erfurt 1757.—Sammlung chirurgischer Bemerkungen, aus verschiedenen Sprachen übersetzt. Gotha. 5 Theile. 1758-70.—A. G. Richter, Chirurgische Bibliothek. Göttingen. 15 Bde. 1771-97.—Auserlesene Abb. prakt. und chir. Inhalts. Aus den Londoner philos. Transactions. 5 Bde. 1774-80.—J. Cl. Tode, Med. chir. Bibliothek. Kopenhagen. 19 Bde. 1775-86.—Neue med. und chir. Wahrnehmungen, aus verschiedenen Sprachen übersetzt. Gotha 1778.—(Sommer) Sammlungen der auserlesensten und neuesten Abhandlungen für Wundärzte. It is seen that Germany in the second half of the century was rich in medical and surgical periodicals, one after another of which, indeed, suspended after the first volume. Among the first of the journals which appeared regularly was the *Berliner Nachrichten* of Prof. Samuel Schaarschmidt, which recited numerous cases and operations. It consisted of one sheet a week and was sold for a groschen. Those periodicals were very popular which appeared quarterly, four making a volume. They contained exhaustive reports of the current publications, and also of foreign works. In medicine, Professor R. A. Vogel made the beginning, in Göttingen, in 1751; he furnished only extracts from the best books, and used for foreign material, the *Gentleman's Magazine*, the *Monthly Review*, and the *Journal des Savans*, if they did not appear at the same time. Besides medicine, he discussed botany, chemistry, anatomy and zoology. In 1771, A. G. Richter founded a similar quarterly for surgery, the first, as well as the best in Germany, through which he rendered the highest service to German science. He gave faithful and complete extracts from the best surgical and obstetric writings at home and abroad. The royal library in Göttingen, which had a rich collection of English works, was of great service to him. He opened his quarterly for the study of cases, but retained the right to abridge them. With the thirteenth volume (1793), Richter took Professor Loder of Jena, who had just become his son-in-law, as a colleague, and announced that only an unexpected accident could deter him from continuing this work. Four years later the first volume of *Loder's Journal für Chirurgie* appeared, which was a continuation of Richter's quarterly, and Richter gave up his work with the fifteenth volume, after twenty-seven years labor. This quarterly combined the best from all countries of Europe and was indispensable to every surgeon. It served as a bridge over which our old, but yet living surgeons passed to English and French, and joined to the surgery of the foreigners the modern German surgery, when Langenbeck, in 1806, began to

publish a review for surgeons. He said he would deem himself happy if he could approach in some small measure to his great predecessor. After Richter, followed the Danish professor and dramatic poet Tode in 1775, with his medical and surgical review, taking as a model the Edinburgh Medical Commentaries. He wished among other things to show everything which appeared in Denmark. With the different personalities, the kind of *criticisms* also changed, which, if they were harsh, threw the authors into a passion. One feared, yes hated the people, of whom Goethe said, "der tausend Sackerment! schlagt ihn todt den Hund! Es is ein Recensent!" Vogel wrote decorously; on the contrary, the prolific Tode, whose name as author or translator is found on 127 different works, was sharp and abusive, and with his gay, trivial expressions was apt to be sarcastic. His bitterness was especially poured upon the works of Gruner and Baldinger, of whose magazine he said, that the master of a mountain-rat had never, at the opening of his curiosity basket, promised more and performed less. Theden could not bear the blame attached to him for his "Instruction for Under-Surgeons," and he wrote Tode an ironical letter thanking him most heartily for the criticism and promising to lay before him a later work, begging his judgment of it. The severely criticised surgeon Bruns also complained in a bitter letter. Tode exacted the highest standards of excellence of the leading surgeons, and he censured Schmucker for offering lack of time as an excuse for a negligent style. He held that it is no mark of respect to a stranger to receive him in a dressing gown, and no fault in a Schmucker can escape criticism, since whatever the first surgeon-general of the Prussian army allows himself to do will be counted a virtue by the great mass of lesser surgeons. Richter's criticisms were iraproachable. He possessed the enviable gift of hitting the nail exactly on the head, avoiding diffuseness, expressing himself clearly and definitely and clothing his thoughts in a pleasing garb. He rarely passed a judgment, but when necessary, "he observed the rule of frankly asserting the truth according to his own conviction, even against the opinions of those whom he honored, and he was equally frank in hating those cynics and cowards who were too craven to appear by day with uncovered faces, but like scholarly bandits, crouch in the darkness, and masked and mailed thrust a dagger into the back of the object of their hatred." Richter's sound judgment, his emphasis of the merits of others and his high appreciation of them, together with the admission of his own mistakes and his efforts to overcome them, qualities which were greatly admired in the surgical reviews, had a powerful influence upon the development of German surgeons. Laconic brevity alternated with pungent sarcasm. His critique of Henckel's "Chirurgische Operationen" consisted of these four words, "es bleibt beim Alten," and of a certain "Odontology," he says, "a treatise on toothache in which almost nothing is said about toothache."

Besides the reviews, there were collections containing treatises or translations and extracts from dissertations. There were also Latin programs and academic theses, often containing but a few pages and of only temporary interest. As many of these, in spite of their merit, were difficult to obtain, A. von Haller collected into five volumes (1755) the most important of the Latin surgical treatises. To make these more available, the Naumburg physician, F. A. Weiz, began

(1769) to publish in the German language full extracts from theses and treatises on surgery, and this work was swelled to twenty-six volumes. German surgical literature did not possess the abundance of essays, such as those brought out by the Edinburgh Medical Essays, the Medical Transactions and the Medical Observations and Inquiries; the German work lacked sufficient detail. In 1776 the Surgeon-General Schmucker began some notices of the Prussian army physicians, which were collected in the miscellaneous surgical essays published by him, but not until Arnemann's *Magazin für die Wundarzneiwissenschaft* appeared, in 1797, do we find the first periodical whose object was to report especial cases. It was to contain practical treatises and special notes on surgery, further descriptions of operations and their methods, unusual cases, new surgical remedies, sections reports, questions in surgery and surgical literature; criticisms were entirely excluded. Biographies of living physicians were at that time very well received in Germany. Börner issued the first one, in three volumes (1749); Baldinger followed him, and toward the end of the century, Elwert. In them all, as might be expected, the number of surgeons noticed was much less than that of physicians. A new kind of literature came into fashion in France, the lexicons, in which they expounded the whole science in little broken bits, without coherence (Sue, junior, 1773). Bernstein introduced this kind of literature into Germany.

The number of journals, magazines and collections increased so considerably that in the latter years of the century men began to complain of them, and at the same time good text-books appeared but seldom. The periodicals alone would fill a small library, and it gave the practitioners no little perplexity. For a large part of them the periodicals formed the only source of information and it became more and more impossible for them to collect all these publications and to follow the progress of science.

Most of the teachers of surgery felt obliged to bring out a special *handbook, or text-book*, for their lectures, and for that reason the number of such works was very large compared to those of our time. Within fifty years (1750-1800) there appeared in Germany some sixty handbooks, text-books, principles, guides, manuals and instructions. The most important of these were those by Heister, Platner, Ludwig, Theden, Plenck, Pallas, Eller, van Swieten, A. G. Richter, Bilguer, Bernstein, Loder, Arnemann, Metzger, Ackermann, and others. This number includes twelve translations of text-books, or works of a similar nature; among them the works of de Villars, Sue le jeune, de la Motte, Chopart, Desault, Portal, Lara, Aitkin, Benjamin Bell, White and Nessi. Instead of inserting here a catalogue of surgical books, such as we will have occasion to give from time to time in the course of this work, we will mention in passing only those works which were recommended to German surgeons by their teachers (Professor Plenck and Surgeon-General Theden). They were as follows:

For anatomy.—A. Schaarschmidt, Anatomische Tabellen, 1759.—Plenck, Anfangsgr. der Anatomie.—Cassebohm, Anweisung zur anat. Betrachtung und Zergliederung 1769.—Kulmus, Anat. Tabellen, 1741.—Verdier's und Winslow's anat. Beschrieb.

For physiology.—Haller Erster Umriss der Geschäfte des menschl. Lebens, 1770: Anfangsgr. der Physiologie. 8 Theile, 1762.—Heuermann, Phys. 4 Th. 1751.

For pharmacology.—Plenck, Select. mat. chirurgicæ, 1775. Auswahl der chir. Arzneimittel, 1775.—Gerhardt, Mat. med. 1781.—Gleditsch, Verzeichniss der gewöhl. Arzneigewächse, 1769.—Löseke, Mat. med. 1755.

For medicine.—Tissot's Schriften.—Zimmermann, Von der Erfahrung, 1763.—Löecke, Therap. spec. int. 4 Th. 1767.—Home, Grundsätze der Arz. 1772. Zückert, Abh. über Nahrungsmittel, Speisen u. s. w.

For surgery.—Heister, Grosse Chir. 1718, kleine Chir. 1747.—Z. Platner, Einleitung in die Wundarzneik. 1749.—E. Platner, Zusätze, 1776.—Plenk, Anfangsgründe, 1783.—Ludwig, Anfangsgründe, 1766.—Pallas, Chirurgie, 1764.—Pott, Abh. über versch. Gegenstände der Wundarz. 2 Theile.—Abh. der Académie de Chirurgie.

For bandaging and the use of instruments.—Henckel, Anleitung zum chir. Verbands, 1750.—Garengot, Traité, 1720.

For operations.—Bertrand, Abh. 1770.—Heuermann, Abh. 1754.—Henckel, Abh. 1770.

For diseases of the bones.—Petit, Kirkland, Pallas.

For cases in the field.—Works by Bilguer, Theden, Baldinger, van Swieten, Pringle.—Surgical notes by Bilguer, Schmucker, Pheden, Plenk, Leber, Hagen, Henckel, le Dran, Acrel, Bromfield, Goulard.—Bibliothek der Chirurgie by Richter, Weiz (Auszüge aus Disputat.), Sue (chir. Lexicon.)

The following figures may give an idea of prices of books at that time:

I do not know what the dealers paid for surgical works. In general the receipts of literary men in the middle of the century were not inconsiderable if they were university teachers and men of prominence. In Schiller's time, as is known, the book trade showed itself in a very honorable light, prostrating itself before our poet and begging for the privilege of publishing his writings. But in general the revenues were slender; for example, in 1737 a very honorable Herr Lesser received only sixteen good groschen per printed page of a Chronicle of Nordhausen.

(To be continued.)

SOCIETY PROCEEDINGS.

German Medical Society of the City of New York.

Stated Meeting, Feb. 1, 1897.

W. FREUDENTHAL, M.D., in the chair.

Dr. SIMON BARUCH read a paper on

FAULTY HYDROTHERAPY,

in which he opened with the statement that despite its antiquity water has not yet obtained a firm footing in therapeutics; despite its marked clinical results it still requires to be brought to the attention of practitioners; despite its espousal by the best authorities in ancient and modern medical practice and literature, the average medical man is not familiar with its history, action and merits.

Dr. Baruch regarded as the chief reason for this state of affairs, the absence of instruction in hydrotherapy in the curriculum of medical schools, to which is due the ignorance of the rationale of the action of water and the unfamiliarity with its correct application, which are found among the majority of public men. The consequent indifference to definite methods has rendered its application in the hands of many unsuccessful and discouraging. Failure is the sure result of inattention to details. As the physician must judge the value of a remedy by his experience, it followed that failure to achieve the results which the experience of others had led him to expect, has brought this remedy into disrepute, the fact unhappily remaining unrecognized that not the remedy, but its improper application, was at fault.

Although water is a simple remedy and appears to be so easily applied, Dr. Baruch believed that no remedy in the

entire materia medica demands a like judgment and care in its application. As an illustration, an incident was referred to showing how a brilliant young hospital physician shrank from the Brand bath in typhoid fever, because he had seen a case die under cold water treatment, which consisted in wrapping the patient in a sheet and sprinkling her with ice water. He insisted that the object of the Brand bath is to sustain the nerve centers first and to reduce the temperature afterward.

Although the latter was regarded as an index of gravity in most cases, the bath was not intended to combat it. A bath of 65 degrees F., with friction for twenty minutes every three hours, whenever the body temperature reached 102.5 degrees F., is calculated to arouse the nerve centers from their lethargy and give an impetus to all the dormant functions depending upon them. The low temperature of the bath irritates the peripheral sensory filaments, from which the irritation is conveyed to the central nervous system, to be reflected upon the heart, lungs and secreting organs. Friction adds to the irritation by multiplying it, the cold water being kept in motion; cold affusion over head and shoulders is added to promote the same object. To whip up the nervous system (as is done in poisoning by narcotics) is the object of the Brand bath. But day by day, with occasional disappointments, a fifth, or a quarter, or a half degree of temperature is gained; the heart maintains its vigor, the kidneys increase their work, the stomach receives more kindly the proffered nourishment; sleep is won.

By this method the enemy can not be routed, the disease can not be shortened, but we hold him in check surely and completely until his reinforcements fail. The bacterial life period reaches its end, the toxins cease to be evolved, and at last the physician stands conqueror of this deadly enemy. This is the true aim, the correct rationale of the Brand bath. Were temperature reduction the chief need, we would find the key to the situation in our splendid coal tar antipyretics; were pulse reduction the desideratum, veratrum viride would prove an open sesame; were nourishment the chief object, there is no lack of this in modern culinary and chemical art. But all these are as naught in the face of a toxemia which overwhelms the nerve centers of the most robust as well as the most feeble patient. To wrap the patient in a sheet and then sprinkle him with ice water, as was done in the case cited, was a deviation from the correct technique of the typhoid fever bath. Such a procedure does not fulfil the main object of arousing the nervous system. After the first shock has passed, no opportunity is given for reaction because the sprinkling of ice water continues, the cutaneous vessels and the elastic tissue of the true skin contract, as evidenced by cutis anserina; the extreme cold imparted by the wet sheet, without remission, benumbs the sensory nerves and thus impedes the transmission of the shock and subsequent stimulus, even if the latter has ensued in an exceptionally strong individual.

Wrapping the patient in a sheet and sprinkling him with ice water did not fulfill these conditions, because of the absence of friction in this faulty technique (which in the Brand bath stimulates to reaction, and by widening the blood area of the skin cools a large quantity of blood) frustrates completely the true aim of the cold bath.

The surface temperature is indeed reduced by this improper method, but the blood is driven to the interior, congestions are favored, the organs are overloaded and the patient emerges from such a bath a shivering, cyanosed weakling. The ideal results obtained by Brand and others in 1,200 cases, without mortality, can only be realized by following the exact technique of Brand.

Dr. Baruch claimed that physicians have failed to obtain ideal results, because they deviated from the ideal technique, each one modifying it to suit his own fancy. He insisted that to the free deviation from its correct technique may be ascribed the lack of appreciation of the therapeutic value of the Brand method. Those physicians who have mastered its technique will agree with Professor Delafield, who teaches that immersion in cold water is the only real treatment of typhoid fever, and the only way to practice this treatment is the exact method of Brand.

In the treatment of all diseases our teachers insist upon correct dosage of medicinal agents, the exact time and mode of their administration, frequency of repetition and even their exact preparation. Dr. Baruch desires to plead for similar care and attention to the prescription of water as a remedy.

In chronic diseases a correct application of water is quite as important as in the acute. A prescription for a bath, or other hydiatic procedure, without exact statement of temperature, duration, pressure and method is as absurd as a prescription for medicine without stating dose and method of administering. The import of pressure, temperature and duration of

every hyriatic procedure requires to be impressed with emphasis. Every physician realizes the difference of effect arising from different temperatures, and yet we commonly read directions for cold, hot and tepid baths.

Dr. Baruch illustrated the correct and contrasted it with the faulty water treatment. He claimed that by gradually accustoming patients to lower temperature and stronger pressure, he has obtained very favorable results in private and hospital practice. If low temperatures are used at once the patient is shocked and depreciated.

The same may be said of neurasthenia and other chronic cases, in which he cited Dr. Draper as claiming that the results of hydrotherapy are striking, but more effective than medicine.

He also referred to other faulty methods practiced by justly eminent teachers who seem to be quiet inexact in prescribing water, but extremely precise in prescribing phosphorus and strychnin. He especially inveighed against the gradually cooled bath, which is intended to avoid shock and be pleasant to the patient. Such a bath does not fulfill its object properly, because the surface vessels are relaxed by the warm water; reactive capacity is diminished by its calming and sedative effect. The vaso-constrictors are depressed. The subsequent cooling of the water finds the sensory nerves unprepared, and chilliness usually results unless the patient be more robust than is the average neurasthenic. It is unhappily a very prevalent error to regard the most agreeable bath as the most salutary. We do not so reason in the application of medicinal agents, of electricity or dist. And the application of water may be made agreeable by gradually accustoming the patient to lower temperatures, slowly reducing them every day or two, making the application brief at first and increasing the duration and pressure day by day. The prime essential, however, should always be borne in mind that reaction is our aim, that this can not be evoked without some shock, that the more intense the latter the more effective the reaction, but the more brief it is, the less unpleasant. If the physician bear in mind that his object in treating such a case is an increase of the quantity of blood circulating in the cutaneous vessels, an enhancement of the nutrition, a stimulus to the entire nervous system, he will endeavor to so order the technique, provided he has mastered its details, that day by day the reactive capacity may be tested and no harm ensue. As the shock and reaction increases day by day, the patient will emerge from the treatment with a ruddy hue. The increased circulation will endure more and more every day, languor and loss of appetite will cease, and if the patient does not fully recover under this domestic treatment, douches of the same temperature and with a pressure of twenty-five to thirty pounds, preceded or not by hot air baths, will bring about a final restoration of health.

In acute cases like typhoid fever, which are under constant observation of the physician, the latter may at once note the result of an improper use of water and modify it, or, as is more often the case, relinquish it altogether. But in chronic cases much damage may be done before the physician discovers it, if the treatment be not in the hands of trained and intelligent attendants who are under medical supervision. Too often the details are left to nurses, because physicians have not received instruction in the rationale and technique.

To enable him to administer water with precision Dr. Baruch has, without neglecting other hyriatic procedures, resorted chiefly to douches, with which he is capable of grading temperature, duration and pressure by means of an apparatus devised by him.

Dr. Baruch concluded by saying:

1. That the therapeutic application of water demands at least as much care as the use of medicinal agents.
2. That owing to the flexibility of water as a remedial agent, greater demands are made upon the practitioner than in the use of medicines.
3. That the best results may be obtained only by following an exact technique in each case.
4. That the reason that different results are obtained by different physicians from the application of water, may be found in the technical errors, committed on account of an erroneous conception of the rationale of hydrotherapy.

DISCUSSION.

Dr. I. ADLER said that in the most modern medical view hydrotherapy plays an important rôle, and that as Dr. Baruch has emphasized, the application of water is so lax, that clinically and diagnostically much less is accomplished than would otherwise be. But this is not alone the fault of physicians, but, perhaps, as much of those who specially cultivate hydrotherapy. The latter seems to be based more on personal impressions than scientific data. We can not accept water, there-

fore, on the same bases as our medicinal agents. As an example, the physiologic action of strychnin upon the spinal cord is exactly known, but of water we can not say this. There should be a knowledge of the physiologic action of water ere we are asked to accept it as scientific remedy.

Dr. Adler thought it is going too far to accept the baths as the only remedy of typhoid. To him the statistics cited by Dr. Baruch, to prove that the mortality has been reduced to almost nothing, are new. Dr. Adler has used the baths more in hospitals than in private practice, where it is more difficult to apply. One may have very good results without baths, although the latter are one of our very best agents where the heart is feeble, delirium is intense and somnolence occurs. But he can not accept Brand's rule, supported by Dr. Baruch, that 102 degrees F., should be the signal for baths. Some patients become delirious at 100.5 degrees; others may have 105 and not be delirious. He would also like to express confidence in small doses of antipyretics, which afford much relief, although he does not approve of their routine application for temperature reduction.

Dr. L. WEBER has always used cold baths in typhoid in the absence of kidney complications; he begins the treatment with a large dose of calomel to clean the intestinal tract and disinfect it. In private practice he has not often had an opportunity of applying the Brand method. There seems to be a silent but active opposition to it among the nurses. There is no doubt that Brand's method offers great advantages, and is specially adapted for enhancing the resisting capacity of the nervous system. Dr. Weber uses antipyretics in small doses for temperature reduction. In neurasthenia Dr. Weber has seen much of hydrotherapy. It seemed to him, however, that many of these cases recover under any treatment.

Dr. A. ROSE opposed Dr. Adler's views that hydrotherapy was not based upon sufficient scientific investigations and experiments. It would seem that the statements of quacks are more regarded than those scientific experiments. He referred to the plethysograph of Winternitz, by which the passage of blood, driven from one part of the body by cold baths, was demonstrated in other parts. Dr. Rose referred to his experience in erysipelas, and his observations with the permanent baths in obstinate rheumatism.

Dr. A. SEIBERT believed that the complaints made by hydrotherapists, that their doctrines have not been generally accepted by the profession, are to be charged to their own writings, in which they use many hyperboles. The Brand bath is not responsible for the reduction of mortality of typhoid fever during the past thirty years, but rather to the general improvement in the treatment of the disease. A large acquaintance with statistics enables him to say that many sins are committed with statistics. In his hospital practice Dr. Seibert uses the Brand method only on patients who are received in a somnolent condition. He prefers to reach the seat of the disease by cleaning and bathing the intestinal tract rather than to cool the skin and then excite the nervous system.

Dr. Seibert regards as novel the claim that the early adoption of the Brand method is capable of affording absolute protection against complications.

Dr. TALMEY believed that one reason for the non-acceptance of hydrotherapy lies in the objections of the public; another reason lies in the inistance of the hydrotherapist upon so many details, which no ordinary man is presumed as capable of executing as well as they.

Dr. BARUCH closed the discussion by regretting the brief time at his disposal. He insisted that the proof exists showing that the action of water is more rational and scientific than that of any other remedy. Very little is known of the action of strychnin in non-toxic dose. It may be administered for days, weeks and months without any subjective or objective evidence of its presence, in the pulse, blood pressure, respiration, etc. Our knowledge of its effects in disease is learned almost entirely from non-toxic doses. Of water we know much more. It may be dosed with precision afforded by a latitude of 70 degrees of temperature (35 to 110), a duration of a second to many minutes, a pressure of from one to forty pounds. We also have various methods of applying it; by applying packs, baths, douches, etc., by which its effects may be graded. A few days ago he subjected an attendant in the Hyriatic Institute to a tub bath of 80 degrees F., for ten minutes. The effect was at once pronounced upon the pulse, as ascertained by the finger and the sphygmograph; the blood count showed an increase of 700,000 red cells and 1,500 white cells in blood drawn from the lobe of the left ear. Is any analogous experiment with non-toxic doses of strychnin on record? So far from there being a lack of scientific experiment of the action of water, these abound within the past five years, having been made in Zuntz's and other laboratories by Breitenstein, Loewy, Knoepfmacher and others.

Thayer, of Johns Hopkins Hospital, has confirmed the statements of Winternitz and Rovighi, that the red and white blood cells increase after cold water applications; the sphygmomanometer has demonstrated that the force of the heart is increased by them; Vinaj has shown with the ergograph of Mosso with exactness how the muscular power is enhanced by them. Roque and Weil have shown that the urotoxic coefficient of the urine in typhoid fever is increased manifold after the use of the cold bath.

That early cold baths prevent complications has been demonstrated as no fact in medicine has been demonstrated before. Dr. A. Vogl, medical director of the Bavarian army, has collected from the records of the Military Hospital of Munich all the cases of typhoid fever which were treated during a period of forty years in that hospital. He gives the type of the disease each year, the symptoms, the treatment, mortality and results of autopsy. Since the strict bath treatment was adopted he found the mortality ranged from 15 to 30 per cent. This proves that the result is not due to a change of the type in the disease, which the records show to have varied from year to year during this long period, but that it is entirely the result of the bath treatment which prevented lethal complications. Although the Brand method must be applied before the fifth day, every fever patient may be bathed with advantage. Dr. Baruch stated that he invariably uses it in private practice, that he declines to treat the patient otherwise, and that he has been dismissed from a case but once for this reason.

Contrary to Dr. Talmey's naïve accusation, modern hydrotherapists have taken pains to simplify hydrotherapy and make it the common property of physicians. But this can not be accomplished so long as the latter persists in their skeptical attitude. The most superficial study would demonstrate that water produces a thermic and mechanical excitation of the cutaneous nerve endings which operates upon motor and sensory tracts as a reflex upon the circulation, respiration and secretions. These demonstrations are so abundant in literature that Dr. Baruch would have regarded it as an insult to the intelligence of his audience to have reiterated them.

That a woman may be aroused from syncope by the simple sprinkling of cold water upon the face is known to almost every lay person, and the scientific explanation of this process is recognized by every tyro in medicine to be a powerful irritation by cold, which is conveyed from the cutaneous nerves to the central nervous system and thence by reflex to the vagus. This seems, perhaps, too simple; rabbits and guinea pigs are not required for the "scientific" explanation of the powerful effect. If such sacrifices are demanded, however, to establish water as a scientific remedy, the classical experiment of Maximilian Schuler upon trephined rabbits may be offered. Schuler exposed the vessels of the pia and, placing the rabbits in water at different temperatures, observed the effects of these applications on the animals, he demonstrated more clearly than has ever been done in the study of any medical agent the effect of these water applications. He showed conclusively that the latter called into action a hydrostatic effect, which makes water a powerful agent for influencing the circulation of blood in an animal. Besides, Winternitz and others have demonstrated in the most exact manner by laboratory experiments that the corpuscular elements of the blood are subjected to such decided changes by water applications that no medical agent is capable of approaching their effects.

A very fruitful but sadly neglected field lies before the practical physician who does not meet hydrotherapy with a shrug of the shoulders.

To Dr. Talmey's insinuations that hydrotherapists are so insistent upon details that it is difficult for ordinary mortals to follow their directions, Dr. Baruch replied by protesting against the tendency of physicians to leave the water treatment of chronic cases to bath attendants or other nurses who claim to know all about it, but really do not know anything but the mechanical part. Does not every physician who orders a cold bath in typhoid fever give the nurse directions regarding the temperature, friction, drying, duration, etc.? Why then should physicians leave such important details to a nurse when ordering a wet pack, douche, etc., for a chronic case. Would it not be far easier for physicians to consult some work on this subject and use their own judgment in ordering the necessary temperature, duration, etc. It is just as absurd to leave these important details to self-important nurses as it is to leave the doses, etc., of a medicine to the druggist to prescribe and administer. Indeed the latter would be safer, because the druggist is, at least, an educated man. As Vogl has said, leaving the treatment entirely in the hands of lay people has brought hydrotherapy into disrepute.

With regard to clinical observations this discussion again makes evident the fact that many physicians have occupied

themselves with hydrotherapy insufficiently. In reply to Dr. Seibert's statement that the Brand method is not entitled to the credit of reducing the mortality of typhoid fever, Dr. Baruch referred to Dr. Vogl's statistics for positive evidence to the contrary. Moreover, Prof. G. Gerhardt of Berlin said in his recent opening lecture before his class at the University: "The mortality of typhoid fever has been reduced by the Brand cold water treatment to one-fourth."

That the hydrotherapists "resort to many hyperboles in their writings and lectures" may, as Dr. Seibert states, be true. But the most eminent physicians also resort to "hyperboles" when they have mastered hydrotherapy and applied it correctly. This will be demonstrated by the following excerpts:

Prof. F. A. Hoffman of Leipsic ("Lectures on General Therapeutics," 1892) says: "Herein lies the unexcelled value of cold water in therapeutics; we invigorate the nervous system and thereby enhance the cardiac capacity." (p. 88.) "I am convinced that in time all chronic organic diseases will come into the domain of the bath treatment." (p. 392.)

"Cold affusions have justly been elevated to become the chief remedy in the catarrhal pneumonia of children." (p. 130.)

Prof. Wilhelm Erb of Heidelberg writes in Ziemssen's Cyclopaedia: "Among the most effective and powerful agents in our branch are cold and cool baths and cold water treatment. Its results in all possible chronic nerve troubles are extraordinarily favorable. We have few remedies which exert a similar powerful influence upon the nervous system."

Professor Kussmaul of Strasburg writes: "There is no doubt that the belief in the prescription is waning among educated people, and the confidence in dietetic remedies and the remedial value of water is in the ascendant. Water especially has won for itself a constantly growing confidence as a remedy, because, unlike any other, it may be applied by reason of varied temperature and methods to the most varied curative purposes."

Semmla, the recently deceased professor of therapeutics at the Naples University, whose work has been translated into German and supplied with a laudatory preface by Nothnagel, writes: "Hydrotherapy excites cutaneous activity, and with it all functions affecting tissue changes and organic purification, so that frequently real marvels of restoration in severe and desperate cases have been obtained by it."

From Professor von Leyden's Berlin clinic Klemperer reports ("Publications of the Hufeland Society," 1896) "that in hydrotherapeutic effects we observe quite extraordinary and incompatible stimulation of the nervous system, which is exerted upon the various organs."

"In our clinic we regard hydrotherapy as quite an essential factor in bronchial asthma.

"Much greater is its rôle in nervous diseases of the heart—but it plays quite a powerful rôle also in organic heart diseases.

"As much more effective do I regard these hydrotherapeutic influences in stomach and intestinal diseases. Here hydrotherapy remains the most powerful factor. I may say briefly that we have treated the most varied pathologic conditions of the gastro-intestinal tract—chronic constipation, diarrhea, enteralgia, hydrotherapeutically with great benefit."

Dr. Baruch said that he might quote many "hyperboles" from the writings and lectures of the most eminent clinical teachers. These gentlemen have not been deterred by the "hyperboles of the hydrotherapists;" they have investigated the subject as have Delafeld, Peabody, Osler and Draper in our own country, and have become consistent advocates.

One thing Dr. Baruch desired especially to emphasize, namely, that in his article, as in all his writings, he has never lauded water as a universal remedy. Dr. Baruch claimed that his observations in hydrotherapy were gathered in the capacity of family and hospital physician, in which respect he stands alone. As a practitioner of thirty-five years, Dr. Baruch did not feel prepared to throw aside calomel, salicylic acid, morphin, quinin and other approved remedies. Despite this fact, he felt compelled to acknowledge that water has served him well in the most desperate chronic cases after other most approved remedies had failed in his own hands as well as in the hands of colleagues. For this reason he would say with Pindar, ἀριστον μὲν ὕδωρ. And herein he felt himself sustained by the most eminent clinicians of the present time, whose opinions he desired to impress upon his colleagues.

Argentol as an Antiseptic.—On account of its extreme instability, argentol is superior to itrol and actol, so highly recommended by Credé, and gradually being endorsed by others, for the treatment of wounds. It is the quinaseptolate of silver and decomposes into the original oxyquinilin and silver, in contact with septic matters, each of which is a powerful antiseptic.—*Nouv. Remèdes*, April 8.

Kentucky State Medical Society.

Abstract of the Proceedings of the Forty-second Annual Meeting, held at Owensboro, May 5, 6 and 7, 1897.

FIRST DAY—MORNING SESSION.

The Society met in the County Court House and was called to order by the President, Dr. R. C. McCHORD of Lebanon.

An Address of Welcome was prepared by Dr. J. W. Ellis, but through his illness and absence, it was read by Hon. Thos. L. Petit, an eloquent response to which was made by Dr. Dudley S. Reynolds of Louisville.

The reports of the Treasurer and Secretary were read and adopted. About sixty applicants were elected to membership during the sessions. The Association then adjourned until the afternoon.

FIRST DAY—AFTERNOON SESSION.

Immediately upon reassembling, the reading of papers was proceeded with, and a series of contributions were presented on "The Fevers of Kentucky."

Dr. W. W. RICHMOND of Clinton read a paper on

REMITTENT FEVER.

He said remittent fever may be considered a secondary development of malaria, assuming intermittent fever to be the natural or primary offspring. Its different forms had been divided into the congestive, comatose and hemorrhagic, the former more properly belonging to intermittent fever in the form of a congestive chill; the two latter he assumes to be the chief irregularities of remittent fever, regarding the term typho-malarial as unscientific and one that should not be recognized, basing his judgment upon the fact that while germs of two distinct diseases may operate at the same time in the same person, and recognizing the fact that affiliation is a distinct characteristic of malaria, it was not the nature of germs to mix or to cooperate in the production of something contrary to the nature of their individual kind. It may be asked, Why in a malarious district, when intermittent fever prevails every year, do the different forms of remittent fever occur only in certain seasons and certain localities? The rational answer should be, close proximity to the place of development of the poison, its quantity or concentration, and its intensity of action.

Intermittent fever occurs to some extent every year in certain portions of Kentucky, and when there is an unusual amount of rainfall late in the spring and a late rise of the river, overflowing the bottom lands, followed by the necessary continued temperature, decayed vegetation being almost always present, remittent fever with the other forms of malaria makes its appearance.

The chief symptoms of remittent fever in its simplicity are high temperature, quick pulse, obstinate head and backache, epigastric tenderness with sick stomach, the latter often continuing throughout the entire course of the fever, which usually lasts from seven to ten days. In the case of complications the disease continues beyond that time. Cases of the disease were then reported and the treatment outlined.

Dr. B. W. SMOCK of Oakland followed with a paper on

EPIDEMIC CEREBRO-SPINAL FEVERS AS SEEN IN KENTUCKY.

The author defined this malady as a specific, infectious pandemic disease, slightly contagious, probably microbic in origin, occurring sporadically or in epidemics, characterized anatomically by inflammation of the membrane of the brain and cord, and clinically by irregular nervous phenomena pointing to profound disturbance of the cerebro-spinal functions, the most prominent of which are pain in the head and often in the extremities, hyperesthesia, contraction of the muscles of the back and neck, vomiting, irregular fever, delirium, and in several cases, coma.

As far as the author was able to ascertain, the first appearance of this dread disease in Kentucky, in anything like epidemic form, was in 1842 in the city of Louisville, and again in the same city in 1861. Since then occasional outbreaks had been noticed at different times in almost every section of the State. In Floyd County, where the author was able to make personal observations, there were in this outbreak twenty-five cases with eighteen deaths. The disease spent its force in about three weeks and disappeared almost as suddenly as it appeared.

In an epidemic which occurred in Edmonson County, in February, 1896, contrary to the opinions previously held as to the non-contagious character of the disease, the author was able to trace an almost house to house infection. The disease appeared here first in a young married woman, 22 years of age, and from her seven cases developed in a few days, all of which terminated fatally.

The characteristic symptoms of the malady as they appeared

during the epidemics were dwelt upon. As to medicinal measures, opium was the only drug which seemed to combat the ugly symptoms of the disease.

Dr. T. B. GREENLEY of Meadow Lawn, followed with a paper on

TYPHOID FEVER,

the history of which he said was, comparatively speaking, of modern origin. As far as he had examined the literature, he has found no account of it previous to the commencement of the present century. It was not recognized as a distinct disease in Great Britain much before 1850, being known only by the cognomen of typhus.

In 1840 Dr. A. P. Stewart of the Middlesex Hospital, pointed out the characteristic differences between the two diseases; but little attention, however, was given his views until Dr. Jenner, Physician to her Majesty, published two papers on "The Identity or Non-Identity of Typhus and Typhoid Fever." In his papers Jenner agreed with Dr. Stewart and very plainly described the characteristic phenomena of the two diseases, as did also several subsequent observers.

Dr. Greenley then dwelt minutely and exhaustively upon the causes and symptomatology of the affection, and considered at some length its pathology. He thinks the main reason why writers on typhoid fever fifty or more years ago were impressed with the belief in the personal contagion of the disease was, in many instances, due to mistaken diagnoses. Many of the symptoms of this disease were so similar to those of typhus, that the latter was taken for the former. If the author is in doubt about the true character of typhoid, when it closely simulates remittent fever, he is in the habit of testing it for forty-eight hours with quinin, the latter giving way usually in that time. For a long time the speaker has been impressed with the opinion that in many cases of summer and fall typhoid, malaria plays an active part, and he has therefore given quinin as a perfect treatment.

Dr. HENRY E. TULEY of Louisville, contributed an interesting paper on

THE SERUM DIAGNOSIS OF TYPHOID FEVER.

He began by saying that the discussion of typhoid fever at this time would hardly be complete without a consideration of its diagnosis by means of an examination of the blood. Few discoveries in the field of bacteriology or serum therapy had caused such widespread interest as the serum diagnosis of typhoid fever. Reference was then made to contributions on the subject by Dr. Wyatt Johnston, Florence Brandeis, Pfeiffer, Widal, Appel and Thornbury, and others.

Dr. Tuley gave a description of the technique of the examination of the blood as advised by Biggs and Park in their investigations in the New York City Board of Health, and which the essayist himself follows in the main. He gave a brief report of fourteen cases examined by him, which we give herewith.

Case 1.—Woman, aged 24 years. First specimen obtained during the fourth week of a typical typhoid attack, and the second on the fortieth day. Reaction was immediate in both instances. The first specimen was examined on the day it was obtained and the second after two weeks. A sample obtained from this same patient a few days ago proved negative.

Case 2.—Male, age 8 years. Clinical diagnosis, typhoid fever, maximum temperature 105. Constipation throughout. Examination after blood drawn two weeks, the reaction being prompt. The subsequent clinical diagnosis was typhoid fever.

Case 3.—Male, aged 27. Blood obtained in the second week of his illness, the clinical diagnosis being obscure. Blood examined twenty-four hours after being drawn, the reaction being very marked. The subsequent clinical diagnosis was typhoid fever.

Case 4.—Male, aged 30. Clinical diagnosis, typhoid fever in relapse. Blood obtained on the fortieth day of the attack, the maximum temperature was 103.5. Blood examined five days after being drawn, the culture was fifty-two hours old and very active. The reaction was obtained. First the immobilization, then the clumping followed later.

Case 5.—Female, aged 7 years. Headaches, nose bleed, fever, abdominal pain and diarrhea. Clinical diagnosis pointed to typhoid fever. Blood examined twenty four hours after being drawn and no reaction could be tried after several trials. Subsequent diagnosis was remittent fever.

Case 6.—Male, aged 27 years. Clinical diagnosis quotidian malaria, without verification by the microscope. Blood examined after second week of illness with a very active culture, but no reaction was obtained.

Case 7.—Female, adult. Reaction present and marked. Blood obtained during the second week.

Case 8.—Male, aged about 30. Clinical diagnosis not made,

but afterward proved to be malaria. Blood examined with negative results.

Case 9.—Male, adult, City Hospital. Admitted with all the symptoms of typhoid fever. Prodromal symptoms had lasted for several weeks. The prominent symptoms on admission were epistaxis, tenderness in the right iliac region with gurgling, spots on the abdomen very closely resembling the rose spots, and low muttering delirium soon developed. Provisional diagnosis of typhoid fever. Specimen of the blood was obtained two days before his death, and examination showed no reaction after repeated trials. The autopsy revealed a tubercular meningitis, with consolidation of the right apex of the lung, congestion of the intestines with absolutely no evidence of typhoid ulceration and a small spleen. There were no pupillary symptoms during life and none that would suggest meningitis save the delirium and stupor which developed later.

Case 10.—Male, aged 35 years. Sick three weeks with what was supposed to be septicemia from an abscess on the hand. Examination of the blood obtained on the twenty-third day showed a marked and immediate reaction. There is still a difference of opinion as to the diagnosis of this case among the physicians who saw him, but the preponderance of evidence is that he had typhoid.

Case 11.—Medical student, aged 26. Clinical diagnosis was made provisionally of typhoid fever, and a pseudo-reaction was obtained after a number of trials, the clumping never being marked. The reaction that was obtained was perhaps due to a too concentrated solution of blood being used. The patient afterward developed measles.

Case 12.—Male, aged 18 years. Clinical diagnosis was malaria, but as it did not respond to quinin, and delirium supervened, typhoid was suspected and the blood examined. Quite a prompt and a very marked reaction was obtained. If this case was one of typhoid fever it was an anomalous one, as the onset was rather sudden, ushered in with chilly sensations, though there had been prodromal symptoms for more than ten days before he went to bed. In fact, the symptoms were so acute and aggressive as to suggest its being cerebro-spinal meningitis. It may have been such a case as Tyson describes under the head of "nervous typhoid."

The fact, however, that there was no reaction in case 9, reported above, on whom an autopsy was performed and a meningitis was found, would lead us to believe that this was typhoid with meningeal complications.

Case 13.—Medical student, aged 25 years. Sick four days with influenza. Blood examination negative.

Case 14.—Male, aged 40. Fever developed some weeks after an operation for radical cure for hernia was done. Clinical diagnosis was typhoid fever, but it later proved to be rheumatism. Blood examination was negative.

THE MANAGEMENT OF TYPHOID FEVER.

This paper was read by Dr. JOHN G. CECIL of Louisville. He summarized the principles of management under the following heads: 1, control the fever within reasonable bounds; 2, maintain the strength by judicious feeding; 3, intestinal antiseptics; 4, meet special indications and complications by specific agents; 5, watchful care and scientific nursing prolonged through convalescence.

In keeping the fever within reasonable bounds, without expense to the heart, lies the secret of improved mortality. The measures in common use are the Brand treatment, the sponge bath, cold pack and antipyretic medicines. These were considered in the order mentioned. Medicinal antipyretics to control fever were condemned. In importance, not second to anything in the management of typhoid fever, was the maintenance of strength by judicious feeding. That intestinal antiseptics have a place in the management of typhoid fever was quite true, but that such agents could be so applied as to counteract and destroy the bacilli, was quite another question.

In meeting the special indications that ordinarily arise, it should be done in the most direct way and with the fewest possible drugs. Medicines so applied should be directed to the control of symptoms, and are in no sense specific agents for the disease itself, until the more important conditions or complications could be noticed.

Diarrhea was an important feature. Patients properly fed seldom suffered a serious diarrhea; hence by special attention in this direction and by the use of intestinal antiseptics, it might be prevented or relieved. Tympanites, as a complication, was better treated by preventives. Intestinal hemorrhage is best controlled by allaying the fears of the patient, by absolute quiet, cold applications to abdomen, and by narcotic doses of deodorized tincture of opium. Teaspoonful doses of turpentine sometimes act with striking effect.

Perforation of the bowel in cases of typhoid was amenable

to surgical interference. Recent statistics show that this is not only a feasible operation, but a successful one. For general asthenia and heart failure, nothing is superior to strychnia and good whisky.

Lastly, in no disease was the value of faithful and intelligent nursing more apparent, and if recent years had added nothing besides the trained nurse, her introduction would mark an epoch in the management of typhoid fever.

Dr. J. G. BROOKS of Paducah read a paper on

BLOODLESS AMPUTATIONS.

The author said that amputation at the hip joint was not a difficult operation, yet it was one usually attended with a great deal of shock, and to control or prevent hemorrhage would in a great measure prevent or lighten the shock. By the use of the Wyeth pins together with the Esmarch bandage a bloodless operation can be done, but the same can be said of Senn's rubber tubing alone, which the author preferred. Indeed, he could see no necessity for the Wyeth pins. He believes it is only claimed that the pins prevent the Esmarch apparatus from slipping off when the soft parts have been divided. He had made several hip joint amputations, and all save one had been successful.

FIRST DAY—EVENING SESSION.

The President, Dr. R. C. MCHORD of Lebanon delivered his Annual Address. He selected for his subject

PREVENTIVE MEDICINE.

Those who were familiar with the history of medicine, and in memory reverted to the period when the barber's pole of today was the sign of the physician, would recall that the application of leeches gave him humble employment, and, in part, a title to his calling. He asked his hearers to observe the contrast today. He who was once scoffed at and repudiated, is now honored, trusted, and a leader in science, the recipient of national rewards and exalted honors. Medicine of today is but the outcome of the progressive spirit which dominated such active minds as Billroth, Lister, Virchow, Pasteur, Koch and many others, and a greater enthusiasm exists in its future development than the past has ever witnessed.

In his closing remarks, President McChord referred to the question of a National Department of Public Health, with an executive officer at its head, who shall be a member of the President's cabinet and have a voice in its deliberations. Let us, said he, as individuals and as a Society, join with the AMERICAN MEDICAL ASSOCIATION and other medical societies to the utmost of our capabilities, in their efforts and demand of the people outside of the medical profession and the rulers, a place of honor in their councils, which is ours by right of equity and justice. When this has been obtained and our nation has obtained the protection offered by an unselfish profession against preventable diseases, then will the demands of modern enlightenment be satisfied.

At the conclusion of the President's address, Dr. J. B. Marvin of Louisville, introduced the Hon. REUBEN A. MILLER, who delivered a popular address, in which he said that he could not unduly magnify the high and priestly office of the family physician; but in the sharp and perilous crises of life, especially in that dark hour when the home is hushed and when loving hearts are waiting to be blessed with hope or broken with despair, his very presence is an inspiration, and his words of encouragement come like a benediction. This tender relationship endears him to every hearthstone and virtually incorporates him into every family circle.

SECOND DAY—MORNING SESSION.

Dr. JOHN MASON WILLIAMS of Louisville reported cases in rectal surgery; and Dr. G. J. MONROE of the same city reported four cases of fissure of the anus.

Dr. C. C. LEWIS of Stamping Ground read a paper on "Rest versus Medicine."

The author advocated the administration of less medicine to patients. While he did not wish to be understood as conveying the idea that he had lost faith in remedies, at the same time he would urge physicians to avoid their use when other means will accomplish the end in view.

Dr. J. C. CARRICK of Lexington contributed a paper on

THE IMMEDIATE REPAIR OF INJURIES OF THE PELVIC FLOOR.

Practically there are three varieties of lacerations, which, however, vary greatly in degree and extent of the injury.

1. A clean cut median laceration, starting at the posterior commissure and passing back to a greater or less degree, directly through the middle of the perineal body, the simplest form of perineal laceration and such as produce but slight inconvenience to the woman, even when quite extensive.

2. Lacerations of the perineum involving the skin in the

median line, even as far back as the folds of the anus, associated with extensive injury of the posterior vaginal wall. This internal tear proceeds upward a little to one side of the median raphe, and often passes up on both sides of the vagina, in which event one branch of this jagged Y-shaped tear is shorter and extends more obliquely upward than does the other.

3. Lacerations of the posterior vaginal wall without any rupture through the skin. These tears are usually V-shaped, one arm being longer than the other, the point of the V being situated at the posterior commissure. The technique of the operation of repairing these lacerations was described at length.

It has been said that the only objection against the immediate operation is that the laity unjustly blame the accoucheur, holding him personally responsible for the laceration and attributing its occurrence to his inexperience and carelessness. This objection can be met only in part by an honest acknowledgment on part of every practicing obstetrician and by making the laity better acquainted with the facts in the matter. The author then quoted a few statistics from well-known obstetricians regarding this point.

Crédé, in 1,000 deliveries, had 392 lacerations, over 39 per cent. M. Liebman, 1,064 cases, 170 lacerations, about 15 per cent. Of these 471 were primipara, with 145 lacerations, 30 per cent.; 593 were multipara, with 45 lacerations, about 4 per cent. Schroeder found 34 per cent. of lacerations in primipara and 9 per cent. in multipara.

The frequency as to age was, from 15 to 20, lacerations 30 per cent.; from 24 to 25, 34 per cent.; from 26 to 30, 38 per cent.; over 30, 50 per cent.

The essayist then briefly reported one of his cases.

Dr. D. C. BOWEN of Nolin reported a case of double castration and double herniotomy for sarcoma of the testicles, and exhibited the specimens.

Dr. C. W. AITKIN of Flemingsburg read a paper entitled

THERAPY OF ACETANILID.

The author is fully persuaded that as good, if not better results are obtained from acetanilid as from any of the proprietary remedies with which he is acquainted. In reference to the action of this drug upon body temperature, unless there is a hyperpyrexia a medium dose will not exert any influence whatever upon the body heat. He observes, however, within half an hour after the administration of a dose of from five to ten grains to an adult, who has an elevated temperature, that the patient complains of excessive heat and occasionally a slight dyspnea. This in five or ten minutes is followed by free diaphoresis; the heat-producing element of the system is decreased; the dyspnea disappears, the temperature lowers, and the patient is decidedly more comfortable.

The comfort which this drug gives patients suffering from pulmonary tuberculosis is sufficient to commend it to every physician.

The antipyretic action of the drug is only one of its many valuable properties; it is also used as a sedative, analgesic, anodyne, antispasmodic, antirheumatic, and antiseptic. In combating pain, we have in acetanilid a most potent remedy, in that "it quiets the sensory portion of the nerves and spinal cord."

Dr. DAVID BARROW of Lexington read a paper entitled

REMARKS ON THE SURGERY OF THE KIDNEY,

in which he said that if the physician will look for it, movable kidney would be frequently found. The gynecologist finds it in one out of six cases that consult him, some putting it as frequent as one in four. He makes it a rule to examine all gynecologic patients for movable kidney, and has been surprised at its frequency. In his experience the symptoms have been largely referable to the nervous system, but the digestive tract has nearly always been more or less involved.

That so many movable kidneys fail to produce symptoms, has caused some physicians to treat rather lightly all such cases. This, in the opinion of the author, is a mistake, for there is no doubt that many patients suffer from this condition of the kidney, who are not relieved until fixation is resorted to. The condition is often associated with pelvic disease in women, and some failures to cure after operations on the pelvic organs are due to the kidney displacement. In these cases, by fixing the kidney all symptoms will promptly disappear.

Stone in the kidney, although not common, is more frequent than is generally supposed. The symptoms are often indefinite, and the patient may suffer but little, and not infrequently the disease is never recognized. The operation for stone, if the kidney is healthy, is safe. The mortality is not more than 3 per cent. When the kidney is diseased, the mortality is much greater, probably 10 per cent. In some cases the kidney is practically destroyed, being nothing more than a large abscess sac, and a nephrectomy may be required to save the patient.

The operation, until the kidney is reached, is the same as for nephroscopy.

Abscess of the kidney may be due to several conditions, such as a direct blow or wound, or stone irritation; tuberculosis is frequently responsible, and occasionally the contents of a cyst will become purulent. One or both kidneys may be involved. If only in one kidney, and the abscess is single, incision and drainage will usually be successful, but if both kidneys are diseased, surgery can do no good.

Solid growths of the kidney are nearly always malignant, the great majority being either sarcoma or carcinoma. No age is exempt, and proportionately children are more often affected. Nephrectomy is the only treatment to be considered. This operation is attended with large mortality for all the conditions that require it, about 40 per cent. For malignant growths, the primary mortality is 70 per cent., and of those that recover from the operation, the great majority die of recurrence within three years. Of sixty cases of nephrectomy for renal sarcoma in children, 28 per cent. died primarily, and of the rest, only three had passed the three year limit.

Nephrectomy may be performed by either the lumbar or abdominal incision. For the lumbar operation, the author prefers a vertical incision about three inches from the spine, curving the lower end forward above the crest of the ilium, when more space is necessary. When the tumor is small, this incision will answer all purposes, and should always be the one made when there is uncertainty as to whether a nephrotomy or a nephrectomy will be required.

Dr. CURRAN POPE of Louisville considered the subject of "What can we do for the Chronic Invalid?"

(To be continued.)

SELECTION.

Are Malarial Diseases Air-borne?—Malaria or "bad air" is not a disease but rather a cause of malarial diseases. This being admitted, not merely from the point of view of the purist, but from that of a fact-searcher, we are prepared to welcome any well conducted study that will throw light upon every avenue of ingress of the parasite of Laveran. Dr. Rupert Norton in a paper, before the Johns Hopkins Society, maintains that malarial infection is not water-borne. Our friends in the North Carolina State Board of Health, whose health-saving work in the advocacy of a purer water supply in rural communities, we have watched with interest, are controverted in a scientific manner along with many others, whose names are given by Dr. Norton in his paper, namely Drs. Smart, West, Zwisohn, Waggener, Hyland, Daly, Norbury, Jones, Cadwallader, Newton, Quine, Lewis, Hurley, Cowan, Ross, Hehir, Rogers, Manson and others; concerning some of whom, at least, the suggestion is made by Dr. Norton that: "Is not malarial disease your weak point in diagnosis?" This suggestion very logically and profitably opens the door—not so much to polemics as to an avilment of the methods of Laveran and Widal in all dubious cases, or better yet, in all miasmatic cases. Dr. Norton quotes Sternberg as follows: "The facts which have been developed with reference to the transmission of cholera and typhoid fever, considered in connection with numerous recorded observations relating to the supposed development of malarial fevers as a result of drinking surface waters, have led some authors to the conclusion that malarial infection, also, commonly results from the introduction of the malarial parasite in this way. Without denying that this may occur, I am disposed to believe that much of the evidence which has been advanced in favor of this view is unreliable. In many cases the so-called malarial fevers which have been traced to the use of surface water from wells, streams, etc., have been of a 'continued type' and not controlled by quinin. In the absence of positive evidence of the presence of the malarial parasite in the blood, continued or remittent fevers which resist the specific action of quinin can not, in our opinion, be properly classed with the malarial fevers. If not due to infection by the typhoid bacillus, they are, at least, more nearly allied to typhoid than to the typical malarial fevers." With this as a kind of key-

stone, Dr. Norton builds an arch, in proof of a negation, that will bear a great deal of pressure from the "water-borne" partisans. He quotes Kelsch and Kiener, who hold that paludal infection is by the lungs, at least in the great majority of cases. They think the water-borne theory is not confirmed by facts, and that the cases on the *Argo* (a Sardinian ship, whose history is referred to in the classical narrative in Boudin's "Treatise on Periodic Fevers," 1834), do not support the theory. They say, however, that malaria may arise at sea, and relate one instance which furnishes no stronger proof than that of the *Argo*. Soldiers in Algeria, they note, who while marching drink foul water, are no more affected with fevers than when in camp using pure water. Towns on heights around the Roman Campagna are free of malaria, although their inhabitants drink water coming from malarious regions. This they bring forward as proof against the water-borne theory and say that foul water simply acts as a force to reduce the resistance of the body to morbid influences. The observations made by Italian physicians are among the most interesting we have. Celli, one of the best students of malarial fever, has written a paper of great value on this subject. It is a short article going to prove that water does not transmit malaria. He gives a chart showing that introduction of new water supply into a certain city did not diminish the number of cases of malaria. He says popular ideas on this matter are fallacious, and notes that persons may live in a malarious place and drink pure water and yet have malaria, while others in the same place drinking foul or "paludal" water do not have malaria. He himself gave water from the Pontine Marshes, which are acknowledged to be very malarious, in large quantities to a certain number of patients who had never had malaria, without its giving birth to this disease in them. Similar evidence is furnished by Salomone-Marino: "He experimented in the same manner as Celli, giving 5 to 24 liters daily of paludal water for from six to twenty-four days, and did not succeed in a single instance in producing malaria. He says that those cases of malaria which are suspected to have been caused by infection through the digestive tract are usually grave cases with short periods of incubation. He relates two such cases, which, as the blood was not examined in either case, do not furnish proof of his statement. One patient was very ill and took three weeks to recover (typhoid?). Stagnant water is likely, he thinks, to contain poisonous or noxious bodies which could produce gastrointestinal symptoms similar to those sometimes caused by malaria. Bonizzardi, without relating any cases, concludes one short article with a number of deductions, from which I take the two following: 'Intermittent fever may be contracted as well by drinking water as by air,' and 'infection by air is far more fatal than by water.' Moscato, who has also carefully studied the question of malarial fevers, states, without furnishing any proof, that drinking water as a source of infection has been noted daily by observers: 'l'acqua potabile, come sorgente del velino palustre fu riconosciuta anche da Ippocrate; quale verita e stata anche sanzionata dagli osservatori odierni.' The statement has been made that malaria may be transported from one infected district to another healthy one by a new water supply, but the proof here is not sufficient, since the turning up of the soil for the pipes may have been the real cause. Most of the Italian observers, it is seen, are opposed to the water-borne theory." Dr. Walter Reed, of the U. S. Army, has written well on the aerial side of the case, and his contribution to this year's volume of the Reports of the Surgeon-General is mentioned with special favor by Dr. Norton. Dr. Reed has paid special attention to the cases of fever at Washington Barracks and Fort Meyer, and has examined the blood of many patients. Dr. Reed does not believe in the water-borne theory. He states that "the water supply at Washington Barracks has not been changed; it has always been the same as that of the city. The supply at Fort Meyer was

changed in November, 1894, from well water to Potomac River water. The following year the men and officers drank, as a rule, filtered and boiled Potomac River water, with the result that there were more cases of malarial fever in 1895 at Fort Meyer than during any one of the previous twenty-three years. It was also higher at the Barracks in 1895 than during any of the previous twenty-three years." There is much malarial fever in the city of Washington, and it is really endemic along the river flats, but has no apparent connection with the drinking water of the city, since otherwise the people in the upper part of the city should naturally suffer as much, which they do not. The reports from the army posts are hard to analyze, since the officers in charge are frequently changed, and their personal views as to malaria and typhoid fever vary materially. But, as yet, all the evidence coming from the army posts is rather against than for the water-borne theory. The time is coming, we hope it is near at hand, when the laboratory for diagnostic and other medical work will be so well supported and utilized that the *ex cathedra* citation of authorities and classic cases will no longer be the order of the day. The busy practitioner can not hope to much longer "get along" with his thermometer and his library; he must have a laboratory, not too far distant, to help help him out in all his doubtful zymotic cases. Therefore, say we, multiply the laboratories! And, furthermore, let us have a strong National Ministry of Health. That many profitable lives and much added happiness in health are hinged upon these propositions, the future is destined to make plain either to us or to those who follow us. How soon the improvement may come we do not know, but come it will and must.

PRACTICAL NOTES.

Storbeck's Depilatory.—Alcohol 12 grams; collodion 35; iodine 0.75; essence of turpentine 1.5; castor oil 2. Apply with a brush on the affected parts for three to four days in thick coats. When the collodion plaster thus formed is pulled off, the hairs adhere to its inner surface.—*Nouv. Rem.*, April 8.

Denzel's Hemostatic Tincture.—Bibring prepares this as follows: After mixing 10 grams pulverized ergot, 20 grams alcohol and 2 grams sulphuric acid, he pours over it 500 grams boiling water and reduces by boiling to 200 grams. Then he adds 2 grams of calcium carbonate, submits the liquid to pressure, evaporates to 70 grams and adds 30 grams alcohol and 3 drops of essence of ginger, and sets aside to settle, and filters.—*Pharm. Ztg.* No. 19, 1897.

Mercurial Ointment to the Treatment of Wounds.—Majewski has been using for three years a concentrated mercurial preparation in the form of a salve, as the grease prevents too rapid absorption of the mercury. The ointment is applied in a thin layer on a piece of gauze, and very carefully restricted to the wound itself and not allowed to encroach on the adjacent normal tissue. With these precautions all kinds of abscesses, phlegmons, and wounds, contusions, etc., healed with remarkable rapidity and completeness. He reports in the *Cbl. f. Chir.*, April 10, 626 cases thus treated in 1895 and 806 in 1896, and recommends the method in high terms, to army surgeons especially. His formula is: 25.0 hydrarg. oxydat. flav. to 100.0 vaselin, applied after careful evacuation of all the pus.

Bone Transplantation as a Substitute for Amputation.—Bardenhauer (*Revue de Chirurg.*, January, 1897) has lately resorted to division and transplantation of one-half of a healthy metatarsal bone for disease and death of an adjacent bone shaft. In cases of the partial or complete destruction of one of the metacarpal or metatarsal bones, by this method he has had in several instances the most gratifying results. Twice he applied this device to exterior destruction of the lower end of the radius. He has also executed a remarkably ingenious opera-

tion for the restitution of the upper end of the humerus, by detaching the spine of the scapula from its muscular attachments, cleaving through the ridge close to its base and freeing it on either end. He then transported this segment of live bone into the gap left by the removal of the destroyed shaft. The result, as in his other cases, was successful. In young subjects the scapular spine is reproduced, care being taken to always leave the periosteal investment behind.

Gastric Neurosis.—A physician at Kissingen has had occasion frequently to observe patients sent there for the waters, with the diagnosis of gastric catarrh, whose affection was merely a form of neurosis, with excess of hydrochloric acid, and was aggravated by the saline waters. He mentions the following points for differentiation: It is frequently the result of the abuse of alcohol, tobacco, coffee or tea, but in these cases the alcohol is always taken diluted. The hydrochloric acid is constantly in excess, more or less superior to the normal, all the time, without much variation, in which it differs from the gastric form of neurasthenia, as the chemic action in this case is extremely variable from day to day. There is not continuous excess of acidity. The little gastric juice that can be obtained from the stomach is always inactive. It can not be confounded either with acid gastritis, as there are none of the symptoms of inflammatory processes in the viscera, not even the production of an unusual amount of mucus.—*Berlin. klin. Woch.*, No. 7.

Constipation in the Insane.—Alessi finds that mental troubles are aggravated when there is constipation and improved when the functions are regular. He also finds that in the melancholic forms of insanity, the intestinal atony preceded the outbreak of the insanity, while in violent mania it follows and seems to be produced by it, as there is evidently some connection between the action of the intestines and the degree of excitability of the special cerebral nerve centers. He concludes his interesting study of 90 cases in the *Gaz. degli Osp. e delle Clin.*, of March 28, with an account of a woman brought to the clinic in violent mania, which had developed suddenly that day. Inquiry of her mother elicited the fact that she had not had an evacuation for fifteen days, and the administration of 80 centigrams of calomel and 60 of scammony, restored her promptly to sanity, as the intoxication had not lasted long enough to impair the integrity of the nerve cells.

Introduction of Hydrotherapeutics into Practical Medical Instruction.—Vierordt writes from Heidelberg to the *Deutsch. med. Woch.*, (March 11) to proclaim the satisfactory results attained by the "ambulatory" hydrotherapeutic establishment connected with his polyclinic and dispensary. It has been established over a year and a half, and has been found of the greatest benefit in instructing students and others who are eager to learn the technique of the successful application of hydrotherapeutics, in connection with their general medical training. Winternitz has an institution of the kind in Vienna, but he makes a specialty of it. Vierordt deprecates this, and merely urges the introduction of such an adjunct to the dispensary as a minor branch of the regular curriculum. It has been found a great boon to many patients who derive great benefit from this treatment while they are able to pursue their usual occupations. One of Vierordt's assistants has the supervision of the establishment and resides there.

Ovarian Tumors.—D'Urso concludes as follows a comprehensive study of twenty-one observations, most of them personal: 1. In the cortical substance of the normal ovary there are remains of germinal epithelium in the form of cystic formations, which sometimes present the appearance of modified sweat glands. 2. The Kobelt tubes of the mesosalpinx in the adult have sometimes irregular and papillary outlines. 3. The tubes of the epoöphoron penetrate into the hilus and the medullary substance, and produce cavernous papillary formations, besides

the isolated tubulous. 4. There are also found in the mesosalpinx, altogether at the abdominal end, small knobs of epithelial tubes, which proceed from the remains of the Wolffian body. 5. The cysts of the ovaries and broad ligaments can be classified into: a, cystic adenoma, glandular neoplasms formed from the epithelial remains of the cortex; b, simple Wolffian cysts; c, papillary Wolffian cysts, developing from the epithelial remains in the hilus and mesosalpinx, without glandular formations. 6. Malignant papillary cysts present a peculiar proliferation of the epithelium, contrary to malignant papillary Wolffian cysts. 7. Dermoid cysts show evidences of transformation from simple cysts to true teratomas. Some can be traced to fetal contents, others probably to embryonal development from the ovum cell. 8. Ovarian fibromas can develop in the connective tissue of the corticalis, independently of the corpora lutea and the regressive metamorphoses of the Graafian follicles. 9. Among the simple, connective tissue ovarian tumors, endotheliomas often occur, not infrequently malignant, which can not be explained by peculiarities in the histologic structure. He has nothing to say in regard to the histogenesis of alveolar sarcoma and endothelioma except the query whether the theca folliculi may not be the matrix. 10. There is a simple true epithelioma of the ovary; it develops very slowly and probably originates in the epithelium of the papillary embryonal remains of the hilus.—*Cbl. f. Chir.*, April 10.

Fatal Polyneuritis Following Mercurial Treatment of Syphilis.—Brauer (*Berliner klinische Wochenschrift*, March 29 and April 5, 1897) has reported the case of a man, 24 years old, with a good family and personal history, who was treated for five weeks with mercurial inunctions for syphilitic infection, beginning with forty-five grains daily, later increased to sixty grains. At the end of a month, in the absence of stomatitis or salivation the patient noticed numbness in the hands, which became partially flexed. There was also twitching of the small muscles of the hands and of those upon the flexor aspect of the forearms. The arms appeared weak, while the legs seemed normal. In a short while disturbance of vision manifested itself, with confusion and double sight. The gait became uncertain and staggering. In the course of the succeeding day numbness appeared in the legs, with twitching of the calf-muscles and inability to stand and to walk. When in bed the man was able to move the legs quite freely. On the third day articulatory disturbance of speech was noticed. The movements of the lips and tongue were interfered with, and deglutition was difficult, only liquids being swallowed. Twitching of the face was present, especially about the eyes and the mouth. In the course of eight days this ceased, although that in the hands and legs continued. The weakness also persisted. The ocular disturbance disappeared. At no time was there fever or pain. Later, weakness of the bladder manifested itself and there was an absence of erections. Pain in the sacral region appeared, but no girdle-sensation, no palpitation of the heart, no dyspnea. After this improvement the patient gradually grew worse again and symptoms of secondary syphilis made their appearance. Mercurial treatment was resumed, intramuscular injections of gr. $\frac{1}{3}$ of a mercury salicylate being given twice weekly. Following this the syphilitic symptoms disappeared, but the others were aggravated. The urine presented no abnormality. The pupils were active in their reactions and there was no nystagmus and no ocular paralysis. The face was puffy and expressionless, but not edematous. The left naso-labial furrow was not as marked as the right and the left angle of the jaw drooped a little. There was no appreciable atrophy of the facial muscles and no fibrillary twitching. Sensibility was not obviously deranged. The tongue was not atrophic. The palatal reflex was preserved and speech now presented no defect. The larynx appeared to be normal. There was no disturbance of the special senses. The arms and legs pre-

sented symmetric marked paresis, most pronounced at the periphery. There was no rigidity. The atrophy was proportionate to the degree of weakness. There were no trophic disturbances. The movements were ataxic, but there was no tremor. In the affected portions sensibility was impaired in all its forms. The tendinous and the periosteal reflexes were wanting and the cutaneous reflexes diminished. The paretic muscles exhibited fibrillary contractions. Some of the larger nerve-trunks were tender on pressure, but the paretic muscles were rather more so, and they presented also partial reaction of degeneration. The action of the sphincters was weakened and constipation existed. Later a sense of stiffness appeared in the muscles of the face, together with reaction of degeneration. Finally dyspnea set in and became aggravated in attacks of asphyxia from paralysis of the diaphragm. Death took place four months after the appearance of the first symptoms, in consequence of bilateral pneumonia of the bases, which was confirmed at the postmortem examination. The brain, the cord, a number of spinal ganglia, a number of peripheral nerves and a number of muscles were carefully examined. The most marked changes were found in the nerves, which presented degeneration of their medullary sheaths with thickening of the perineurium. No changes were found in the blood-vessels. Only slight changes were found in a number of the ganglion-cells of the anterior horns of the cord. The muscles were but little changed. From a careful consideration of all of the elements of the case the conclusion is reached that the symptoms were not dependent upon demonstrable anatomic syphilitic lesions, though perhaps upon the toxic products of the syphilitic infection. It is not believed that the mercury had alone any influence in the development of the changes in the nerves, although it is not denied that the action of the mercury, by depressing the general bodily vigor, may have favored the activity of the syphilitic poison.

Anti-venomous Serum of Calmette.—Dr. Hazard, of the French Colonial Service, reports a case of recovery from snake bite after injection of Dr. Calmette's anti-venomous serum. In December last at Martinique a soldier, aged 23 years, was bitten in the left thumb by a vigorous trigonocephalus (bothrops lanceolatus), nearly five feet in length. When the accident occurred the man was in a squatting position, but although he instantly jumped to his feet the action failed to dislodge the reptile, which remained for some moments firmly fixed to his digit, and it was not until he struck it on the head with his fist that it relaxed its grip and fell to the ground. There were two punctured wounds about half an inch apart, one of which was bleeding slightly. With a penknife the soldier enlarged it superficially, and he sucked the place three or four times. An officer then bound a ligature tightly round the root of the thumb, and dispatched the man to the hospital, where he arrived breathless from running some ten or twelve minutes after receiving the bite. To save time he was attended in the office. Ten cubic centimeters of anti-venomous serum (which had been received from Lille in the course of the preceding month) were subcutaneously injected into the patient's left flank. The seat of injury was washed with hypochlorite of lime, and five cubic centimeters of the latter solution having been injected into and around the punctures, the constricting ligature was removed. Soon afterward the principal medical officer arrived at the hospital, and the case being in his opinion very grave, he ordered a second injection of ten cubic centimeters of serum, as well as a second local injection of four cubic centimeters of the hypochlorite. The patient was then put to bed under several blankets and given strong coffee to drink at frequent intervals. For forty-eight hours he complained of darting pains in his arm, loss of appetite and sleeplessness—the last symptoms being no doubt due to the coffee—but with these exceptions the indications were entirely favorable. There was

no local tumefaction, and the axillary glands remained unenlarged. On the fifth day the man had perfectly recovered and was discharged to duty. Immediately after he was bitten he says his forearm became heavy and numb, as though it were asleep, and neither the incision he made himself nor the hypochlorite injections caused him the least pain. This anesthesia only lasted a few hours, the sense of feeling being fully restored by the next morning.—*Archives de Médecine Navale et Coloniale*, March.

Spontaneous Hemorrhage in the Vitreous Body, or "apoplectic eye," offers an unfavorable prognosis unless effective treatment is instituted at once to prevent the occurrence of the same hemorrhage in the other eye, when the patient becomes totally blind. Professor Panas remarks that it is usually consecutive to syphilis, gout, alcoholism or nasal affections, and therefore the blood should be disinfected, alcohol replaced by milk, the nasal passages rendered antiseptic, and he administers, even when there is no syphilis, biniodized oil as a general antiseptic, in 4 milligram injections, supplementing it later with hypodermic injections of arsenic, as he has witnessed a supposed double sarcoma of the orbit vanish completely with the administration of sodium arseniate alone. He concludes his study of the subject in the *Presse Méd.* of April 3, by calling attention to the infective nature of such troubles, which involve the highest questions in general pathology.

Resection of the Gasserian Ganglion for Rebellious Facial Neuralgia.—Marchant and Herbert (*Revue de Chirurgie*, April 10, 1897, p. 286) report two cases of extirpation of the Gasserian ganglion for the relief of rebellious facial neuralgia and they analyze ninety-three additional cases collected from the literature. Among the whole number there were seventeen deaths (17.8 per cent. In sixty-six the temporal course was followed, with eleven deaths (12.12 per cent.), three of which were open to doubt. In twenty-nine the pterygoid course was followed with six deaths (20.6 per cent.). Among fifteen cases of complete extirpation of the ganglion there were five deaths, three of which were open to doubt (13.13 per cent.). Among sixty cases of incomplete extirpation there were eight deaths (13.33 per cent.). Among fifteen cases of simple resection of the painful branches there was but a single death (a mortality of 6.66 per cent.). From a study of the literature of the subject the conclusion is reached that certain rebellious facial neuralgias originate in the Gasserian ganglion, and the only treatment of these cases consists in destruction of the ganglion. When no appreciable lesion of the ganglion existed and its removal was none the less followed by a disappearance of the neuralgia, this result is to be explained by the destruction of a nervous center containing neurons or nervous cells whose prolongations only are affected by simple section of the nerve. The temporo sphenoidal course is the best to follow for the removal of the ganglion. The finding of one of its branches and especially the inferior maxillary in the oval foramen constitutes one of the most certain guides for the detection and seizure of the ganglion. The ganglion may be completely extirpated. Commonly the extirpation is incomplete and the ganglion is finally destroyed by curetting and crushing. Often only its branches have been resected. Hemorrhage, wounding the nerve and cerebral compression are the immediate operative accidents to be feared. Secondarily there may be infection, hemorrhage, iodoform intoxication, ocular disturbances and otitis. As an immediate result of the operation there is a cessation of pain and also an abolition of general sensibility in the distribution of the three branches of the nerve and especially in the second and third branches; but this does not persist long. Taste, smell, hearing and vision are variously affected. The movements of the jaw may remain impeded. From a therapeutic point of view recurrence is less to be feared after destruction of the ganglion than after simple resection of the branches. The evidence indicates that complete extirpation should be superior to simple destruction of the ganglion.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the Association living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, MAY 15, 1897.

MEETING OF THE AMERICAN SURGICAL
ASSOCIATION.

The last meeting of the American Surgical Association was notable for the large attendance, the number of scientific papers read and the interest manifested in their discussion. The president, Dr. J. COLLINS WARREN, selected as the subject of his address, "The Influence of Anesthesia on the Surgery of the Nineteenth Century," in which he gave a short history of anesthesia and showed its influence in broadening the field of operative surgery. In his paper on "The Indications for and the Technique of Hysterectomy," Dr. HOMANS laid down clear and reliable rules which should govern the surgeon in the selection of cases, and gave sound advice by what route and by what method the uterus should be removed for different pathologic conditions. The paper was ably discussed by Drs. VAN DER VEER, MUDD and LANGE.

Dr. J. W. WHITE's paper on "The X Ray in Surgery" was profusely illustrated by skiagraphs showing the value of this new and valuable diagnostic resource. Dr. DEFOREST WILLARD exhibited also a very valuable collection of X-ray pictures, most of them illustrating bone and joint affections, fractures and dislocations. One of the most valuable contributions was the one by Dr. BRADFORD on "Tendon Anastomosis." Tenoplasty was first suggested by NICOLADINI. There are now about sixty-seven recorded

cases in which this procedure has been resorted to with advantage in the treatment of paralysis following anterior poliomyelitis. The paper was made clear by numerous well-executed drawings. Dr. BRADFORD's experience in substituting a "living" for a "dead" muscle by tendon anastomosis has been encouraging. Dr. SOUCHON's paper on "The Operative Treatment of Irreducible Dislocations of the Shoulder, Recent or Old, Simple or Compound," evinced a painstaking search in gathering reliable statistics upon which to base a safe practice. It must, however, be remembered that statistics are often deceptive and misleading. Surgeons, as a rule, are more anxious to report their successful than their unsuccessful cases. There can be no question that in cases of irreducible dislocation of the shoulder joint, recent or old, when manipulation fails, reposition by operative measures is warranted. It appears that such operations are more prone to be followed by infection than operations for other pathologic conditions of the same joint, a fact which should induce the surgeon to resort to the minutest details in securing asepsis. Dr. J. B. ROBERTS' paper on "The Surgical Treatment of Suppurative Pericarditis" is a valuable contribution to surgical literature and a worthy addition to his monograph on "Paracentesis of the Pericardium," published a number of years ago.

The unveiling of the statue of the late Prof. SAMUEL D. GROSS was a solemn and impressive occasion. Dr. C. H. MASTIN, who conceived the idea of such a tribute to the memory of America's greatest surgeon, and who did more than any one else in securing the necessary funds, presented the statue to the United States Government in an eloquent speech. General STERNBERG was selected by the President to receive the statue for the United States. Surgeon-General STERNBERG's speech was a glowing tribute to the character and scientific work of Dr. GROSS. The address of Dr. W. W. KEEN, the successor of Dr. GROSS, was well worthy of the great occasion and was a beautiful eulogy commemorating the life, character and professional work of his illustrious predecessor. Thanks to the efforts of Dr. C. H. MASTIN and others, the beautiful grounds of the Smithsonian Institute in front of the Army Medical Museum are now graced by the noble bronze statue of one beloved by all, honored and respected by all of his pupils and professional colleagues.

The paper of Dr. TIFFANY on the "Technique of Cranial Surgery" was replete with practical details of the different intracranial operations and was fully discussed by Drs. KEEN, WEIR, PARMENTER and MIXTER. Dr. TIFFANY called the attention of the members of the Association to the advisability in serious cases of intracranial operations in doing the work in two instead of one operation. The first operation should have for its object the creation of the

cranial defect, and often the wound has healed in the course of two or three weeks, attack the intracranial lesion through the soft tissues covering the cranial defect. This suggestion received the warm support and endorsement of Dr. KEEN. Dr. McF. GASTON reported a case of inoperable sarcoma cured by electrolysis and cataphoresis, combined with the internal use of Donovan's solution. Although the diagnosis of sarcoma was confirmed by microscopic examination of the tumor tissue some doubt still must remain as to the nature of the affection owing to the muscular results following the treatment as described.

Dr. DUDLEY P. ALLEN read a paper on the "Origin of Appendicitis," profusely illustrated, in which he took the ground that the most frequent cause of appendicitis is obstruction of the organ from congenital flexion. He illustrated, by the drawings which he presented, the muscular hypertrophy which follows mechanical obstruction. The mass of the profession will hardly endorse such a mechanical condition as a prominent etiologic element in the causation of appendicitis, as flexion is probably more frequently caused by antecedent inflammatory affections than by a congenital defect.

Other interesting papers were read by Drs. FENGER, POWERS, FORBES, RANSOHOFF, HART, PARKHILL, JOHNSTON, BURREL, ELLIOT and RICHARDSON. The forthcoming volume of transactions will be one of unusual interest and one which will show the higher character of the work done by its members from year to year. The work of the Association in the Congress of American Physicians and Surgeons was represented by a discussion on the "Classification, Prognosis and Treatment of Acute Peritonitis." Dr. SENN discussed the classification, Dr. ABBE the prognosis and Drs. DEEVER, MCCOSH and FOWLER the treatment. The Association numbers now eighty-nine members, leaving but eleven vacancies. Dr. PREWITT of St. Louis was elected president for the ensuing year and New Orleans was selected as the place for holding the next meeting.

THE AFTER-CARE OF THE INSANE.

The American Neurological Association through a committee of which Dr. HENRY R. STEDMAN is chairman, is engaged in a movement that deserves the full support of not only the medical profession, but of all those who are at all philanthropically inclined. It is a preliminary inquiry as to the best means for providing for patients discharged from asylums for the insane, especially during the first weeks or months after their release. It is a well-known fact that the recovered lunatic, if dependent upon his own devices, suffers from special disadvantages and that the hard lines of life that may have been the direct cause of his mental breakdown are likely to be even more his lot on his release. A convict who has served his time

is better off in a purely temporal point of view, he has more resources and, unless he is what it is to be feared the most of them are not, a reformed man, he is simply replaced upon his old footing. The law, moreover, generally provides that he starts out with a small sum of money, not much it is true, but something to meet his immediate necessities. There are also organizations that look out for released criminals; he has the sympathy and help of good people if he is reformed, and the ready fellowship of his old associates if he is not. The recovered but friendless lunatic on the other hand is liable to be thrust on a cold world with nothing in his pocket and a certainty that a knowledge of his misfortune is almost an insurance of distrust and repulse of all his efforts of self-support. The consequence is too often a relapse to his former state or a worse one and the multiplication of chronic cases and charges upon the public.

It has been the custom in some of our asylums to provide some employment at such small wages as their resources would admit, for recovered patients, for a short period, so that they did not start out penniless, and could say that they had already had employment, thus modifying to some extent the stigma (in the popular estimation) of their insanity. It afforded them at least a chance for a sort of justifiable *suppressio veri* as to their antecedents in starting out again into the competition of active life. A large institution could thus provide for a limited number, but of necessity many more would fail of this provision. In France there have existed for some time what are called *sociétés de patronage* or aid societies for discharged patients from the asylums and they have worked so well that, while limited at first to a single department, they have lately been adopted by the government and generalized throughout the country. Similar organizations have been started and in operation for some time in other countries under private auspices, and the movement seems likely in time to become universal throughout Europe.

It is not particularly to the credit of this country that we are behind any other in this matter and the present action by the Neurological Association is a timely one. It is desirable that the system devised be one adapted to this country and, if possible, an improvement on any existing one. For this reason the committee have sent out circulars asking the views of superintendents and others as to what are in their opinion the best plans for the after-care of the insane. The answers to these inquiries are utilized in a report which will form a basis for future plans and it is to be hoped will be the starting point of a very useful charity.

The question whether this after-care of the insane should be provided for at the expense of the public funds or as a private charity, is an important one and is one of those in the circular sent out by the com-

mittee. There are some very good reasons why a separate establishment for the oversight and welfare of discharged lunatics would be better under private auspices; it would be free from political interference, and as residence there would be purely voluntary it would require no State inspection. It would or should be simply a home where discharged patients can stay under friendly oversight and if possible do something for their self-support, and from which, if desirable, some oversight can be exercised for their welfare even after they are no longer in residence. An absolute disconnection from the asylum will be, for some cases and in some respects, an advantage; a complete change of scene and associations is often as useful for perfecting a recovery as is the change from home surroundings to the hospital for primarily inducing it. A private charity of this kind ought, if properly conducted and controlled, to be better insured against certain disadvantages to which our public institutions under their present systems are liable, and its voluntary support by those who are able and willing to give it, will be a relief to the constantly increasing public expenses.

The State can, however, usefully aid in this matter, and at slight cost, by continuing and extending the practice, already mentioned as existing, of giving temporary employment at very moderate wages to impecunious patients who, while practically recovered, yet are better for a certain degree of care and observation before being sent out to depend upon their own resources. There are, in a large institution, numerous opportunities for utilizing advantageously the services temporarily of such patients, and many of them are very glad to avail themselves of the chance. When they finally leave the institution they are already in the way of earning their living and their insanity is sufficiently in the past to be no longer a stigma and an embarrassment, as it would be had they left it immediately as discharged patients. A very small additional appropriation would go a great way in providing for such cases and should perhaps be as judicious and advantageous an employment of public funds as any that can be devised. The hospital would thus care for certain special cases, leaving others to the aid societies outside, and by both methods combined a much better future is opened to the recovered lunatic. With one or both of these resources at his command, the often sorely puzzled head of a hospital for the insane will be greatly relieved and the extent of his therapeutic resources materially increased. There are also cases that can not be safely discharged under the conditions that exist too largely at the present, whose friends, if they have any, are afraid to receive them, and yet to whom further detention in an asylum is a positive detriment and may turn the scale in favor of their permanent insanity. If these aid societies can also meet the needs of this class,

who are often perfectly suited for their care, their usefulness will be largely augmented.

All these matters have undoubtedly been fully considered by the committee of the Neurological Association, and the publication of its report will be awaited with interest. It is to be hoped that it will be the direct inciting cause of a new and exceedingly useful application of public and private benevolence.

MEDICAL CONSIDERATION OF THE METHODS OF PUBLIC EDUCATION.

The popular idea of education seems to be a filling of the mind with a conglomerate collation of truths and untruths conveniently designated as knowledge, by a systematic process of cramming from text-books and lectures, mechanically pursued and methodically planned, regardless of individual capacity and mental and physical temperament. A natural sequence of such a procedure is a desire on the part of the student to further cram the burdened mind with a smattering of every possible subject not already thrust upon it, by the indiscriminate reading of books, newspapers and magazines. This corollary to modern "educational methods" is highly commended and apologetically called by its progenitive Solons "the modern thirst for knowledge."

Nothing could be more fallacious than such conception of education. The very etymology of the word disproves it. Anyone with the slightest knowledge of philology should know that education does not mean a putting in, but, the direct converse, a drawing out. Realizing the error of some of the so-called educationists, Dr. SHUTTLEWORTH, in an address before the British Medical Association sagely says, "Bearing in mind the physiologic interdependence of bodily and mental development, we may say that true education consists in processes of training which will produce in a given individual the most favorable evolution possible of all the faculties both of mind and body. A rational educational system will recognize the fact that all children are not cast in the same mold; that there are inherent, often inherited, differences in each pupil's powers, and that, to obtain the best results, instruction must be adapted to idiosyncrasies and proportioned to varying capacities. . . . From the medical standpoint we shall reply in the affirmative to the query of PLATO: 'Is not that the best education which gives to the mind and to the body all the force, all the beauty, and all the perfection of which they are capable?'"

What a sad contrast to these beautiful principles is the public system of education in vogue in this country at the present day! Rigid rules as to definite standards of acquirement, regulated chiefly by age and not by the varying capacities and different temperaments, make the backward and deficient children the martyrs to the baneful influence of excessive hours of study, or

failing in their requirements, render them indifferent to a righteous pride. Stimulated to active competition by praise at home and honors in school the more intelligent are slaves to their unfortunate ambition. The willing and anxious child is virtually worked to mental and physical dissolution by thoughtless teachers, aided by the fondest of parents to whom the physical conditions underlying mental evolution and critical epochs of development are unknown.

In this country particularly are these circumstances deleterious to the health of the growing race. The average American child is not only mentally precocious, but is of a peculiar neurotic temperament, which, while increasing its mental capacities beyond that of the child of other countries, at the same time renders it more susceptible to mental over-strain and nervous exhaustion. Again, the age of greatest strain is shortly after puberty, a period which, particularly in girls, has been justly considered of "profound nervous and neuro-physiologic import." The headaches, backaches and the rest of the common ills of our American girls, are often directly attributable to excess of study and misdirected efforts at education during critical periods of development.

In our public system of education the mental over-strain is required just at a time when minimum study and maximum outdoor exercise and recreation are demanded. We heartily endorse as applicable to the American system of public education the reforms which Dr. SHUTTLEWORTH advocates in the British high-school system, namely, 1, amendment of excessive hours of study, especially during spurts of growth and development; 2, correction of the deficiency of systematic outdoor exercise and recreation, and 3, more regard of physiologic functions differentiating the capacity for work at certain times of girls as compared with boys.

ACUTE LEUKEMIA IN CHILDHOOD.

Leukemia is usually a disease of insidious onset and slowly progressive course. Occasionally, however, it makes its appearance with the abruptness of an acute infection, being attended with febrile symptoms and other manifestations of constitutional disturbance. Of the etiologic influences we know little, if anything. The disease has been observed in connection with malaria, syphilis, other infectious diseases, traumatism, over-exertion and profuse hemorrhage. It has developed during pregnancy, and sometimes an hereditary predisposition has existed. The disease has also been observed in some of the lower animals. Males seem to suffer more commonly than females. No age appears to be exempt, though it is probable that the disease is most common during the middle period of life.

To the rather small list of cases of acute leukemia in childhood THEODOR (*Archiv für Kinderheilkunde*,

B. xxii, H. 1, 2, p. 47) adds the report of an additional instance, together with an analysis of all that he has been able to gather from the literature. The case occurred in a boy, four years old, previously healthy and well nourished, who fell from a horse that he was being taught to ride, striking his face and nose. Copious epistaxis followed, which failed to yield to the ordinary remedies at hand, and only ceased after ten hours, upon plugging of the nares by the medical attendant. It was at this time first observed that there were present on the extremities a number of large and small hemorrhagic extravasations, which were attributed by the parents to contusions received in various ways. Examination showed further the spleen to be slightly enlarged, and the blood exhibited the characteristic conditions of leukemia, with a preponderance of lymphocytes.

In the further course of the case the temperature became moderately elevated; hematuria appeared, with the presence of hyaline and granular tube-casts, and the cervical, axillary and inguinal glands became enlarged. There was at no time pain referred to the bones. Under treatment with abdominal compresses, inunctions of iodvasogen, arsenic and preparations of blood and bone-marrow, in conjunction with fresh air, distinct improvement set in for a time, but subsequently the symptoms returned and death took place in the sixth week of the disease from pulmonary edema. A postmortem examination could not be secured. Bacteriologic examination of the blood failed to disclose the presence of pathogenic organisms. The father of the child had been syphilitic.

Of the forty-five cases of acute leukemia only six occurred in children under the age of ten years. Only those are considered in which the disease did not last longer than nine weeks. Up to the age of fifteen years there were four additional cases. Of the whole number twenty-five were in males, thirteen in females, while in seven the sex is not specified. The patients varied in age from two and a half to fifty-nine years.

MALPRACTICE IN WEST VIRGINIA.

Dr. THOMAS R. EVANS of Charleston, West Virginia, states in a recent number of the *Medical Record* that the statutes of West Virginia are in a decidedly antique condition as regards malpractice suit. According to Dr. EVANS any physician or surgeon who "resorts to any expedient whatever," may be mulcted in heavy damages in case his patient dies; and he is not allowed to testify in his own behalf, nor can any other person testify for him. Finally, there is no stated time when such a suit can be outlawed. Dr. EVANS declares that one medical man was recently under this enactment condemned to pay a fine of \$10,000. The first part of Dr. EVANS' charge against the West Virginia statutes ignores completely the fact that this is a part of the common law principle of due diligence

which has protected so many practitioners in malpractice suits. The practitioner is only required to show that he had the ordinary skill of his profession and that he exercised this in the given case. If he adopts new procedure the burden of proof would rest on him to show that these were suited to the particular case and were merely an extension of the ordinary principles. As TRACY C. BECKER remarks (WITTHAUS' "Medical Jurisprudence"), experimentation, whether upon charity patients or pay patients, is equally prohibited by well settled rules of law. In other words, a departure from known methods of treatment for the purpose of, or by way of, trying unknown remedies or operations not usually adopted by the profession, if an unfortunate result occurs, renders the defendant liable (McNevins v. Lowe, 40 Ill., 209). What constitutes reasonable care and skill is, BECKER remarks, a mixed question of law and fact, like any other question of negligence. Where the evidence is undisputed and no conflicting influences can be drawn from the facts presented it is the duty of the court to determine whether or not there is sufficient proof of want of ordinary care and skill to be submitted to the jury. Where, however, the evidence is conflicting on that point or the inferences to be drawn from the facts established might be differently drawn by different men having the same opportunity for observation, and the same circumstance before them, it is for the jury to say whether or not the defendant has exercised reasonable care and skill guided by proper directions from the court as to the measure of skill required. These involve the question as to how far the practitioner is bound to be familiar with the methods, appliances, drugs and methods of treatment of his profession in general. The rules of evidence which, Dr. EVANS states, are part of the West Virginia statutes, are so destructive of the constitutional rights of citizens of the United States that there is no doubt but that the Supreme Court of the United States would declare all such statutes unconstitutional. While there has been a great deal of what has been called "freak" legislation lately, statutes of the type described are clearly relics of "old dominion" days when law was largely made for the purpose of enriching the king by forfeitures in case of felony.

THE JOURNAL SPECIAL TRAIN.

Medical gentlemen from Illinois and vicinity, the Pacific Coast and the Northwest, who intend to be present at the great jubilee meeting of the ASSOCIATION, are invited to take the JOURNAL SPECIAL, which will go by the Pennsylvania Railway without change from Chicago to Philadelphia. The time limit of ten days is as long as granted by any other route. See advertisement in another column, and make no mistake. The JOURNAL guarantees the most perfect of modern railway equipment.

CORRESPONDENCE.

What Is Wrong with This Prescription?

CHICAGO, April 27, 1897.

To the Editor:—I should be very much obliged if you could have the following questions answered in the columns of the JOURNAL.

Some time ago I was called to see a sick lady and prescribed the following ingredients in capsule. Each capsule contained:

Sod. salicyl.	gr. 2½
Salol	gr. 2½
Codein	gr. 1/8
Hydrarg. chlor. mite	gr. 1/8

The patient took only one and within half an hour became very sick, developing severe poisonous symptoms, and later becoming unconscious and extremely depressed, etc. Now I should like to know: 1. What ingredients, if any, were incompatible? 2. If incompatible, what product was formed? 3. If a poison were formed what dose would ordinarily prove fatal? 4. What would be the physiologic action on the various systems, as nervous, urinary, digestive, etc.? 5. What would the mental effect be? 6. What other effects, if any, would be produced on the individual?

I have withheld the symptoms in this case as observed, in order that the answers might not be influenced by a description of them.

Yours very respectfully.

M. D.

Syphilis and Drunkenness.

KANE, PA., May 8, 1897.

To the Editor:—In closing a recent editorial entitled "Legislation against Degeneracy," (April 17) our editor touches the key-note of the situation. Having clearly proven in the preceding paragraphs the futility as well as the injustice of all legal restriction imposed upon the marriage of epileptic and insane, he ends by saying: "The only real safeguards against the propagation of degenerates are to be looked for in the higher moral education of the public and the cultivation of practical moral standards."

How are we to attain these practical moral standards? As our editor remarks, immorality and illegitimate births will be greatly increased if we are to render it illegal for those of epileptic, insane or tubercular tendencies to marry. While, too, it can not be denied that their taints do often exist as an inheritance, it is equally true that, given a suitable environment and mental, moral and physical cultivation the children of just such alliances may grow up sound in body and mind, frequently proving themselves even the superiors of their more careless as well as more fortunate neighbors.

The practical moral standard should be raised and our nation properly educated to a realizing sense, not of the danger in alliances of the epileptic, insane and the tuberculous; for their condition, though the result of an inheritance is but an indication, a symptom, of a far reaching and more dreadful condition from which they usually result, and as I said they may live down their defective and diseased condition.

We should raise our standard of temperance and chastity and our legal enactments should be directed against the social evil, syphilis and drunkenness.

While few deny that tuberculous, epileptic, insane and neurotic parents tend to produce like conditions in their offspring none can deny a far more potent cause for all these conditions and a multitude of others. This is the drunkenness and debauchery which is adding to the number of dipsomaniacs and syphilitics and is so appallingly on the increase of late years.

These are met with everywhere and in all ranks of life. They fill our hospitals, insane asylums, almshouses and prisons. They create hordes of tramps and criminals to over-run our

country and propagate disease, while they teach immoral practices.

For every epileptic, tuberculous and insane person who inherits his condition from a parent similarly affected, at least ten bear their disease as the result of a parent's debauched life or inherited syphilis or of the drunkenness of the father at the time of conception, or the prolonged indulgence of one or both parents in alcoholic liquors, tobacco and other narcotics.

Yet despite the well known truth of my present assertion the medical profession advises a higher standard of education and rigid legislation chiefly against trivial matters, such as the expectoration of tubercular sputa, the communion cup and marriage in insane and tuberculous families. At the same time they would countenance the legalized saloon and brothel where a business is made of seducing and debauching our girls and boys, polluting their pure minds and contaminating their sound bodies.

One might wish as much reason regulate the method of conduct and improve the morals of a mad dog in order to prevent hydrophobia as to strain at the gnats of epilepsy and tuberculosis while he swallows such camels as syphilis and drunkenness.

Is it not high time that the profession becomes aware of the true source of the diseases which are devastating our country and taxing its resources to their utmost to find institutions large and numerous enough to hold the victims.

EVAN O'NEILL KANE, M.D.

Compact Portable Sterilizer.

NEW YORK, May 6, 1897.

To the Editor:—Dr. Wetherill's description of a "compact portable sterilizer for surgical instruments and dressings," (May 1, page 856) shows the need he experienced of demonstrating, in a feasible manner, the ease with which sterilization can be obtained anywhere and everywhere, thus taking from surgery the greatest impediment to success.

This is especially gratifying to me, particularly as Dr. Wetherill, to whom the thanks of the profession are due for his lucid description, publishes an exact counterpart of my nested sterilizer, which was shown at the forty-sixth annual meeting of the AMERICAN MEDICAL ASSOCIATION in Baltimore, May 7, 1895, at the Berlin exhibition last summer and which was described in the JOURNAL, July 27, 1895, and more fully in my little book on "Surgical Asepsis," page 119, published by Saunders of Philadelphia in March, 1895.

Those who know Dr. Wetherill will appreciate that this note is in no sense a stricture upon his above mentioned letter. I merely pen these lines to call his attention to the facts so that he may at his convenience, correct any misapprehension that may arise regarding the origin of this sterilizer. I know Dr. Wetherill will do this as readily as would yours very truly,

CARL BECK, M.D.

ASSOCIATION NEWS.

Executive or Business Committee.—The first meeting of this Committee will be held in Parlor C, Hotel Walton, cor. Broad and Locust Streets, Philadelphia, on Monday May 31, 1897, at 5:30 p.m. Subsequent meetings will be held at the same place and hour, unless otherwise ordered by the committee, for the consideration of matters referred to it by the ASSOCIATION, and for the transaction of business.

L. DUNCAN BULKLEY, M.D.,
Secretary of Committee.

Medical Aid Section.—An effort will be made at the approaching Semi-Centennial of the ASSOCIATION in Philadelphia, to complete the organization of a Medical Aid Section for the benefit of disabled physicians and of the widows and orphans of physicians, members of the Section, with the coöperation and

endorsement of the several State and municipal medical societies; the friends of such Section of a Medical Aid Society hope to organize and have appointed all the officers required to make the Section a corporate body of the ASSOCIATION and to convince the profession, that those now throughout the country who are non-members will find it to be to their advantage to join our ranks.

Section on State Medicine.—The annual dinner of this Section will be held at 8 o'clock, Tuesday evening, June 1, at the Aldine Hotel. Those who desire to join with the Section at this dinner in celebration of the twenty-fourth anniversary of its organization, are requested to notify the chairman, Elmer Lee of Chicago, or the secretary Louis F. Bishop of New York.

Section on Diseases of Children.—Dr. J. A. Larrabee, the chairman of the Section on Diseases of Children of the AMERICAN MEDICAL ASSOCIATION, extends a cordial invitation to the members of the Philadelphia Pediatric Society, and others to attend its sessions during the meeting of the ASSOCIATION June 1 to 4, and also to attend the dinner on the evening of June 1, the subscription to which is \$2.00.

Committee on Registration.—The Bureau of Registration will be opened in Horticultural Hall at 1 P.M., on Monday, May 31.

JOHN MARSHALL, M.D.

Chairman of Committee on Registration.

SOCIETY NEWS.

Association of American Physicians.—Twelfth annual meeting held at Washington, D. C., May 4, 5 and 6, 1897. Dr. J. M. Da Costa, president, in the chair. The president delivered the Annual Address (see p. 911).

Dr. George B. Shattuck of Boston then delivered an address on the "Serum Test for Typhoid Fever." Seventy-three patients were studied and the tests were made under the supervision of Dr. Leary of the pathologic department of the Boston City Hospital. The clinical statements are unnecessarily subject to the unavoidable peculiarities of hospital practice, but the effort was made to have them as accurate as possible. The date of the beginning of typhoid fever is counted from the first symptoms, but the examiners are not always correct even when they wish to be. A few cases have been thrown out; thus in some of these cases a large number of these tests might have been made had more time been at our disposal. Liquid blood was used and only incidentally could we make out the proportion of serum in the typhoid cultures. The diazo reaction has been used in a large number of these cases and in the laboratory a longer maximum of time, an hour, was allowed for the reaction than some would consider justifiable. Many of the reactions had occurred in less time and the room culture reacts more promptly than the thermostat culture. Of the 145 cases 125 were typhoid fever, 17 were not typhoid fever and one was doubtful, which is not much to go on. The method of bacteriologic testing was next taken up. But in this suffice it to say that the spleen of the patient was taken as a basic culture and from this daughter cultures were made. All the tests were made with cultures given at the room temperature, they seeming to be more satisfactory, for in the room culture the organisms were fewer in number and larger and more motile; the reactions, while perhaps slower, were absolute. In the thermostat cultures sediment of dead organisms interfered with the diagnosis. The technique was that commonly practiced, but an hour was made the limit of time for the test and a shorter limit would have made many tests doubtful. With 116 cases with a clinical diagnosis of typhoid the reaction occurred in 16 before the tenth day and in 1 as late as the 122d day. Eleven cases gave a doubtful clinical diagnosis, and of these 4 gave no reaction at any time. One was without doubt meningitis; another was an old endocarditis; the third and fourth were probably typhoid, although it is very uncertain. In five of these eleven doubtful cases a positive result was obtained. In the first of these there were almost no symptoms but the reaction took place on the twenty-second, twenty-third and twenty-fourth days. The second case was a professional man of 52, he was a steady drinker, he suddenly became mentally confused while in another city and later had another attack resembling vertigo with aphasia; the urine contained blood, albumin and casts, the serum test gave prompt reaction. The third case was probably meningitis but

reaction showed that typhoid was with it. The fourth case was evidently of an ambulatory typhoid; the fifth case was considered uremia, but as the history and symptoms were so vague no positive diagnosis could be made; the patient died and the autopsy showed a typhoid case. Two were doubtful cases of which positive and negative results were obtained on different days. In the eighteen cases with a clinical diagnosis other than typhoid fever there was no reaction in fifteen and there was a reaction in three. One of these three being pneumonia, one thought to be acute miliary tuberculosis and one only exophthalmic goitre. The pneumonia case died and no autopsy was obtained. The case of ophthalmic goitre also died and typhoid ulcers were seen at the autopsy. The case of acute miliary tuberculosis gave a positive result. Questions have been asked whether the blood serum from the negro was more prone to this reaction than the blood of the whites. Tests were made with thirteen colored patients in eight of whom there was no reaction. In three there was reaction more or less satisfactory and in two the reactions were positive. Typhoid fever can not be excluded from the history of these two cases in the past six months. The diazo reaction was recorded in eighty nine cases, was found in forty-two and not found in forty-seven and its presence did not always coincide with the serum test.

The following conclusions were drawn:

1. The serum reaction may be obtained toward the end of the first week of typhoid fever, but is both more pronounced and more usual later in the course of the disease.
2. It may be present without relapse at the end of the fourth month.
3. It may be absent one day and present the next.
4. Of 125 cases of typhoid fever the reaction was absent in only one case. In three cases it failed, but there was in each only one test, in one case on the twelfth and in the other on the eighty-second day.
5. In nineteen cases of other diseases clearly uncomplicated by typhoid there was no reaction.
6. In one case, where the diagnosis must remain doubtful, although typhoid can not be positively excluded, there was a reaction.
7. In the number of difficult and perplexing cases the serum test was of distinct service in establishing or correcting the diagnosis.
8. This test will probably prove itself a useful aid to clinical diagnosis, and especially in hospital practice.

Dr. A. C. Abbott of Philadelphia said that the conditions which surrounded this work in the city were not the same as those in a hospital, nevertheless the results in Philadelphia had been fairly good. They had received 164 cases of dried blood and 115 of these had histories. Sixty-eight were clinically diagnosed typhoid fever and 66 gave the Vidal reaction; that is to say 2.9 failures. This reaction takes place as late as the thirty-second day and in many cases less than a week. In two cases in which the primary reaction was negative the secondary was positive and in seven cases where the doubtful primary reaction had showed a positive one later; two cases came in with very meagre histories; he had been much pleased with the results of the work in the municipal laboratory in Philadelphia.

Dr. J. H. Muser of Philadelphia said that there was one period when this reaction was confusing, and that is in the latest stages of the illness when typhoid was a terminal infection. He mentioned several cases in which the reaction failed to show until very late in the course of the disease, which made him think the disease was not originally typhoid.

Dr. Wm. Osler, Baltimore, said that in forty-four cases which had been examined before him by Dr. Bloch at the Johns Hopkins Hospital, reaction had proved satisfactory in all, and quite a number of these patients were admitted later on in the course of the disease. In one there was slight recrudescence of the disease; again in another meningitis. In most cases it was rare to get this reaction before the sixth day.

Dr. Herman M. Biggs, New York, said that it was very difficult to obtain the reaction from the blood, but in quite a number of cases he had applied a cantharidal blister and had obtained the reaction with the serous fluid which was raised by the blister.

Dr. James Tyson, Philadelphia, said that many cases of typhoid fever aborted spontaneously. He mentioned the cases of two young girls who went skating on the Schuylkill and becoming thirsty, they drank some of the water through a hole in the ice; they both had the fever and very early in the course of the disease they gave characteristic reaction; one got well in a week and the other one in three weeks. He mentioned another case which was supposed to be typhoid fever, but the blood was examined and the reaction was not obtained;

he thought it must be miliary tuberculosis, but could get no signs of the disease, but the clinical picture was so much like typhoid that he held to his opinion. At the autopsy there were no signs of typhoid fever except an enlarged spleen, and the case was one of tuberculosis.

Dr. Frank Billings, Denver, said that mistakes were often due to faulty technique. In his article Dr. Wyatt Johnston stated that an old culture should be used, which was an error, and what he meant to say, and what he did say afterward, was that an old culture should be used as a basic culture and daughter cultures from this should be used. It was very important that the technique of this method should be understood before attempts of diagnosis are made; for there is the age of the culture and the proportion of serum to the test, and the influence of the serum of the typhoid organisms; all have to be considered. In one case in which the typhoid fever occurred three years ago the blood reacted to the test. Vidal says seven years is the longest time he knows. It is important, therefore, to understand the method of reaction and to be acquainted with the exceptions to this diagnostic means.

Dr. Jas. T. Whittaker, Cincinnati, then related a case of a patient who he at first thought had Bright's disease, and then he thought it was miliary tuberculosis. He examined the blood and got the typical reaction during convalescence, and he concluded that the case was one which had recovered from typhoid fever.

Dr. F. C. Shattuck, Boston, then related a case in which the diagnosis at first was rather obscure. The patient felt badly, had chills, later fever and then albuminuria, which was supposed to be Bright's disease; the fever went up as high as 106 degrees, the blood gave the characteristic test, and he concluded that it was what the Germans call "nephrotypus."

Dr. E. G. Janeway, New York, said he had seen the danger of trusting to the negative side of this test too early in the course of the disease. He had been called in quite a number of times when the test was negative and when the case was supposed to be typhoid fever but no certain diagnosis had been made. In one case it was not until the twenty-eighth day that the typhoid reaction was obtained, and there had already been collapse and perforation of the intestines. The negative test does not deprive typhoid fever of its dangers, but rather tends to throw one off guard. The great danger is in regarding this test as pathognomonic, thus we are misled by the negative results and treat the case as if it were something other than typhoid, when in reality it is typhoid. He mentioned a case in which the reaction was not obtained until the convalescence; he thought we ought to be very careful in negative tests.

Dr. A. Lawrence Mason, Boston, then read a paper entitled "Gall-bladder Infection in Typhoid Fever." This was a case of inflammation of the gall bladder with perforation and intestinal rupture following a complication of typhoid. It is not a common disease and he had found about forty cases in literature, and most of them were postmortem discoveries. His case was a woman 30 years old who in the second week of typhoid fever began to suffer from anorexia, vomiting and constipation. The blood was tested and the reaction was positive. She had pain in right hypochondriac region with swelling; great tenderness at times; the liver dulness was normal. A cyst was discovered and it was aspirated, a thick yellow fluid being withdrawn; there were no gallstones found. The relief from pain was immediate and the pulse fell to normal; the gall bladder was resected; defervescence promptly ensued. The specimen of fluid which was passed around showed that it was very much unlike bile. Typhoid organisms were found in this fluid, tests were made with it and animals were inoculated. Not many cases of this kind are recorded. Rokitsansky and Frerichs have written the best studies on this trouble. It is only in the last ten years that bacteriologists have made it possible to investigate these cases thoroughly. The biliary ducts contain the typhoid organisms, and also some gallstones were found, but not many. Infections might have taken place from the gall bladder. The prognosis was unfavorable. If the gall bladder is much distended, the treatment should be toward relieving pain and for preventing absorption, or else surgery should be called in. He related a case in which laparotomy had been performed in this trouble.

His conclusions were, 1. That the gall bladder is often affected in typhoid fever. 2. Cholecystitis may result. 3. Gallstones predispose to this complication. 4. Gall bladder may be the means of infecting the body.

Dr. Wm. Osler, Baltimore, then read a paper on "Hepatic Complications of Typhoid Fever." He considered the subject under the following headings: 1. Focal necroses. 2. Jaundice in the course of the disease. 3. Abscesses which might be in the form of a suppurative pylephlebitis or a solitary abscess.

4. Affections of the bile passages which were due to typhoid bacilli of the gall bladder and typhoid fever, or as cholecystitis and cholangitis as a complication or sequela of the disease, or else of the form of typhoid fever and gallstones. He spoke of the rarity of jaundice in these cases. He had not been able to find it in 500 cases in the Johns Hopkins Hospital except in two instances. Blochstein showed that the bacillus lived fifteen and a half weeks in the biliary passages and the colon bacillus was always there. In fourteen cases in which the gall bladder had been examined of those who died, typhoid bacilli were found in seven cases and other organisms in the disease and in these seven fatal cases there had been no hepatic symptoms. There is a great possibility of infection through the gall bladder. The production of an acute cholecystitis without typhoid in any individual is possible, as the record of the present day will show. He had seen a case; the subject of the case was a man who had suffered from gravel. After a hearty meal of beefsteak and potatoes he was seized the next day with violent vomiting and vomited his two previous meals; he had a tumefaction over the gall bladder region. Dr. Halsted operated and found no bile, but stones and a yellow liquid. He also found the colon bacillus. The studies of Chiari on this subject show very great care. It is exceedingly rare, for in an analysis of 2,000 cases in Munich only five were found. The number of recent cases is greater than is usually reported. He spoke of one case in which there was laparotomy and recovery and then related the following cases:

Case 1.—Typhoid fever. Fever lasted twenty-seven days, colon bacillus was found during convalescence; the patient subsequently recovered; then three months later he grew worse and was operated on for cholecystitis; a laparotomy was first performed for appendicitis and nothing being found wrong with the appendix the gall bladder was found adherent with a perforation in it, from which oozed a yellow fluid; this fluid was removed and the stone was also removed and the gall bladder was packed with iodoform gauze and the case recovered.

Case 2.—In the third week of typhoid fever; got better later; had a relapse and became violently jaundiced. On admission a large gall bladder was found and the fluid extracted; the colon bacillus was found; the patient died.

Case 3.—The patient had been sick eighty-two days; had a slight remission; typhoid fever was diagnosed, but Vidal's reaction was dubious. On the thirty-fifth day of the fever, had extreme pain in the hypochondriac region; a laparotomy was performed and the patient recovered.

Case 4.—Typhoid fever; pain in the side; got better, but later was re-admitted; he then complained of headache, weakness, and then had a chill which lasted half an hour; the blood gave marked Vidal reaction; he was jaundiced. The cultures from the fluid were sterile; later he had parotitis.

American Pediatric Society.—Ninth Annual Meeting, Washington, May 4, 5 and 6, 1897. The meeting was opened by the president, Dr. Samuel S. Adams, of Washington, who delivered an address entitled "The Evolution of Pediatric Literature in the United States." In this address he reviewed in chronological order the various works on the diseases of children which have been written in this country during the past one hundred years. Every author writing upon this subject before 1870 was mentioned. Since that date the contributions have been too numerous to receive individual mention. The first definite contribution to pediatric literature was made by Dr. Rush in 1789, in a description of influenza. Following this were mentioned the names of Caldwell in 1796, Stuart in 1806, The American Matron in 1810, Jackson in 1812, Miller in 1814 and Logan in 1825. There were numerous contributions between that date and 1848 when J. Forsyth Meigs published his important work on the diseases of children, the last two editions of which appeared under the authorship of Meigs and Pepper. The next important name in pediatrics appeared ten years later when Jacobi in 1858 wrote his first paper on children. It is also notable that J. Lewis Smith wrote his first paper on children in the same year. The first edition of his well known work on diseases of children appeared in 1869.

The most important names which have since appeared as the authors of systematic works are those of Keating in 1889, Starr in 1894, Sachs in 1895, Rotch in 1895 and Holt in 1896.

Dr. James C. Wilson read a paper upon "Tic Convulsif" and reported a case which belonged to the class of nervous diseases which includes the "jumpers" described by Beard. Dr. B. Scharlau presented a synopsis of fifty-six cases of empyema operated upon during 1896 with very favorable results. Dr. W. D. Booker reported a case of congenital diaphragmatic hernia associated with recurrent attacks simulating asthma dyspepticum. During one of these attacks the child died and the true pathologic conditions were revealed by the autopsy.

Dr. J. P. Crozer Griffith reported two cases of "Unilateral Tremor" in children. Dr. J. Henry Fruitnight read a paper on a "Frequent Significance of Epistaxis in Children." He believed that this symptom was frequently the result of cardiac disease and should always receive full attention. Dr. George N. Acker reported two cases of meningitis apparently tuberculous in nature, with recovery.

Dr. Joseph O'Dwyer reported a case of congenital stenosis of the larynx in which relief was obtained by gradual dilatation with steel sounds. Dr. William Osler read an extended paper on "Adherent Pericardium in Children," and reported cases. Dr. A. Jacobi reported a case of sarcoma of the skin in a newly born infant and read a paper upon the origin of such growths.

Dr. F. Gordon Morrill reported an analysis of "One Hundred Cases of Broncho-pneumonia," that term being used rather than lobar pneumonia because of the confusion produced by the use of the latter term when applied to the pneumonias of children. Dr. Floyd M. Crandall read a paper on "Hereditary Tendency in Pediatric Practice," and called particular attention to certain misapprehensions which sometimes arise regarding that subject. Dr. B. K. Rachford read a paper on the "Symptoms of Lithemia" as they appear in children and considered the special symptoms in detail.

In a paper on "Retro-esophageal Abscess," Dr. J. P. Crozer Griffith called particular attention to the great difficulties experienced in making a diagnosis of that condition. Dr. C. G. Kerley reported a case of exophthalmic goitre apparently cured by the use of thyroid extract. The case was an undoubted one and the beneficial effects of the extract seemed to be equally clear. Dr. Henry Koplik reported the extensive use of thyroid extract for the purpose of testing its value in different diseases of the blood and bones, and his conclusions suggested its more general use in those diseases. Dr. Francis Huber also presented a paper reporting a cure of goitre by thyroid extract. The report of the committee on the collective investigation of the antitoxin treatment of laryngeal diphtheria in private practice was read by the chairman, Dr. W. P. Northrup, the conclusions being as follows:

Dr. Joseph O'Dwyer read an important paper on retained intubation tubes, this term being used to mean the necessity of continuing intubation long after the disappearance of the original disease. Dr. T. M. Rotch reported cases of diphtheria of the eye and discussed the subject of antitoxin in diphtheria. Dr. Henry Koplik exhibited an apparatus by which the bacteriologic diagnosis of diphtheria could be made within three or four hours.

Dr. Edward P. Davis presented an important contribution on pre-natal infection in infancy causing diseases which develop during the first month of life. Dr. Irving M. Snow reported a case in which poisoning by acetanilid had resulted from the absorption of that drug in the umbilical wound. Dr. T. M. Rotch presented a specimen of ileocolitis and Dr. R. G. Freeman presented an improved nursing bottle.

Papers were read by title by Drs. J. Lewis Smith, W. F. Lockwood, W. P. Northrup, R. G. Freeman, H. D. Chapin, Francis Huber, C. G. Jennings, C. P. Putnam.

The following officers were elected for the ensuing year: President, Dr. L. Emmett Holt; first vice-president, Dr. Henry Koplik; second vice-president, Dr. Charles G. Jennings; secretary, Dr. Samuel S. Adams; recorder, Dr. Floyd M. Crandall; treasurer, Dr. F. A. Packard; member of council, Dr. Charles P. Putnam.

The following were elected members: Dr. J. H. McCollom, Boston; Dr. J. P. West, Bellaire; Dr. Churchill, Chicago; Dr. E. E. Graham, Philadelphia; Dr. Harold Williams, Boston.

The subject of infantile scorbatus was selected for collective investigation, the report to be made at the next meeting. The following committee was appointed: W. D. Booker, J. P. Crozer Griffith, C. G. Jennings, A. Cailé, J. Lovett Morse.

Cincinnati was named as the next place of meeting, the exact date of the meeting not being decided.

PUBLIC HEALTH.

Reports of Contagious and Infectious Disease.—Commissioner George B. Fowler, M.D., of the Health Department, New York City, as against the charge of tyrannical authority over the profession, states that criticisms of the Greater New York charter are unjust, inasmuch as the sections involved are not new. "They constitute Sections 608-610 of the Consolidated Act of 1882, under which the city has been governed for fifteen

years and were originally passed forty-seven years ago. Sections 1247 and 1249 being in Chapter 275, Laws of 1850, and Sections 1248 in Chapter 384, Laws of 1851."

A Sewage Lawsuit in Ohio.—An interesting trial will occur shortly at Fremont. The village of Clyde turns its sewage into Green Creek, and Mr. J. N. Winter, a farmer, raises hogs on a farm lower down the stream. Recently hog cholera greatly reduced his assets and he lays the blame to the pollution of the stream and has sued the village for \$3,140 damages. Once the principle of securing indemnity for this sort of damage is established, we will hear much less of insanitary towns and villages. The pleadings of the medical profession for good sewerage systems will be listened to with more respect in the future.—*Cleveland Journal of Medicine*, April.

Sanitary Economics in Michigan.—A Michigan journal states that the statistics of the State Board of Health show through compliance with the recommendations of that Board during the five years, 1890-94, there were probably saved to the people of Michigan 112,843 cases of sickness and about 5,261 deaths, from the four diseases—diphtheria, scarlet fever, typhoid fever and measles. At a very low estimate the money value thereby saved the State during these five years is \$5,097,800, or over one million dollars per year, from these four diseases. The basis on which this estimate is made is as follows: For medical attendance and other necessary expenses in each case of sickness, \$20; for each funeral prevented, \$40; value of each life saved, \$500. (Before the late war a slave was worth about \$800, for what it would earn over and above its cost of maintenance, and now the courts count an average person's life worth about \$5,000—ten times the amount used in this estimate). If all the dangerous diseases were considered, the saving would undoubtedly be much more.

"The State Board of Health exists for the purpose of guarding the highest interests of every man, woman and child in Michigan; and, if it had the coöperation of all, and its advice was fully complied with, the results of the work would be still more effective. As it is, the money values saved to the people of the State greatly exceed the cost of the public health work, being, in fact, nearly half as much as the entire amount required to sustain the State government and all the State institutions. From an unhealthful State, Michigan is fast becoming one of the most healthful."

NECROLOGY.

B. F. KITTRELL, M.D., died at his residence in Black Hawk, Miss., April 22. Dr. Kittrell was born at Greensboro, Ala., Dec. 24, 1836. He graduated from Irving College, Tenn., in 1855, and from the New Orleans School of Medicine in 1861. He entered the Confederate service as a private in 1861, but in the following year he was appointed assistant surgeon of the 22d Mississippi Regiment, which position he retained until the close of the war. In 1866 he located at Black Hawk, Miss., where he continued in the practice of his profession until his death. Dr. Kittrell was an active member of the State Medical Association, and did much to elevate the standard of medical attainments in the State and also in shaping medical legislation. In 1889, he read an article before the Association on Medical Legislation, in which he suggested that, instead of having a board of examination for each congressional district in the State, it would be better to have one board for the State at the capital, to examine all applicants for a license to practice medicine. The Association concurred in his views, and immediately appointed a committee to memorialize the State legislature on the subject, which action resulted in the change being effected. Dr. Kittrell was at different times vice-president, orator and president of the State Medical Association. He was a member of the State Board of Health for seventeen years, and was president of that body in 1884.

J. A. NOEL, M.D., of Redfield, Iowa, died in De Moines,

Iowa, April 23, aged about 40 years. His death followed a few hours after an operation for intestinal obstruction. Dr. Noel was a graduate of Missouri Medical College, 1886. He was a permanent member of the Iowa State Medical Society, and was a charter member of the Dallas County Medical Society, of which society he was president in the year 1895-96.

ERNST KRAMER, M.D., Berlin, 1856, died April 18, in Milwaukee, Wis., in which city he settled in 1865. He was 64 years old and a surgeon on the first steamer to New York of the North German Lloyd Company. In 1859 he resigned and went to Madison, Wis. During the war he had a varied experience as assistant surgeon of the 7th Wisconsin Infantry, from which he was promoted surgeon of 1st Wisconsin Cavalry, June 13, 1862, and from this he resigned Feb. 27, 1863. He was finally mustered out of service as surgeon of the 45th Wisconsin Infantry Dec. 8, 1864. For nearly twenty years he was a pension examining surgeon.

CHARLES M. SHIELDS, M.D., of Richmond, Va., died April 16, aged 41 years. He was a member of the AMERICAN MEDICAL ASSOCIATION and Medical Society of Virginia as well as an ex-president of the Richmond Academy of Medicine and Surgery. Four years ago he became Lecturer on Diseases of the Eye, Ear and Throat in the Medical College of Virginia, from which he was graduated in 1879.

GRAFFINS MILLER COUCH, M.D., Maryland School of Medicine, Baltimore, 1883, died at his residence in Altoona, Pa., April 25, aged 47 years. He was a member of the Altoona Academy of Medicine and Surgery.

EDWARD H. FOSTER, M.D., of Concord, N. H., died April 5. He was a graduate of the Medical School of Maine, Brunswick, class of 1866, and was widely known in his section of the State.

JEFFERSON J. O'CONNELL, died in Honesdale, Pa., April 12, from gastric ulcer. He was born in 1859 and was graduated in 1887 from the College of Physicians and Surgeons, Chicago.

HUGH McDONALD STRUBLE, M.D., University of Pennsylvania, 1875, and of Middletown, N. Y., died April 30. He was born in Newton, N. J., in 1852.

BOOK NOTICES.

Surgery of the Head and Neck. By LEVI COOPER LANE, A.M., D.D., M.R.C.S., W.L.D. Professor of surgery, Cooper Medical College, San Francisco. Published by the author.

If the reader of this little volume will leave bacteriology out of the case he will find a very instructive and entertaining volume. The long experience of the author, his powers of close observance, the excellence of his English and the purity of his diction will commend the work and arrest the attention of the reader, and as a record of the experience of a surgeon during a long and active life, the work will find an appropriate place in the library of every surgical scholar and practitioner.

We hope to see other volumes of regional surgery following in due course. In the description and treatment of the various surgical diseases of the head and neck few surgeons can speak from a longer experience, and few have better set forth the result of that experience. The literature of the subject discussed has been exhaustively quoted wherever applicable. The proofreading has been done with great care and the author has apparently spared no pains to insure accuracy.

The Twenty-second Annual Report of the Secretary of the Michigan State Board of Health, for the year ending June 30, 1894, pp. 526. Lansing: Robt. Smith & Co., 1896.

This report is somewhat belated, but it is none the less valuable in containing a detailed statement of the efficient services of an excellent Board of Health under an accomplished executive officer. Few can arise from a perusal of this report without having an increased respect for the intelligence, skill and zeal which have characterized the operations of which it gives an account.

Syriogomyelia. The 1895 Alvarenga prize essay of the Philadelphia College of Physicians. By GUY HINSDALE, A.M., M.D. pp. 74. \$1.00. Philadelphia: International Medical Magazine Co. [P. Blakiston, Sen & Co.] 1897.

This little essay is dedicated to S. Weir Mitchell. It places in evidence the most complete bibliography on the subject that has thus far been collected, amounting to 514 references. Of these says the author, 230 are from Germany and Austria, 136 from France and 85 that appear in English.

The author has gone to the original sources of analysis, 180 cases since 1890. The essay is based on the study of these and two unpublished cases which have been added to the list. The essay has been revised and re-published from the *International Medical Magazine* of November, 1896, and November, 1897. It is a very complete statement of the subject. It is well illustrated and will be found very useful for the general practitioner and likewise the specialist in nervous diseases.

The International Medical Annual and Practitioners' Index. Forty-one contributors, English and American, pp. 629. \$2.75. New York and Chicago: E. B. Treat.

This is the fifteenth year of this book and it preserves the same general characters it did in the beginning, viz., very comprehensive scope of great compactness and judicious selections. The book has few superiors in its special line, and among the many excellent year-books it occupies a very high rank.

MISCELLANY.

Not Natural Results of injuries.—Loss of memory or impaired mental constitution, the supreme court of Kansas holds, in *Atchison, T. & S. F. R. Co. v. Willey*, March 6, 1897, are not the natural or probable results of mere bodily injuries negligently inflicted by one person upon another, and, in consequence, before recovery therefor, as items of damage resulting from such injuries, can be had, they must be specifically pleaded.

Surgical Scissors are Scissors.—In the matter of the protest against the decision of the collector of customs at New York as to the rate and amount of duties chargeable on certain surgical scissors, the United States general appraisers at New York find, under date of January 20, 1897, "that the said surgical scissors are scissors," and affirm the assessment of duty at 45 per cent. under paragraph 140, act of August 28, 1894.

Extirpation of Cancer of the Cecum.—The neoplasm weighed 400 grams and was attached to the rear wall of the cecum, of which 20 cm. were resected with it. The operation was extraperitoneal, and concluded with the union of the end of the ileum to the end of the ascending colon. Normal intestinal functions were resumed in four days and the patient was dismissed completely cured in three weeks.—*Gaz. d. Osp. e delle Clin.*, 7, April 11.

Societies.

THE PRACTITIONERS' CLUB of Newark, N. J., gave their ninth annual dinner on May 4. The election previous to the festivities, resulted as follows: A. K. Baldwin, president; R. G. P. Duffenbach, vice-president; H. C. Herold, secretary and treasurer.

THE WESTCHESTER COUNTY MEDICAL SOCIETY of New York State, after the Medical Society of New Jersey (incorporated in 1790), said to be the oldest in the United States, celebrated its centennial May 8, in the county court house, White Plains, N. Y. The occasion was made memorable by hunting, speeches, an historical address, a poem and a banquet. About one hundred out of the one hundred and fifty members were present.

Hospitals.

There are 21 hospitals in France that dispose of over 500,000 francs; 116 over 100,000 francs, and 1,389 less than 30,000

francs—a total of 1,773 hospitals in all.—St. Vincent's Hospital, New York city, is to have an addition of a new wing, the erection of which the advisory board hope to begin with the proper support of their friends. This hospital in 1896 received 4,307 patients, an increase of nearly 300 over the previous year. In the out-door department 10,611 patients received treatment and 5,702 prescriptions were filled. The death rate was 8.43 per cent.

New York.

AN INSANITY LAW AMENDMENT.—A bill providing for the immediate disposition of lunatics of the dangerous class, received some informal consideration in the New York State Legislature before its adjournment. The proposition was for the temporary commitment of dangerous or violent lunatics for five days upon the sworn certificate of two authorized medical examiners in lunacy, pending the outcome of the legal proceedings for the final disposition of the cases. This period to carry a three days' option at the discretion of a judge of a court of records. It was also proposed that the alleged lunatic, his family, relatives or friends be notified as soon as he is temporarily committed that he is entitled to counsel. If no counsel appears within two days, it shall be the duty of the district attorney of the county in which the alleged lunatic resides to appear at the hearing for the purpose of protecting his interests, so far as consistent with public safety. The present insanity law, which perhaps aimed to be too comprehensive, has been in operation since July 1, 1896, a period too short, in the opinion of the chairman of the lunacy commission, to require a change. The present status of the measure, so far as can be learned, is that it did not reach a vote, but may come up in some form at a future session. The law, whether to its credit or not, generally inclines to liberty of the person.

Washington.

THE FOURTH TRIENNIAL CONGRESS OF PHYSICIANS AND SURGEONS.—This meeting of the Congress has been most successful and the arrangements completed by the Committee in charge were perfect, owing to the able management of the chairman, Dr. Samuel S. Adams. Valuable and instructive papers were read in each component society and the meetings were well attended. Relaxation and the "social" was provided through luncheon by Drs. A. F. A. King, Jos. T. Johnson, S. S. Adams and T. M. Murray. A smoker at the Cosmos Club, and a reception at the Arlington Hotel in honor of Dr. Welsh. A commendable feature at the Club of the Congress was the unveiling of the statue of the late Dr. Samuel D. Gross. After prayer by Rev. B. L. Whitman, D.D., president of Columbian University, Dr. Claudius H. Mastin of Mobile, Ala., made an address, at the close of which he, on behalf of those who had raised the money to erect the monument, presented it to the government. Dr. Mastin's speech was a masterly effort, and comprised an interesting history of the life of Dr. Gross, in which mention was made of the most noted achievements of the latter for the cause of medicine and surgery. The life and work of Dr. Gross were reviewed at length by Dr. W. W. Keen, the successor of Dr. Gross in the chair of surgery at Jefferson Medical College. Dr. George M. Sternberg, Surgeon-General U. S. A., in accepting the monument for the government, followed with a very eloquent and interesting speech. The Gross statue stands in the lawn directly north of the Army Medical Museum and Library. The following officers were elected for the ensuing year:

Pediatric—President, L. Emmet Holt, New York; first-vice-president, Henry Koplik, New York; second vice president, C. G. Jennings, Detroit, Mich; secretary, S. S. Adams, Washington, and treasurer, F. A. Packard, Philadelphia.

Association American Physicians—President, F. C. Shattuck, Boston; vice-president, G. M. Baumgarten, St. Louis; recorder, I. Minnis Hays, Philadelphia; secretary, Henry Hun, Albany, and treasurer, W. W. Johnston, Washington.

Physiological—President, Prof. Russell H. Chittenden, New Haven, Conn.; secretary and treasurer, F. S. Lee, New York. Council—H. P. Bowditch, Roston; Prof. R. H. Chittenden, New Haven; W. H. Howell, Baltimore; F. S. Lee, New York, and W. P. Lombard, Ann Arbor, Mich.

Surgical—President, Dr. T. F. Prewitt, St. Louis; vice-presidents, Dr. J. McF. Gaston, Atlanta; Dr. M. H. Richardson, Boston; secretary, Dr. Herbert L. Burrell, Boston; treasurer, Dr. George R. Fowler, Brooklyn; recorder, Dr. De Forest Willard, Philadelphia.

Neurological—President, Dr. G. M. Hammond, New York; vice-presidents, Drs. Philip Zenner, Cincinnati, and J. J. Put-

nam, Boston; secretary and treasurer, Dr. F. L. Durenn, Philadelphia; members of the council, Drs. H. T. Patrick, Chicago, and C. K. Mills, Philadelphia.

Laryngological—President, Dr. Thomas R. French, Brooklyn; vice-presidents, Dr. T. Morris Murray, Washington, and Dr. H. S. Birckett, Montreal; secretary and treasurer, Dr. Henry L. Swain, New Haven; librarian, Dr. J. H. Bryan, Washington, D. C.; Council, Drs. D. Bryson Delavan, New York, John O. Roe, Rochester, W. H. Daly, Pittsburg, and Charles H. Knight, New York.

Dermatological—President, Dr. J. Nevis Hyde, Chicago; vice-president, Dr. E. B. Brown, New York; secretary and treasurer, Dr. J. T. Bowen, Boston; member of council, Dr. G. T. Jackson, New York.

Ophthalmological—President, Dr. Geo. C. Harlan, Philadelphia; vice-president, Dr. O. F. Wadsworth, Boston; corresponding secretary, Dr. J. S. Prout, Brooklyn; recording secretary, Dr. S. B. St. John, Hartford; delegate to the executive committee of the congress, Dr. John D. Rushmore, Brooklyn.

Genito-urinary surgeons—President, J. W. White, Philadelphia; vice-president, Dr. J. C. Bell, Montreal; secretary, Dr. W. K. Otis, New York; member of the council, Dr. R. W. Taylor, New York.

Otological—President, Dr. Arthur Mathewson, Brooklyn; vice-president, Dr. H. G. Miller, Providence, R. I.; secretary and treasurer, Dr. J. B. Vermyne, New Bedford, Mass.; delegate to the executive committee of the congress, Dr. William H. Carwalt, New Haven, Conn.

Climatological—President, Dr. E. Fletcher Ingals, Chicago; vice-presidents, Drs. Samuel A. Fish, Denver, and John C. Munro, Boston; secretary and treasurer, Dr. Guy Hinsdale, Philadelphia; council, Drs. Willis E. Ford, Utica, N. Y., Roland G. Curtin, Philadelphia, Isaac Hull Platt, Lakewood, N. J., S. E. Solly, Colorado Springs, Colo., James B. Walker, Philadelphia; member of the executive committee of the congress, Dr. Frederick I. Knight, Boston.

WASHINGTON GYNECOLOGICAL AND OBSTETRICAL SOCIETY.—The 263d meeting of the society was held on the 7th instant. Dr. Fry read the paper of the evening entitled the "Treatment of Asphyxia Neonatorum by the Hypodermatic Injection of Strychnin." Dr. J. T. Johnson presented a uterus which he successfully removed per vaginam. Dr. H. L. E. Johnson presented a calculus which he removed from the urethra of a woman.

The American Pediatric Society's Report on the Collective Investigation of the Antitoxin Treatment of Laryngeal Diphtheria in Private Practice. 1896-1897.—In this second and supplementary investigation, the aim has been to ascertain: 1, what percentage of cases of laryngeal diphtheria recover without operation under antitoxin treatment; 2, what percentage of operated cases recover. The report now submitted may properly be limited to answering these two inquiries.

Since the beginning of the use of general intubation, no disease has been more thoroughly observed and more fully reported than laryngeal diphtheria. Operative cases, especially, without hesitation, whether ending fatally or favorably, have been fully and promptly put on record. The result has been a collection and tabulation of cases available for control, such as few diseases offer. There are thousands of intubation cases before the days of antitoxin, and thousands since, available for comparison. It is, then, to cases of laryngeal diphtheria, especially those requiring operative interference, that we may apply the crucial test of the value of the antitoxin treatment.

Sixty thousand circulars containing the following questions have been distributed:

Age of patient? Diagnosis confirmed by: 1. Presence of other cases in the family? 2. Appearance of membrane elsewhere? 3. Bacteriologic cultures? How many days and parts of a day after the first appearance of the disease was antitoxin first administered? How many doses of antitoxin were administered? Dose of each injection in antitoxin units? Whose antitoxin used?

Non operative cases—evidence of disease: Hoarseness? Aphonia? Stenosis?

Operative cases: 1. Intubation? On what day? 2. Tracheotomy? On what day? How long, in days and fraction of a day, was tube in the larynx or trachea?

Sequelæ (in recoveries): 1. Broncho-pneumonia? 2. Paralysis? 3. Nephritis?

Death, cause of, and on what day? 1. Broncho pneumonia? 2. Extension of membrane to the bronchi? 3. Sudden heart paralysis? 4. Nephritis? 5. Sepsis? 6. Accidents of operation? Recovery? Remarks, especially on fatal cases?

These circulars were distributed throughout the United

States and Canada, the following means being employed: Contributors to first report, members of the Society acting as agents for their respective localities, boards of health, local medical societies and antitoxin manufacturers. At the outset, in this connection, it is a pleasure to acknowledge that the labors of the Committee have been much lightened by the uniform good will of all addressed, more aid coming spontaneously than in the previous investigation. It is also a pleasure to especially acknowledge the Society's indebtedness for efficient aid in distributing circulars and securing returns to H. K. Mulford Co., Parke, Davis & Co., Lehn & Fink (Gibier's), the Health Departments of Chicago, St. Louis, New Orleans, Denver, San Francisco, Boston, Washington, Buffalo, Providence, Ann Arbor, Newark, Montreal, Toronto and others.

To the New York Health Department is due the thanks of the Society for every possible courtesy in distributing blanks and, through their inspectors, of securing returns of operative cases.

In order to reduce sources of error it was desirable to bring together a large number of cases, from widely distributed localities, from many different observers and operators, and from a period of time including all seasons of the year. All returns have been examined by the Committee and only such cases accepted as bore satisfactory evidence that they were first of all, diphtheria, and secondly that the lesion had invaded the larynx.

A total of 1,704 cases of laryngeal diphtheria are ours for present study. A few cases (228) had not satisfactory evidence that there was laryngeal involvement; indeed, some were reported through misunderstanding the fact that only laryngeal cases were wanted, and a few were reported in which there was no mention that antitoxin was used. These cases are not included in the number referred to above. Of the 228 cases, 218 recovered, and 10 died.

In a total of 1,704 antitoxin-treated cases of laryngeal diphtheria, there was a mortality of 21.12 per cent. (360 deaths).

TABLE OF ALL CASES SHOWING AGE AND RESULT OF TREATMENT.

	Fatal cases.	Recoveries.	Totals.	Mortality. Per cent.
1 year and under . . .	25	35	60	41.66
1 to 2 years	77	219	296	26.01
2 to 3 years	81	260	341	23.75
3 to 4 years	42	216	258	16.27
4 to 5 years	47	160	207	22.70
5 to 10 years	72	845	417	17.26
10 to 15 years	9	64	73	12.32
15 to 20 years	2	24	26	7.65
Over 20 years	5	17	22	22.72
Unknown	0	4	4	
	360	1344	1704	21.12

Cases not operated on.—The first inquiry of the circular was what percentage of cases of laryngeal diphtheria recover without operation under antitoxin treatment.

Of 1,704 total cases, 1,036 were not operated upon (60.79 per cent.). Of these, most did not require operative interference, a few cases were thought to require it but operation was refused. All cases are included, and it will be noted, there are no eliminations.

Among the 1,036 cases not operated on, there was a mortality of 17.18 per cent. deaths (178), or, to answer the inquiry of the circular exactly, of 1,036 cases not operated on, 82.82 per cent. recovered (or 858 cases).

As good as is this percentage of recovery in so large a number of diphtheria of the severest type, it is believed it is not as good as it ought to be. Cases of laryngeal diphtheria not requiring operation, according to the testimony of consulting intubationists, are seldom heard from a second time, and less often find their way into reports. It was formerly estimated that about 10 per cent. of cases of laryngeal diphtheria recovered without operation. The present report shows that in 1,036 cases 82.82 per cent. recovered.

Cases operated upon.—In analyzing this class of cases, it is believed a more exact conclusion as to the value of the antitoxin treatment can be arrived at than in the non-operative.

There will be entire harmony of opinion as to the severity of laryngeal diphtheria which requires operative interference. In the early days of intubation it was customary to speak of the percentage of recoveries, and 25 per cent. and 27 per cent. were considered good results. In the last report the recoveries had crept up so high in the one hundred cases that it seemed more natural to speak of the percentage of mortality.

In this connection it is interesting to inquire what were the best reliable statistics of intubation, taking cases as they occurred, without selection, in pre antitoxin days. In 5,546 intubation cases collected by McNaughton and Maddren in 1892, the mortality was 69.5 per cent., or, to bring the facts into line, 30.5 per cent. recovered.

O'Dwyer's personal experience, in private consultation, brings us more nearly face to face with the old-time experience with diphtheria. Note that the following 500 cases came under the observation and care of one practitioner, a skilled operator, extended over a dozen years of time, and therefore included all types of the disease.

Exclusive of the first 100 cases of intubation, which O'Dwyer regards as experimental, the results stand as follows:

2d	100 intubations, recoveries,	27 per cent.
3d	100 " " "	30 "
4th	100 " " "	26 "
5th, 70 on the 100	" " "	27 "

Total percentage of recoveries, 27.56. When he had reached 70 on the fifth hundred something occurred which carried the phraseology up over the divide so that it was appropriate to speak of mortality percentages. At this point in history, antitoxin arrived and interrupted forever the old series. In O'Dwyer's next 59 cases the mortality was 14 deaths, or 23.7 per cent.

In a total of 1,704 laryngeal cases there were 668 cases operated upon. In the 668, there were 182 deaths, or a mortality of 27.24 per cent. In the former report, in 553 intubated cases the mortality was 25.9 per cent. In approximate figures there is a difference between 27¼ per cent, and 26 per cent.

Summary.—Sixty thousand circulars were distributed throughout the United States and Canada.

Time allowance, the eleven months ending April 1, 1897.

Whole number of cases in this report, 1,704; mortality, 21.12 per cent. (360 deaths).

The cases occurred in the practice of 422 physicians in the United States and Canada.

Operations employed: 1. Intubation in 637 cases; mortality 26.05 per cent. (166 deaths). 2. Tracheotomy in twenty cases; mortality, 45 per cent. (nine deaths). 3. Intubation and tracheotomy in eleven cases; mortality, 63.63 per cent. (seven deaths).

Number of States represented, twenty-two, the District of Columbia and Canada.

Non-operated cases, 1,036, 60.79 per cent, of all cases; mortality, 17.18 per cent. (178 deaths).

Operated cases, 668 or 39.2 per cent, of all cases; mortality, 27.24 per cent. (182 deaths). Two facts may be recalled in connection with this paragraph. First, that before the use of antitoxin it was estimated that 90 per cent, of laryngeal diphtheria cases required operation, whereas, now, with the use of antitoxin, 39.2 per cent, require it. Second, that the percentage figures have been reversed, formerly 27 per cent, approximately representing the recoveries, whereas, now, under antitoxin treatment, 27 represents the mortality. To put it in other words, before the use of antitoxin, 27 per cent, recovered, now 73 per cent, recover, and this in the severest type of diphtheria.

The present report will strike many members of the society as revealing a mortality a little too large in each of the two classes. The mortality is large, larger than the personal experience in private practice of many would expect.

The reasons for this are: 1, that antitoxin is still used too late, either from procrastination on the part of the physician, or objection on the part of the friends, or 2, in a half-hearted way which shows itself in doses from one-tenth to one-fourth as large as they should be. In truth, both the physicians and the friends of the patient are timid.

This report it must be admitted, shows too large a mortality. In the opinion of the committee it is a larger mortality than will ever be shown again. Antitoxin is gradually being used earlier in the disease, and it will soon be used in sufficient doses.

To the society, the committee desire to say that they have sought to carry out their wishes in putting antitoxin on trial, to accept no testimony that did not bear the stamp of reliability, that they have employed the methods approved in the case of the first investigation and report, and that they have confined their work to definitely answering the main questions which the society and profession now have in mind. Points that were settled in the first report and have since been corroborated by general medical literature, are not again taken up.

If the committee are asked to put forth the three most valuable points established in this eleven months work, they are:

1. The mortality of laryngeal diphtheria at present rests at 21.12 per cent.
2. That 60 per cent, approximately have not required intubation.
3. That the mortality of operated cases is at present 27.24 per cent.

[Signed] W. P. Northrup, M.D., Joseph O'Dwyer, M.D., L. Emmett Holt, M.D., Samuel S. Adams, M.D., Committee.

The committee recommend: *Antitoxin* should be given at the earliest possible moment in all cases of suspected diphtheria.

Quality.—Of the products on the market some have, by test, been found to contain one-half to one-third the antitoxin units stated on the label. Select the most concentrated strength of an absolutely reliable preparation.

Dosage.—All cases of laryngeal diphtheria, the patient being two years of age or over, should receive as follows: First dose—2,000 units at the earliest possible moment. Second dose—2,000 units, twelve to eighteen hours after the first dose if there is no improvement in symptoms. Third dose—2,000 units, twenty-four hours after the second dose, if there is still no improvement in symptoms.

Patients under two years of age should receive 1,000 to 1,500 units, the doses to be repeated as above.

THE PUBLIC SERVICES.

Army Changes. Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from May 1 to 7, 1897.

First Lieut. George A. Skinner, Asst. Surgeon, will proceed to Ft. Spokane, Washington, and report for temporary duty during the absence of Capt. Edward R. Morris, Asst. Surgeon, on leave for six months, to take effect on or about May 18, 1897.

The following named officers are detailed to represent the Medical Department of the Army at the seventh annual meeting of the Association of Military Surgeons of the United States, to meet at Columbus, Ohio, May 25 to 27, 1897: Lieut.-Col. William E. Waters, Deputy Surgeon-General; Major Henry Lippincott, Surgeon; Capt. Robert J. Gibson, Asst. Surgeon.

RETIREMENT.

Col. Charles T. Alexander, Asst. Surgeon-General U. S. A., retirement from active service this date, May 8, 1897, by operation of law, is announced. By direction of the President.

Change of Address.

LECTURE.

NERVOUS DYSPEPSIA.

A clinical lecture delivered in Rush Medical College.

BY HENRY M. LYMAN, A.M., M.D.

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE.

Gentlemen:—You have recently had opportunities for witnessing the effects of inflammation of the mucous coat of the stomach in several patients who have exhibited, with varying degrees of severity, the symptoms of acute and chronic gastritis. This morning I wish to call your attention to a case that illustrates another form of gastric disturbance—nervo-muscular dyspepsia. It has been taught by the dominant school of pathologists that such disturbances of digestion are always due to catarrhal gastro-enteritis. But the opinion has long been held, and is gaining ground, that in certain cases the disorder of digestion is dependent upon alterations in the nervous system, and that inflammation takes little or no part in its causation. This is apparently true of the gastric crises of *tabes dorsalis*; though, in default of an autopsy, it is always possible to imagine the existence of a latent inflammation that is only prominent during a paroxysm of gastric disturbance. But, on the whole, it seems more likely that the relation in such, and in similar cases, is analogous to what is sometimes observed in the laryngeal cavity when its muscular apparatus is attacked by muscular rheumatism, producing hoarseness or complete aphonia without actual inflammation of the overlying mucous membrane until a day or two after the beginning of recovery from the muscular disorder. In like manner severe pain and disordered secretion may occur in the gastrointestinal canal without manifestation of the ordinary symptoms of inflammation until after the beginning of digestive disturbance.

Nervo-muscular dyspepsia may therefore be defined as a complex of symptoms, dependent chiefly upon a disordered condition of the nervous system. The history of the patient before you will amply illustrate this proposition. He is a thin and angular person, about 45 years of age, who from boyhood has been engaged in sedentary and intellectual pursuits. He was an unusually good scholar while a student in the public schools. He was subsequently employed as a general utility man in connection with a country newspaper, to which he occasionally contributed an effusion of his own. Then he studied law in a night-school, and tried to get practice in a large city, but broke down in the attempt. After this experience he was for a number of years employed as a copyist in a government office. He could never afford to take a wife, but admits occasional excursions on the street, and probably rather frequent masturbatory excesses. He, however, has thus far escaped syphilitic infection, and denies having had gonorrhoea. He is almost

totally abstinent from alcohol, but is an almost constant smoker, latterly using a pipe instead of cigars, which he can no longer afford to purchase. For three or four years he has been "down on his luck"—out of employment part of the time, and continually harassed by debt and its accompanying trials. Naturally gifted with good health, his elastic temperament has long preserved him from serious disease, but during the past year he has lost vigor, is depressed in spirits and suffers with frequent pain in the epigastric region. This pain, however, is not aggravated by taking food. On the contrary, it is for a time quite abolished after each meal, and recurs about three hours after eating, when the stomach is nearly or quite empty. A glass of milk and one or two crackers will then restore comfort again. Sometimes he is awakened in the night with similar sensations of distress, so that he has learned to carry a crust of bread to bed with him, for use before morning. On examination of the gastric juice, free hydrochloric acid is found to be present in more than the ordinary proportion. Other acids are insignificant in quantity, and cause no considerable difficulty. The gastric contents that are obtained with the aid of the syphon after a test meal are simply the remains of that meal alone, showing that the stomach is capable of emptying itself into the duodenum within four or five hours. Muscular atrophy of the stomach can be therefore excluded.

But here is another patient who, if subjected to this test, furnishes the debris of one or two previous repasts in addition to the substances derived from the test meal. He presents the usual symptoms of chronic catarrhal gastritis, and on rising in the morning splashing sounds can be heard in his stomach if he be vigorously shaken. Inflation of his stomach places its greater curvature a little below the umbilicus. His bowels are constipated, and he suffers frequently with intestinal flatulence. In his gastric juice there is deficiency, but not complete absence, of free hydrochloric acid. In short, without going farther into particulars, we may say that he is a victim of gastric dilatation not dependent upon malignant disease, but accompanied by frequent attacks of pain and gastrointestinal uneasiness, which are only less severe than the paroxysms of gastralgia that frequently occur as a consequence of chronic gastritis.

Between these types of neuro-muscular distress many shades of disorder may be discovered, but they can be all grouped into a few classes. An attempt has been made to form a classification based upon the chemic qualities of the gastric juice with reference to the relative quantity of hydrochloric acid that may be present. But the amount of acid thus present in the juice is quite variable, while the nervous phenomena are always predominant, and should be principally considered both in the diagnosis and in the treatment of nervous dyspepsia. The relative acidity and

catarrhal condition of the gastric contents are subordinate factors that must receive due consideration, but may not be made preëminent. It is, accordingly, advisable to regard nervous dyspepsia as comprising those digestive disturbances that are chiefly dependent upon disorder of the nervous system, and are characterized by symptoms of nervous derangement. Like all other nervous phenomena, therefore, there may be either exaltation, depressions or incoördination of function, giving rise to increase, or reduction, or perversion of sensation, muscular movement, circulation and secretion in the stomach. Indigestion may be, therefore, either painful or painless; it may be hurried beyond measure, or it may be retarded by atonic conditions of the muscular fibers in the gastro-intestinal wall; there may be excessive hyperemia and inordinate secretion in the mucous membrane, or the contrary condition may obtain; and finally, as a result of incoördination of nervous functions, the quality of the gastric juice, in the matter of digestive ferments and hydrochloric acid, may exhibit considerable variation from the normal standard.

Obviously, a chemic examination of the gastric juice is needful for the determination of these different qualities of the digestive fluids. Dyspepsias have been, therefore, subjected to a chemic classification based upon the relative quantities of hydrochloric acid that can be demonstrated by analysis. In certain cases the acid is present in excess (hyperchlorhydria), while in others it is deficient (hypochlorhydria), or entirely absent. But in a considerable number of instances clinical observation discovers evidence of disordered digestion without any notable deviation from the normal acidity of the gastric juice. So complicated is the web of symptoms that it is impossible to arrange all cases under a few simple species, like animals in a menagerie. Each patient exhibits individual symptomatic peculiarities, like the numerous varieties presented by certain plants whose species shade into each other after a fashion that renders exact classification almost impossible. But, for the sake of convenience, we may recognize three principal groups into which nervous dyspepsias may be divided—always, however, remembering their susceptibility to variation, and their consequent liability to pass from one group into another, or even to merge themselves among the host of inflammatory disorders in which nervous phenomena occupy a comparatively subordinate position. These three groups may be conveniently considered in succession.

SIMPLE NERVOUS DYSPEPSIA.

This form of digestive disorder is most frequently encountered among neuropathic subjects with rickety antecedents, or among members of the arthritic family. Retarded dentition, profuse sweating during sleep, local spasms, laryngismus stridulus, and intellectual precocity are of common occurrence in the early life of these patients. As the years advance, many of them become victims of eczema, dandruff, early whitening of the hair, premature baldness, bronchitis, asthma, palpitation and irregularity of the heart, neuralgia, gallstones, renal calculi, varicose veins, hemorrhoids, diabetes, polyuria, obesity, rheumatism and gout. Catarrhal conditions of the alimentary canal are often experienced, especially in the childhood and old age of such persons. Dyspepsia thus inaugurated frequently is associated with or replaces the phenomena of muscular and nervous rheumatism. It is easily

induced by fatigue of mind and body and is one of the most common causes of persistent neurasthenia.

The general health and appearance of the patient exhibit little alteration in this form of dyspepsia, unless the function of the small intestine be seriously hindered. There is frequent complaint of epigastric uneasiness after eating, and this is accompanied by a feeling of distension in the stomach, and by eructations of tasteless and odorless gas. Sometimes there is a sensation of impediment in the act of respiration "as if the breath would not go down to the bottom of the lungs." The head aches; the countenance is flushed; the bowels are constipated, and hemorrhoids often exist. Shortly after eating, considerable pain may be experienced; it is a dull, vague sensation of distress that is not definitely located, but is felt with varying severity throughout an ill-defined region beneath the diaphragm. Sometimes the patient experiences vertigo, or feels as if a band compressed the cranium above the eyebrows; occasionally the temporal arteries beat violently, and the corresponding veins are distended with blood. In certain cases it is impossible to lean forward without exciting severe pain in one or both sides of the head. There may be a feeling of weight or pressure in the occipital region, and it is not an uncommon event for the patient to hear a cracking sound in the back of the neck when the head is rotated upon the axis, especially on turning from side to side in bed. Usually there is great depression of spirits, and a tormenting fear of impending evil. The feelings exhibit great instability, passing rapidly from an extreme of vivacity to the profoundest depths of despair.

If the abdomen be examined an hour or two after a meal, considerable gaseous distension of the stomach and intestines will be discovered. Sometimes a succussion sound is audible in the stomach if the body be violently shaken. The differential diagnosis between simple distension of the stomach caused by nervous dyspepsia and permanent dilatation of the organ can be established by examination before breakfast, at which time succussion sounds can not be evoked in cases of temporary distension; whereas they can be always demonstrated when there is persistent dilatation of the stomach.

Palpation of the abdominal wall, in nervous dyspepsia, seldom indicates any extensive tenderness or special uneasiness under pressure. Frequently, however, a moderate degree of tenderness can be detected just below the tip of the ensiform cartilage, and in rheumatic subjects the upper portion of the recti muscles is often sensitive under manipulation.

Provided that intestinal digestion be not seriously hindered, the amount of free hydrochloric acid in the gastric juice may vary considerably without materially affecting the nutrition of the patient. Mere chemic examination of the gastric juice, therefore, affords little information regarding the totality of the digestive process. Of far greater importance is the condition of the nervous system. So long as actual dilatation of the stomach does not exist there will be no extraordinary delay in the passage of food into the intestine, there will be little if any fermentation, and no remarkable failure of health, even though the amount of free hydrochloric acid in the gastric juice should fall below the normal standard.

Such disturbances of digestion as are present are not confined to the stomach alone; they also involve the intestinal canal. In many instances there is some

distension of the colon; constipation and hemorrhoids afford evidence of intestinal and hepatic disorder. Occasionally the phenomena of pseudo-membranous enteritis make their appearance.

NERVOUS DYSPEPSIA WITH EXCESSIVE SECRETION OF HYDROCHLORIC ACID.

In certain cases of nervous dyspepsia accompanying neurasthenia the secretory nerves that should regulate the formation of gastric juice do not exert their normal coördinative influence, and there is an excessive production of hydrochloric acid. Sometimes the acid thus furnished is sufficient to be a veritable cause of inflammation. Such excessive secretion is not unusual during the paroxysms of vomiting that constitute the gastric crises of tabes dorsalis.

In typical cases of this variety of dyspepsia great pain, beginning two or three hours after a meal, is experienced in the epigastric region. Considerable relief may be procured by swallowing milk, or an aqueous solution of an alkaline salt. It is completely removed by the ordinary meals, which, virtually, are equivalent to the administration of a full dose of alkaline salts; but the cessation of pain is only temporary, and suffering is renewed as soon as the stomach is empty again. In this way sleep is often disturbed after midnight by a burning sensation, or by vague feelings of uneasiness in the epigastrium, sometimes radiating into the interscapular region. Vomiting may occur, and it is sometimes voluntarily excited by the patient, who has learned how much relief may be obtained through evacuation of the stomach. Similar relief is afforded by irrigation of the gastric cavity. In many cases, however, there is absence of nausea, but the acid contents of the stomach are eructated, causing an intensely burning sensation in the esophagus and fauces. Such patients are thirsty; they often have a craving appetite that impels them to its frequent gratification; and they instinctively prefer animal food, because it is digested more easily than vegetable food. Usually, there is considerable emaciation; the skin assumes an earthy hue; nervous exhaustion is indicated by irritability, fatigue, restlessness and inability to sleep. Many of the sufferers are despondent and hypochondriacal to the last degree.

Milder forms of the disease are less painful. There is merely a sensation of epigastric uneasiness beginning within several hours of eating and arrested by the following repast. These patients desire food at short intervals, and if the usual mealtime is passed without taking nourishment they experience a feeling of exhaustion with distress at the pit of the stomach, often accompanied by a throbbing headache and vertigo. They are generally nervous, irritable, neuralgic and predisposed to arthritic disorders. The bowels are constipated, though occasionally there is obstinate diarrhea—especially in the night or early in the morning—that does not yield to astringents and opiates. Sometimes tenderness on pressure is felt over the pyloric region, and percussion indicates distension of the stomach. Actual dilatation is not to be presumed unless a succussion sound can be obtained in the morning before food has been taken. Catheterization of the stomach yields a liquid that is strongly acid, ropy and of a yellowish color. By washing out the stomach at bedtime, and on the following morning removing the liquid contents of the organ before food has been taken, it is easy to deter-

mine the fact of hypersecretion and gastric dilatation if hydrochloric acid be present.

In a certain proportion of these cases the patient is tormented by repeated attacks of vomiting, which may continue for several days together. Such attacks are frequently induced by intellectual fatigue, and are an expression of nervous disorder accompanied by headache, pain in the stomach and nausea; all of which may be relieved by vomiting the excessively acid contents of the stomach or by their neutralization with an alkaline solution.

NERVOUS DYSPEPSIA WITH DIMINISHED SECRETION OF HYDROCHLORIC ACID.

In the third variety of nervous dyspepsia the symptoms do not materially differ from those which are experienced in the previous form; but the amount of hydrochloric acid, both free and combined, is considerably reduced, or may be temporarily absent. Fermentation consequently occurs in the contents of the stomach, liberating various organic acids and acrid substances. In such cases there is loss of appetite, pain in the epigastric region, distressing eructation and frequent vomiting. The stomach is distended with gas, and succussion sounds are distinctly audible; pain is felt soon after eating, but it is usually less severe than the suffering that is caused by an excess of hydrochloric acid. In many cases there is regurgitation of bile into the stomach, hindering gastric digestion and adding to the discomfort of the patient who loses flesh and acquires a cachectic hue suggestive of cancer of the stomach.

Evidently, these forms of dyspepsia can be differentiated only by the aid of chemical analysis. The mere presence or absence of free hydrochloric acid can be readily determined by the ordinary color tests; but for an accurate diagnosis a quantitative analysis is required. The prognosis depends upon the duration of the disease and its severity. Mild and recent cases occurring in young subjects, usually recover, but dilatation of the stomach, and excessive secretion of hydrochloric acid are unfavorable symptoms. In the severer forms there is reason to fear the passage from simple nervous excitement to actual inflammation, ulceration, or malignant disease.

The indications for treatment are three-fold: 1, to relieve pain; 2, to correct nervo-muscular disorder, and 3, to rectify the secretions.

1. Uneasy sensations occurring when the stomach is empty, or when it contains an excessive quantity of hydrochloric acid, may be temporarily relieved by the administration of milk, or water containing bicarbonate of sodium. But when there is intense gastralgia nothing less than hypodermic injections of morphia and atropin will give relief. Moderate pain may be suppressed by the use of Hoffmann's anodyne, cannabis indica, cocain, hyoscyamus, or a saturated aqueous solution of chloroform. This last remedy is the most prompt and efficient of all, except morphia. In every case of severe pain the stomach should be thoroughly evacuated by an hypodermic injection of one-tenth of a grain of apomorphia. A large poultice, into which have been stirred a drachm each of chloroform and tincture of opium, should be laid over the whole abdomen and lower half of the thorax. A cathartic should be administered as early as possible; it may consist of ten grains of calomel with five grains of bicarbonate of sodium, to be followed four hours later by an ounce of castor oil. Sometimes considerable relief

may be derived from copious draughts of hot water. Solid food should not be taken until the acute symptoms have yielded to treatment and rest.

2. Inefficient muscular contraction in the walls of the stomach and intestines demands the use of nux vomica, ipecac, massage, electricity, injections of hot water into the colon, and stimulant laxatives. Nux vomica is a better tonic than strychnin; it may be given in doses of five to ten drops of the tincture, a quarter of a grain of the extract, or half a grain of the powdered nut, after each meal. Ipecac stimulates the secretion of bile, and is especially useful when there is gastro-intestinal flatulence after eating; it should be given in doses of one-tenth of a grain, associated with nux vomica, piperin, ginger, and other aromatic stimulants, as in the well-known pill of Fothergill, which may be thus modified:

R. Pulv. ipecac. gr. 1-10
 Ext. nuc. vom. gr. ¼
 Pulv. piper. nig.
 Ext. gentian āā gr. i
 Fiat pil. No. 1. Sig. One such pill after each meal.

Aloin in appropriate quantity may be added when there is constipation; and an occasional dose of blue mass and colocynth is often useful.

3. For the chemic rectification of the secretions, when there is excessive production of hydrochloric acid, the patient must abstain from alcoholic beverages and highly seasoned food. Mastication must be slowly and thoroughly performed. Starchy and saccharine substances should not be eaten; milk, eggs, peptonized meat powders, minced meat, tender steak, and other nitrogenous articles of diet should constitute the bulk of the food. When the excess of acid is present during the period of digestion alone, causing pain as the stomach becomes empty, sodium bicarbonate may be given in doses of five to twenty grains about three hours after each meal. If the bowels be constipated an equal quantity of Husband's magnesia may be added to each dose. When the stomach is continually charged with hydrochloric acid it will be necessary to increase the dose of sodium bicarbonate to four or six drachms a day. Vichy water, lime water, lithia water, and Murray's fluid magnesia may also be used as antacids. When there is evident dilatation of the stomach with stagnation of its contents, the syphon should be employed, in order to remove the irritating liquids. In default of such apparatus, the older physicians gave emetics of lobelia with good results.

When, without dilatation of the stomach or stagnation of its contents, there is a deficiency of hydrochloric acid in the gastric juice, ten or fifteen drops of the dilute acid may be given in a teacup of hot water after each meal. An equally good result follows the similar use of the other mineral acids; hence the extensive popularity of Horsford's Acid Phosphate, and kindred acid preparations. But it must be noted that acids and pepsin and other digestives so often administered are not curative of dyspepsia. They are merely palliative, and give only partial and temporary relief. The disease can be overcome only by the removal of its cause, whatever that may be. In the vast majority of cases it is an exhausted state of the nervous system that underlies the disorder, and the patient must reform his whole course of life before he can be cured.

Dilatation of the stomach, and an excessive acidity due to fermentation and the production of the organic

acids in its contents require daily irrigation of the stomach, and the administration of salol, salicylic acid or beta-naphthol, before meals. In mild cases much benefit is derived from the long continued administration of small doses of the alkaline salts. Potassium citrate or acetate or carbonate, with sodium bicarbonate, associated with a bitter tonic like nux vomica, compound tincture of gentian, or the elixir of calisaya bark, electricity, massage and hydrotherapy are indispensable in this class of cases. Change of occupation, change of habits, the attainment of prosperity, long vacations, mountain climbing, sea-voyaging, and cool baths are far more effectual than the most elaborate medication.

ORIGINAL ARTICLES.

PRIMARY PAPILLOMA AND PRIMARY CARCINOMA OF THE FALLOPIAN TUBE.

Read at the Meeting of the Chicago Pathological Society, April 12, 1897.

BY EMIL RIES, M.D.

PROFESSOR OF GYNECOLOGY, POST-GRADUATE MEDICAL SCHOOL, CHICAGO.

The two cases which I present here were operated on by Dr. T. J. Watkins, who kindly offered them to me for pathologic examination. They are of great clinical as well as pathologic interest, one case indeed being unique in its kind. Only six cases of primary papilloma of the tube are contained in the literature, the present being the seventh case. Of primary carcinoma of the tube the tables of Doran¹ and of Saenger² contain nineteen cases, the present being the twentieth.

I. Primary papilloma of the tube. Secondary papilloma of both ovaries. Repeated vaginal drainage for purulent salpingitis, at last salpingo-oöphorectomy by laparotomy. Recovery. Good health fifteen months after the operation.

Clinical history.—Patient, 34 years old, gives a history of inflammatory disease of the pelvic organs after a miscarriage in her twenty-ninth year, from which she recovered perfectly. In her thirtieth year she suffered some violent injury to her left inguinal region. This was followed by "inflammation of the ovary," which remained painful until operation. The diagnosis was pyosalpinx and in June, 1894, the swelling in the pelvis was opened through the vagina. The tumor evacuated a quantity of pus. In November, 1894, the tumor had to be opened again and patient wore a drainage tube for eight months. In August, 1895, third operation. Patient wore the drainage tube for two months after she left the hospital. At last in January, 1896, laparotomy was performed and the appendages were removed. The patient recovered uneventfully. She was seen a few days ago by Dr. Watkins and was found to be in perfect health. She does not menstruate and has no leucorrhœa. The uterus is atrophied and freely movable.

Macroscopic description of specimens.—Left side: Ovary not enlarged (35 x 26 x 20 mm.). Its surface is covered in several places by wart-like excrescences, which in some places sit on the ovary with a broad base, while in others they are distinctly pedunculated. The tube is normal externally with the exception of a slight thickening of its isthmus part. The fimbriated end is open. Cross sections through the tube show nothing abnormal. The ovary contains on sec-

tions small cysts, most of which have smooth walls, while some contain small papillary growths. (Fig. 1.)

Right side: Ovary not enlarged (40 x 25 x 30 mm.). The portion of the tube removed is 6 cm. long; the fimbriae are not visible; the abdominal end is dilated, while the uterine end is of normal size. A part of the surface of the ovary is covered with wart-like excrescences, a few of which are also found on the surface of the tube. An opening in the ovary, which was probably made in the course of the treatment, leads into a small cavity the size of a hazel-nut, which is invested with an abscess-membrane and contains some pus. This cavity also contains numerous papillomatous growths. The dilated tube, which contains a small quantity of hemorrhagic fluid, communicates with the cavity in the ovary through a narrow opening, toward which the folds of the tube converge and which represents the abdominal orifice of the tube. The cavity of the tube is studded with papillomatous growths, which extend throughout the external half of the tube. (Fig. 2.)

Both ovaries and tubes are covered with many adhesion-membranes, but there are no papillomas in or on these membranes.

Microscopic structure.—The microscopic structure of the papillomas is alike in ovaries and tube. One layer of long slender columnar epithelium covers the connective-tissue framework of the papillæ, which

FIG. 1.—Papilloma of left ovary (Case 1). Piece of ovary removed to show cysts in ovary.

arise from the mucous membrane and branch out into more and more delicate ramifications. The papillæ of both ovaries and tubes contain numerous small gritty bodies with concentric striation, calcareous concretions, which are almost normal in all sorts of papillomatous growths.

The wall of the tube with papillomas is thin and shows a few small areas of round-cell infiltration. Toward the mucous membrane there are a few cyst-like epithelial formations, which are even found outside the circular muscular layer. These cysts, however, do not contain papillomatous masses nor solid epithelial growths. They are lined by one single layer of low columnar epithelium. The cysts are round or roundish, sometimes with slight constrictions. I have not been able to discover an endothelial lining around them, but will not lay much stress on this fact, as the state of preservation of the specimen was very bad when I examined it.

The uterine end of each tube contains adenomyomatous structures. These are more pronounced and extensive on the side of the papillomatous tube than in the healthy tube. The papilloma has not affected the adenomyoma, the epithelium of which is more or less columnar with well-pronounced cilia, while the epithelium of the papilloma presents no cilia. There is no communication to be found between the adenomyomatous tubules and the tubal cavity.

The little cysts of the left ovary which do not contain papillomas are lined with a simple low cuboidal epithelium and look like simple hydropic follicles. No corpus luteum cysts are found. The little cysts which contain papilloma prove to be of a different structure. They are invested with a columnar epithelium, which is in direct continuity with the epithelium of the papillomas filling the cysts. In several places the communication of the cysts with the surface can be observed consisting in a narrow cleft lined with the same epithelium as the papilloma itself. It appears unlikely that the growth started in the substance of the ovary. I believe rather that it penetrated from the surface as the development of the neoplasm on the surface is much more extensive and much more pronounced.

Review.—We are now confronted with the question whether the tumor originated in the tube or in the ovary. The same question arose in one of the six cases of papilloma of the tube contained in the literature. This case was observed by Doran,¹ who des-

FIG. 2.—Papilloma of right tube and ovary (Case 1). Tube and ovary cut open. 1, papilloma on surface of ovary; 2, papilloma in cavity of tube; 3, papilloma on surface of tube; 4, ovary; 5, abscess cavity in ovary; 6, abscess-membrane; 7, uterine end.

ignates it as a case of papilloma of the tube. Where ovary and tube present papilloma the primary seat of the tumor must be assumed to be in the tube if the ovary has as in our case remained small in size, as our experience leads us to believe that ovarian papillomas belong among the most rapidly growing tumors of the ovary. This reason makes it at least likely that the papilloma in our case originated in the tube and spread on to the ovaries. This event was facilitated by the therapeutic efforts which gave the papilloma of the tubal cavity the opportunity of reaching the surface of the pelvic organs. The absence of ascites in this case also tends to exclude the ovaries as primary seat of the tumor, as ovarian papilloma is almost invariably accompanied by ascites.

The history of inflammatory symptoms is usual in cases of papilloma, so that Doran,¹ and Saenger and Barth² attribute direct etiologic importance to the inflammation. The papilloma of the tube was observed in five out of the six cases published and was so

in our case. Four of the reported cases survived the removal of the tumor and are reported well three, four, four and sixteen years after the operations. To this I can add the present case, which Dr. Watkins saw a few days ago in perfect health, that is to say, fifteen months after the operation.

II. Primary carcinoma of both Fallopian tubes. Adenomyoma of both Fallopian tubes. Myofibroma of the body of the uterus. Numerous metastases of the carcinoma. Abdominal salpingo-oöphorohysterectomy. Speedy recurrence and death.

Clinical history.—Patient, 45 years old, has always enjoyed good health; had one child twenty-three years ago; no miscarriages. She came to the hospi-

88 mm. long in all, the removed part of the cervix 12 mm. long. Wall of the fundus 10 mm. thick. Middle of anterior wall 26 mm. thick. Posterior wall contains a fibroid with well marked capsule. Posterior wall 88 mm. thick, 16 mm. being the thickness of the uterine muscular tissue, the rest fibroid.

The fibroid (F. Fig. 3) is submucous covered by a very thin layer of mucous membrane. The latter is thin throughout the cavity with the exception of one flat elevation (E. Fig. 3) on the left anterior side of the cavity. The fibroid presents the usual arrangement of bundles and resembles in shape a ball compressed in the longitudinal diameter of the uterus. The uterine cavity (C C Fig. 3) is narrow, cleft-like;

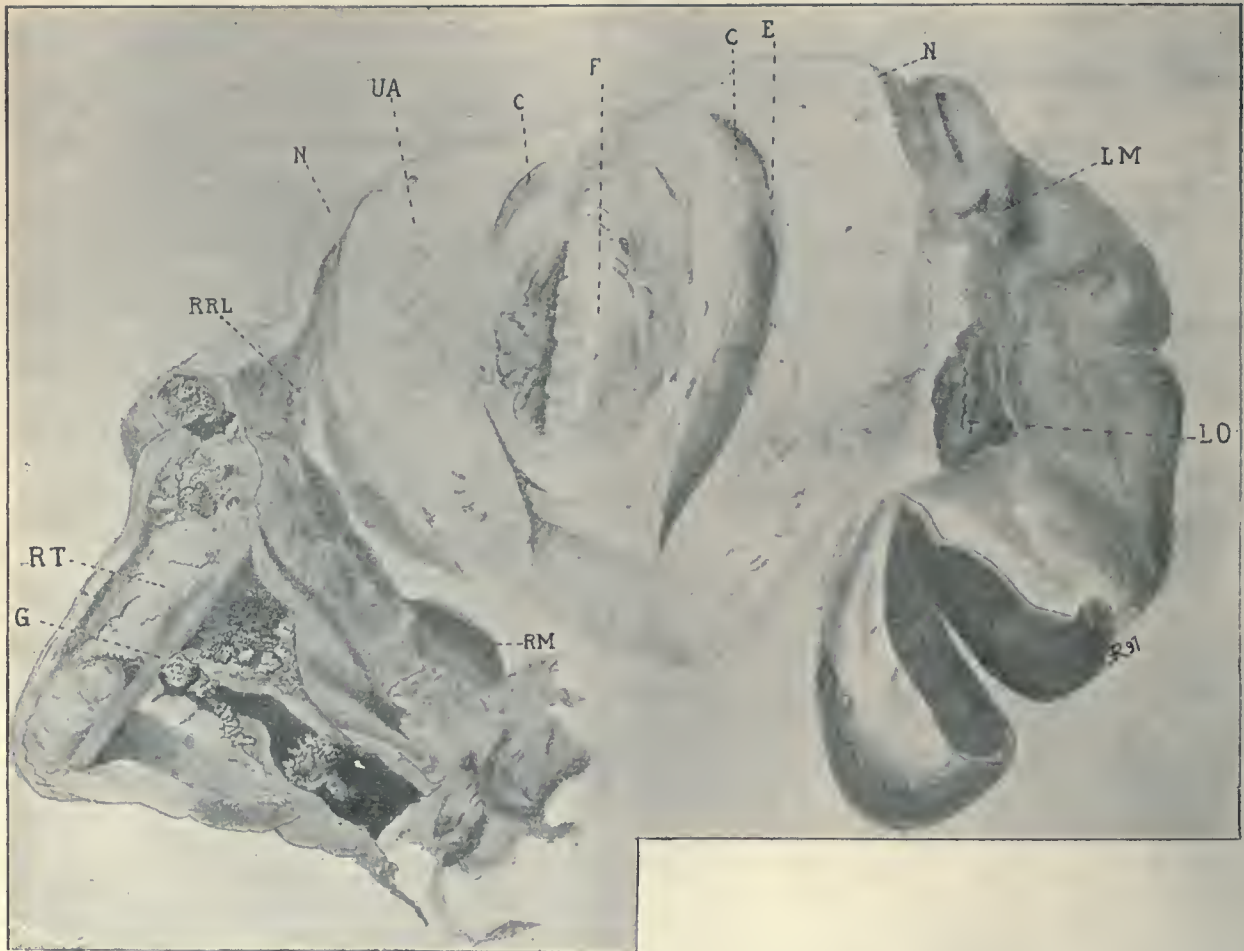

FIG. 3.—Specimen of double papillo-carcinoma of the tubes (Case 2). Anterior view. Uterus cut open through anterior wall. Right tube held open by glass rod, G. tal on account of difficult urination and pain in the pelvis. These symptoms had begun about ten days before patient entered the hospital. The operation was performed on Sept. 1, 1896. Uterus, tubes and ovaries were removed; the operation was made difficult by numerous and strong adhesions. Patient recovered and was discharged on October 6. She returned to the hospital on Dec. 13, 1896, with a large tumor extending from Douglas' pouch to the umbilicus. An effort to remove this proved the tumor to consist of a soft mass resembling granulation tissue, which could not be entirely removed. Discharged from the hospital Jan. 3, 1897, died a few weeks later.

Microscopic description.—(See Fig. 3.) Uterus

measured over the fibroid it is 84 mm. long. Right and left broad ligaments are easily recognizable. Each uterine horn is formed by a nodule (N. Fig. 3), which has 15 mm. antero-posterior diameter on the left and 17 mm. diameter on the right side. An incision into the right nodule shows three small cavities filled with colloïd masses. Nothing similar on left side. On the left half of the fundus are two subserous nodules the size of lentils, slightly lobated; a larger one (17 x 10 x 5 mm.) is found on the posterior surface which presents numerous and firm masses of adhesions. A nodule of the same size as the last mentioned is situated on the fundus close behind the nodule of the left uterine horn.

The length of the right tube measured along its upper border is 260 mm., its largest circumference 180 mm. Just outside the nodule on the uterine horn the tube becomes narrower, then it swells considerably and presents four large convolutions. The anterior side of the tube is with the exception of some adhesion-membranes smooth; the posterior side presents on the lateral four-fifths of its length more or less bulky papillomatous growths. The abdominal end of the tube, which has the large circumference mentioned above, is sharply bent to below and behind so that it touches the isthmus part. The ovary (40 x 30 x 15 mm.) is located between the abdominal and uterine portion of the tube. There is almost no trace of an ovarian ligament, the ovary being almost contiguous with the uterus. The ovary presents a few adhesion-membranes, but no papillomatous masses. On a cross section several corpora lutea and follicles are seen. The cavity of the tube (RT. Fig. 3) con-

FIG. 4.—Microscopic section of L M, Fig. 3 (Case 2). PC, primary carcinoma of tubal mucosa, the wall of the tube with C circular and L longitudinal muscular layers, and BV blood vessels. S, serous coat of tube with SC solid carcinomatous masses in it.

tains flat and prominent papillomatous masses, which fill the narrow isthmus part completely while they cause only a thickening of the wall of the abdominal end. The tube is so tortuous that on cross sections of the isthmus part the cavity appears double. The wall of the abdominal end is one to three mm. thick, the wall of the isthmus part is double this size. Near the broad ligament the tubal wall of the isthmus portion forms a white mass 5 mm. thick and is covered outside by a stratum of papillomatous masses about 4 mm. thick. Several thick masses of adhesions connect the abdominal portion of the tube with a tumor mass (40 x 40 x 5 mm.) (RM. Fig. 3). On cross section this mass consists of a white substance which contains a central cavity. The cavity presents several wart-like excrescences.

The left tube, measured along its external border, is 315 mm. long, the largest circumference (165 mm.) being at the abdominal end. Distinct furrows divide the tube outwardly into four convolutions. Near the first furrow, counting from the uterus, the anterior surface of the tube presents a tortuous elevation (L M, Fig. 3) about 30 mm. long and one to two mm. thick, a cross section of which contains a white mass. The anterior and posterior surfaces of the tube are covered with pseudo-membranes. The ovary of this side (LO. Fig. 3) has an ovarian ligament 22 mm. long. The ovary (54x20x18 mm.) contains numerous corpora candidantia and follicles. Cross sections through the nodule on the isthmus part present a thick wall and a cleft-like cavity. Further on the wall of the tube is a pretty homogeneous white mass. It is stained brownish near the cavity. The cavity itself is filled with a blood clot which reaches from the isthmus to the abdominal end. If the blood clot is lifted away from the wall low papillomatous masses are seen everywhere. The wall of the abdominal portion is two mm. thick, near the uterus the wall is five to seven mm. thick.

FIG. 5.—Microscopic appearance of nodule N of left side, Fig 3 (Case 2). Section of uterine horn of left side showing tubal cavity T, with its circular muscular layer, the adenomyoma AM, with its muscular tissue, and the carcinomatous masses PC, with papillae and cyst-like formations.

The abdominal ends of both tubes are closed. The right tube contained sero-purulent fluid which escaped during the operation, as the tube burst.

Microscopic description; right tube.—The wall of the tube does not show any remarkable changes, with the exception of some round-cell infiltration along capillary vessels. The mucous membrane presents a multitude of smaller and larger papillary elevations. The elevations consist in the largest part of epithelial masses, while the connective tissue skeleton of the papillae is scarce, and frequently so crowded with round cells that very few connective tissue cells are visible. The epithelial masses form labyrinthian coils winding in and out, often so close together that no connective tissue whatever remains between them.

The epithelium is arranged in single or multiple layers, mostly in the latter. The individual cells are columnar epithelial cells, some very long and thin, some shorter, almost cuboidal. The larger papillæ contain blood vessels. Small hemorrhagic areas occur in many of the papillæ. The surface is covered with many detached and degenerated cells and cell detritus.

The arrangement of the epithelial cells is not always distinctly papillary. In many places sections contain apparently glandular or cystic formations which, however, are only produced by the knife cutting away recesses between papillæ. The epithelium does not grow downward into the wall of this tube.

The peritoneal coat of this tube shows no pathologic changes in the macroscopically normal portion of the serosa.

Left tube.—The mucous membrane of the narrower part presents the same appearance as the right tube, the papillary growths and the inextricable coils of epithelial formations existing here in the same manner as on the right side. The cavity contains considerable detritus consisting of white blood corpuscles, detached and degenerated epithelial cells and more or less distinct red blood corpuscles. The epithelium does not penetrate the mucous membrane in this part of the tube. The muscular coat contains a few areas of round-cell infiltration of no large extent. In the place mentioned in the macroscopic description where the tortuous elevation resembling a dilated vessel is seen on the tube, the peritoneal surface presents a very striking appearance (see Fig. 4). Between the external muscular layer and the surface there is an accumulation of solid epithelial masses divided by smaller or larger strings of connective tissue which form a network, the meshes of which are filled by the tumor cells. The tumor cells are many-shaped, mostly roundish with large nuclei (some presenting unmistakable karyokinetic figures), others are very large cells with one large nucleus, while still others are real giant cells. The epithelial cells form rounded masses, or appear as rosary-shaped strings with more or less pronounced constrictions. The large epithelial masses are in some places arranged in strings along and around capillaries which have preserved their endothelium. The latter is seen as a single line of flattened cells dividing the blood corpuscles from the tumor cells. In other places the endothelial lining has disappeared, so that the blood space, as it is to be called then, is limited by the tumor cells themselves. Smaller epithelial masses, sometimes containing one or several vacuoles, do not contain blood vessels. They are separated from the surrounding connective tissue by a line of flat endothelial cells; in other places this endothelium is rather cuboidal or even gives rise to small epithelioid buds. Taking all this together, I conclude that these tumor masses are located in lymph spaces, especially those sheathing blood vessels. The importance of this observation with regard to the dissemination of carcinoma by the lymph and blood currents is evident.

A section of this left tube, comprising the insertion of the isthmus part on the broad ligament, shows the papillo-carcinomatous condition of the tube very much like the right tube; hemorrhages, however, being more numerous and covering larger areas than in the other tube. The explanation of these hemorrhages may be found in an obstruction of the venous current, indicated in the sections by the many vessels choked with red blood corpuscles. The peritoneal surface shows

some solid carcinomatous nodules resembling those described above, but on a smaller scale. The parovarian tubules in the broad ligament are very distinct. They are without any pathologic change. The wall of this part of the tube contains carcinomatous nests in several places. These nests show the path which the carcinoma has followed from the mucosa to the serous coat. The nests are either solid or they have still preserved the papillomatous or coiled arrangement peculiar to the primary growth of the mucosa. Some of these nests are distinctly located in lymph vessels, as is demonstrated by the layer of endothelial cells which is still visible in some places, while in other places there is no such lining of the carcinomatous nests, which are imbedded in the tissue itself.

The nodular enlargements of the isthmus part of the right and left tubes present an extremely interesting combination of neoplasms (see Fig. 5), which is described here for the first time, and has not been mentioned in any other case of carcinoma of the tube. The enlargement of the tube here is not caused by a dilatation of the tubal cavity but by a thickening of the tubal wall. This thickened portion contains a normal tubal cavity, a slit of stellated or more or less straight shape with the cuboidal or low columnar epithelium normally found in this part of the tube. Around the mucous membrane there is the normal circular muscular layer. Between the latter and the serous surface the cause of the thickening is found. The wall of the tube contains: First, the elements of an adenomyoma, and secondly, papillo-carcinomatous masses. The adenomyoma presents the usual appearance as first described by von Recklinghausen.⁴ There are epithelial tubes, straight or curved or ramified, surrounded by more or less cytogenic tissue and a well-pronounced muscular coat. I need not further dwell on this adenomyoma as I have discussed it fully in a paper on "Nodular Forms of Tubal Disease."⁵ I must add that in each of these nodules a process of the mucous membrane of the tube was seen penetrating the circular muscular coat of the tube so that here as well as in the cases described in my paper mentioned above, it was hard to decide whether the epithelium of the adenomyoma had originated in Mueller's or in Wolff's duct. Beside this adenomyoma the thickened wall contained beautiful papillo-carcinomatous growths, which in some places were simply papillomatous while in others they were more or less solid nests. In several instances the little cavities which contained the neoplasm were partly lined with a single layer of low columnar epithelium while the rest was lined with multiple epithelial layers or was the seat of papillary growths. This leads me to the conclusion that some at least of the carcinomatous nests developed in cavities primarily belonging to the adenomyoma, supplanting or as it has been called, "infecting," the original epithelium. Under the serous coat there are numerous solid carcinomatous nests filling lymphatics. Some of these nests are so large that they form carcinomatous nodules visible with the naked eye. The small cavities mentioned in the macroscopic description are partly simple cysts of adenomyoma partly filled with papillomatous masses.

Uterus.—On the left side I followed up the extension of the neoplasm into the body of the uterus and found that solid and papillomatous masses were spread a short distance into the muscular coat of the uterus, but did not penetrate deeply into it. Along the

serous coat, however, the neoplasm had spread extensively, so that small subserous fibroids of the posterior wall and fundus of the uterus as well as the adhesion membranes on the uterus everywhere contained carcinomatous masses. The fact that the progress of the malignant neoplasm largely took place along the subserous lymphatics is also proven by the observations made on the body of the uterus, the round ligament, the myoma contained in the uterus and on the endometrium. The endometrium presented nothing but a very slight glandular hyperplasia. The muscular coat of the uterus (with the exception of the external layers mentioned above) and the myoma contained absolutely no epithelial formations. The myoma or rather myofibroma had a well-pronounced capsule and had none of the characteristics of an adenomyoma. The round ligament showed small carcinomatous nodules in and under its serous coat, but its substance was free from epithelial elements.

The carcinomatous infection of the adhesion-membranes around the uterus and its ligaments has produced quite bulky tumors, especially on the right side of the broad ligament where the tumor which is mentioned in the macroscopic description (RM. Fig. 3) and which has almost attained the size of an ovary, is a pure carcinomatous growth. The formation of adhesions with the *ovaries* has also given rise

FIG. 6.—Microscopic section of ovary (Case 2). E, germinative epithelium of ovary interrupted where carcinomatous masses C adhere to the surface of the ovary. The substance of the ovary, O, is normal.

to the growth of metastatic carcinoma on the ovaries (Fig. 6). The substance of the ovaries is without a trace of carcinoma, but the surface of the ovaries is studded with carcinomatous nodules. Their metastatic nature is proven by the fact that in many instances the carcinomatous nodule and the ovarian substance are separated by a well-preserved line of germinative epithelium which is interrupted at the places where the adhesion membrane has grown to the ovary. The carcinoma is arranged in the same way as in the subserous nodules on the surface of the tubes and uterus, that is to say, in solid strings of cells following the lymphatics. Where we see a tumor originating in the germinative epithelium of the ovary the structure of the tumor is entirely different, the epithelial neoplasm developing on the surface primarily and essentially in marked contrast to the condition prevailing in this case.

To recapitulate briefly, we have a primary papillo-carcinomatous tumor of both tubes with metastatic growths in the uterus and in the serous coats of the surrounding organs.

Conclusions.—It seems to me that there can be no doubt as to the tumor's origin in the tubes. The only

other organ which produces such tumors and would have to be considered is the ovary, the origin in the uterus being excluded by the observation of the neither considerable nor malignant changes in the endometrium. The tumors can not have originated in the ovaries, as according to the histologic description given above the substance of the ovaries is unchanged and the nodules on the surface of the ovaries are of a purely metastatic character.

The origin of the tumors in the tubes is therefore indisputable. The description given above tallies perfectly with the descriptions of the nineteen cases contained in the literature. One observation, however, which marks this as a unique case is worthy of some further discussion, namely, the observation of two neoplasms in each tube: adenomyoma and papillo-carcinoma. Is it possible that the carcinoma originated in the epithelium of the adenomyoma and grew secondarily on the tubal mucous membrane? Or was the adenomyoma the secondary seat of the neoplasm which had originated in the tubal mucous membrane? It is interesting that thickening of the isthmic part of the tubes is mentioned in several cases of tubal carcinoma which perhaps on closer examination might reveal the presence of adenomyomas. It is furthermore noteworthy that von Recklinghausen⁴ describes cases where uterine adenomyoma coexisted with malignant adenoma of the uterus. Von Recklinghausen arrived at the conclusion that the presence of adenomyoma in the cancerous uterus was accidental and that the adenomyoma was attacked secondarily by the malignant neoplasm. I believe that we must arrive at the same conclusion with regard to the coexistence of the adenomyoma and the papillo-carcinoma of the tube. The adenomyomas of the tubes are decidedly frequent tumors even though they escaped discovery until very recently. I have in the course of the last year met with six cases of adenomyoma of the tube and the more tubes I examine carefully the more frequently I find those neoplasms. If the present case is the only case of adenomyoma in a carcinomatous tube the proportion would be one in twenty, a proportion which according my experience is much smaller than the proportion of adenomyomas in tubes generally. This latter proportion appears to be nearer the rate of one in five or ten.

There is another reason which causes me to regard the seat of the malignant tumor in the adenomyoma as secondary. The papilloma has left many of the adenomatous tubules intact and it is not likely that a malignant neoplasm which has spread over both tubes and a large peritoneal surface should have shunned reverently the rest of a small nodule from part of which it had originated. This is the more unlikely as communications of these adenomatous tubules exist which would have offered a ready path to the progress of the neoplasm before it ever spread into the cavity of the tube. On the other hand the small slit-like communication between the cavity of the tube and the adenomatous tubules gave the carcinomatous infection, if I may use this term, ready access to the tubules. The progress of the bearer of the carcinomatous infection must have been facilitated by the fact that the occlusion of the abdominal end of the tube and the narrowness of the uterine end of the tubal cavity produced considerable pressure of the contents of the tube.

We arrive therefore at the ultimate conclusion that the carcinoma originated in the epithelium of the

tubal mucosa. If now we compare the papillomatous formations in the tubes with those described above in the case of simple papilloma of the tube we can not fail to recognize the very great similarity between the two. It has been generally assumed that a benignant papilloma of the tube can undergo malignant degeneration and on the other hand that papillo-carcinoma of the tube frequently springs from a non-malignant papilloma. This appears to be quite likely, in fact the tumors are so much alike that a differential diagnosis has been found a matter of great difficulty. We encounter the same doubts here as in the cases of papilloma of the ovary, where clinical experience has led some authors to consider every papilloma malignant, at least to suspect it of malignancy. In our case of papillo-carcinoma the pathologic examination revealing the numerous solid metastases and the clinical history recording recurrence of the disease and death of the patient agree very well. But in our case of "benignant papilloma" I am by no means sure that I may not have overlooked some true carcinomatous nest or that the operator has not failed to remove the neoplasm completely so that in spite of our present diagnosis and the patient's apparent good health there is just the shadow of the possibility of a recurrence.

There is, however, a clinical aspect of this question which is well worth consideration. If there is papilloma of the tube it is impossible without microscopic examination to differentiate between a benignant and a malignant neoplasm. If we have a malignant neoplasm of the tubes the probability of metastatic growths in the organs connected with the tubes is very great. Therefore these organs must be removed with the tubes. To recognize this it is absolutely necessary to cut the tubes open while the operation is proceeding and not to throw them aside for an examination to be made after the abdomen is closed or, as occurs too frequently, never to be made. The advice to open every tube removed was first given by Saenger² and I think it is very good advice.

I wish to add a little advice of my own which is suggested by a careful investigation of the post-mortem reports of cases of papillo-carcinoma of the tubes which had succumbed to recurrence of the disease. Metastases were found in these cases not only in the uterus but in the retroperitoneal glands. It is perfectly feasible to remove these glands as I first proposed⁶ and recently demonstrated in an operation for cancer of the cervix uteri which I performed at the Post-Graduate Hospital in the presence of my class and which the patient has stood very well. (She was discharged cured two weeks after the operation.) These glands as well as the uterus should be removed in every case of papilloma of the tubes. The danger of recurrence can thereby be avoided in a higher degree than by the mere removal of the tubes. Let us look for instance at our case of carcinoma of the tubes. If the uterus had not contained a fibroid it would have appeared unnecessary to many operators to remove it. The consequence of leaving it would have been that all carcinomatous masses contained in the uterus as described above would have remained in the patient. It is true that the recurrence was not avoided by the removal of the uterus. But we do not always meet with such far-gone cases as this and in the cases of limited extent of the neoplasm we have to remember the old rule concerning operations for carcinoma, to remove the tissues to as large an extent

around the apparent limits of the neoplasm as possible.

It remains to consider the relations of our case of papillo-carcinoma of the tubes to the other cases recorded of which Doran¹ enumerates nineteen, our case bringing the number up to twenty.

The age of the patients varies between 36 and 60, most of the patients (among them the case presented here) were about 45 years old. The patients were either sterile or had given birth to one child many years (twenty-three years in our case) before the tubal disease was noticed. According to Saenger² and Doran¹ the disease was on one side only in twelve cases, on both in the rest of the cases among which ours is to be rubricated. In twelve cases the tubes alone were the seat of the disease. Chronic inflammatory conditions with pus accumulation are very frequently observed.

The prognosis of the operation according to the most recent reports as given by Doran¹ is expressed in the following numbers: Death occurred shortly after operation in three cases, death from recurrence in five cases (10 months, 10 months, 18 months, 5 months, 1 year after operation). Alive with recurrence were three cases, without recurrence, five cases (7 years, 7 months, 19 months, 1 year, 3 months after operation).

The diagnosis has never been made correctly before the operation, but after once the attention of the profession has been directed to this possibility it will probably not take long before the clinical side is so well worked out that we are enabled to make a clinical diagnosis. I refrain from further discussion of the clinical side of this question as I have only made a pathologic examination of the cases reported here.

THE MANAGEMENT OF LABOR BY EXTERNAL EXAMINATION.

Read at the Meeting of the Obstetric Staff of the Chicago Health Department, Jan. 16, 1897.

By KARL F. M. SANDBERG, A.M., M.D.

Professor of Gynecology Jenner Medical College; Obstetrician, Cook County Hospital; Gynecologist National Temperance Hospital and Norweglan Hospital; Member of the Obstetric Staff of Health Department.

CHICAGO, ILL.

The greatest danger that threatens an obstetric case is septic infection. In comparison with this one other dangers fall into insignificance. The main channel of entrance for the septic material is the vaginal canal. It may attack any laceration or abrasion in any part of this, or simply pass through it into the uterus.

The most common carriers of infection in obstetric cases are foreign bodies introduced into the vaginal canal, such as douche points, fingers or hands, instruments, lubricants, etc. Air and auto-infection are generally admitted to be rare, and the principal factors of contact infection are those mentioned.

The principal aim of the Obstetric Staff of the Health Department should be to avoid puerperal infection in the practice of its members and to aid and assist the midwives, and perhaps other practitioners, in the avoidance of the same. While the anti-

septic and aseptic eras have witnessed a most gratifying decrease of the mortality from puerperal infection in the lying-in institutions, no such decrease, in fact no very perceptible difference has been noticeable in the home cases. How to enable also these to share the full benefits of asepticism, and how to still further decrease the mortality in the institutions, is at present the main questions claiming the attention of the obstetricians in all countries, and should especially interest any obstetrician associated with a department whose function is to combat all avoidable diseases. From what has been said before, it would seem that this can most easily as well as most surely be accomplished by avoiding introduction of any foreign body into the parturient canal. The next question would then be, how far can we avoid this?

The different kinds of obstetric instruments have their certain well-defined fields, and their uses do not concern this paper, which only deals with normal or apparently normal cases. In such cases vaginal douches can be dispensed with. This is proved by a series of experiments made at the Koenigliche Frauenklinik in Dresden under supervision of Professor Leopold. I quote from his report: In 1885, 1886 and 1887 a vaginal douche of weak sublimate solution (1-4000) was given to every patient before and after internal examination, as well as after finished labor. At that time, as the midwives in the Kingdom of Saxony, according to the royal instructions, were not permitted to use vaginal douches in their public practice, it was decided to dispense with vagina douches in normal labor cases. But now suddenly bacteriologic researches discovered the most different pathogenic microbes in the vaginal secretions of the pregnant, and strong advices were given, not only to continue the douches in all cases, but also to try and remove the suspicious secretions by gentle washing. From May 1, 1888, the method adopted was, therefore, to douche and wash gently the vagina of every labor case with a solution of bichlorid of mercury of 1 to 4000. Of 1,136 cases treated by this method 80 per cent. had no temperature over 38 degrees C. (100.4 F.), but 20 per cent. had fever. In 1887, with only ordinary douches, there were 82.8 per cent. of cases with no temperature over 38 degrees C.—almost 3 per cent. more. The result showed at least no improvement. "Is it surprising," Leopold remarks, "that after the unnecessary removal of the vaginal mucus, perineal and vaginal tears, small hemorrhages, numerous sutures and febrile puerperia gathered together." From April 25, 1889, to the middle of March, 1890, 1,123 deliveries were made in normal labors without any douche or washing of the vagina, otherwise with the ordinary precautions. Of these 90.29 per cent. were without fever; temperature never over 38 degrees C. This seems convincing evidence; and in addition to this, the latest bacteriologic investigations inform us that the normal vaginal secretions are free from pathogenic microbes.

The next question then is, Can we dispense with vaginal examinations? Before arguing the question, I shall briefly report the results of some other series of experiments made by Professor Leopold. From Jan. 1, 1892, to June 30, 1894, 1,768 labor cases out of a total number of 4,035 patients, were not examined internally. This number does not, however, comprise the number of labors that might have been managed without internal examination, as a great number were examined internally to give students and midwife

pupils instruction. To find the number we must from the total number of cases deduct, in the first place, all those that already were delivered before entering the hospital, or that entered the same with deep standing or already visible fetal head, or in which delivery followed so rapidly that an accurate external examination was impossible; also all cases of abortion and miscarriage before the eighth month. Then all cases requiring operative interference must be excluded, and by operative interference is meant introduction of instruments, colpeurynter or hand to facilitate the course of labor. Then must be deducted all cases in which there was any indication for internal examination, and as such is considered any irregularity in the normal course of labor, for instance, irregular labor pains, premature discharge of the amniotic fluid, etc., or graver diseases as eclampsia, heart disease, etc.

In the last series of 1,693 cases, June 30, 1893, to June 30, 1894, the total number of cases coming under these classifications was 489, leaving 1,204 cases in which internal examinations could have been dispensed with. This would make 71.11 per cent. of the total number, 76.20 per cent. of the number, leaving out the two first classes (those already delivered and the cases of abortion and miscarriage) and 90.25 per cent. if we also leave out the cases calling for operative interference. The percentage could be still further increased by excluding a certain number of pathologic cases, cases suffering from general or local diseases. Of this number 436 cases were examined internally with no other object than instruction of the students and midwife pupils.

The results as to mortality and morbidity in these series are unfortunately not stated. As to the value of the external examination to ascertain the presentation and position of the fetus, the following figures will give some idea: In the first series of 1,000 cases diagnostic mistakes were made 65 times (6.5 per cent.). There are 971 cases of occiput presentations with 54 mistakes, 6 cases of forehead presentation with 2 mistakes, 12 breech presentation with 2 mistakes, 6 face presentations with 6 mistakes and 4 twin pregnancies with 1 mistake. In the second series all 1,580 cases were externally examined and the diagnosis made, even in those cases where later an internal examination was made. The number of mistakes was here reduced to 28 (1.77 per cent.) as follows; 25 cases of forehead presentation with 3 mistakes, 80 cases of breech presentation with 8 mistakes, 14 cases of face presentation with 8 mistakes, 13 cases of twin pregnancies with 4 mistakes and 5 mistakes in cases offering special difficulties. These figures would seem to prove that the principal objection to the limitations of internal examination, viz., that the external examination often gives too uncertain results to replace the internal one, is unjustified.

Another objection is, that the exact diagnosis and prognosis of the labor would be impossible, as the condition of the pelvis and the soft parts would not be known, and that presentation or prolapse of extremities or the cord could not be recognized. To this objection can be answered, that obstructions to labor caused by pathologic conditions of the soft parts or of the bony pelvis not recognizable by external measurements, and in which there have not been symptoms to raise even a suspicion of their existence, would be very rare. In cases where the presentation or prolapse of extremities cause a misproportion between the pre-

senting head and the pelvis, the difficulty can be recognized externally by the persistent high standing of the head. And prolapse of the cord is undoubtedly, in very many cases, caused just by the internal examination, the head being pushed up or the membranes ruptured. The progress of labor can probably, with some practice, be judged almost as well by external as by internal examination. The many advantages of avoiding internal examinations are too well recognized to require more than a passing mentioning.

Let us at last consider how the examination should be made, and by what signs we ascertain the presentation and position of the child as well as the progress of labor. Having decided that external examination, as much as possible, shall take the place of the internal, it is our duty to perfect the first one as much as possible, and by constant practice make ourselves as accomplished as possible. Inspection, mensuration, percussion and auscultation, and the results to be obtained from them, are too well known to be gone into here, and it is only necessary to impress the necessity of making use of them in all cases.

Palpation is the part of the examination that gives us the most important information and that enables us to follow the progress of labor, and Professor Leopold has divided this into four steps. The examiner is seated at the side of the patient, facing the same. Patient is in horizontal position and must be examined between the pains. Abdomen is uncovered.

1. Both hands are placed transversely on the abdomen, with the tips of the fingers of one hand touching those of the other. They are then moved lightly over the abdomen to the fundus and the position of the same in relation to the umbilicus and epigastrium ascertained. One can easily ascertain: 1, the period of gestation; 2, size of the child; 3, the position of the child, longitudinal, oblique or transverse; 4, the presentation of the child, head or breech in fundus.

2. The hands are moved from the epigastrium, one to each side of the abdomen, and placed flat on the sides of the uterus. Under the one the extremities are usually felt, under the other a long smooth surface, the back of the child. One of the hands can also be placed on the abdomen in the median line and a light pressure be made, whereby the amniotic fluid will be pressed to one side and the back of the child to the other, nearer the abdominal wall, where it can be palpated more easily.

3. Either hand may be used, and the fingers should be spread as much as possible. The thumb and the second finger grasp the presenting part of the child over the pelvic inlet. In case this is hard and round, it can only be the head. If it is much softer and uneven it is likely to be the breech. In case the presenting part can only be made out indistinctly, and it seems softer than usual or covered, one would think of a low insertion of the placenta. In case no presenting part can be felt over the pelvic inlet, the examiner should look for the head (or breech) at the sides of the abdomen.

4. The following procedure is used when the presenting part already is in the middle, or at the outlet, of the pelvis. In this the back is turned toward the patient's face. Starting above the inguinal region both hands, with the insides turned toward the uterus, are slowly and gently pressed down along the pelvic walls. If the presenting part is deeply located, one hand may be used at a time. By deep-seated head one can plainly feel that a hard round part of the child occu-

pies the space of the pelvis, and the chin may be felt by the right hand in O. L. A. and by the left hand in O. D. A. position. The prominent and rounded forehead in the one side can be distinguished from the flatter neck in the opposite side. Or one can feel that the hard prominence of the occiput gradually loses its hardness, as the hand is moved upward, but that still a distinct resistance remains (the neck). The frontal prominence is in the first place located higher up, and in the second place an abrupt depression is felt above the same; no resistance is felt any more (over the face). The face slants, as the chin rests on the chest obliquely, inward and can not be felt. Above the forehead the extremities may be felt. This examination should always be performed systematically, and one should always know what place on the presenting part the fingers are touching, and how its position is changed in the course of labor.

As to the possibility of teaching students and midwives the external examination, Leopold states it as his experience that physicians generally after two to three weeks make quite certain diagnoses externally, and that midwives, even the less gifted ones, after three months only exceptionally make mistakes; not oftener, or perhaps not as often, as by internal examination. The external examination, being much more harmless, can be made much oftener than the internal one, and gives the students more opportunity to learn. And how is it about the certainty of the internal examination made by midwives, and also by many physicians? Is it not, as Hegar says, often done only for a show, and nothing is ascertained?

When one can feel on the one side the forehead, on the other side and somewhat lower the occiput, the head is clearly in the ordinary position with the occiput presenting. In a vertex presentation (*Vorderhauptlage*), forehead and occiput stand in the same plane, the occiput sometimes even higher. The more the chin is removed from the chest, the greater the changes from what is usually found; this is most pronounced in face presentations. In these an unusually large hard part, the occiput, can be felt on the one side, but on the other side one can press deeper into the pelvis, without encountering any prominence resembling the forehead. If one only thinks of the possibility of a face presentation the diagnosis is not difficult. The other results of the examination are also characteristic. The back can generally be felt only very indistinctly and far back. On account of the extreme extension of the head the back is strongly lordotic and turns during the course of labor more and more backward. The extremities can be felt so much the plainer, apparently directly under the abdominal wall, and the fetal heart tones can also here be heard the plainest.

Of other abnormal presentations, the one of the posterior parietal bone can easily be recognized externally. The head is felt surprisingly close under the abdominal walls; it presents as a prominent hard ball over the symphysis pubis, in appearance resembling the distended bladder. Above this comes a depression, caused by the flexion of the neck. The anterior wall of the womb is not, as usual, convex, but shows generally a visible concavity. Lateral deviations of the head toward one iliac region can also be recognized externally.

It can furthermore be ascertained by external examination in what pelvic plane the head is. The head that is free over the pelvic inlet is easily recognized,

but it is still advisable always in such cases by the fourth step to ascertain if the pelvis really is empty, and that it is not the shoulders one has felt, while the head is deep in the pelvis.

If we have a case of occiput presentation with the head in the pelvic inlet, and only a small segment has entered the same, the occiput can by the third step be felt equally as well as the forehead, and stands above the pubic bone. In this position the head may still be somewhat movable. This can be ascertained if one using the third step makes a pressure with the thumb or second finger, and with the other fingers feel if the head yields to the pressure. If the head is right in the pelvic inlet, the forehead only can be felt by the third step as ordinarily made. To reach the occiput we must palpate lower down in the pelvis. This position of the head is usually found in primiparæ already during the last three or four weeks, providing the pelvis is normal, and is also generally the position found in labor cases at the time we are called in. On further progress the head gradually disappears for the third step. But on changing the position of the hand somewhat by directing the fingers more downward in the pelvis, the prominence of the forehead can still be felt. The head is now deep in the inlet very near the middle of the pelvis. When the head can not be felt any more by the third step, but still is palpable with the fourth one, it stands exactly in the middle of the pelvis. One can reach the forehead on the one side, but not the occiput on the other; here the neck only can be felt, and this can easily be distinguished from the occiput and still easier from the forehead, by its lesser degree of hardness and its perfectly flat form. Finally, when the head can not be reached either by the third or the fourth step, it is below the middle of the pelvis. Here the external examination has its limitation, but it is also no longer necessary, having fulfilled its mission. The head can now be felt by pressing on the perineum externally, or is already visible on separation of the labia, and the perineum generally bulges out during the pains.

The rotation of the head can be followed externally in the same way as the descent; the marking point is the forehead and one must notice the position of this from the beginning. The farther the head descends in normal occiput presentation, the more posteriorly must the examination be made to feel the forehead, and the more anteriorly the occiput is to be looked for. External examination of any other head presentation are made in a similar manner.

In cases of narrow pelvis the diagnosis can almost in all cases be made by the external examination and this is especially valuable for midwives. Suspicion is always aroused, if in the case of a primipara in the last weeks of pregnancy the head is found free over the pelvic inlet or when in a case of a multipara the head does not descend in spite of strong pains. If the quantity of amniotic fluid is great, it may also with a normal pelvis take a long time before the head engages. If in cases of narrow pelvis the membranes are ruptured prematurely the head will apparently engage, but the high position of the forehead and the occiput will signify that it is not engaged *in* but only *on* the pelvic inlet. As to the form of the narrow pelvis, exaggerated flexion of the head and deep location of the occiput are characteristic in cases of generally contracted pelvis, while in cases, in which the forehead and the occiput stand in about the same plane the pelvis is a flat one.

If we (with Michaelis) call all pelvises with a conjugata externa under 18.5 cm., narrow, providing the weight of the child is at least 3000 grams, we have in the first series of 1,000 cases managed by external examination 163 cases of narrow pelvises. In 45 of these the child weighed 3500 grams and there were pelvises with a conjugata vera as short as 9 $\frac{3}{4}$ cm. In cases of generally contracted pelvis one is liable to be deceived as well by the external as by the internal examination. On account of the pressure from all sides the head is stretched to such a length that it may happen, that the most prominent part of the head, generally the caput succedaneum, may be visible during the pains, while the forehead still can be felt from above. By external palpation it is difficult to realize how far the occiput may have advanced and by internal examination it is equally difficult to realize how high the forehead still may be standing when the occiput is right at the outlet.

Pawlik has drawn attention to the possibility of palpating the furrow of the neck and the chin, and Veit has suggested to palpate the presenting part through the incisuræ ischiadicæ majores, when it already is deep in the pelvis.

The fontanelles can only in exceptional cases be felt. The superior orbital margin can frequently be felt; also the angle between the frontal and the temporal bone and these points serve to distinguish between the occiput and the forehead. The temporo-frontal angle can plainly be felt, for example in the O.D.A. position, and the third step of the examination by placing the third phalanx of the second finger of the right hand on the frontal surface, the second and first phalanges on the temporal surface, or in the fourth step of the examination by spreading the fingers so the index rests on the temporal bone, the three other fingers on the frontal.

Breech presentations can generally be easily told from head presentation. If the breech should already be engaged and the crista ilii be mistaken for the forehead, one will fail to find the characteristic signs of the forehead and also the furrow of the neck; the most audible point of the heart tones is higher and the head can generally be palpated in the fundus. In case it should be difficult to feel this on account of overlying placenta or lack of amniotic fluid it may be necessary to press the fingers in from one side or the other, even under the right lobe of the liver. When the breech descends deeper, it can be palpated from the perineum.

In closing this paper I desire to impress upon this organization, in our official capacity, of the necessity of emphasizing as much as possible the great importance of the external examination and the desirability of limiting the internal examination.

DISCUSSION.

Dr. A. H. BURE said that he relied on the vaginal touch to determine the progress of labor. That dangers of sepsis were exaggerated, that there were many other causes of puerperal fever beside the doctor, *e.g.*, old roller bandage tampon, infected before labor, pus tubes, etc. There is little danger if asepsis is practiced.

Dr. SIEMENOVICZ said the midwives are filthy and will not obey instructions; they will treat four or five sepsis cases a week and care for labor cases at the same time. He detailed some amusing experiences.

Dr. NILES said he approved of external examinations but that we can not do without internal exploration. We can sterilize the hands but can not be sure of the vulva and surroundings.

Dr. EFA V. DAVIS approved of making external examinations popular, but needs internal examinations, which are without danger, since we can sterilize the hands. Different methods of

doing this, vary in efficiency. Dr. Davis had 150 cases, including operative cases, without fever.

Dr. C. S. BACON suggested that a temperature of 100 degrees might be due to infection.

Dr. J. M. SLOANE emphasized external examination, but said he could not tell the progress of labor by it.

Dr. WYLLIS said it was rare to see a doctor boil his syringe. He seldom gives douches, believing they do more harm than good. He never has trouble if the hands, the vulva, the towels, etc., are clean.

Dr. J. B. DELEE said the external examination should always precede the internal, and if the heart tones are good, and the position determined, the internal is not needed, unless to see if one is safe in leaving the case. On an average two examinations should suffice for a normal case.

Dr. C. S. BACON said that internal examinations are in the line of an operation, and are needed to tell the size of the cervix and pathologic conditions.

Dr. SANDBERG in closing the discussion said the principal idea in the paper was in relation to the midwives. One should set them a good example, and recommend the external method of diagnosis.

THE SOURCE OF SUGAR IN DIABETES MELLITUS WITH A THEORY AS TO ITS EXCRETION UNCHANGED IN THE URINE.

BY EDWARD L. MUNSON, M.A., M.D.

ASSISTANT SURGEON U. S. A., FORT ASSINIBOINE, MONTANA.

The proteid molecule is not to be considered as a perfect chemic body, but is to be looked on as a complex, composite mixture, that is, composed of several organic radicals. To quote from the elaborate article of Krukenberg ("Separat-Abdruck" a. d. Sitzungsberichte d. Jenaisch. Gesellschaft f. Med. u. Naturwissensch. 1885): "The molecule of albumin is to be considered as a composite of different chemic atom groups. Many of these atom groups can be lacking or split off in crystalline form without the reactions of the remaining body being affected." He believes that albumin contains groups which yield leucin, tyrosin, indol, etc., together with others which give the biuret or xanthroproteid reactions or the coagulation tests. He also found a group which had the power of reducing copper oxid on heating in alkaline solution, thus demonstrating the presence of the carbohydrate group. There is also a fatty group.

It was shown by Pavy in 1894 ("Physiology of the Carbohydrates," p. 27) that proteid matter generally, whether derived from the animal or vegetable kingdom, was in constitution a glucosid. In one experiment he took purified egg albumin and treated the same with a solution of potash. By the action of the potash he obtained an amylose carbohydrate corresponding to Landwehr's "animal gum," which on treatment with sulphuric acid yielded a body which gave the characteristic reactions of sugar. It was found, further, that sugar is yielded by the direct action of sulphuric acid on egg albumin and that the same occurs as a result of pepsin digestion. It was subsequently shown by Ling ("Epicriticism," 1895) that the osazone derived from the cleavage product

was a sugar osazone. These results reached by Pavy had also been arrived at by Schuetzenberger (*Bull. de la Soc. Chimique de Paris*, Vol. xxiii, p. 161, 1875), who found that the action of strong sulphuric acid on egg albumin caused the appearance of a non-nitrogenous body which reduced Fehling's solution energetically, was precipitated by ammoniated acetate of lead solution and appeared to be glucose or an analogous body. He also found that on exposing egg albumin to baryta water at 100 for a period of 120 hours he obtained a non-nitrogenous body, insoluble in alcohol, precipitable by ammoniated acetate of lead, not reducing Fehling's solution but transformable on boiling with sulphuric acid into a body which did. Its elementary composition was found to agree very closely with dextrin, with which, as Schuetzenberger remarks, it presents the greatest analogy. That proteid can be produced from carbohydrates alone has been shown by Pasteur who found that yeast cells multiplied freely in a medium composed of sugar, ammonium nitrate, the ash of yeast and water. In this experiment the only source of the carbon of the proteid is found in the sugar. According to Pavy (*London Lancet*, Oct. 17, 1896) carbohydrate matter incorporated in the proteid molecule during its construction can again be split off from it by chemic or ferment action and in the tissues this is probably the source of the free carbohydrates found to a certain extent in various parts of the body. There could be no doubt that in the grave form of diabetes the sugar eliminated is largely derived from the tissue albumin.

An albumin, then, is a mixture of proteid, carbohydrate and fat radicals and it is believed that the carbohydrate group enters directly into its production rather than that it is formed within it. It is believed that upon the decomposition of the proteid molecule two primary divisions will be obtained, the nitrogenous and the non-nitrogenous. How large the proportion of the non-nitrogenous part really is can be seen by comparing the proportions of carbon and nitrogen in a proteid with urea, its chief decomposition product. The following table is taken from Foster ("Textbook of Physiology").

	C.	H.	O.	N.	S.
Urea . . .	20.00	6.66	26.67	46.67	—
Proteid . .	53.00	7.30	23.04	15.53	1.13

It is readily seen that the proteid contains far more carbon than is necessary to unite with the nitrogen present to form urea. The non-nitrogenous group probably splits up in the formation of glucose and the fatty acids. According to Cohnheim ("Vorlesungen über allgemeine Pathologie") there are two kinds of oxidation which go on in the healthy organism. One is the decomposition of albuminoid bodies, resulting in the sugar, fats, fatty acids and nitrogenous decomposition products. In this oxidation it is probable that a certain amount of heat is evolved. The second kind of oxidation is that by which the sugars, both ingested and that produced from albumin, are oxidized to their end-products of CO₂ and H₂O in the production of heat and energy. It is believed by the writer that in health these two processes run parallel and vary directly with each other. In diabetes, on the contrary, this equilibrium is lost, the decomposition of albumin is increased while the capacity of the system to burn the sugar produced in this albumin decomposition is greatly diminished.

The writer has come to the conclusion, as the only possible explanation of certain of the phenomena in

diabetes, that the sugar so produced from proteids through cell activity is an isomer of ordinary glucose, distinguished from this by being less readily oxidized in the system and, by not being readily dehydrated by the liver cells into glycogen. It is well known that many bodies created by cell activity differ in various respects from the same substances which may have been chemically prepared. As an instance, beta hydroxybutyric acid, so frequently present in the saccharine urine of diabetes, is optically inactive when manufactured synthetically although the same substance, when a product of systemic metabolism, shows a left rotation by the polariscope. Many facts favor the above theory.

1. An increase, in moderation, of carbohydrate food leads to an accumulation of glycogen in the liver but does not affect the quantity of blood sugar.

2. An increase in the decomposition of proteids does not materially affect the quantity of liver glycogen but does cause an increase in the blood sugar. Bödeker (Landois' "Physiologia," p. 458) was able to produce an artificial glycosuria in healthy men by giving a diet composed exclusively of meat and chondrin.

3. The blood sugar remains constant in hunger, the sugar then coming almost wholly from the systemic albumin with possibly a small portion derived from the liver. Prolonged nitrogenous diet greatly decreases the amount of the liver glycogen. Whatever glycogen is found in such cases is believed to be manufactured by the liver cells themselves, since it has been demonstrated that they have the power of directly producing a small amount of glycogen.

4. Large amounts of carbohydrates taken in a short time may temporarily increase the proportion of blood sugar simply because the liver is capable of dehydrating into glycogen a definite amount of glucose in a fixed time.

It has been shown in a previous article that the diabetic suffers from an especial predisposition toward albumin decomposition and tissue waste, and that this abnormal metabolism must consequently result in an increase of the nitrogenous and non-nitrogenous decomposition products. In diabetes, however, these products do not bear the same relationship to each other that they do in health. It has already been advanced that the non-nitrogenous part of the proteid molecule yields sugar and fat, the latter more especially during health, when there is a limited oxidation going on, since it is well-known that a limited supply of oxygen furnishes a most favorable condition for the production of fat from proteids. Adipocere, for instance, is produced under these conditions. In diabetes, however, an entirely different state of affairs exists. In this disease an excessive oxidation and metabolism is going on which is extremely unfavorable for the production of fats but in which the greater part of the carbon radical in the proteid molecule is converted into a sugar which is thought by the writer to be an isomeric form of that obtained from a vegetable source. This existing tendency toward metabolism is increased if all carbohydrate sources of sugar are cut off, since such a dietetic condition imposes the necessity on the system of creating from proteids such sugar as is essential for the well being of the economy. Such a process must necessarily increase the severity of the disease in mild cases, and, sooner or later, in true diabetes as distinguished from simple glycosuria, this excessive metabolism results in the production of more isomeric sugar than the

system is able to completely oxidize. Since the sugar derived from an albuminoid source does not appear to be readily dehydrated into glycogen and stored up in the liver the excess of such sugar is excreted unburned in the urine.

Although it has already been shown that in diabetes there is an increase of the first kind of oxidation resulting in an excessive decomposition of albumin, an entirely different condition prevails in the second class, by which sugar is burned in the production of heat and energy. This power of oxidizing sugar is so much impaired that the isomeric sugar, produced in an albumin decomposition, being less readily oxidized or converted into glycogen than is sugar derived from a carbohydrate source, is excreted unchanged if a free-ingestion of carbohydrates be allowed and thus a sufficient supply of a readily assimilable sugar is at hand to meet the needs of the system. If carbohydrates are taken in moderation no sugar derived from them appears in the urine, the sugar excreted being only the less easily burned isomer.

It is well known that mannite, inosite and levulose are entirely oxidized in the diabetic organism. Experiments made by Voit (*Zeitschrift für Biologie*, Vol. xxviii. Sec. 3) show that milk sugar also is very much more readily burned in the diabetic organism than is dextrose. As the conversion of lactose into dextrose in the diabetic organism is impossible, as no trace of milk sugar can be found in the urine and since the excretion of dextrose under the ingestion of lactose is very much increased, he believes that the more readily oxidized milk sugar takes the place of a certain quantity of glucose which would otherwise have been burned in the organism but which, under these conditions, is excreted unchanged. His work also shows that sugar derived from albumin is not readily dehydrated into glycogen. He takes a diabetic who excretes sugar even on a proteid diet, examines his urine for grape sugar, finds the amount and on the following day, under exactly the same conditions, gives 100 gm. of milk sugar.

	Sugar in urine.	After fermentation.
Exp. 1, 1st day, Proteid diet	17.461 gm.	none
2d day, 100 gm. lactose	66.818 gm.	none
Exp. 2, 1st day, Proteid diet	57.633 gm.	none
2d day, 150 gm. lactose	165.715 gm.	trace

Both lactose and glucose respond to Fehling's test but the former is not affected by fermentative action. In the last experiment the glucose excreted after the administration of 150 gm. of lactose minus the previous excretion on a known proteid diet, represents the total amount of sugar produced from albumin which the patient had been able to oxidize. Beyond this point, then, there would be no relation between the excretion of glucose and the ingestion of lactose.

Furthermore, if a diabetic be placed upon a proteid diet until the excretion of sugar has entirely ceased, the ingestion of sugar bears no relation to its excretion as may be seen by the following tables of Külz (*Marburg Elwert*, S. S. 222, 1874). The patient was excreting no sugar on a mixed diet. One hundred gm. of dextrose was given in solution every twenty-four hours.

	24 hours urine, c. c.	Sugar excretion, gm.
1	1273	0.946
2	1527	2.994
3	2144	1.526
4	1622	1.950
5	1653	1.710
6	1353	3.996

	24 hours urine, c. c.	Sugar excretion, gm.
7	1278	3.510
8	1344	5.898
9	968	4.536
10	1226	4.914
11	1299	5.220
12	1454	3.319

The same investigator reports (*loc. cit.*) a series of experiments made upon a diabetic excreting an average of 47 gm. of sugar upon an exclusive proteid diet. The patient received 100 gm. of glucose in the twenty-four hours.

	24 hours urine, c. c.	Sugar excretion, gm.
1	2496	79.8
2	2763	90.0
3	2444	71.6
4	1905	85.1

From the above results the usual daily excretion of 47 gm. must be subtracted, thus showing an actual increase of only about 33 gm. But how is it possible that a patient apparently manufacturing more sugar than he can burn will excrete only a slightly increased amount when ingesting large quantities of carbohydrates? It must be explained like the conclusions of Voit with regard to milk sugar. The diabetic organism does not oxidize all sugars with equal facility and sugar produced from carbohydrates is more readily oxidized or stored up in the liver than is sugar derived from an albumin source.

If now the quantity of sugar be estimated which a diabetic on starvation is able to excrete, and then known amounts of albumin be given, it is found that the amount of the sugar excreted in the urine varies directly with the quantity of albumin ingested. This point has also been demonstrated by K ulz (*Arch. f. Exp. Path. u. Pharm.*, vi. 140) in the following experiments. The food used was casein, free from fat and sugar.

	Amount casein, gm.	24 hours urine, c. c.	24 hours sugar exc., gm.
Exp. 1 . . .	200	4180	79
	240	4100	70.1
	300	4950	87.1
	500	6420	137.1
Exp. 2 . . .	200	4460	66
	240	6140	65.7
	300	6620	96.7
	500	7210	126.9
	240	5250	86.6

The above tables show that sugar is produced from ingested proteid, that the production of such sugar varies directly with the amount of proteid ingested, that the sugar so produced from proteid is burned to some extent in the diabetic organism, it may be in mild cases to the extent of its production if no carbohydrates are given but that, if carbohydrates are allowed, such sugar is excreted unburned. These tables also show that a diabetic is able to utilize sugar given by the mouth gram for gram, but that the sugar produced by the diabetic from ingested proteid is largely eliminated as an excrementitious body. They also show that while sugar produced from proteid is burned with reluctance by the diabetic organism the liver is apparently wholly unable to convert it into, and store it up as, glycogen, with the result that what can not be utilized in any given time is excreted unburned.

Ordinary glucose and diabetic sugar have the same chemic formula and the same gross characteristics, but this does not prove them identical in all their qualities. There are at present at least three isomers of ordinary glucose, differing from each other in being dextro-rotatory, levo-rotatory and optically inactive. A new sac-

charin body has also been lately discovered by Low (*Berichte d. deutsch. chem. Gesellsch.*, xxii, S. 471), which has the properties of dextrose and levulose and is intermediate between them. From the above facts it is evident that the occurrence of an isomeric form of ordinary glucose in diabetic sugar is more than probable and apparently furnishes the only key to the unsolved problem of the oxidation of sugar in diabetes. The writer hopes to continue work on this subject with the idea of definitely settling this question. To sum up:

1. Sugar appears in the urine in health after inordinate ingestion of carbohydrates simply because the capacity of the liver cells to convert a definite amount of sugar into glycogen, in a given time, is exceeded.

2. Sugar appears in the urine in diabetes because the system produces more sugar by the decomposition of albumin than it can completely oxidize, this sugar not being stored up by the liver as glycogen and being less readily oxidized by the diabetic organism than sugar produced from carbohydrates.

3. It disappears from the urine, if mild cases of diabetes are placed upon a proteid diet, because a withdrawal of all carbohydrates from the diet forces the system to burn the isomeric albumin-sugar in the maintenance of the necessary heat and energy.

4. It subsequently appears in the urine under such treatment because, with the progress of the affection, sugar is produced in quantities too large to be completely oxidized and the diabetic does not appear able to store up this sugar as glycogen.

5. The excretion of sugar by a diabetic, upon a proteid diet, may rise to a certain point upon the ingestion of carbohydrates, since the more readily utilized carbohydrate sugar saves the isomeric albumin-sugar from oxidation and the latter is excreted as a waste product.

It will be observed from the above that it is the belief of the writer that ordinary sugar, ingested in moderation, no more appears in the urine in diabetes than it does in health and that the excreted sugar is wholly a product of proteid decomposition.

ANTIPATHY TO BINOCULAR SINGLE VISION; AND THE LINE SEPARATING THE RETINA INTO ITS TWO HALVES.

BY G. C. SAVAGE, M.D.
NASHVILLE, TENN.

That there are cases of strabismus in which it is impossible to establish binocular single vision, most oculists who have had a few years of practical experience will attest. Graefe saw a few of these cases and, on at least two occasions, wrote about them, always confessing that he could do nothing for them. In studying these cases he reached the conclusion that the cause was either faulty projection depending on injured nerve centers, or on the impossibility of obtaining associated action of muscles when these had been long unaccustomed to association. In his cases the visual power of each eye was quite good, for the strabismus had been of the alternating type. By operations and by prisms he could make the images approach but he could never cause them to fuse. "The images would pass from side to side, above and below, or one behind the other, always on the point of uniting, but never united."

Stevens has seen and studied these cases. Having

been more fortunate than Graefe, in that he has occasionally succeeded in establishing binocular single vision, he offers, as an explanation, unequal tension of corresponding ocular muscles, under the influence of corresponding nerve-impulses directed to them. He teaches that this unequal tension may be in the lateral muscles as the result of wrong operations in attempting to correct the squint; but he specially emphasizes the idea of unequal tension of the vertically acting muscles as a cause of the antipathy. In some of his cases he has brought about equality of tension by operative means, and binocular single vision has resulted. In other cases he has failed. To the mind of the writer this shows that there are two classes of cases, the one curable, the other incurable. Unequal tension may cause double vision when the head is erect and the eyes attempt to look straight ahead; but in these cases prisms ought always to fuse the images, as does a posing of the head, or moving the object in a definite direction.

In a typical case of antipathy to binocular single vision, fusion can not be had either by posing the head, by moving the object up, down, in or out, or by means of prisms; and fusion by operative means would, consequently, be impossible. We have had two such cases. In each there was good acuteness of vision in both eyes; and there had always been alternating squint. Others had operated on these cases and had failed. Ignorant of what we now believe to be the true cause, we, too, operated and—failed. In each case we added to the confusion by bringing the images close together—we could not fuse them. Our study of the last case was earnest and, for some time, most confusing. By prisms we could make the images “kiss” and then they would recede or change sides; again as the false image approached the true it would rise above or go below the true and thus get on the other side. They would not fuse.

We believe the true cause of a typical case of antipathy to binocular single vision to be: The macula in one eye is connected with the right side of the brain, while the macula in the other eye is connected with the left side of the brain.

We are taught in the books that the temporal half of the right retina and the nasal half of the left retina are connected by optic nerve fibers with the cuneus in the right occipital lobe; and that the temporal half of the left retina and the nasal half of the right retina are connected, in the same manner, with the cuneus in the left occipital lobe. That the line of separation does not always divide the retina into two equal parts has been clearly shown by intra-cranial disease. Nettleship has reported a case in which disease of one side of the brain caused total blindness in the temporal half of one retina and in the nasal half of the other, the line separating the blind and seeing parts of each retina being vertical and passing through the macula. We have had two cases in which meningitis destroyed the right optic tract. The line separating the blind from the seeing part of each retina was not vertical, but passed to the right of the macula, in one case missing it 10 degrees and in the other about 5 degrees. In each eye both of these cases had perfect central vision, peripheral vision being normal in the right field, but limited, as indicated above, in the left field. We have had one other case in which, after a puerperal convulsion, there was central and left-field total blindness, the right field being normal except that it failed to reach the vertical plane of each

eye by about 5 degrees. In this case the line separating the blind from the seeing part of each retina was not quite vertical, and passed about 5 degrees to the left of the macula. Here are four cases: In one the lines of separation passed through the macula; in another, 10 degrees to the right of the macula; in another about 5 degrees to the right of the macula; and in the fourth about 5 degrees to the left of the macula. If these lines can vary in the same direction in the two eyes, may they not vary in opposite directions? and would not such a condition account for some cases of squint in which there is incurable antipathy to binocular single vision?

Nettleship does not so state, but it is reasonable to suppose that his case was ambidextrous; our two cases first noted are right-handed; the last case was not interrogated on this point, but a reasonable conclusion is that she is left-handed. May it not be that the connection of the macula with the left brain determines right-handedness; with the right brain, left-handedness?

There are some patients, especially those subject to sick-headache, who complain of temporary loss of a lateral half of the central field. If looking at a face the right or left half disappears. This must be due to a temporary suspension of functional activity on the part of a portion of the cuneus in one side of the brain while the corresponding part of the other side of the brain continues to do its work. This symptom would occur only in those cases in whom the line dividing the one-half of the retina from the other passes through the macula. Such cases are not numerous, therefore it is reasonable to conclude that this retinal line does not often pass vertically through the macula.

FATAL LEPTO-MENINGITIS DUE TO ENDO-METRITIS ORIGINATING FROM THE DIPLOCOCCUS PNEUMONIÆ.

BY ERNEST B. SANGREE, A.M., M.D.

PROFESSOR OF PATHOLOGY AND BACTERIOLOGY, VANDERBILT UNIVERSITY, NASHVILLE, TENN.

A few days since I had an opportunity to perform an autopsy especially interesting through its unexpected outcome. Autopsies are difficult to obtain in this region, and this one was obtained because of the well-known suspiciousness and ignorance of the negroes. Several weeks since I was permitted to hold one on the body of a woman simply because she was supposed to have been “hoodooed” to death.

In this case I was informed by the decedent's roommate that “the lady next door had sold them five cents worth of dumplin's an' I aint sayin' she was poisoned but she said ‘Oh Sallie, I'm poisoned, I knows I is,’ an' I ate the dumplin's too but they didn't hurt me an' I wants you to fin' out all about it, I does.” Though, under the circumstances, it was impossible to get any consecutive and clear history of the case, this is what I obtained. The dead woman, a washer-woman, had worked on Thursday all day. That evening she complained of toothache, and in the morning said the toothache was still worse. She stayed in bed a portion of Friday, yet walked about some, complaining during the afternoon that the toothache was the worst that she had ever had, and finally said that her head hurt also. About 7 o'clock Friday evening she went into a convulsion of pain, though not unconscious, they said, and rolled over the floor through the agony

in the teeth and the head. At 8 o'clock she died. The necropsy was performed the next morning at 9. My findings were as follows: Body of a large, well nourished colored woman of about 20 (said to be 17) No rigor mortis, no external scars or marks of note. Abdominal cavity normal in appearance and omentum down over intestines. Appendix very long, free and pointing upward, backward and to the right; diaphragm to the fifth interspace on both sides; liver just below the border of the ribs. Pleuræ entirely free, no fluid in pleural cavities, lungs on section rather pale and markedly edematous. Pericardium free and contains one ounce of clear serous fluid, ventricles contracted, left empty, right contains a little fluid blood; auricles distended with fluid blood, a mixed clot extending into the pulmonary artery; heart musculature normal in appearance, valves also normal. Spleen slightly enlarged, malpighian bodies very prominent; no perisplenitis. Kidneys normal with exception of marked congestion. Liver somewhat congested. Intestinal mucosa and serosa normal. Ovaries about three times normal size, cystic and fibroid; uterus congested and with purulent endometritis. Though there were no abdominal markings the uterus and breasts looked as if she had either had a child or a miscarriage at some time. The calvaria was slightly adherent along the longitudinal fissure; the pial veis widely distended with blood, and a small amount of fibro-purulent exudate was found both above and below the pia, especially over the convexity of the right hemisphere; and a small amount of more fluid pus was discovered at the base, the pineal gland especially being bathed with it. The petrous portion of the temporal bones was removed to expose the middle and the internal ears, but these were found free from pus.

The brain was taken to the laboratory for further examination, as well as a piece of the lung and the kidney and the entire uterus. Thinking the pus in the latter probably of gonorrhæal origin I wished to look for the gonococcus. Cover glasses spread with pus from the brain disclosed no other organism than the diplococcus lanceolatus and very few of them. There was no pneumonia and no middle ear abscess and I was at a loss to account for their entrance to the brain. Some blood slides from the pial vessels were carefully gone over but revealed nothing except the leucocytosis usually so marked in purulent meningitis. Upon staining the pus from the uterus, what was my surprise to observe nothing but the same diplococcus I had just gotten from the brain, and as in the brain few in number. The pus in the uterine fundus had scarcely any, that in the cervical portion more. The reaction of the pus was neutral or at most faintly alkaline. Believing that I was now certainly on the track of the method of infection, I stained a number of slides prepared with blood from the kidney and was rewarded by finding a few diplococci in them, but now with capsules, whereas those from the brain and uterine pus were without. A more thorough search also disclosed a few organisms in the slides prepared from the blood of the pial vessels. I did not succeed in finding any, however, in the exudate squeezed out from cut pieces of the lung.

A small piece of the fibrinous pus from the brain was inserted under the skin of a very heavy full-grown rabbit, and a little of the pus from the uterus put under the skin of a common house mouse. In twenty-four hours both animals were plainly sick, and a slide made of blood from the rabbit showed the encapsuled

diplococcus. In thirty-six hours the mouse died, and in forty-eight the rabbit succumbed. Slides made from the blood of each animal yielded nothing but the encapsuled diplococcus, and in such numbers as to show a marked virulence and profound infection. Cultures made in agar from the heart's blood of each animal gave pure growths of the diplococcus lanceolatus, developing in the manner usually characteristic of this organism.

It would seem from this presentation that there can be no doubt the brain infection was due to the absorption of virulent diplococci from the inflamed uterine mucosa into the blood and their transference to the meninges. As I am not aware that any one has as yet suggested the possibility of such an infection as a cause of endometritis, the case is also interesting in that connection, and it might be well for those who have such conditions to treat to make thorough bacteriologic examinations of the pus in order to establish the fact whether or not this is a very exceptional instance. If not, then to the already long train of ills accompanying this condition, there is added another danger which up to this time no one has feared.

IMPROVED METHOD OF COCAIN ANESTHESIA FOR NASAL MUCOUS MEMBRANES.

BY P. L. ANDERSON, M.D.

CHICAGO.

Many of the unpleasant effects of cocain may be averted and much of the dread of operations may be dispelled by using the following method of local anesthesia.

As a preliminary step (preparatory for the application of a stronger solution) a spray of one-tenth per cent. cocain solution is used. In about half a minute, the same spray may be repeated and the thirty seconds between these two sprays may be utilized in arranging a very small amount of cotton on the probe for immediate use. Although this requires but a minute of time, the membranes are sufficiently anesthetized to allow the introduction of the probe without giving the patient any annoyance from the contact of the cotton with sensitive parts. The cotton on the probe has been moistened in a 25 per cent. solution of cocain. Anesthesia will take place in from three to five minutes, by rubbing the probe back and forth gently, but continuously, allowing the cocainized cotton to reach every desired part of the membrane. This simple process fully prepares the membranes for either acid cautery, galvano-cautery, snaring of polypi, or for any operation for ledge, spur or deflexion of the septum.

Formula for the stronger solution:

R. Cocain	ʒij	800
Resorcin	grs. x	65
Aquædistil	ʒj	3200

Five drops of this solution added to ʒj aquæ distil. makes the spray solution. This solution will keep indefinitely and does not crystallize around the stopper of the bottle, while the resorcin is antiseptic and adds to the anesthetic effect. The advantages of this method of cocain anesthesia are:

1. Saving of time, not requiring more than from three to five minutes, while the tampon method requires fifteen to thirty minutes.

2. The very small amount of cocain used, thereby lessening the toxic effect upon the patient.

3. The equal distribution of anesthesia produced by the gentle rubbing of the entire surface desired, as compared with the tampon which causes only the part touched by the tampon to be anesthetized, whereas the probe may reach and conform to every part of the membrane and produce a complete anesthesia. The cotton on the probe need not be renewed or replenished with cocain, for the admixture with mucous does not dilute or lessen the anesthetic effect, as may be supposed. It will also be found that this continuous friction is a much quicker process than by introducing the probe again and again at intervals of from one to three minutes. This not only requires more time, but causes more irritation and produces a toxic effect upon the patient, and a suspense or dread of cautery or operation often occurs from the unnecessary delay. The use of the spray, alone, for the complete anesthesia should be condemned, for the reason that too much unnecessary surface is anesthetized and too much cocain is absorbed. Should alarming symptoms from cocain occur while the patient is in an upright position, as for cautery, snaring, etc., lower the head as in fainting, loosen the clothing if tight, and usually a breath of cool air revives the patient. The use of stimulants or antidotes is quite unnecessary.

For operations, arrange the patient as for general anesthesia, using either operating chair or table. The prone position insures perfect safety against fainting, dizziness, nausea, etc., and is just as necessary in cocain anesthesia, as it is in general anesthesia when chloroform or ether is used. Special attention is invited to this point, for the writer has never observed, from any physician, the mention of this prone position in cocain anesthesia for operations upon the nose.

A CASE OF INFANTILE ATRESIA OF THE NASAL FOSSÆ, WITH UNUSUALLY RAPID RESPIRATION.

GEO. C. STOUT, M.D.

INSTRUCTOR IN DEPARTMENT OF DISEASES OF THE EAR PHILADELPHIA POLYCLINIC, PHILADELPHIA, PA.

Paul B., aged three months, was referred to me on Feb. 28, 1897. When born he was covered with eczematous scales, which at the time of his first visit had cleared up, with the exception of a few scaly areas on the scalp. He had been given bichlorid of mercury and iodid of potassium for the above condition by the mouth. He was apparently healthy and well nourished, but for the scales spoken of and his remarkably rapid breathing. His respirations were short and shallow, and numbered about 105 to the minute. His physician told me that he had had continuous rapid and noisy breathing since birth and occasionally had attacks simulating laryngismus stridulus. During these attacks his breathing became very labored; he became cyanotic, struggled for breath, and his condition became so alarming as to make recovery seem impossible. These attacks he had weekly, and at times oftener. It had always been necessary to feed him by a teaspoon on account of the difficulty of respiration. Examination showed the nasal fossæ to be almost absolutely closed. There was no discharge from them, but upon forcing a small cotton-tipped probe gently into the fossæ each was found to contain a thin isinglass-like scab, which extended posteriorly to just behind the vestibule. In spite of the almost total atresia of the nose, most of his breathing was

through that organ. The smallness of the apertures being made up for by the rapidity of breathing.

Only the smallest probe could be introduced at first. On manipulating for a time with a cotton-tipped probe, it was forced back until it reached the rhino-pharynx, and by gentle but persistent pressure the passages were enlarged to (or even beyond) their normal size. At this visit a generous application of the official ointment of yellow oxid of mercury was applied through the fossæ, and upon all parts of the mucous membrane which could be reached. An ointment was ordered consisting of: Menthol (crys.), gr. iii; acid boric, gr. v; ung. petrolei, ʒi, with directions that a piece the size of a small pea be inserted into each nostril morning and evening of each day and allowed to melt and run into the nose. The bichlorid and iodid of potash were continued as well as the method of feeding by spoon. The child returned March 7 much improved; had not had its weekly attack of strangling since the first visit.

At two succeeding treatments, a week apart, the forcible dilating or bougieing was repeated and the result was a practical cure of the condition, the respiration at the last visit being very easy and about 45 or 50 to the minute.

An interesting feature of this case was the persistent effort to breathe through the nose, even though the respiration had to be increased to such a remarkable degree, in order to compensate for the narrowness of the fossæ, the case thus confirming the fact (long since pointed out by Kussmaul¹) that children are essentially nose breathers, even when the nasal obstruction is extreme. In this case the tongue was drawn upward and backward, its base resting upon the hard palate and thus oral respiration was prevented, even though the lips were parted and the mouth open almost continuously. Although the relative size of the meatus of infants is very small² and but little swelling of the pituitary membrane would close the normal infant's fossæ entirely, still cases of such marked difficulty in breathing are rarely seen and more rarely reported.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

(Continued from page 938.)

VI.—LORENZ HEISTER AND CONTEMPORARIES.

Heister; Z. Platner; Günz; Ludwig; Mauchard; Kaltschmidt; Bass; Haller; Schulze; Eschenbach; Vater; Detlef; Holtzendorff; Eller; Senff; S. and A. Schaarschmidt; Muzell; S. Pallas; Z. Vogel; J. E. and O. J. Wreden; Schwarz; Walther.

Whilst in the seventeenth century the main supporters of German surgery were legitimate surgeons, the professors of surgery occupied the foreground in the first half of the following century. We will review them in order, beginning with *Lorenz Heister*, the first on the list of trained scientific surgeons in Germany. The great influence he exerted over the Germans was astonishing and he was considered so good an authority, that many believed themselves incapable of performing an operation better than he could, and thought it a crime to find fault with him.

¹ Zeitschrift f. rationale Medicin, 1865, p. 107.

² Kohts and Lorent, Handbuch d. Kinderkrankheiten von Professor Gerhardt, 1878.

Heister, who was the son of an innkeeper, was born Sept. 19, 1683, in Frankfurt-on-the-Main. At the age of nineteen he entered the University of Giessen. Afterward he accompanied Dr. Möller to Wetzlar, where under his guidance he studied chemistry for four years but gave most of his attention to the study of botany. The great reputation which the Dutch school enjoyed induced him to go to Amsterdam in 1706, where at the time, Ruysch was the anatomist, Rau the city operative surgeon, both of the Verduyns and Couerding, instructors. Rau cheated the students; for instance, when Heister and two others desired to hear a course of his lectures, he charged them 100 specie thalers, half of which had to be paid in advance, but did not, as he had promised, produce the bodies. A number of these Ruysch then placed at the disposal of young Heister, who was thus enabled to continue his preparations and practice (operative) surgery. In the following year he went to Brabant, where he enlisted as a volunteer of the Allied Armies, and visited the hospitals of the English and Dutch armies in Brussels. While in Ghent he met Palfyn. In 1708 he heard Albin lecture in Leyden, and studied chemistry and ophthalmology with Boerhaave. He graduated the next year in Hardewyk and in his dissertation (*de tunica choroidea oculi*) he refuted the idea that the choroidea was a continuation of the meninges. Ruysch loved Heister like his own son and resigned his position as anatomist in his favor. The latter, hereupon, began delivering a course of lectures on anatomy and surgery, in the German, Latin and French languages. But, on account of his great fondness for surgery, he returned to military services among the Dutch, joining them in the siege of Tournay and Mons, in 1709. Here he had operations to perform and after the battle at Malplaquet was very busy attending to 5,000 wounded in Brussels. He remained five years in Holland, and then accepted a position as Professor of Anatomy, Surgery and Botany at Altdorf, entering upon his new duties after a sojourn of four months in Cambridge, Oxford and London. Heister taught in all the different branches of medicine and was so successful in his practice, that he soon rose to be one of the most famous physicians and the most sought-after instructor of surgery in Germany. His correspondence extended over many foreign countries and during his lifetime he found several biographers. In 1719 he was appointed Professor of Anatomy and Surgery at Helmstädt, but soon resigned this position and taught scientific medicine, botany and surgery. Here he founded a botanical garden and conservatory, which were classed among the rarities of that time. Several offers which he received from parts outside of Germany met with a refusal. Peter the Great tried to tempt Heister to accept a professorship in Russia with a salary of 2,000 rubles (\$1,600); the archbishop of Würzburg was very liberal in his offer: \$1,000 remuneration, "with an adequate supply of fruit and wine," and promised him, a Protestant, an undisturbed worship of his own religion; and Göttingen had striven to capture him as head professor of medicine, when her university was established; but all was in vain. An offer from the Duke of Holstein to come to Kiel, as well as a Professorship in Rostock, Heister also declined. He retained his position as the Most Illustrious Court Councillor of Braunschweig-Lüneburg and became a member of scientific societies at home and abroad. Heister was a good Christian, very

amiable in his intercourse with mankind, and of a most obliging disposition. His lectures were very deep, thoroughly prepared and explicit. April 18, 1758, while on his way to Bornum, whither he had been bidden for a consultation, he died, in his 75th year, a most renowned man. "He was an adult in sagacity, experience, piety and worth, but a youth in society and in his intercourse with human nature." This is a quotation from the funeral sermon delivered at his grave in Stephani Cemetery in Helmstädt. Although a famous anatomist and botanist who did not share Linné's revolutionary ideas, he merited the greatest honors as a surgeon. With great fervor he fought for the combining of surgery and medicine, and in 1718, when he was thirty-five years old, wrote the most complete and most famous book then existing. Its title was, "Surgery, in which everything that pertains to the same is thoroughly discussed according to the latest and best methods and which contains thirty-eight copper-plate illustrations of the newest and most useful instruments, besides the most convenient positions of the hand in surgical operations and in applying bandages." (The 5th edition comprises 1078 pages.) How great Heister's literary influence was, may be inferred from the fact that this book, which Benjamin Bell termed the "First complete systematic work on the science of surgery," was still used as a text-book in Vienna as late as 1838. One hundred and twenty years it had served as a means of education for the young! That surgery was so superficially carried on in Germany and that the most important operations were performed by quacks and vagabonds, Heister considered mainly due to the want of a complete manual. Furthermore most of the text-books on surgery had been written by physicians who had never learned the art of operating or by uneducated surgeons. At first Heister had his work copied by his listeners, but yielding to their urgent requests had it printed later on; he wrote it in German on account of the German surgeons, but afterward caused a Latin edition to be printed for the sake of foreigners. Translated into many tongues his production was prepared according to the best home and foreign authorities and fraught with his own experiences. In the same, Heister divided surgery into three parts: The first, treating of wounds, fractures, dislocations, swellings and ulcers; the second, of operations, including ocular and obstetric operations, and the third, of bandages, thus making a distinction between medical surgery and practical surgery. The former was: The theory, that is, the science of how to cure and perform operations without making any; the latter was the actual practice, that is, the art of how to operate." A true surgeon ought to know both, a physician, at least, the theory. Heister neglected no opportunity to call the attention of the young people to the great extent and the difficulty of surgery, to spur them on and to recommend to them the study in large hospitals and on the battle field. He also very warmly urged them to study anatomy and, in a special dissertation, pointed out that the sad conditions of German surgery principally resulted from the neglect of that science, of which a surgeon has so much more need than a physician. He did not cling to principles, for he knew that "the general doctrines of surgery are often harmful, unless one has recourse to those of special cases and eminent exceptions." His love for truth he proved by publishing his failures as well as his successes; he did not hesitate to

openly confess that, in connection with a difficult birth under the impression that the child was dead, he had placed a grapple into its head and drawn it out alive, whereupon it died within three days. The most unfavorable side of Heister's accomplishments was that he was no critic. In his "Surgery" he simply placed the different opinions and methods side by side without passing judgment on them, leaving the young people without any guide in the matter. He also did harm by describing and illustrating instruments and bandages that were valueless; he once for all considered a knowledge of instruments a "general necessity" for every surgeon. It also appears that Heister was more of a scholar than a teacher, there being nothing known of any famous pupils, except Mauchard; partly due, perhaps to the smallness of his sphere of activity in Altdorf and Helmstädt. As an abstract of his great work on surgery, a small one was published in 1747. Also his work on anatomy created a great stir in 1717. This, translated into several different languages, was one of the principal text-books of the times. Heister wrote 200 different works. Even when seventy-one years old he noted medical, surgical and anatomic observations, and compiled a work in which he related all the strange things that came to pass during his "fifty years' experience," 680, mostly common occurrences succeeding each other chronologically from the time of his college life up to his settlement in Helmstädt. While this was being translated, Heister died, so Professor Cappel of Helmstädt published the same, which was not much of a credit to the departed one, for most of his experiences from 1721 to 1758 had been somewhat hastily and incompletely recorded. We will here insert his services to ophthalmology and obstetrics, because these sciences will not be taken into consideration later on. In dissecting an eye infected with a cataract, Heister found that the disease was not, as had been generally accepted, caused by an abnormal skin in the eye, but by a darkening of the lens, which had become cloudy by a preceding inflammation. This observation, which he published in 1713 and afterward defended in dissertations, involved him in a quarrel with Woolhouse for many years. While Mauchard shared the opinion of the latter, St. Yves, Platner and Morgagni sided with Heister, whose idea was soon received as correct. He admitted the existence of cataracta capsularis and held the opinion that glaucoma was a darkening of the vitreous humor. In case of a fistula in the aqueous humor, he advised the use of Anel's method in 1716, hitherto unknown in Germany. In obstetrics he deserves great praise for insisting upon Cæsarean section when a woman died in childbirth, as the infant might live if removed. To obtain this end he demanded of the state to pass a law as the prejudices among the laity were still very great; for, did not one peasant in Helmstädt threaten to shoot Heister if he dared to open the body of his deceased sister?

Less famous than Heister was *Zacharias Platner* (1694-1747), although we can not deny that he merited praise for his efforts in trying to free German surgery from its chaos of empiricism and arrange it in a scientific way, as well as to systematize the same. Educated in Paris, he was appointed professor of anatomy and surgery in Leipsig in 1721. His "Institutiones Chirurgiæ" (1745), written in classic Latin was, along with Heister's "Surgery," the most valuable text-book in Germany, which had been intro-

duced in most of the universities and was used by nearly all surgeons. Clearness of expression, good judgment and the special use made of the French literature were distinguishing features of the same; on the other hand though, it was deficient in experiences, unquestionably Platner's weakest side. It is characteristic of the times, that in the German edition, many theoretic and literary examinations, which are found in the Latin books, are omitted, because German surgeons were too ignorant to comprehend them or to manifest any interest in them. Platner divided surgery into six parts: 1. Synthesis, including the fractures and dislocations, bandaging, the healing of wounds, etc. 5. Dieresis, the section, sawing, trephining, cauterizing, etc. 3. Exeresis, with the extirpations. 4. Apheresis, with the amputations. 5. Prothesis, to which belonged the application of artificial feet, the setting in of teeth and eyes and the filling of cavities. 6. Diarthrosis, straightening of the deformed members of the body. Platner urged the combination of medicine and surgery. He was one of the most learned and popular physicians of the time. When he died he bequeathed the professorship of anatomy and surgery to his favorite pupil, *J. Gottfried Günz* (1714-1754). A Saxon by birth and educated in Leipsig, he began here as an unsalaried professor, then spent a year in Strassburg and Paris, attending, principally, the lectures of le Dran, Guerin and St. Yves. In 1747, he was appointed professor of physiology in Leipsig, but soon thereafter taught anatomy and surgery. He then went to Dresden, 1751, where he accepted a call as private physician. Having an excellent knowledge of the ancient classics, he was entitled to a most promising future, but, unfortunately, he died young. Among other works, he published one on hernias ("Obs. Anat. Chir. de Herniis, 1744), the first and best of its kind written, and scarcely surpassed by any today. The third learned professor of therapeutics from Leipsig worthy of mention was *Gottlieb Ludwig* (1709-1773). He followed in the footsteps of his two colleagues, taking charge of the anatomy and physiology and was a true ingenious representative of the times, inasmuch as he wrote a Latin compendium, comprising all the various branches of the medical sciences (physiology, pathology, general therapeutics, medical jurisprudence and surgery). He instructed the barbers of Leipsig in the fundamental principles of surgery, in consequence of which he published his "Institutiones Chirurgiæ" in German. This book, which contains many citations from Heister and Platner, was exclusively used at that time, not only by Germans but also by foreigners.

In Tübingen *David Mauchard* (1696-1751) taught anatomy and surgery. He was a pupil of Heister, with whom he lived and whose day of death was his birthday. He continued his studies in Strassburg, then attended the lectures of Duverney, Winslow and Petit in Paris. Here he lived with Girard, the surgeon of the Charité, where he had a chance to practice operating. For nine months he and Platner visited the lectures given by Woolhouse on ophthalmology in Paris. The latter had invented an eyebrush for the lids, but which he kept secret. Now Platner, who was originally wealthy, possessed himself of the same by paying a high price for it, while Mauchard, who was poor, learned it by stratagem. Woolhouse was very fond of wine, and one day when Mauchard had treated him several times, gave away

the secret while under the influence of liquor. Mau-chard settled in Tübingen and obtained a salaried professorship in 1726. Having made a specialty of ophthalmology, he wrote mostly ophthalmologic works, which can be found in Haller's collection; he also wrote a treatise on hernias in 1748. The University of Jena had a most estimable teacher of surgery in *K. Friedrich Kaltschmidt* (1706-1769). After pursuing the study of jurisprudence for two years, he took up medicine. He became the physician of the Duke of Weimar. He then was an unsalaried professor, and after eight years advanced to the position of salaried professor, at first receiving no salary and having no authority. He taught practical medicine, jurisprudence and surgery, always having a good attendance. A great number of Latin works, which are very verbose, bear his name and are found in Haller's compilation. In order to obtain certain solutions he experimented on rabbits, inflicting similar liver wounds to one he had successfully treated. Kaltschmidt was a very fearless operator, as shown by his extirpation of a large tumor of the neck (goiter), but in removing the same he had the misfortune to cut the carotid and not being able to stop the bleeding, the patient died.

Heinrich Bass (1690-1754) born in Bremen and educated in Halle, Strassburg and Basel, was made professor of surgery in Halle in 1718. He published the first German work on bandages, illustrated by twenty copper plates in 1720, which was received with great approbation. Although written according to the ideas of Verduc, the distinguishing features were the concise and intelligent language used and the perfection of its illustrations, beside containing much that was new. Bass and Heister were the first men in Germany who laid particular stress upon good bandages. Of less value are his "Illustrated Bric-a-Brac" (1728) and his "Obstetric and Anatomic Surgery" (1731). In Göttingen, the famous *A. von Haller* occupied the professorial chair of surgery for seventeen years, but never dared to perform a single operation on a living person, a remarkable circumstance for one engaged in surgical work so long (*etsi chirurgicæ cathedra per septemdecim annos mihi concredita fuit, etsi in cadaveribus difficillimas administrationes chirurgicas frequenter ostendi, non tamen unquam vivum hominem incidere sustinui, nimis ne nocerem veritus*. "Bibl. Chir." II, p. 171). People did not hesitate to take heroic medical treatment, but shrank from the simplest surgical operation. Haller contended that not a single great man had distinguished himself so that a period of surgical history might be named after him; besides surgery had ever been dependent upon medicine and without it could make no progress. Haller's principal works were five volumes of "Disput. chir. selectæ" (1755-1760) for which he had collected 163 surgical treatises, partly complete descriptions of diseases and partly of rare cases and new instruments. The first volume contains twenty-nine dissertations on injuries of the head; the second, twenty-eight on diseases of the head, throat, chest, etc. These dissertations by Haller as well as the surgical works of the Richter collection, which appeared later on, probably most fully utilized the least valuable parts of surgical productions in Germany, during the past century. Another valuable work by Haller is his history of surgical achievements, in two volumes (*Bibliotheca chirurgica*, 1774), in which he passes criticism on all surgical journals published up to his time and

comments on the editors of the same. Professor von Creutzenfeld of Vienna compiled a similar work in 1781. Of the rest of the German university professors belonging to the first half of the 18th century scarcely one deserves mention. But there was Heister's successor in Altdorf, *J. H. Schulze* (1687-1744), a poly-historian, who taught also Greek and Arabic, then went to Halle to teach medicine and eloquence and among his great literary works also produced a compendium (*Chir.* 1747). Prof. *C. E. Eschenbach* of Rostock in 1754, so sharply separated medicine from surgery that he did not wish internal remedies mentioned in surgical journals, contending that they were of no concern to a surgeon. The physician alone was to care for the remedies of external diseases and in disputed cases, his idea was to prevail as had been decreed by the state. He was also greatly in favor of specialties in surgery and thought it by far better for a surgeon to pursue but one branch of operative surgery, as daily observations had proven that the most uneducated oculists and dentists often performed operations in their line faster, more fearlessly and successfully in consequence of their great amount of practice than the others. *A. Vater*, professor in Helmstädt, wrote a "Museum Anat." in which he narrates several strange surgical cases (1750). Haller's pupil and demonstrator in Göttingen, *P. Detlef*, was one of the first to attempt the production of callus from bone humor and the vessels of the callus (*ossium calli generatio*, 1753).

One might expect Berlin, so rich in material on account of the great preference given the Charité over many universities, to have good surgeons, but there was nothing more supplied here than barber surgery. A progress in the sciences could not be looked for from King Frederick I., who appointed his executioner as body physician. His successor, Frederick William I., who declared himself to be very German in his ideas, did not wish to have anything to do with those roguish and flitting French. This may have been a very brusque remark on the part of his royal highness, who was rather indifferent to science, so that he considered Leibnitz of no account; nevertheless, he did much toward furthering the development of medicine and surgery by founding the Charité and by establishing the collegium med. chir. in Berlin, as well as by his famous edict regarding the medical system. Having a great fancy for tall people, such as were found among his grenadier guards at Potsdam, he attempted to raise a tribe of giants, by procuring very tall mates for them. The experiment, however, proved a failure. The surgeons also were measured, but it has been especially noted that Henc- kel, although not very tall, received the appointment of field surgeon of the regiment at Potsdam. There was great danger of their being put into a strait waistcoat. When Theden was made field surgeon of the Holstein regiment, his commander wanted him to be a fusilier on account of his height, but he narrowly escaped through the interference of the surgeon of the regiment, who furnished him with a pass to leave the city. Several physicians and surgeons of the Charité were highly esteemed by Frederick William I. The surgeon of the staff, *Holzendorff*, had founded the anatomic theater in Berlin, as well as furnished the plans for the Charité and the Collegium Med. Chirurgiæ. Frederick's body physician, *J. Theod. Eller*, also had a part in the erection of the Charité, wrote out reports on the operations performed there

in his "Med. Chir. Remarks" (1730), and besides this compiled a "Complete Surgery" (1763), which, although of no great value, was published three years after his death. One of his co-surgeons at the Charité, *G. Senff*, did not write anything, but invented a knife for the operation of the seat fistula and a compress for aneurysms. Eller's successor as physician, *Samuel Schaarschmidt* (1709-1748), at first studied theology in Halle, then medicine, and in 1736 became professor of physiology and pathology at the Colleg. Med. Chir. In all the various branches he was a prolific writer; besides his "Accounts of Berlin," we have a short sketch and view of the human body (1736), a treatise on diseases of the bones (1749), on venereal diseases (1750), a book on obstetrics (1751), a physiology (1751), a dissertation on military diseases (1758), prescriptions (1768), and on wounds (1763). In general, he represented good surgical principles. His brother, *August Schaarschmidt*, professor at the University Bützow of Mecklenburg, compiled anatomic tables or synopses, which were extensively used. Samuel's successor at the Charité was the body physician *Muzell* (1715-1784), who, in the absence of the head surgeon, also attended to his duties. A few of his remarks ("Med.-Surgical Observations," 1754, 72) show very plainly how ignorant the Prussian army surgeons were, but more of this hereafter. Muzell's surgical colleague, Professor *Simon Pallas* (1694-1770), noted as a good operator, wrote a "Guidance for the Science of Practical Surgery" (1763), in order that the students need not spend any of their valuable time in copying. In this he described clearly and concisely the principal operations in twenty-two chapters. As a hint on operations, he made the rule not to operate, when certain that thereby the disease could neither be cured nor mitigated; on the other hand, if a cure could only be effected by a dangerous and doubtful operation, it would be better to undertake the same than to keep one's hands in his pockets. Besides, he published practical directions for treating diseases of the bones, advising gentleness when handling fractures and luxations.

Not one of the surgeons of that time became especially noted. The surgeon at Lubeck was *Zacharias Vogel* (1708-1772), who wrote a work on hernias ("Dissertation on all Kinds of Fractures," 1738) which was considered valuable then, but today is worthless, and in which, among other things, he fought against castration by surgeons. Furthermore, there exist from his pen, "Strange Tales of Patients" (1756), and an "Anatomical Surgery and Medical Observations" (1759). The following is an example characteristic of his surgical maxims: In a case of hydrocele scroti, he made a puncture and set the patient's dog to lick the wound, looking on as a highly amused spectator. The swelling went down, but the dog had a terrible vomiting spell, whereupon Vogel gave him milk to lap, then the sucking was continued until the swelling disappeared the following day. Sound surgical opinions were expounded by *J. Ernst Wreden*, private and the general-staff's surgeon at Hanover, of whom we will again speak in connection with vaccination. In his "Collectanea Chirurgiæ" 1722-23) he imparted his observations on a thrust wound made in the heart, on gangrene caused by a cut in a corn, gangrene of the penis after gonorrhœa, on the extirpation of an eye, on the successful excision of a ganglion, the healing of aneurysms of an arm by means of the split and double ligatures, and

on others; for a broken lower jaw he had a tin box made. He also wrote a very unimportant work bearing the title, "Surgical Military Chest" (1722), comprising forty years of his experience as army physician, and detailing medicaments, instruments, etc. His son, *Otto Just Wreden*, the above mentioned publisher of the first German topographic anatomy, as well as other anatomic and physiologic works, wrote some very superficial directions for the practice of surgery and caused a new edition of his father's "Military Chest" to be illustrated. Of no consequence were the surgical remarks by the Schleswig-Holstein surgeon *J. C. Schwartz* (1713), nor the "Medical and Surgical Treasure," by *C. L. Walther* of Halle (1715).

It must be confessed that among the best German surgeons of that day, there was no special genius, who might have opened a new career for surgery, or by means of prominent discoveries, or the establishment of new views promoted it as a science. Rich in learning, but poor in ideas, they followed the trail delineated by the French and English, which they often lost. This censure in no wise diminishes the credit due the few, to whom German surgery owes her first scientific and methodical cultivation. Heister did much to advance and promote surgery in Germany, but comparatively little toward its progress as a science. This period, in which the learned mass of physicians was prepossessed by prejudice, superstition and credulity, when many a writer gathered only such observations as confirmed his pet ideas (hobbies) and omitted everything that did not agree therewith, and when they even invented stories of patients for base purposes, such a time must retard the growth of surgery. What little culture some of our best forefathers possessed is proven by several publications of self-operations, to which an artless child would hardly pay any attention, did they not throw some light on the easy belief, or rather the falsity of the authors. Thus Holtzendorff, surgeon of the general staff, related to Professor Schaarschmidt a case of self-amputation which, according to the patient's testimony, was legally authenticated. A man, 76 years old, said that forty-five years ago, he cut off his own leg. Sphacelus set in and the flesh of the foot began to decay. A physician promised to amputate it, if he would support him with three servants and four horses. This was impossible. The patient now fastened a bandage as tight as possible above his knee and began to saw off his leg below the same with an old saw. Not succeeding, he tried a sickle, and finally the files of a locksmith, his wife holding his leg, and so he filed it off. Having recovered from a swoon immediately after the operation, he washed the wound with urine and bandaged it with sugar, alum and wintergreen. Nine months later the wound had healed. Schaarschmidt published this story in his "Accounts of Berlin" (1740, p. 6) and defended the authenticity of the same. Another case of "Table Surgery" was a self-made cut into one of the testicles, which can be found in *C. L. Walther's* "Medical and Surgical Treasure" (1715, p. 196). A surgeon in Koenigsberg related that a cooper's apprentice, 21 years of age, had himself made a cross incision between the testicle and the penis and after passing off the urine had felt the stone with his finger. He enlarged the cut and removed two hundred stones, then felt a still larger one and increased the size of the fissure. Decaying death inevitable, he wished to see the stone that

had so long tortured him. After the third cut he procured a sprinkling can with which he rinsed out the remaining pebble, then hunted a needle in his mother's sewing basket, but found none, to sew up the wound. After two days he summoned the surgeon of Koenigsberg, who cured him, and at the end of six weeks he was able to resume his work. Another one of these farcical cases of self-operation is mentioned at the end of the century. This time the hero was the English Colonel Martin of India, who used a file to extract the stone in his bladder. Into this the daring officer, it is said, inserted a thick steel wire, which was in an elastic catheter and to the convex end of which was fastened a file as thick as a straw, and so filed through the stone. During this procedure he squatted down in order to move the stone nearer the neck of the bladder and injected lukewarm water. This operation he performed three times within twenty-four hours, until the stone was pulverized (*Arnemann's Magazine Wound Medicines*; ii, p. 413, 1799).

SOCIETY PROCEEDINGS.

Association of American Physicians.

*Twelfth annual meeting held at Washington, D. C.,
May 3, 5 and 6, 1897.*

(Continued from page 954.)

Dr. J. M. DA COSTA, President, in the Chair.

Dr. W. T. Gouncilman of Boston spoke of the frequency of finding the typhoid bacillus in the gall bladder. Indeed he said it was almost always present. The bacillus entered the gall bladder from the blood. They are always in the liver, that is practically always and there are very few organisms in the blood which can escape the liver; they can easily pass into the bile vessels. He then showed some beautiful specimens of typhoid ulcers.

Dr. James Tyson of Philadelphia, then read a paper on "Urea Estimations in Cases of Typhoid Fever Treated by the Brand Bath Method." He spoke of a case of typhoid fever which came into the hospital and on the third day after admission he found albumin and hyaline casts; he gave milk and liquid diet and then on the fourth day he began the use of the Brand treatment, at the same time he collected the urine which he found contained 2.9 per cent. of urea; during the bath treatment the secretion was markedly increased. For instance the patient was tubbed five times and found the urine and urea were increased; again on the twenty-eighth day there were 2100 c.c. of urine and 29.8 per cent. of urea; on the twenty-ninth day there were 2100 c.c. of urine and 24.7 urea; on the thirtieth there was 2280 c.c. urine and 32 of urea; the albumin fell to one-twelfth of the bulk and then disappeared, as did also the casts. At first expectoration was copious but later the cough grew less and there were no tubercle bacilli, but otitis media developed in both ears but there was no defect in the hearing. The nephritis became much milder and was what Stockton calls an upper renal complication; such a condition would not prevent him from using the Brand method. There is no stagnation of the blood in the body during the bath treatment but the blood flows rapidly through the kidney and thus can do no harm in the congestion of the kidney. Many other persons also use the Brand treatment in nephritis; of 138 soldiers in hospital suffering from typhoid fever 69 were treated with the Brand method, 5 having nephritis and none died and 69 without the Brand treatment; 9 had nephritis and 5 died. The urea can come from two sources; from the amount of nitrogen ingested through the food taken or it can come from changes in the tissues.

Dr. George Dock of Ann Arbor, Mich., then read a paper on "Cancer of the Stomach in Early Life; and the Value of Cells in Effusions in the Diagnosis of Cancer of the Serous Membranes." The report was of a cancer of the stomach (scirrhous) in a man of 19 years. There was extensive filtration of the stomach with early obstruction of the cardiac orifice. Metastasis in the peritoneum and pleura with fatty ascites; later, effusion in the pleural cavities, first left, then right. In the various effusions were cells which besides containing fatty granules and vacuoles, showed, in a large proportion karyo-

kinetic figures, both typical and atypical. After a reference to the literature a comparison was made with the findings in other effusions in serous cavities, tending to give to such cells a certain diagnostic value. The paper was read in abstract, giving the salient points in the history and histologic examinations, with demonstration of specimens and drawings.

The case which he presented was one of typhoid in which there was a swelling in the abdominal region and a hard mass was felt. After drawing off about five liters of liquid, the mass seemed to have disappeared and at the postmortem a very small stomach was found and a tumor in the serous membrane; the patient was young and the fluid was of a thin watery consistency; this disease runs a slower course and remains longer in the stomach in younger persons than it does in older, so that an operation gives more chance for success. The diagnosis by the cells alone is not an easy one and it is much better if considerable portions of tissue can be obtained. The intracellular figures and the nuclei were very well shown in the drawing that he passed around.

Dr. Simon Flexner of Baltimore spoke of a case which he had examined in the autopsy room in the Johns Hopkins Hospital which was a large tumor extending into the intestines. There was some fluid which contained cells. The case was supposed to be cancer, but a very careful examination microscopically showed that it was tuberculosis of the peritoneum.

Dr. Francis Delafield of New York, then read a paper on the "Inflammation of the Colon," and in this paper he spoke of the various forms of colitis which ordinarily occur in New York and gave results in his experience as to the prognosis and treatment. He exhibited a large number of beautiful photographs. He divided the dysentery into acute, the climatic, ordinary and amebic. In the acute ordinary form there was no change in the intestinal wall, but there were two varieties in this; one was the mucous and the other was a serous condition.

1. The mucous variety is so rarely fatal that specimens can not be easily obtained. There is sometimes bleeding and the cells are covered with mucus, the lymphatic glands being swollen and inflamed; the cause is not known. A variety of organisms had been found and they were characteristic of impure drinking water and impure milk. High temperature of the air and overcrowding are the principal causes. The symptoms are local, little fecal matter passes but there is great rise of temperature. Some patients do not go to bed at all and others even continue their work. When the colon is affected then the condition is worse still. Adults usually recover, but children often die. The main treatment is rest in bed, careful diet, emptying the colon, relieving the pain with opium, weak injections of flaxseed in the rectum are the best means known. The disease may be chronic. There is usually no change in the mucous membrane but there is some thickening of the glandular coat.

2. The serous variety is characterized by large exudations of serum; these are not to be confused with functional disturbances of the colon. The disease is not fatal and he has never seen a specimen postmortem. This disease is very common in New York, especially before the heated weather, but it occasionally occurs in winter. Some are predisposed to it and have it summer after summer. There is a feeling of necessity to empty the bowels and the quantity discharged is considerable, sometimes as much as two quarts. A large number get well by a variety of treatment while others recover with no treatment at all and some continue in spite of every thing. He placed great reliance on castor oil, salol and opium. In this variety there is more or less infiltration in the connective tissues of the coat of the intestines. This tissue is much thickened, there is an inflammation in the upper rather than the lower part of the intestinal canal and the disease may last anywhere from a few days to a year. The treatment is not satisfactory.

3. In this there is an increased production of mucus and of serum and also a number of blood cells. There is a growth of the connective tissue with a certain change in the glandular coat. The inflammation is somewhat extended and there are many small superficial ulcers of microscopic size with overhanging edges. The cause is very obscure, the invasion may be sudden or gradual. Many of the symptoms appear on the first days and some may last for a few days, while others may continue their course for weeks and months. He has seen a case die in seven days; the prognosis is serious, the treatment should be begun at once, milk diet is necessary, good food, dry climate, rest in bed, irrigation of the rectum in the early stages and opium, salol and castor oil.

4. In the croupous or diphtheritic dysentery the treatment is much different; he had caused an artificial membranous dysentery in dogs by administering to them large doses of corrosive sublimate.

5. Amebic colitis; of this there are two varieties. One is lymph inflammation and in one there are deep ulcers formed,

but the treatment is weak irrigations of the colon with quinin solutions.

Dr. D. W. Prentiss of Washington then exhibited "Two Cases of Erythromelalgia." 1. Female neurasthenic, aged 58 years. Left hand only affected. Has continued in intermittent attacks since August 1895, presenting, in a characteristic form, the train of symptoms described by Dr. Weir Mitchell as peculiar to this disease. 2. Widow, aged 37 years. Neurasthenic and hysteric. Pain in the heels extending to the soles of the feet and, when more than usually severe, up the calf of the legs. No history of previous disease, except the neurotic tendency, in either case, to throw light on the cause. Diagnosis, pathology and treatment will be discussed with special reference to relation to other diseases, classed as vasomotor. The treatment especially is worthy of note, since heretofore it has proved almost unavailing. While the reporter does not anticipate adding much in this direction, it is hoped other members with more extended experience will be able to do so, especially with reference to surgical interference, that having been contemplated in first case by cutting or stretching nerve in forearm.

WEDNESDAY, MAY 5.—SECOND DAY.

Dr. A. McPhedran of Toronto related "A Case of Pancreatitis Followed by the Formation of a Cyst." He spoke of a case which came to the hospital; he suffered from colic, jaundice, and had repeated attacks. During the next five years the attacks grew more frequent; he left the city for the summer and on coming back in the autumn gallstones were discovered and an operation was advised. On September 6 he suffered from pain, prostration and vomiting; the pain lasted three days; fever was 101 degrees. He began to improve later but was still uncomfortable; he was given Carlsbad salts and his diet was regulated. October 5 he had a pain over the pancreas; October 8 a large cyst was found over the epigastrium extending over the right of the pancreas; his temperature was 99.5 degrees; an operation was done and a clear serous fluid was evacuated. At the bottom of the wound the pancreas was found enlarged; the liver was healthy and the gall bladder was not reached. The opening was closed without drainage, with a pulse of 130 and temperature 101.5 degrees. Later he suffered from cyanosis and dyspnea. Ten days later a collection of purulent fluid was found in the lower part of the incision, probably due to fat necrosis. The pancreas seemed to have increased in size. In June he seemed to be much improved and went to his office, but his digestion was still disturbed and he had flatulence; the tumor had grown and was found pressing upward and forward; the urine was free from sugar. In March another operation was done and a cyst with walls 2 mm. thick was evacuated and a flocculent fluid containing albumin and leucocytes and being alkaline was found. There was no digestive ferment present. He made a good recovery, but the fistula persisted; the discharge was free and the skin was excoriated; the fluid was pancreatic in character and had some digestive powers. The general health of the patient continued good; the sinus continued and the discharge persists. The first attack and the subsequent ones were undoubtedly due to the beginning troubles of the pancreas. He then spoke of three kinds of pancreatitis, simple, hemorrhagic and suppurative.

Dr. J. H. Musser of Philadelphia then read a paper entitled "Angina Pectoris; Its Relation to Dilatation of the Heart." The paper was entirely clinical. The contention of the paper was to the effect that patients who have had an attack or attacks of angina pectoris are relieved of the paroxysms if dilatation of the heart supervenes. Often, if dilatation persists, the patient may live for years and no other paroxysm occur. It seems the pain, as long ago pointed out, is due in large part to the stretching of a tense ventricle from intra cardiac pressure. Such stretching is not so likely to occur in dilatation because of "safety valve action" in the heart. The idea appears to explain the infrequency of angina in the young; in mitral valvulitis with regurgitation; in women possibly, and in the occupants of infirmaries and hospitals. In the latter class the vigor of the heart muscle is lessened from lack of food, etc., which obtains in the better class. Certainly it is not because of the absence of atheroma of the coronary arteries, for endarteritis is very prevalent among senile, usually alcoholic, perhaps syphilitic inmates of the hospitals and almshouses.

If the contention is true, the diagnosis, prognosis and the treatment, tentatively admitted, is influenced thereby. The diagnosis, in that angina like paroxysms in dilatation of the heart are probably not due to true angina pectoris. The prognosis, in that, if, as rarely happens, an undoubted attack of angina occur in a case of valvulitis with dilatation, and even failing compensation, the patient on the one hand is not likely to perish from the angina, because of the safety valve, while on the other hand, it indicates that there is sufficient strong

muscle fibre to insure cardiac recuperation. Further, if a patient subject to attacks of angina presents signs and symptoms of dilatation, the angina will disappear, or at least never be so severe as to terminate fatally.

That the pain is due to intra-cardiac pressure is more possible because of the presence of dilatation of the heart in angina sine dolore. Attention is called to a similar association of pain with increased tension of the globe, in acute glaucoma.

In connection with the above the writer showed the influence of "safety-valve action" in the relief of some peripheral symptoms of high arterial tension.

Dr. Wharton Sinklar of Philadelphia said that the question as to the cause of the pain in this trouble was of great interest; and Dr. Musser's explanation did not seem to be entirely satisfactory. We have also a pseudo-angina with pain and a great discomfort and he related a case of the kind in which one grain of morphia was given and failed to relieve and there was no evidence of disease of the heart at any time.

Dr. J. C. Wood of Philadelphia asked what was the cause of the increased intra-ventricular pressure. The pressure in these cases can not come from any condition of the heart itself. If the pain of the angina pectoris is due to increased intra-ventricular pressure, then one would expect the arterial symptoms to play the chief role and not the heart. Nitrite of amyl is interesting in this connection; it relieves the aortic pressure and takes away the resistance of the heart. In digitalis it is noticed that the action is not good in this disease. If Dr. Musser's theory is correct then angina could be stopped by hypodermic injections of tincture of aconite, or if we gave enough aconite we could do away with the ventricular pressure altogether, but this is only theory.

Dr. E. G. Janeway of New York mentioned several cases. One was a man who was much frightened in an accident on the railroad; he went home and complained of a pain in the right side and not in the left; he was ashy pale and had pericarditis. The diagnosis was made of thrombosis of the coronary artery with rupture of the heart. One day as he was feeling better he suddenly sat up in bed and died. At the autopsy the coronary arteries were found diseased and the septum of the left ventricle was ruptured and there was a thrombosis in the right coronary artery. Dr. Musser's theory does not explain this. In the second case a man walking across a field was suddenly taken with a sharp pain in the side; he died in three weeks, alone, and at night under rather suspicious circumstances, and poisoning was suspected. At the autopsy both of the coronary arteries were found thrombosed and the left lesion was found to be older than the right, showing that one attack had antedated the other. He also referred to other cases and to the effect of nitroglycerin on persons with low arterial tension.

Dr. Charles Carey of Buffalo spoke of this increased tension of the heart as parallel with the increased tension of glaucoma. He thought that Dr. Musser's theory was open to question and did not fit every case.

Dr. F. R. Kinnicutt of New York said that his theory might explain some cases, but he said there was often great pain in which the heart walls were stretched.

Dr. Musser said in conclusion that he did not mean to refer all cases of angina pectoris to this cause, but he wished to lay stress on the fact of the safety valve action of the mitral valve; the pain was certainly decreased.

Dr. F. C. Shattuck of Boston then read a paper entitled "Pericarditis; Some Points in the Diagnosis and Treatment." He said that pericarditis was frequently overlooked and was often not sought for. The disease was one that was well known and rheumatism was often the cause, as endocarditis and pericarditis may co-exist. So often in the beginning of the disease the doctor does not see the patient. It often follows pneumonia. In fact the two are often associated. The diagnosis must rest on the physical signs, but the friction sound is very much circumscribed and may come and go between each examination; it may be present one day and absent the next and *vice versa*. He had seen several cases in which pericardial effusion had been suspected after pneumonia and had been carefully looked for but not found until after the autopsy. Dry pericarditis without friction sound is also hard to make out. The shape of the dullness in his experience was not pyriform or triangular but similar to that of enlargement of the heart. He had been able to map out the shape of the heart itself in many cases in the cadaver in carefully percussing the chest wall and then sticking pins at the edge of dullness and thus he mapped out the exact shape of the heart. The changes in the percussion sound are of great importance; the pericardium sound is not often prominent and is easy to make out when the lungs are retracted away from the heart. If the treatment is other than rest it is of little use. The effu-

sion will increase without the resort to remedies. He used opium for rest, alcohol for stimulant, but did not advise blisters. Ice pack was very well for the comfort of the patient. He tapped seven cases and six successfully and in two was sure he saved life. Removing a small amount of the fluid will often cause absorption of the rest. There is no strict rule when to tap. Each case must be studied itself, but the point of election for tapping is in the fifth space, one to two inches to the left of the left nipple. In one case he withdrew 16 ounces and in another 36.

Dr. James T. Whittaker of Cincinnati, spoke of the latency of the disease, and said it is often not recognized until the postmortem. He thinks that the clear fluid often indicates a tuberculosis. He lets the stethoscope hang in his ear allowing the top just to touch the chest of the recumbent patient. He punctured in every case he suspected; he preferred the second or sixth left interspace as he had gotten fluid there when he could not get it anywhere else. He always feels the heart with a trochar.

Dr. G. L. Peabody of New York, spoke of the importance of selecting the right place for tapping and mentioned one case of his in which he passed the trochar in the sternal cartilage.

Dr. H. A. Hare of Philadelphia, said that the danger of hurting the heart muscle was not very great and spoke of his experience on dogs in which he stabbed a number of dogs in the heart and on examination after death found the wounds healed and little blood in the pericardium. He thought the result would not be fatal unless the heart centers were stuck and this was not likely. He mentioned a case in which tapping a man the trochar had pierced the heart, and later when the man died the wound was found almost healed. He asked the members if they thought digitalis was the best heart stimulant to give in this trouble.

Dr. Rotch of Boston, said that Dr. Hare's work agreed with his own. He said that it was hard to make a diagnosis in these troubles but as the effusion flooded the heart upward the tapping would naturally have to be done below. It is always better to avoid the heart if possible. He said that the space just below the scapula was a good place to tap.

Dr. James Tyson of Philadelphia, thought it was very easy to outline the pericardial effusion and he felt sure that we got the triangular pericardial shape in most cases. He thought that Dr. Shattuck was too literal. He wanted to refer to the utility of the phonendoscope in making the diagnosis. He thought as a means of mapping out internal organs it would prove very useful. We ought not to let the blister go; it will often save tapping. He had never tapped a pericardium but when Dr. Shattuck finished his paper he felt as bold as a lion and ready to tap the first case, but since the others had spoken he had lost his courage.

Dr. A. McPhedran of Toronto said that the myocardial infection should be considered; it was often the chief disease.

Dr. E. G. Janeway thought that we could always make out the pyramidal shape and referred to a case of puncture of the heart in which the patient died.

Dr. Shattuck said in conclusion that there was only one case in which the fluid was not obtained. There were some dry taps but they all afterward proved productive except one.

Dr. M. H. Fussell of Philadelphia, then read a paper on "Pneumonia in Private Practice." The paper embraced a series of cases treated privately in which accurate notes have been kept. They were analyzed and deductions as to mortality, symptoms, physical signs and treatment made.

Dr. J. E. Graham of Toronto, then related "Two Cases of Broncho-Biliary Fistula." The further history of a case of broncho-biliary fistula which was reported at the first meeting of the association. A second attack occurred after an interval of ten years. The patient coughed up large quantities of bile, almost daily for a period of eight months. Great loss of flesh and strength. A cholecystenterostomy. Gall-stones were found. Death from cholemia and hemorrhage. Short notes of some similar cases. Some remarks on the pathologic anatomy of such cases. Notes of a second case of broncho-biliary fistula in which the lesion followed a traumatism.

Dr. Beverly Robinson of New York, then read a paper on "Diagnostic and Therapeutic Considerations with Respect to Certain Diseases of the Upper Air Tract." He spoke of the utility of the laryngoscope and rhinoscope in throat trouble and said that throat surgeons had been largely led away by fads, one of which was that a deviated septum must always be either cut through or perforated. Another one was that the turbinated bodies must be cauterized, cut, etc. In spite of all these fashions these troubles still continued. But the specialist should remember that the nose and throat alone should not be treated but the general health should need attention. Many general practitioners can just as well treat the simple throat

and nose disorders as the specialist, but it is only in special operations and the more delicate manipulations that the specialist should be called in. It should be remembered for instance in an affection of the pharyngeal tonsil rheumatism plays a part so that the salicylates and colchicum are indicated. Thus the specialist and the general practitioner must work together in the treatment of these cases.

Dr. J. C. Wilson of Philadelphia, then read a paper entitled "Nervous Deafness in Diphtheria; a Case." The abstract is:—Follicular tonsillitis in an adult; Moderate fever, occipital headache, tinnitus aurium et cerebri; fourth day, dense pelli-cular exudate upon right tonsil, conjunctivitis, increasing tinnitus and deafness, injection of diphtheritic antitoxin serum; a few hours later, total deafness with slight vertigo, great chemosis; gradual defervescence completed by the thirteenth day, at which date there was partial paralysis of accommodation together with paresis of the extensor muscles of the head, persistent tinnitus, slight vertigo and absolute persistent loss of hearing. The following topics were considered: The rarity of the case, its importance, the antitoxin injection, the general subject of sudden nervous deafness in the infections, theoretical considerations, diagnosis, prognosis, treatment.

Dr. Beverly Robinson of New York said it was an interesting and unique case and very fully reported. It is also interesting from the standpoint of certain cases which he had seen; cases in which the Board of Health diagnosis had rather led him astray. While it is very gratifying to know from the Board of Health that a certain case is not diphtheria, still in a number of cases he had told the parents of the patient that it was diphtheria, and treated it as such. We must pay more attention to the clinical diagnosis than to the pathologic report of one who has never seen the case. Too much importance is paid to the personal investigation of certain individuals who are skilled in technique, but who never see the patient.

Dr. I. E. Atkinson of Baltimore said that in reporting cases it was well to look at them carefully and see that no link in the chain of the history was wanting. In this case the bacillus was not found. Could we account for these symptoms in another way? It might have been some form of septic meningitis, and which looked like deafness of cerebro-spinal meningitis. He had been called in to see a child 14 months old who had a slight rash over the body, and later had a patch on the tonsil. The staphylococcus was found; the temperature was up to 105 and 106. This was reduced by baths. The child finally recovered, but was deaf in both ears.

Dr. M. H. Fussell of Philadelphia also reported a case of deafness with obscure symptoms.

Dr. W. W. Johnston of Washington said this was an era of anomalous cases, and he thought many of them were all due to epidemic influenza, which took on so many different shapes. He thought that Dr. Atkinson's case was certainly influenza, and probably Dr. Wilson's, but this was merely a suggestion. We know how profoundly the nervous system is affected by this disease.

Dr. J. C. Wilson said in conclusion that there was certainly a link missing in the demonstration of this case, but it does not seem worth while to go out of the way to make a diagnosis, although the diphtheritic organisms had not been found. Germicides had been used and the patient had been carefully isolated. He had also seen a great many anomalous cases of influenza, but he had not seen a case like this.

Dr. J. P. Crozer Griffith of Philadelphia then read a paper on "Types of Edema in Infancy and Early Childhood." The author discussed the obscurity which attends many cases of edema occurring at this time of life. He referred first to the possibility of nephritis being present in earliest infancy, and then took up the question of the production of nephritis by congenital syphilis. He reported two cases seeming to be proof of the occurrence of this form of renal disease, and referred to some instances from medical literature. The existence of nephritis in an infant as one manifestation of general septic infection was instanced by the report of a case. Edema consecutive to heart disease and to marantic conditions was then touched upon, and then that going by the name of edema neonatorum. The relation of this condition to sclerema neonatorum was next considered and an instance of the latter reported. He then reviewed the cases of sclerema occurring in America. Next angioneurotic edema as seen in infants and children was reviewed, and the various reported cases abstracted. He reported two cases occurring in his own experience. Finally, instances of edema of entirely doubtful origin were taken up and two unusual cases detailed. He also exhibited some beautiful normal and pathologic specimens in which the colors had been preserved.

Dr. D. D. Stewart of Philadelphia then read a paper on "A Further Communication on the Occurrence of a Hitherto

Undescribed Form of Chronic Nephritis, Unassociated with Albuminuria." This paper was a continuation of those on this subject which appeared in the *American Journal of the Medical Sciences*, December, 1893, and the *Medical News*, April 14, 1894. It dealt with an unrecognized form of chronic nephritis with distinctive symptoms, in which albumin, even in traces, by the commonly employed tests, was persistently absent from the urine, and yet uremic symptoms were common. Although unable to present the result of a necropsy on a personally observed case of this sort, a portion of a kidney removed from one of them in life threw some light on the pathologic condition present.

Dr. H. A. Hare of Philadelphia then read a paper entitled "A Study Concerning the Cumulative Action of Digitalis." He stated that the experiments were intended to test the effects of digitalis on the thickening of the heart muscles. He took twelve young pigs of about the same weight and put six in one pen and six in another. They were fed in exactly the same way. To the first six he gave digitalis in increasing doses until they were taking 15 minims three times a day, the other pigs taking no medicine. The digitalis pigs grew very much larger, were very lively, tried to jump out of their pen and gained about twenty-nine pounds apiece, so that the country farmers noticed their increase in size, while the other pigs continued as before. The postmortem examination showed that the heart muscles were considerably thickened and strengthened. He defined the cumulative action of digitalis as a more or less sudden development of the regular action of the heart with gastric distress. The effect was cumulative, not the drug. He quoted many authorities to sustain his point. He does not believe that the cumulative effect is of an uncanny kind. There are no premonitory symptoms, but it occurs suddenly. He had addressed a large number of questions to physicians asking them if they had noticed this cumulative action, and what form of digitalis they had used and what were the doses. He thought that the action was due to the fact that the drug was more slowly eliminated than it was administered, and believed its effects were stored up, and his belief was that it should not be given more frequently than twice a day.

Dr. William Osler of Baltimore thought that this action was extremely rare and felt very badly to hear one of his few friends in the materia medica brought to trial. He gives it largely and with a free hand, and has never seen the cumulative action, but we all know the dangerous pulse with 40 at the wrist and 80 at the heart. In certain chronic valvular diseases of the heart he had given it for a long time, and thought that the cumulative action was so rare that it might be disregarded.

Dr. E. G. Janeway of New York asked if we attributed the sudden deaths in hospitals to the right cause. He had looked up the records of sudden death, and found in many cases that the patients had been taking digitalis and they had low heart beats and slow pulse beats. The sudden deaths he thought are due to the drug and not to the disease. He thinks that many sudden deaths in pneumonia are caused by digitalis, and he is sure he knows of deaths which have been attributed to Bright's disease.

Dr. Wilkins of Montreal said he had used it and had observed the cumulative action, and mentioned several cases.

Dr. J. C. Wilson of Philadelphia said that sudden death can come from other causes as well as digitalis; he had never seen the cumulative effect and had never given it in pneumonia as a routine measure. He does not give it in fever; it does no good and often does harm. It interferes with digestion. He gave 15 minims three times a day for three or four weeks and observed no effects. He always followed two rules in giving digitalis; one was he stopped it after a few weeks and then began again after a few weeks rest; he also gave it in moderate doses.

Dr. J. T. Whittaker of Cincinnati has seen cases of the cumulative effect, and he has stopped it on account of nausea and vomiting occasionally. In his city it was quite common to give it in the crisis of pneumonia.

Dr. Charles Carey of Buffalo has never seen any poisonous effects from it, and he mentioned several cases which had been taking doses continuing for longer periods with no bad effects.

Dr. A. McPhedran of Toronto asked if these effects were due to the retention of digitalis in the system, or to over-stimulation of the heart, and he felt very sure that in cases which were affected by the drug there was also a decreased secretion of urine, which would account for the bad effects.

Dr. H. A. Hare said in conclusion that Dr. Osler had proved just what he did not intend to prove; he wished to state clearly that it was the effect that was cumulative, and not the drug. He thought that the various opinions expressed at this meeting were due to the difficulty in obtaining a uniform preparation of digitalis, for he had examined a number of prepara-

tions and had found that the proportion of active principles, such as digitonin and digitoxin, varied greatly.

THURSDAY, MAY 6—THIRD DAY.

Dr. J. T. Edes of Jamaica Plains then read a paper entitled "The Relation of Neurasthenic Conditions to the General Nutrition," of which the following is an abstract: Gain in body weight and improvement in neurasthenic symptoms usually go together, but there are enough exceptions to the rule to show that the nervous nutrition is something more than a mere sample of the general. The more symptoms approach in character the "fixed idea" of the insane the less amenable are they to the beneficial effect of mere somatic therapeutics. The blood color (Fleischl) of a considerable number of neurasthenic patients corresponded quite closely with that of the employes in the same institution. It was not possible to establish any correspondence between the degrees of anemia and the intensity of nervous symptoms. Measurements of the excretion of uric acid afford no sufficient ground for supposing that neurasthenic symptoms depend in any way upon this substance. There may be such a thing as a chronic uric acid headache, but the ordinary continued neurasthenic headache is not of this character. Indian determinations have not been numerous enough to be decisive, but do not seem to indicate that the poison consists in this substance or in those which may be transformed into it. If neurasthenia is a toxic condition, the poison has not yet been satisfactorily identified.

Dr. James J. Putnam of Boston corroborated his statement and said the neurasthenic patients often looked pale and bloodless when they would have a normal amount of blood and hemoglobin. He thought that Haig's writings were attractive but they were devoid of that critical spirit which one would look for in dealing with such an important subject; there were loopholes for error in every step of his theory. Changes in metabolism are affected by the nervous system and normal and pathologic activities are immediately connected with changes in metabolism. When two subjects are so closely connected it is difficult to say which is the cause or which is the effect or if it is merely a coincidence.

Dr. Norman Bridge of Los Angeles, Cal., read a paper on "Reflex Neuroses of the Abdomen." His object was to set forth from a clinical standpoint a large number of those reflex neuroses or symptoms, some of which are frequently overlooked and some confusing in diagnosis. These reflexes are hard to understand. They give the patient great annoyance and cause suffering and some simulate grave diseases and continue for months and years. A common one is increased peristalsis of the intestines, causing diarrhea. This form is very frequent; it is the diarrhea of the colon and it is hard to understand why the attacks follow so closely each meal when it is probably from the previous meal. He said that emotion and excitement and even diffidence and fear would bring on this attack and these exciting causes were extra-abdominal. He referred to several cases in which surgeons were taken with these nervous attacks before performing an operation or clergymen were overcome with diffidence and were not able to fulfil their pastoral duties. This trouble was characterized by a form of gas in the intestines after a meal and there is also some indigestion and flatulence and escape of gas with borborygmi. There was often pain in the head especially in women, which was relieved by a cathartic. Mental excitement will also cause these attacks. Another reflex is a slight sciatic pain on both sides which was relieved after a passage. Another reflex which is commonly called "growing pains" is often caused by an overcrowded condition of the stomach and bowels; a free evacuation will stop it. Prurigo of the legs is another reflex from the same cause and is cured in the same way. He then referred to certain rashes of the skin or urticaria from eating crabs, fish, strawberries, etc. Some attacks, such as asthma, are also reflex in character and are caused by a muscular spasm of the lung. He said that some cases of insomnia were successfully treated by an enema at bedtime.

Dr. William H. Welch of Baltimore referred to urticaria as a reflex phenomenon and spoke of Dr. Gilchrist's work in his laboratory. Dr. Gilchrist has studied the class of cases in which there was a redness of the skin after a slight scratch; he cut out some pieces of skin and found on a microscopic examination that five minutes after the irritation there was a certain amount of serum and emigrated leucocytes present and in fifteen minutes there was a large collection of leucocytes. There must be something outside that attracts the leucocytes and it is not clear what it is. The expression "reflex phenomenon" does not explain it altogether but there must be something in this chemotactic action.

Dr. Charles G. Stockton of Buffalo was interested in two points mentioned. One was post-prandial diarrhea which

occurred with sufficient frequency and in a sufficiently regular physiologic course to deserve a name. There was not only hurried evacuation of the intestinal canal after a meal, but later there is gastric anacidity; that is the stomach seems to lose all of its acidity. He has recorded a number of cases in which there was also this reflex, a striking error of refraction of the eye. He does not say that this reflex depends on the the ocular error but he thinks the two must be connected. Another point is painful neuroses in the abdomen and parts below which are caused by a descent of abdominal organs, such as a misplaced kidney. He had seen cures result from fixation of the kidney.

Dr. Francis H. Williams of Boston read a paper on the "Roentgen Rays in Thoracic Diseases." He first spoke of the general principles involved in this X-ray apparatus and described its physical, chemic and physiologic properties. He had found the apparatus especially useful in detecting disease of the lung and he had examined about four hundred cases of lung trouble and had never had any harmful results from the X-rays. He had the patient brought in on a stretcher from the ward and laid upon a table and with the Crooke's tube below and the fluoroscope above he carefully studied the condition of the lungs and heart. He referred to the different powers of resistance of air, water or other media and said that air was more permeable than water. In order to obtain any results from these examinations one must be familiar with the use of the fluoroscope and be acquainted with the appearance of the internal organs in a healthy condition. He showed some beautiful radiographs, clearly indicating some lesions in the lungs and changes in the heart. He had examined principally cases of pneumonia and tuberculosis. He had watched over forty cases of pneumonia and in some the lungs had been normal in appearance for months after an apparent recovery from pneumonia. He showed also carefully the pulsations of the heart and observed that the movement of the heart in beating was more marked at the left side on the base than at the apex.

Dr. R. H. Fitz of Boston then showed some beautiful radiographs of disease of the heart and aneurysm.

Dr. Osborne of the New Haven Medical School reported an acromegaly. A man had come to the New Haven Hospital with an edema of the lower extremities; he grew better and went home. Later he returned and grew rapidly worse and died. He was a man 47 years old and had the disease twenty-three years. He first noticed a ringing in the ears and then there was a gradual hypertrophy of the fingers, toes and of various bones throughout the body. Dr. Osborne exhibited photographs of various parts of the body and of the man as a whole and of the skeleton. He also exhibited some of the bones which showed the changes of the disease. He found that the heart weighed two pounds and nine ounces, which is probably the heaviest heart on record. The thyroid gland was much enlarged and in nineteen cases which he had collected of this disease he found large thyroid glands, and so he thinks that myxedema is closely connected with acromegaly. At the conclusion of his paper the thanks of the Association were extended to him for the exhibition of this case.

Dr. John J. Abel of Baltimore then read a paper on "The Chemical Properties of the Blood-Pressure Raising Constituent of the Suprarenal Capsule." He said that the suprarenal capsule was an organ of vital importance which furnished the blood and vascular system a muscular stimulant. He quoted many authors showing how this gland had been studied and stated that while he had obtained a powder which he exhibited he had not been able to isolate the active principles of the fluid and we do not know exactly what it is.

Dr. William Osler of Baltimore asked if he had examined the commercial products of the market to see if this blood-raising property was present in some of them. He had had several cases of Addison's disease and had had no good effects from remedies so far offered.

Dr. Abel replied that he had not looked into the subject from this point of view but he had no doubt that these commercial products did contain some such substance, as they were very simply made, by drying the gland and pulverizing it.

Dr. Simon Flexner read a paper "On the Occurrence of the Fat splitting Ferment in Peritoneal Fat Necroses." Upon the etiology of peritoneal fat necrosis much light has recently been shed, partly through the findings in cases occurring in human beings and partly through animal experimentation. A study of the cases in the literature would make it appear that the occurrence of fat necrosis was not always due to the same cause. Although infection seems in certain cases to play a part, it is probable that it is not by any means the most important factor. The view has gained ground that the disseminated forms of necrosis met with in the peritoneal cavity, as well as the more circumscribed lesions in the pancreas itself, may

result from a perversion of the pancreatic secretion. Again, since it has been shown that trypsin, when injected into the peritoneal cavity, does not set up this condition, the suggestion that the fat-splitting constituent of the secretion, steapsin, might possibly prove to be the chief cause, has been ventured. In the literature no record occurs of any attempt to demonstrate the presence of this body in the areas of necrosis, and it is possible that investigators were deterred by the belief in its extreme sensitiveness. A suitable human case having presented itself, I undertook to prove the presence of this body in the fat necrosis and its absence from the normal fat. A satisfactory demonstration of this point having been arrived at, I next instituted a series of experiments in order to study more particularly the conditions under which the necroses make their appearance and the length of time the ferment is demonstrable in them. He drew the following conclusions: 1. In peritoneal fat necroses the fat is demonstrable. 2. It is present in the early stages and may disappear later. 3. The ferment is the direct cause, but this can not be proved. 4. The escape of pancreatic secretions is the origin of the necrosis.

Dr. William H. Welch of Baltimore said that several years ago he had brought before the Association a case in which the organisms were present, and it was the first demonstration of the colon bacillus. At that time he made the remark that the organisms had nothing to do with necrosis, and since that this has proved to be true. It is very satisfactory to have these observations so fully confirmed by Dr. Flexner's work.

Dr. A. C. Abbott of Philadelphia then read a paper on "Further Studies upon the Pathogenic Spirilla of the Schuylkill River at Philadelphia," which was the conjoint work of himself and Dr. D. H. Bergey. This was a continuation of the work begun about a year ago, in which he attempted to study some of the organisms of the Schuylkill river. He found that some spirilla were present in the Schuylkill all the year around, also in the Delaware. He had not examined the water of the other rivers, but felt sure that this organism was due to some sewage contamination. He had found 110 varieties of organisms in this water, and he had attempted to classify them, but without any satisfactory results. Some pathogenic organisms were so weak as to be almost non-pathogenic, and some non-pathogenic organisms answered in every other way to the best of the pathogenic tests.

Surgeon General George M. Sternberg, U. S. A., said that these observations at this time, when there was no cholera in the country, were especially valuable. If they had been found at the time of cholera, they would have been thought to be cholera spirilla.

The next papers were "The Effects of Various Metals and Metallic Salts on the Growth of Certain Bacteria," a continuation of a similar paper read before the Association of American Physicians May 30, 1894, by Drs. B. Meade Bolton and W. G. Brown of Columbia, Mo. The zones that are formed by the bacteria around bits of metal laid on plate cultures are due to the fact that the solution of the metal tends to concentrate in one or more zones. Where the concentrated zone of the metal is formed the bacteria fail to grow. Metallic salts act in the same manner as the metals. The more soluble the salt, the more pronounced the action. In the zones where the growth is more pronounced than on other parts of the plate the colonies are usually fewer, but larger in size.

"On the Appearance of Certain Amebic-like Bodies in the Blood of Vaccinated Monkeys (rhesus) and Children and in the Blood of Variola. An Experimental Study," by Dr. Walter Reed, Washington, D. C. Following the introduction of Koch's improved methods, the search for the specific causative agent of vaccinia has been made especially along the line of bacteriologic research. Notwithstanding many claims of positive results, these have in the end proven groundless. During the past ten years, and more especially during the last half decade, the attention of investigators has been turned toward the possibility of the animal nature of the parasite. Van der Loeff, L. Pfeiffer, Rieck, and more recently Ogata, have described minute bodies always present in vaccine and variolous lymph, which they assign to the sporozoa. The first attempt to cultivate the supposed parasite of vaccine lymph was made in 1892 by Guarnieri, who used the cornea of guinea pigs and rabbits for this purpose. After forty-eight hours, epithelial scrapings from the inoculated cornea, suspended in a hanging drop of aqueous humor, showed little shining, slowly ameboid bodies, often with irregular margins, within the epithelial cells. Guarnieri considers these bodies to belong to protozoa, and calls the parasite citoryctes vaccinae. These observations have been confirmed by L. Pfeiffer, von Sicherer, Clark and E. Pfeiffer. Ferroni and Massari have failed to confirm Guarnieri's observations. In 1894, L. Pfeiffer reported the finding in the blood of vaccinated children (seventh day), and

calves (fourth day), and in the blood of variola, ameboid cells (provided with pseudopodia) one-half the size (in the calf), of a red cell, and (in the child), one-fourth the size of a red cell. These bodies are not intracellular, but swim free in the blood. They have a nucleus, and sometimes flagella—which can be stained—appear during the stage of fever and disappear with this. My own experiments confirm in some respects Pfeiffer's observations. Bodies of a corresponding size, and ameboid in character, appear in the blood of vaccinated monkeys about the seventh and disappear about the twelfth day. The same bodies are found in the blood of vaccinated negro children, but were much more difficult to find in the blood of white children, and in several cases of the latter could not be discovered. Bodies of a like nature, though differing somewhat, were found in the blood of three smallpox patients during the height of fever, disappearing later.

Dr. F. H. Williams of Boston, read a paper on "An Epidemic of Cerebro spinal Meningitis caused by Diplococcus Intracellulæris Meningitidis" (Jaeger). This was a study of a slight epidemic of this disease in Boston City Hospital. He had attempted treatment by tapping the spinal sac at the second lumbar vertebra and the fluid which he had obtained had been examined by Dr. Councilman. He would report.

Dr. W. T. Councilman of Boston said that he had studied the fluid from these cases and had found the organisms which Weichselbaum had first described in Vienna. Some of these cases came from the extension of the disease from an acute otitis media. He had found staphylococci, diplococci and streptococci. He had examined seventy-seven cases in which the organisms had been found and he had found it in nine out of twenty cases in the City Hospital and in sixteen out of thirty in the Children's Hospital. He had also examined the other organisms; he had found the spleen enlarged in some cases; he had also examined the organisms in the nasal sinuses and in one case in an abscess of the tonsil. The organisms grow best on blood serum.

Dr. Guitéras had seen two cases which he will record later. One case was a nurse at the hospital and one was a newborn child. The organism was found in the blood and there were no other lesions.

Dr. Williams said in regard to the lumbar puncture that it was very valuable in the diagnosis, but the relief was only temporary and about 70 per cent. of the cases died. The fluid was withdrawn gradually.

Dr. W. T. Councilman said that the exudation in quite a number of cases had a tendency to extend along the course of the cranial nerve and in one case it was visible to the naked eye along the optic nerve extending almost to the eye. In some cases that recovered there was loss of both sight and hearing, and the eye affection was found to be due to an infection from the meninges.

Dr. F. C. Shattuck of Boston said he had seen about fifteen cases and his experience had been that not a child died and not an adult recovered.

Dr. A. A. Smith of New York then reported a case of "Levant Fever." He said this disease has a great many names but this was the one most generally used at the east end of the Mediterranean Sea, where the disease was prevalent. His patient was a woman who lived at Beyrout and her husband was a physician and had seen many cases. She was taken sick on July 4, 1896 and he saw her first in January, 1897. He said the fever would continue for three or four weeks and then there was freedom from fever, and then there was a relapse which was more severe than the previous attack and so on with intervals of freedom; the temperature sometimes being normal, but the fever still continuing in this case. It was resistant to quinin. He exhibited some beautiful drawings of the blood and of the organisms which he said caused this disease and it was characterized by an obscure pigment. He said the parasite was much like Laveran's organism but was not the same thing. In reply to Dr. Shattuck, who asked if he had used arsenic, he said he had used everything except phenic acid, and in reply to Dr. Dock, who asked if there were many organisms in proportion to the blood, he said there were a few now but there had been more formerly.

Dr. Dock said that one would think this was a form of malarial parasite as described by some of the Italian writers. The absence in pigmentation and segmentation would do away with the resemblance to the malarial parasite. We do find it in some fever bodies which looked like the malarial parasite and when Laveran published his observations some German writers said that they could find these bodies in other diseases. They looked too much like the protozoa and the appearance of the colored drawings made him very skeptical. We should be slow in believing that the parasite of Levant fever has been described.

Dr. A. Jacobi then read a paper on "A Case of Adenoma of the Liver with Complications."

Dr. B. K. Rachford of Cincinnati then read a paper on "Lithemia," in which he proposed the following prescription: Sodium sulphate 120 grs. wet salts; sodium phosphate 30 grs. wet salts; sodium salicylate from oil wintergreen 10 grs.; tr. nux vomica gtt. 3; aqua q. s. $\bar{3}$ iv. CO₂ q. s. Take before breakfast. Sodium sulphate 30 grs. dry salt; sodium salicylate from oil wintergreen, 10 grs.; magnesia sulphate, 50 grs. wet salt; benz. lithia, 5 grs.; tr. nux vom. gtt. 3; aqua q. s. $\bar{3}$ iv. CO₂ q. s. Take before breakfast.

Dr. James T. Whittaker of Cincinnati then spoke of the "Earliest Possible Recognition of Tuberculosis." He said it was very important to recognize the disease before the first physical signs appeared. He then reviewed the history of the disease, the prominent symptoms and the treatment which had been used heretofore. He said the use of tuberculin was not sufficiently appreciated and in fact many persons objected to it because they said that a reaction was obtained when tuberculosis was not present. Klemperer said that we had no right to diagnose tuberculosis just because we found bacilli in the body, but this is a poor argument. The use of tuberculin will show the presence of bacilli in the body. In giving this he first administers 5 milligrams, then 10, and as much as 2 centigrams. Virchow's objection was that tuberculin aroused latent tuberculosis and caused the bacilli to spread over the whole body and to disseminate the disease, and it was said to appear more frequently in cases treated with tuberculin. We must not use it in too large doses or too late in the course of the disease. There is a prejudice against it, but it is a valuable remedy. Trudeau, Denison and Klebs all use it in a modified form, and he had had success with it. He had used it in 1,000 cases and had never seen a bad result from its use and regarded it as a safe means of diagnosis. He reported quite a number of cases and said that Klebs, Jr., stated that he got a reaction in cases of chlorosis.

Dr. Shattuck said that it had been used in the City Hospital and he had seen no harm come from it. One difficulty was that persons reacted in which there was no evidence of tuberculosis and in whom no reason for reaction could be found. He knew a patient who had a tumor in the epigastrium and reacted typically; later she died; the autopsy showed a cancer of the stomach and other organs and also at the top of the right lung was a small cheesy nodule which had healed up and had given no signs or symptoms of the disease. If tuberculin is regularly used the number of cases would increase and also the number of recoveries from the disease.

Dr. A. L. Mason of Boston had used it to a considerable extent in the Boston City Hospital and had found it especially valuable in determining whether to operate or not in cases of doubtful tuberculous peritonitis in which a laparotomy was indicated.

Dr. E. A. de Schweinitz of Washington read a paper on "Some Products of the Tuberculosis Bacillus and the Treatment of Experimental Tuberculosis by Antitoxic Serum." A description was first given of two of the products obtained from tuberculosis cultures, one of these a crystallizable acid and its probable bearing upon the progress of the disease. A brief sketch came next of some experiments showing the relationship of the attenuated tuberculosis bacillus to immunity followed by a description of some methods for the production of antitoxic serum and its experimental application. He had tried also injections on the live culture but had found that the serum was the best. Horses are the most favorable animals to use. At no time has his remedy produced toxic effects, as it has been very carefully made.

Dr. D. D. Stewart of Philadelphia read a paper on "The Occurrence of Primary Renal Tuberculosis." The diagnosis, frequency of occurrence, and source of infection, of tuberculosis of the kidney as a primary affection, was discussed, and an unreported case of Dr. Stewart's, in which a limited primary tuberculosis of the pelvis of the left kidney occurred, in a case of chronic nephritis.

Dr. H. A. Hare of Philadelphia read a paper on "A Further Study of some of the Untoward Effects of the Bromids." He referred to Weir Mitchell's paper read about a year ago before the Association and said that at that time he thought that Mitchell's work was original; but since then had found that the subject was an old story to all medical superintendents of insane asylums. He addressed a number of letters to physicians in charge of insane asylums asking if they had noticed bad effects from the use of the bromids and to give their experience. He received a number of replies in which many said that acute maniacal delirium was quite common after the use of the bromids, especially in cases of epilepsy, and these nerve storms are often accompanied by homicidal and suicidal mania.

He thought that the sodium salts was better than potassium salts and said that the poisonous effects are often due to the potassium and not to the bromin.

Dr. H. C. Wood of Philadelphia thought that much of the belief of these statements of medical superintendents of insane asylums rested on insufficient basis. For instance a man has epilepsy and bromid is given him. The bromid does not cause the mania but throws the attack into another channel. He preferred ammonium bromid and said that a quack in New York had succeeded in relieving a case which Dr. Weir Mitchell had failed to benefit and he found in analyzing the medicine, that this quack used the ammonium bromid.

Dr. I. E. Atkinson of Baltimore thought that the bromid of potassium was too much used, that many of these bad attacks would have been observed before and would have occurred more frequently. He could hardly believe that this was the cause of what Dr. Hare says it was. It must be in part an idiosyncrasy.

Dr. Hare said in conclusion that almost every asylum physician had asked him to impress upon the general profession the dangers of giving too much bromid and said that when a case entered their asylum the first thing to be done was to rid the patient of the bromid.

(To be continued.)

Kentucky State Medical Society.

Abstract of the Proceedings of the Forty second Annual Meeting, held at Owensboro, May 5, 6 and 7, 1897.

(Concluded from page 943.)

SECOND DAY—AFTERNOON SESSION.

Dr. W. L. RODMAN of Louisville contributed an excellent paper on lithotomy for stone in the bladder.

Dr. JAMES B. BUDLITT of Louisville made some remarks on hospital beds and demonstrated a new method.

Dr. A. M. CARTLEDGE of Louisville reported a case of Cæsar-section.

Dr. R. B. GILBERT of Louisville read a paper on

SUMMER DIARRHEA IN INFANTS.

Under the name of summer diarrhea, he discussed that form of diarrhea which is so prevalent in hot weather, and which carries off so many infants every summer. A revision of the nomenclature of enteric diseases of infancy was needed at this time, especially on account of our constantly increasing knowledge of the etiology of these diseases. The nomenclature should be simplified in order that physicians in different parts of the country would, by using identical names, be the better able to aid one another in their investigations.

The typical summer diarrhea begins with the first spell of hot weather, when the temperature rises to 70 degrees daily for a week or ten days consecutively. The summer season, in a general way, is a prime factor in the causation of this annually recurring diarrheal epidemic. The solar temperature does not of itself cause the diarrhea, as is evident from the fact that hot weather prevails in the rural districts as well as in the cities, and yet the disease is very rare in the country. Doubtless the poison generated by the growth of bacteria in milk is the direct cause of a majority of the cases of diarrhea in infants. It is not surprising therefore that Dr. Starr has given the disease the significant name of "sub acute milk infection." It may be briefly stated that the annually recurring epidemics of summer diarrhea are mainly due to the action of poisons generated by the growth and multiplication of bacteria which are taken in by the air and food, chiefly milk. Acid fruits and vegetables, and milk containing an excess of casein fed to infants, will occasionally cause diarrhea. The symptoms of this form of diarrhea are easily recognized. The prognosis will be influenced by the surroundings of the patient and family history.

From what we know of the causation of this disease, proper preventive treatment would save many lives. Fresh air and wholesome food are essential as preventive measures, and indispensable as curative measures. The question of infant feeding is perplexing. An infant sick of an inflammatory diarrhea should, for the time being, be taken off milk diet entirely. The intestinal bacterial flora multiply and thrive best in milk. If milk be excluded from the food the character of the germs rapidly and radically change. Milk should be excluded for, at least, three days, in which time the diet should consist of fresh egg albumin with a small portion of common salt. The white of a fresh egg beaten up with crushed ice and "a pinch of salt" is most acceptable to the stomach and is sufficient nourishment. Pure sterilized water may be given freely. Soups, meat broths and starchy mixtures should be rigidly excluded. An old fashioned, and yet excellent and palatable, food is fat country bacon. Bacon

broiled half done will be eaten by an emaciated infant with a hearty relish, and the author has seen it work wonderful changes both as a diet and as a remedy in protracted summer diarrhea.

SECOND DAY—AFTERNOON SESSION.

Dr. W. R. BLUE of Louisville read a paper entitled

SPECIFIC URETHRITIS, ITS POSSIBILITIES AND PREVENTION.

The author said that this disease was first described by the Chinese emperor, Hoang-Ty, 2637 B. C., and from that time until the present this misnamed disease, its complications and sequelæ, had been written and talked about more than any affection known to the profession. The researches of such men as Tait, Martin and Olshausen had confirmed the correctness of Noeggerath's views, who considered specific urethritis incurable. Early in life the essayist heard an eminent surgeon, one of his teachers, say that if he were doomed to have a venereal disease, he would rather have syphilis than specific urethritis. The speaker marveled and disbelieved, but said that he now knows that if his teacher included women in his thoughts of the subject, he spoke truly. Syphilis was a relatively harmless disease. It might cause discomfort and distress, and even pain, but he doubts if it ever kills women.

The author quoted from the contributions to the literature of specific urethritis by Lawson Tait, Olshausen, Martin, Neisser, Finger, Lydston and several others.

Dr. FRANK C. WILSON of Louisville considered

SERUM THERAPY IN TUBERCULOSIS.

The author's experience with the use of antitubercular serum and the favorable reports of a large number of physicians who have been using it, leads him to the following conclusions:

1. That we have in antitubercular serum a remedy potent for good when used in suitable cases and with proper antiseptic precautions in its administration.

2. In the earlier manifestations of tubercular infection the results are uniformly good.

3. Even in the more advanced cases, where the microscope fails to disclose the presence of other microorganisms, we may expect marked improvement.

4. Even in cases of mixed infection we may note the disappearance of the tubercle bacilli, although the other microorganisms may continue to multiply unless combatted by appropriate means.

5. In glandular and lymphatic tuberculosis the reduction in size of the enlarged glands may be noticed, but intestinal secondary infection is very apt to occur, and this is influenced very little by the serum.

6. The use of anti-tubercular serum must not preclude other and valuable methods of treatment, and the use of other forms of antitoxins appropriate to the individual cases.

Dr. FRANK BOYD of Paducah read a paper on direct illumination of the pleural cavity for the location of foreign bodies, and reported an interesting case.

Dr. T. C. EVANS of Louisville contributed a paper on

ACUTE SUPPURATIVE INFLAMMATION OF THE MIDDLE EAR.

Before speaking of acute inflammation of the middle ear, he briefly mentioned a few points in regard to its anatomy. Acute inflammations of the tympanic cavity are usually divided into acute catarrhal otitis media, and acute suppurative otitis media; yet the distinction between the two is often so small as to make the differential diagnosis difficult or even impossible. In acute catarrhal otitis media there is hyperemia and swelling of the mucous membrane lining the tympanic cavity and covering the ossicles. This is followed in a certain proportion of cases by an exudation of serum and mucus into the middle ear, and is then spoken of as an exudative catarrh. The disease is common to all ages, but it is much more frequent in childhood. It is caused by diseased conditions of the mucous membranes of the nose, naso pharynx and pharynx. Adenoid growths probably head the list, and then follow the exanthematous diseases, as scarlet fever, measles and diphtheria.

The indications are to relieve pain, to remove the exudation by paracentesis or by absorption, to restore the proper tension of the membrana tympani and ossicular chain, to prevent, if possible, a recurrence of the trouble by the removal of the cause. Unless pain is unusually great, it can be controlled by the application of heat, either irrigation with hot water, or the application of hot water bags or hot salt bags. Poultices are unsatisfactory, uncleanly, and possess no virtue aside from the heat. Every precaution should be taken both before and after the paracentesis to prevent infection, otherwise we will have a purulent instead of a catarrhal otitis media.

The proper tension of the membrane is restored by inflation through the Eustachian tube, preferably by the Politzer method.

The inflation relieves the feeling of discomfort, if not the actual pain, increasing the hearing, lessens the intra-tympanic congestion, as well as the tinnitus. Inflation should be practiced every day in the beginning of the attack, as the trouble begins to subside, two or three times a week until recovery is complete. As the acute otitis subsides, the attention of the physician should be directed to the condition of the nares, nasopharynx and pharynx, and any obstruction to free nasal respiration should be removed.

The essayist then dwelt upon the surgical treatment of suppurative inflammation of the middle ear, saying that the location, extent and direction of the incision had not received the attention its importance demands. Too much had been left to luck, too much to a wild stab in the dark, without reference to either anatomy or physiology. Such reckless incisions made without regard to location, extent or direction, not only failed to relieve pain or afford drainage, but might permanently impair the integrity of the ear by fracture of the ossicular chain.

Dr. J. A. STUCKY of Lexington followed with a paper on

CHRONIC SUPPURATION OF THE MIDDLE EAR,

in which he said that this disease had long been a "thorn in the flesh" of both the general practitioner and specialist, and the old idea still prevailed among some that "a discharge from the ear should not be interfered with, that nature will effect a cure," etc. Acute suppurative otitis media, if not carefully and intelligently treated, as a rule results in chronic suppuration, and the larger per cent. of these cases are undoubtedly the result of lack of proper attention to the first "earache and abscess in the ear" in childhood.

The author believes the causes of chronic otitis media to be: 1, retention of pus; 2, chronic disease of the naso-pharynx; and infection primarily takes place through the Eustachian tube. He thinks the middle ear is rarely infected through the external auditory canal, except as a result of traumatism or extension of an external otitis to the drumhead.

Why we should tolerate the presence of dead bone in the tympanic cavity, he could not understand, and from the results obtained in thirty-six cases in which he had removed one or both ossicles and curetted the attic, he is convinced that ossiculotomy, if caries exists, is not only the most conservative, but the most rational treatment for the majority of cases of chronic suppuration of the middle ear. The object to be attained is the thorough removal of necrotic and carious matter, and to obtain perfect drainage, and I believe this can be successfully done through the auditory canal. Ossiculotomy, when thoroughly done, affords efficient drainage, and renders thorough cleansing easy. As a result, material improvement is noted in the hearing by exposing the stapes to sound vibrations, unless the latter is immovable on account of adhesions. In every case we should be prepared to do the Stache-Swartz operation, if we find that necrosis has extended into the mastoid cells, or if on account of a narrow meatus and canal we find it impossible to obtain thorough and complete drainage and render cleansing and topical applications easy. The operation is done under general anesthesia, and the patient is up and out attending to his duties, usually in from two to four days.

The after-treatment consists of cleansing and facilitation of drainage by use of narrow strips of gauze introduced well into the cavity. This is to be kept up until the parts are thoroughly healed. The results obtained in the thirty-six cases operated upon by the essayist were: Cessation of the discharge; relief of fulness, dizziness and general uneasiness, especially in the diseased ear; slight to marked improvement in the hearing, and improvement in general health.

THE INTRACRANIAL COMPLICATIONS OF SUPPURATIVE DISEASES OF THE MIDDLE EAR.

This was the title of a paper by Dr. J. MORRISON RAY of Louisville, which was read by Dr. Wm. Bailey in the absence of the author. Intracranial complications of ear diseases were divided into: 1, those affecting the membranes surrounding the brain, as meningitis, or subdural abscess; 2, those affecting the substance of the brain, either the temporal lobe of the cerebrum or the cerebellum, producing pus accumulation; 3, those in which pyemic symptoms result from the pyogenic process perforating the walls of the lateral sinus in the sigmoid groove.

Abscess of the brain tissue resulting from the ear is generally found to involve the temporal lobe of the cerebrum by extension from the middle ear through the roof of the attic or antrum, opening directly into the middle cranial fossa; or the cerebellum by necrosis occurring through the back wall of the mastoid, or through the internal auditory meatus, into the posterior cranial fossa. The frequency with which the abscess is situated in the cerebrum indicates the proneness for the suppuration to extend

through the tympanic roof. Barr, in 76 cases found abscess 55 times in the temporal lobe, 13 times in the cerebellum. Keorner, of 100 cases, found 62 in the middle cerebral lobe, 32 in the cerebellum, and in 6 cases both the temporal lobe and the cerebellum were involved. The investigations of Gowers and others further show that nearly three-fourths of all brain abscesses are of otic origin.

In considering an operation, the primary seat of the suppurative process should not be overlooked; therefore the first step should always be to open the mastoid antrum and cells, and thence the middle ear, getting directly at the source of pus formation. If a sinus is found leading through the roof of the antrum or attic, this may be enlarged and the brain cavity opened, or an opening can be made with the trephine. This is best made one and one-half inches above and an inch behind the external canal. In this way we are able to explore the temporal lobe, the most frequent seat of abscess. If, after entering the mastoid, an opening is found leading toward the sigmoid fossa, it is better to enlarge this and lay bare the lateral sinus, as it lies in the sigmoid depression. If evidences of pus surrounding it are apparent, and if pulsation of the blood column is absent, the sinus should be opened and the thrombus thoroughly removed.

Pritchard advises the following in all cases: 1, thoroughly open the antrum and explore the mastoid cells; 2, failing to find sufficient evidence to account for the symptoms, the wound in the skull should be enlarged backward, expose the middle and posterior fossæ above and below the lateral sinus, which should be explored by means of a hypodermic syringe, and subdural abscess looked for; 3, if a clot is found in the sinus, the internal jugular should be tied, the sinus opened and thoroughly cleared of its contents; 4, if suspicion of cerebral or cerebellar abscess exists, exploratory puncture should be made, and, if pus is found, it should be evacuated.

Dr. S. LAMBERT of Owensboro read a paper entitled ENDOCARDITIS, A SECONDARY CAUSE IN THE PRODUCTION OF VALVULAR DISEASES OF THE HEART.

Endocarditis is always a secondary disease, the result of the action of some infectious process, for it is now an established fact that it results from the colonization of microorganisms of infectious diseases upon or beneath its surface. To have an endocarditis, we must have a preceding diseased condition or cause. This cause may be the organisms themselves or their toxins. It is the character and location of the morbid process that the author wishes to impress more than the primary or secondary effect. Endocarditis on special places of the valves is often encountered, but the author doubts if ever a general endocarditis occurs by reason of traumatism. Special diseases more often produce it than others, and what is more peculiar, the mitral and aortic valves are almost exclusively the ones to suffer. Furthermore, it affects the mitral valve on its auricular side and the aortic valve on the ventricular side.

Dr. JAMES T. RINEHART of Springfield followed with a paper entitled

TREATMENT OF PUERPERAL INFECTION

and reported cases. He first considered prevention as the most important part of the treatment. Secondly, he dwelt upon the curative treatment of puerperal infection. The preventive treatment, said the author, sums itself up in one word, asepsis, no matter how it may be attained. The physician should never undertake a case of labor without having himself free from all germs of infection. If he has been attending such a disease as erysipelas, he should thoroughly disinfect himself and make an entire change of clothing.

In closing, the author referred to the administration of hypophosphite of sodium. He believes he has received benefit from it in two and a half grain doses in these cases, repeated at intervals of three to four hours. It seems to act as a blood antiseptic, and as an eliminative as well. It is used by physicians in the South to prevent malarial intoxication. In like manner, the essayist believes it exerts an antiseptic action against blood infection in cases of puerperal sepsis. He believes it is especially useful in phlegmasia alba dolens.

Dr. LEON L. SOLOMON of Louisville read a paper on "Proprietary Medicines—Evils of the Profession."

Dr. J. T. DUNN of Louisville read a paper on "X-Rays in Surgery," and reported several interesting cases. He also exhibited several skiagraphs of cases showing the location of foreign bodies imbedded in the tissues. These cases were operated upon and the foreign bodies removed with excellent results.

The following officers were elected for the ensuing year:

President—Dr. Joseph M. Mathews, Louisville.

First Vice-president—Dr. W. W. Richmond, Clinton.

Second Vice-president—Dr. B. M. Smoek, Oakland.

Treasurer—Dr. J. B. Kinnard, Lancaster.
 Permanent Secretary—Dr. Steele Bailey, Stanford.
 Librarian—Dr. Frank Boyd, Paducah.

After resolutions of thanks to the president, secretary and treasurer for their efficient services had been adopted, the Association adjourned to meet in Maysville in May, 1898.

Medical and Chirurgical Faculty of the State of Maryland.

Ninety-ninth Annual Session, held April 27 to 30, 1897.

FIRST DAY—DAY SESSION, 12 M.

Dr. Osler delivered the president's address entitled, "The Functions of the State Faculty." This Society, which was incorporated in 1798 and called a Faculty, has only one other counterpart in the English-speaking land, that is the Faculty of Physicians and Surgeons at Glasgow. The Medical and Chirurgical Faculty was formerly a licensing body; the Glasgow Society is also a licensing body, but the word "faculty" at the present day is more exclusively applied to indicate men engaged in teaching. Physicians have less appreciation of the value of the organizations than the members of other bodies, and in large cities weakness results from the breaking up of cliques and coterie, the interest of which takes precedence over others of wider and more politic character. Jealousies and misunderstandings are not unknown and there is a every-man-for-himself influence against which this Faculty is protesting. No class of men needs friction so much as physicians; no class gets less, as the daily round of the busy practitioner tends to develop egoism of the most intense kind, to which there is no antidote. A few set-backs are forgotten, all mistakes are often buried and ten years of successful work tends to make a man too dogmatic and intolerant of correction and abominably self-centered. To this mental attitude a medical society is the best corrective and a man misses a great part of his education who does not get knocked about a bit by his colleagues in discussion.

The Faculty has given us today a program which is varied and interesting and which should arouse in you a desire to participate in the discussion. These are days of unification and consolidation and the question has been raised by several members whether the usefulness of the Faculty could not be enormously increased by uniting as sections of the Faculty of various medical societies at present in existence in this city. It would add strength and dignity, and it would make the State Faculty much like the New York Academy of Medicine, or the Philadelphia College of Physicians. The county members could often take part in this extended meeting and in that way the relationship with the Faculty would be closer than it is at present. Unlike many other State organizations this Faculty has an important library, which was founded early in 1830. These books are valuable. A physician who does not use books and journals, who does not need a library, who does not read one or two of the best weeklies or monthlies soon sinks to the level of the cross-counter dispenser. To maintain a library costs money and the members in many ways can help by bringing in new members and by joining the Book and Journal Club of the Faculty. Charles Frick was a benefactor to the library, the men who honored his name have been most liberal in contributing. The Faculty will soon celebrate its centennial and in two years, when that event takes place, not only should the small debt for our building be wiped out, but a large amount should be subscribed from physicians and from friends of physicians to enable us to put up a larger building and strengthen our society. Many of us earn a modest competence and can afford to contribute in a way to the State Society's support.

Dr. E. N. Brush, Superintendent of Sheppard Asylum, then made some remarks on the "Condition of the Dependent Insane in Maryland and Suggestions Concerning their Better Care." He said that the insane were the children of the State and as such should be taken care of by the State. The number of the insane in Maryland is hard to say, but probably about two thousand. A great many of them are in jails and almshouses and are under such mechanical restraint, but if in a hospital it would be considered a reflection on the institution. The State lunacy laws are bad. No sane person should be sent to a lunatic ward. Commitments should be made under very strong and plain laws and the State should exercise full supervision over the dependent insane. The proportion of attendants to the insane was entirely too small.

Dr. Henry M. Hurd of the Johns Hopkins Hospital made some remarks on the "State Supervision of the Care of the Insane and the Inspection and Regulation of Institutions." The Lunacy Commission is suffering from defective laws; the State should see that care is taken of their insane for the protection of society at large as well as for the

persons insane. A large sum of money has been appropriated for the insane and it is due the tax-payers to see that it is properly expended and during a person's insanity his property should be well managed. If the State undertakes to care for the insane the work should be done well. The executive officer of the Lunacy Commission should give his whole time to his work and carefully examine all institutions and almshouses. Then there are no reliable statistics. The Commission report says the insane are clean and comfortable, but nothing is said about the treatment. They require the best medical attention and professional nursing. The nursing of the insane in Bay View Asylum is commended by the Commission, yet every one knows that there is a large number of insane and few attendants and the nursing is very faulty. No State is so lacking in its laws relative to the care of the insane as Maryland. At least none of the Northern States. The almshouse is no place to keep insane persons. The physicians to these almshouses are usually appointed by politicians and take very little interest in their work. As these cases are often curable there should be something more done than simply giving them food and clothing and letting them roam around.

Dr. William Lee, Secretary of the Lunacy Board, then read a paper on the "History of the Steps taken for the Amelioration of the Condition of the Insane by the Lunacy Commission since its Organization." He referred to the amount of time which was given to the discussion of this subject before the Faculty four years ago, and then gave a brief history of what had been done. The Lunacy Commission was organized in June, 1886, and immediately sent out to every public institution for the insane in Maryland, including almshouses, notifying them of the formation of this Commission and the proposed visit to each institution in the State. In October of the same year the first quarterly meeting was held and the reports read showing what was demanded of county almshouses for the care of the insane. Blank forms were furnished each almshouse to be used in making reports of the mental insane or idiotic. Since this time institutions where insane were kept have been changed, new asylums having been erected and altogether great improvements have been made. In the second year a resolution was passed that hereafter all plans for new asylums should be submitted to the Lunacy Commission. Feeling that the institutions of the State were not large enough to accommodate a great number of the insane, the Commission obtained more money and made an addition to the Maryland Hospital for the Insane. The inmates were also allowed the use of the mails. Night attendants were also provided to prevent suicide, and in 1888 the asylum and training school for the feeble-minded was erected at Owings Mills. After five years of existence the Commission was able to say that no one was unduly restrained or secluded in any institution in the State. Separate buildings were then erected for the criminal insane and suggestions for building a hospital for the epileptic insane were also made. The need of a detention hospital was especially recommended and precaution was taken against outbreaks of fire. The Commission called attention to the need of a reformatory for the need of the inebriates.

Dr. George H. Rohé then submitted a paper on the "Economics of State Care."

In the discussion which followed Dr. George J. Preston said that the subject was of far too much importance to let pass by. He remembered ten or twelve years ago Dr. Savage of London, the well-known alienist, told him that the classification of the insane in Maryland was most remarkable, being divided into white and black. He had reference to Bay View Asylum, which in its early days was large enough, but the insane department of which has grown out of date. There is much to be done for the insane. The State of Maryland is very far behind in their treatment. The number of insane is a matter of doubt; we should be able to say exactly how many there are, especially if we are to have a hospital for acute and chronic cases. This all means a great deal of work for some one. These papers will be productive of some good. If the profession does not take an interest in the insane no one else will, and if the profession does, then the result will be felt.

Dr. Charles G. Hill does not think the aspersions against the Lunacy Board are warranted. We have much to do yet to help the insane in Maryland, but that this State is behind all others we very much doubt. Some of the northern and wealthier States may treat their insane better, but on the whole we take better care of ours than many others. Again, reflection upon the law he thinks is all wrong, for he thinks the laws have been well kept and no sane person has ever been detained as insane. But there are plenty of persons who are supposed to be sane who should be confined. He knows of quite a number of paranoiacs in this city.

Dr. J. C. Clarke said that he thought the insane were very

well cared for in Maryland and that the laws were well kept.

Dr. I. E. Atkinson thinks the discussion is not taking the course it was intended; it is not a charge against any one; he knew that the care of the insane was not perfect, but he was surprised to hear Dr. Hurd say that things were as bad as he stated and can hardly believe that the condition of affairs were so bad.

Dr. Mary Sherwood said there was great need for a better care of the insane at Bay View Asylum. She said there was sometimes only one, two or three attendants to sixty patients. There were 400 in the insane department and also 100 more harmless imbeciles who were scattered throughout the building.

Dr. Smart considered the commitments faulty and thought the laws ought to be changed.

Dr. Lee—Some said it was very difficult to get the statistics, as if the Board was at fault. It is very hard to get statistics anywhere. The blanks are distributed and sent to the superintendents of each asylum, or to the physician of each almshouse, and if he would attend to his business and promptly return these blanks filled, the statistics would be very complete. It is only the Board's duty to inspect the statistics which they receive from the heads of the different institutions. Most physicians to the almshouses take no interest because they are politically appointed and from these he is to get statistics.

Dr. Brush said that in order to make any progress we would first have to educate the profession and then the profession would have to educate the public. He referred to a visit he had paid Bay View Asylum several years ago at the request of the Mayor of Baltimore and spoke of the crowded condition there and lack of attendants.

Dr. Osler said that if the Committee from the Faculty and from the Neurological Society would go down to Annapolis and confer with the politicians their results would be better.

Dr. S. J. Fort then related a case of habit spasm in a boy 13 years old, who about a year before had been treated brutally by a teacher who took him by the heels and shook him with his head down until he had a "crick" in his neck, at the same time giving him severe fright. He was a strong well looking boy who from this treatment had developed a general jerking of almost every muscle in the body particularly of the legs, neck and shoulders. He laughed at anything and often at nothing, he talked incessantly and was rarely still. His sleep was unbroken. He was taken to Dr. Fort's Asylum for the Feeble-Minded and was given perfect freedom and allowed to run around the place so that he gradually improved and is now almost well. He was given no medicine. His mother was said to be very nervous, but there was nothing very strong in his family history.

Dr. A. L. Hodgdon then read a paper on "Alcoholic Insanity and Excess." It was discussed by Dr. Charles G. Hill.

EVENING SESSION, 8 P.M.

The special subject for evening, "Peritonitis," was opened by Dr. Simon Flexner, who said that the subject was an extensive one and the manner of approaching it was difficult. He spoke of the pathology and etiology. The peritoneum is able to resist a great deal; it can dispose of foreign substances up to a certain limit. Not all parts of it carry on absorption but only a limited part, that near the central tendon of the diaphragm. Stomata between the endothelial cells do not exist, but fluids may pass through and even solids sometimes escape; they are carried through by cells. Some substances interfere with this power of absorption but quite an amount can be absorbed and even bacteriologic organisms can be destroyed as long as the peritoneum is intact. At the Johns Hopkins Hospital he had a careful record of 110 cases of acute peritonitis in man with the bacteriologic examination and these cases were divided into certain groups. We must admit first of all an idiopathic or primary peritonitis; twelve idiopathic cases were in this number. In all these cases there were preëxisting conditions predisposing to this peritonitis such as chronic heart disease, chronic kidney disease, etc. Persons subject to chronic diseases are more liable to bacteriologic infection. In several cases the peritoneum was one of several serous surfaces involved in the body. There were thirty-three cases of exogenous peritonitis in which the invasion was from without and in these cases laparotomy had been performed and certain operations had been done. Finally there is an endogenous form in which the infection is from within, it is an intestinal form. Fifty out of 110 cases which he found recorded were in the intestinal tract, from a perforated appendix or some such cause. In studying the bacteriology of these cases it was interesting to note that in the first group the staphylococcus aureus and the streptococcus were present as mono-infections. In the second group there are some mono-infection and many poly-infec-

tions, such as the staphylococcus and the streptococcus and the colon bacillus, etc. In the third group it usually comes from some injury to the intestines, there is a poly-infection such the streptococcus and the colon bacillus together. Septic and suppurative peritonitis are terms used as if they were distinct conditions. Peritonitis in the absence of the microorganism is very rare, but it may occur. The fibrino-purulent form is the one more usually met with. The mycotic form is one in which the symptoms run such a rapid course that there is little time for the formation of bacteria and there is very little reaction on the part of the peritoneum. This division, however, is not necessary.

Dr. S. C. Chew then spoke of the "Diagnosis of Peritonitis." The diagnosis of peritonitis is in some cases one of the simplest problems which as physicians we can encounter and in others one of the most difficult that can confront us and between these extremes there are very many degrees of comparative difficulty. In general when the typical and clinical symptoms are present a diagnosis is easy. The decubitus, the flexion of the knees on the abdominal walls, the anxious and somewhat drawn physiognomy with acute abdominal pain and great tenderness, tympanites, elevation of temperature, quick, small and wiry pulse, all point very clearly to the diagnosis of peritonitis. They are not always this clear; there may be many symptoms lacking. In arriving at a correct diagnosis the history of the patient is very important. The principal affections which might be confused with peritonitis are: 1. An extreme degree of tympanites which occurs in typhoid fever; 2. A condition of acute enteritis or entero-colitis; 3. Hysterical abdominal pains; 4. Intestinal obstruction in which there is more or less pain.

Dr. Charles M. Ellis of Elkton then spoke of the "Medical Treatment of Peritonitis." It is not easy to say when a case of peritonitis belongs to the physician and when one belongs to the surgeon. The tendency is to believe that all inflammations are suppurative and therefore of bacteriologic origin, but not when the bacteria can gain access to the peritoneum. Most cases are traumatic from simple ulcers of the stomach, typhoid ulcers, appendical rupture, ulceration of solid organs, the breaking down of pus sacs near the intestines. In all cases the cause is not so clear, therefore the line of demarcation between medical and surgical peritonitis is not easy to be drawn. Peritonitis that has gone for ten days is more apt to get well than to die, therefore operations after this time are very apt to be successful and recoveries more frequent than is commonly supposed. The first indication of the medical treatment of peritonitis is to give rest to the parts and nature promptly undertakes this by an exudation which keeps every part at perfect rest, a recumbent position with flexed limbs, the head and shoulder being elevated, gives the best rest. A mild saline cathartic should be given at the outset, little food should be given by the stomach and opium is used for the relief of pain. Blood-letting is rarely ever practiced.

Dr. Randolph Winslow then spoke of the "Surgeon's Treatment of Peritonitis." The surgical treatment of peritonitis ought to antedate the disease. If delayed until acute peritonitis is actually in progress the time for successful interference in the vast majority of cases is passed. We ought therefore to be zealous in the early interpretation of those phenomena which point to the onset of this disease and should promptly use efforts to prevent its spread or to forestall its development. All cases of appendicitis ought not to be allowed to go beyond twenty-four or thirty-six hours without operation. When the characteristic symptoms of appendicitis are evident operation should not be delayed. When an inflammatory mass is felt through the abdominal walls there is no time for delay.

Dr. J. M. T. Finney reported several cases from the Johns Hopkins Hospital and also related the results from his experiments on dogs showing how peritonitis artificially produced could be cured if operation were undertaken before a certain time in the dog. This was six and one-half days.

Dr. T. A. Latimer agreed in part with Dr. Ellis and said he did not believe that an operation should be done at the very beginning.

Dr. A. K. Bond said that we should not neglect purgation. This paper was further discussed by Drs. Tiffany, Uhler, J. T. Smith and Winslow.

(To be continued.)

Unsuspected Causes of Rebellious Neuralgias.—When sciatica or neuralgia persists for a long while, uninfluenced by treatment, some osseous lesion of the skeleton may prove the cause. Moutard-Martin describes a case of this kind which lasted two years before it was traced to an iliac osteo-sarcoma. Siredey and Grognot have likewise observed Pott's disease develop after months of a persistent and rebellious neuralgia, or more or less complete paraplegia.—*Presse Méd.*, February 27.

SELECTIONS.

Smallpox Among the Unprotected Aborigines of Canada.—Mr. Pugin Thornton, in an article in the *Lancet*, writes concerning the effects of smallpox on a nation or tribe unprotected by vaccination. He quotes Sir William Butler's statements in his book "The Great Lone Land," as to the Indians of the Saskatchewan district. "Smallpox, in its most aggravated type, had passed from tribe to tribe, leaving in its track depopulated wigwams and vacant council lodges; thousands (and there are not many thousands all told) had perished on the great sandy plains that lie between the Saskatchewan and the Missouri. They knew nothing of this terrible disease; it had come from the white man and the trader. For eighty years these vast regions had known at intervals the deadly presence of this disease, and through that lapse of time its history had been ever the same. The camp moved away, but the dread disease clung to it—dogged it with a perseverance more deadly than hostile tribe or prowling war party; and far over the plains the track was marked with the unburied bodies and bleaching bones of the wild warriors of the West. The summer which has just passed had witnessed one of the deadliest attacks of this disease. Fort Pitt, one of the Hudson Bay Company forts, about 1,000 miles from Lake Superior toward the Rocky Mountains, was free from smallpox, but it had gone through a fearful ordeal; more than 100 Crees had perished close around its stockades. From a spot many marches to the south the Indians had come to the fort in midsummer, leaving behind them a long track of dead and dying men over the waste of distance. 'Give us help,' they cried, 'give us help, our medicine men can do nothing against this plague; from the white men we got it, and it is only the white man who can take it away from us.' But there was no help to be given, and day by day the wretched band grew less. Then came another idea into the red man's brain: 'If we can only give this disease to the white man and the trader in the fort,' thought they, 'we will cease to suffer from it ourselves.' So they came into the houses dying and disfigured as they were, horrible beyond description to look at, and sat down in the entrances of the wooden houses, and stretched themselves on the floors, and spat upon the door handles. It was no use, the fell disease held them in a grasp from which there was no escape, and just six weeks before my arrival the living remnant fled away in despair. I now enter upon that portion of the Governor's instructions which had reference to this epidemic of smallpox. In the immediate neighborhood of Fort Pitt two camps of Crees had established themselves, at first in the hope of obtaining medical assistance, and failing in that—for the officer in charge soon exhausted his slender store—they appear to have endeavored to convey the infection into the fort. It is singular that only three persons within the fort should have been infected with the disease, and I can only attribute this to the fact that Mr. John Sinclair had taken the precaution early in the previous summer to vaccinate all the persons residing there," having obtained the vaccine matter from a Salteaux Indian who had been vaccinated at the mission of Prince Albert, presided over by the Rev. Mr. Nesbit, some time during the spring, and yet there are anti-vaccinationists who are willing and ready to go on the stand and testify that variola is a mild disease, and one that is not necessarily fatal in the unprotected.

Chinese Medicine.—According to Dr. Paul d'Enjoy the Chinese doctors both prescribe and sell their remedies. They have a variety of tricks of trade to make their products attractive. They have luxurious shops, and mollify with licorice and other excipients their badly made and vilely tasting pills. These pills are enclosed in capsules of wax as large as pigeon's eggs, which preserve the compound from contact with the air, and are broken when the remedy is taken. Special preparations are

sent out from the large shops of the principal commercial centers. Among the most popular of the specialties are the little-brick-red cholera pills, composed of mangosteen bark and various tropical essences, such as santal, eaglewood and calumba. The Dau-nhu-y is a medicinal oil which produces excellent effects in headaches, and generally in cases of brain weariness of every kind. It is rubbed on the temples, and is inhaled by strong breathing, after having been rubbed upon the nostrils. Relief is obtained through the cold which its evaporation quickly produces. The basis of the preparation is camphor, and, as a whole, its effect may be compared to that of the headache pencils familiar in our drug stores. Chinese medicine is chiefly based on plants, and is taught in books which are often very ancient. In his practice the doctor strictly follows the methods of the master by whom he has been taught. With a very grave face, his eyes protected by large spectacles of thick glass, the old physician feels the pulse of his patient, and never fails to make him show his tongue. Next he examines his eyes, and asks a series of questions, the answers to which will help him out in his diagnosis. Then he writes his prescription on a piece of rice paper and hands it to his pupil, who proceeds to compound it. Generally the prescription is made from the directions in some book, which are simply referred to by name or number. The pupil goes to the book for directions. The seeds, herbs, leaves and stems, the essences of which are to be combined to form the remedy, are generally weighed out or measured, and given to the patients with directions to boil them at home with a prescribed quantity of drinking water to a measure which is exactly indicated: "Put all these plants into an earthenware pot with a large glass of water and boil them over a bright fire down to a teacupful; then strain carefully and drink hot." The remedies are all taken in bed, and rest or sleep, if possible, is recommended. The potions so administered have very powerful effects.

A Young Medical Explorer.—Arthur Donaldson Smith, M.D., of Philadelphia, is the author of a book of travel in Eastern Africa that has been described as the most important since that in which Stanley narrated the doings of the Emin Pasha Relief Expedition. Dr. Smith is not yet 35 years old, having been born in the city above named in 1864, the son of Jesse Evans Smith and Martha J. Knight. The current number of *Book News* says he entered the University of Pennsylvania in 1881, and was graduated in the class of 1885. He studied at Johns Hopkins University from 1885 to 1886; the Harvard Medical School, 1886 to 1888, and the University of Heidelberg from 1888 to 1890. This general training bred in him an interest in science rather than in his profession, and after a brief period of practice, he addressed himself to the work of exploration. With the wisdom beyond that of most men who enter the same task he put himself in communication with the authorities of the British Museum and his expedition was provided with a thoroughly trained scientific staff. Dr. Smith organized his party with care, but on a scale modest compared with that of large African expeditions, started from Berbera, moved a little to the north of west until he was stopped at the Abyssinian frontier, and then succeeded, by tact, persistence and great courage, in passing along westward until he reached Lake Rudolf and Stephanie. From this lake he returned to the coast. Where other men have been forced into conflicts with the natives, Dr. Smith peaceably provided himself with provisions. Where previous explorers had lost heavily, he saved all his men and returned to the coast with a loss of six—little short of marvelous. The difficulty of maintaining steady and continuous collection in a strange region was skilfully surmounted and with care taken in packing, brought specimens to London in extraordinarily good condition. The geographical results proved of the very highest value, a large part of four thousand miles never having been previously covered. Smith displayed, as so many Americans have,

all the qualities which make the English explorer successful, with the tact and discrimination and a consideration for others, which adds to mere success something more and better. A man of liberal, but not of large fortune, whose income could be easily overmatched by scores of idlers in any one of our great cities, Dr. Smith has dedicated himself to the work of exploration, and has just started for a trip to Corea where he expects to continue his prowess as a shooter of big game in Africa. In these days of peace, exploration is almost the only outline for the adventurous, and it is difficult to exaggerate the importance to a nation of the discovery from time to time that it produces men who have all the qualities which bring success and safety in war.

Pegamoid; A New Water-Proofing Substance.—Pegamoid is a crystal-clear, gelatinous fluid, which is easily applied to almost any porous material, and will be found to be applicable to a variety of medical and surgical purposes. After a substance has been saturated with pegamoid it resists all and every influence of humidity, acids, oils, and various other fatty substances without the least deprivation of quality and appearance. It is claimed that every texture, from the finest to the coarsest qualities, and also papers of all kinds can be manipulated with this new invention. All fabrics and articles treated with pegamoid can be cleaned with soap and water, so that the invention, because of hygienic considerations, deserves attention. Paper, leather, cotton, linens, silks, woolens, cloth, and other goods treated with pegamoid are water-proof, protected against vermin, and remain entirely smooth, soft, flexible, unsusceptible to the change of temperature and climatic influences. There is no doubt that pegamoid leather in future will prove to be a great competitor of the genuine morocco leather, being cheaper and as fine in appearance, with the advantage of not getting soiled. All kinds of wall paper can be cleaned after the treatment with pegamoid without suffering loss of color. As to the various applications of pegamoid, there is a large field for speculations and I only desire to mention here what has already been confirmed to be a fact. The invention can so easily be applied that scarcely any object in daily use exists in which it might not be of great advantage. One of the most important uses of this invention is claimed for imitation leather, which after pegamoid has been applied to any texture, can hardly be distinguished by touch or otherwise from the genuine article. A special advantage of pegamoid for tapestry consists in its durability. The surface is, notwithstanding its pliability, very solid and does not split, an advantage which genuine leather does not always possess.—*Consular Reports*, March.

A New Bullet for the British Army.—The Lee-Metford bullet has seen its day and a more effective projectile has been called for. In the Chitral expedition one of the enemy had six wounds from the former bullets in his body and was still fighting hard when the seventh toppled him over. According to the *Field* the new missile, the Dum Dum bullet, has accuracy and good range power, caliber .303. Experiments were made on piles of burned and sun-burned bricks, earth in bags and boxes, wet and dry sand, cans full of water, coal, inch planks tied together, boiler plate, skinned sheep and sheep with the wool on. In every instance the regulation bullet passed through and was picked up in a condition almost fit to use again, but the Dum Dum bullet spread out and had best penetration, but there was a greater shock to the material through which it did go, tearing holes in a sheep big enough to put a fist in.

"Then four and five planks were penetrated by the Dum Dum bullet, twelve and thirteen by the other. I believe that a living body offers greater resistance than a dead one. If so, a clothed living body may offer sufficient resistance to prevent its going through. In that case, the whole of the enormous energy would be expended in the enemy's body.

Judging by the results on sheep carcasses, the hole of exit in a man, if the bullet went through, would be so terribly large that the use of this ammunition would be held to be too inhuman in its effects for use on men or, at any rate, against a civilized enemy. The Geneva Convention would not bar it, for that forbids the use of an explosive in a small-arm projectile, but the effect of the Dum Dum bullet is explosive. I do not see why such a bullet as the Dum Dum should not be used against such uncivilized enemies as the 'Fuzzy' and the Ghizi, who do not 'play the game,' who will not decently fall when hit, but who unreasonably come on after with the advantage of five to one, and even when mortally wounded make things nasty for our men. I shot a wild boar with a Dum Dum at eighty yards. It had its right flank diagonally to me, and the bullet struck just under the backbone, broke a rib, went through a lung and destroyed all the vessels in the throat, lodging in the jaw. The bullet has a small, soft point, where the jacket of nickel does not cover it. This allows the bullet to expand."

PRACTICAL NOTES.

An Application of the X-Rays to Anatomic Preparations.—Diakonof reports that he has made a varied and most instructive use of the Roentgen rays in preparing radiographs of anatomic preparations. Structures like arteries, veins, bronchi and bronchioles may be injected with various materials more or less opaque to the X rays, and the resulting radiograph shows with perfect accuracy their relative distribution. The best material for injecting is mercury, on account of the ease with which it can be manipulated and the fact that the same injecting fluid can be used over and over again. When it is wished to inject two sets of vessels in the same organ and to show their distribution in the radiograph, mercury may be injected into one set and a still more opaque material into the other. The following mixture is suggested: Gypsum, cinnabar and red lead, twenty parts each; flour, ten parts; add enough water to make the mixture sufficiently fluid to flow into the smallest vessels. This mixture is too opaque, and the resulting shadows in the skiagraph too black, to be recommended as a substitute for mercury, but it is useful in combination with it as a contrast.—*Chirurgia*, February.

Untoward Effects In Acute Rheumatism from Sodium Salicylate.—M. Jaccoud has pointed out in the *Journal de Médecine*, etc., February 10, certain of the serious inconveniences that may arise from the employment of sodium salicylate in acute articular rheumatism with visceral localizations. Not only does it not cure these manifestations, but it does not prevent them, and it may even favor the production of certain of them. This drug seems to favor the cerebral symptoms of rheumatism, and its employment should be suspended as soon as delirium sets in, before the diagnosis of cerebral rheumatism is established. This suppression is necessary also if the delirium is of an alcoholic or hysteric nature, or if it arises from any form of intoxication. It is the same also in cardio pulmonary localizations, which are much more important on account of their frequent occurrence. During the past ten years M. Jaccoud has observed that the salicylate acts on the pains and on the fever, but not at all on these localizations, and as it has a depressing action on the heart from the time these symptoms appear, its use must be discontinued. By persisting in its employment involvement of the myocardium in the disease is certainly hastened. Numerous statistics show, moreover, that these localizations are not cured or even prevented.—*New York Medical Journal*.

Large Doses of Olive Oil.—The ultimate disposal of olive oil when given in the enormous quantities frequently heard of, was until recently unknown to me, but is just what consideration of the circumstances would lead one to expect. That the free and available alkalies of the intestines are all seized upon after the fat splitter, steapsin, has separated the esters into

their respective radicals, is not to be doubted. Such a large amount could hardly be saponified, emulsified or absorbed, however excessive amounts of other classes of foods being refused by the economy. That all of it followed the conventional path is not a reasonable proposition, and a recent case enabled me to determine its fate in at least one instance. A confrère had a case of hepatic colic in a victim of chronic malarial disease, and gave two pints of olive oil. Subsequently his attention was directed to some peculiar masses in the vessel. He brought them to me, and I found them to be about the size of marbles, irregular-shaped, translucent, of the consistence of cheese and green in color. The history giving me the cue, I found they were glyceryl palmates colored with oxidized bilirubin. I saponified them with boiling sodium hydrate, precipitated one tube with artificially hard water, salted out another, getting a hard soap. The gallstone was found, and proved to be deposits of cholesterin crystals around an organic nucleus, presumably of mucus or epithelium. The denser palmates were evidently outclassed in the race by the more unstable oleates and came through unchanged. A close analysis of all the feces on an exclusive fat diet of determined composition would be most interesting.—A. T. Mitchell, M.D., in *New York Medical Journal*.

The Causation of Chloroform Syncope.—As the result of personal experience, in conjunction with a critical analysis of the results obtained by other investigators, Hill (*Brit. Med. Jour.*, April 17, 1897, p. 957), concludes that chloroform employed as an anesthetic induces primary failure of the circulating mechanism and secondary failure of the respiratory center. The latter fails to act not only because it is damaged by the drug, but also because of the anemia of the medulla induced by the fall of the arterial tension. This is proved by the fact that the action of the respiratory center can be renewed by raising the arterial tension. The depth of anesthesia depends as does the paralysis of the respiratory center, on the primary fall of the arterial tension. Chloroform, more than other known agent, rapidly abolishes the vascular mechanisms which compensate for the hydrostatic effect of gravity. It does this by paralyzing the splanchnic vasomotor tone and by weakening the action of the respiratory pump. When these mechanisms are totally abolished the circulation is impossible if the subject be in the feet-down position. Chloroform also produces paralytic dilatation of the heart, acting directly, like amyl nitrite, on the musculature of the whole vascular system. There are two forms of chloroform syncope: *a.* During primary anesthetization. The patient struggles, holds his breath, raises the intrathoracic pressure, congests his venous system, lowers his arterial tension and finally takes deep inspirations and surcharges his lungs with chloroform. In the first stage the left heart becomes impoverished; in the second it is suddenly filled with blood. This is drawn from the lungs and is full of chloroform. The chloroform passes into the coronary arteries and the heart is thrown into paralytic dilatation. Respiration and the pulse either cease simultaneously or the pulse before the respiration. *b.* During prolonged anesthetization. This form of syncope arises gradually from giving too much chloroform. The arterial pressure falls lower and lower and secondarily the respiration ceases because of the anemia of the medulla. The heart is in this case not paralyzed by chloroform because the drug is taken in gradually by the shallow respirations and is distributed slowly by the feeble circulation. Artificial respiration and the assumption of the horizontal position, if applied in time, will always resuscitate a patient from the second form of syncope. Artificial respiration, established with the patient in the horizontal posture, is also the treatment indicated in the first form of syncope: the heart should be rhythmically compressed by squeezing the thorax. If this does not quickly renew the pulse the patient should be put in the vertical feet-

down posture. The dilated right heart is thereby completely and easily emptied of blood. Artificial respiration is maintained during this maneuver and the patient is brought once more into the horizontal posture. By rhythmic compression of the chest an efficient circulation is maintained through the coronary arteries; by first emptying and then filling the heart a fresh supply of blood is brought into that organ. If this does not prove successful on the first trial it can be repeated. Inversion, that is placing the subject in the feet-up position, or compression of the abdomen will increase the paralytic dilatation of the heart. In this kind of syncope both these forms of treatment are worse than useless. In the condition of shock or emotional fear the compensatory mechanism for the effect of gravity is almost abolished and chloroform may easily be the last straw to completely paralyze the circulation. Vagus inhibition of the heart is of no importance as an agent in the production of chloroform syncope. Ether is in every respect a far safer anesthetic than chloroform. According to Ringer's experiments on the heart, ether is fifty times less dangerous than chloroform. The chloroform inhaler should be removed when the patient struggles or the respiration is of irregular depth. The work of all physiologists goes to prove that paralysis of the circulatory mechanism and not of the respiratory center is to be dreaded by the anesthetists.

Tuberculosis Treated by Tuberculin in a Solution of Peroxid of Hydrogen.—Hirschfelder of San Francisco offers a provisional report as to his use of a modified tuberculin which he terms "oxytuberculin," a compound that is prepared as follows: Sixty cubic centimeters tuberculin is added to 240 cubic centimeters of a 10 per cent. solution peroxid of hydrogen, and water added until the whole measures 936 cubic centimeters. This mixture is placed in a flask, stopped with cotton, covered with a rubber cap, and sterilized in the steam sterilizer for ninety-six hours. At the end of this time the liquid is dark and turbid; it is clarified with caustic soda solution and 5 per cent. of boric acid is added to the liquid, which is filtered and is then ready for use. To meet the secondary mixed infections, he has prepared an oxysepsin which is used hypodermically with the oxytuberculin. These liquids cause no greater local disturbance than an indifferent fluid would produce; there is no reddening of the skin or other signs of localized inflammation. In a few minutes the fluid injected is absorbed and the patient has no further inconvenience; there is no rise of temperature, or any other unpleasant constitutional effect. Within a few days the cough and expectoration diminish, and the most striking effect is the rapid improvement in the appearance of the patient. His eyes become bright and his color changes from the gray hue of tuberculosis to one more nearly resembling that of health. The appetite rapidly returns and with it a feeling of vigor. This is especially evident in very early cases in which there is little or no fever. In cases in which only slight fever is present, a high temperature soon diminishes and in many instances becomes normal. At the same time the inflammation of the lungs gradually disappears, so that examination fails to reveal any deviation from the normal. The bacilli in the sputum may rapidly diminish and finally disappear altogether. As far as can be known from the comparatively short observation of the method, it having been first begun in November, 1895, the patients that recover remain well. In cases of laryngeal tuberculosis the ulceration rapidly cleans and becomes changed into a granulating surface that soon heals. In one case of tubercular infection of the hand that showed no sign of improvement under ordinary treatment, a rapid healing was produced by a local application of the oxytuberculin. The formation of granulations in this case, and in ulcerations of the larynx, was quite striking. The history of several cases was given in full, showing very favorable results from this mode of treatment.—*American Therapist*, March.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the Association living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, MAY 22, 1897.

ENTEROPTOSIS AND EXOPHTHALMIC GOITRE.

The pathology and etiology of exophthalmic goitre are still to some extent open questions and additional contributions in the way of hypothesis are at least worthy of mention as filling out or perhaps as encumbering the literature of the subject. The latest contribution in this line is that of Dr. C. SCHWERDT, whose brochure, editorially noticed at length in the London *Lancet*, endeavors to prove that it is often the direct effect of misplacement of the abdominal viscera—enteroptosis, or GLENARD'S disease—which he attributes to a primary nervous weakness leading to loss of tone in the muscular system and elsewhere and consequent yielding of the abdominal rigidity upon which the proper position of the viscera largely depends. These being misplaced cause constipation, accumulations of fluids and gases in the stomach, obstruction to the circulation and absorption and retention of waste products with consequent auto-intoxication. Then, apparently accepting the MÆBIUS theory of hyperactivity of the thyroid gland, as the condition underlying the phenomena of exophthalmic goitre, he claims that this excess of function is an effort on the part of the thyroid to counteract this autotoxis, and that in this indirect way the neurasthenia is the cause of the symptoms. The symptoms of exophthalmic goitre have in some respects and in some cases a resemblance to those of GLENARD'S dis-

ease, and this is made the most of by the German author, in support of his theory of the overtaking of the thyroid in its effort to relieve the poisoned organism.

The doctor's views are suggestive, but he goes only a very little way in accounting for the origin of exophthalmic goitre. Like some other disorders of ductless glands which have a known or as yet unknown action on the general nutrition, it has undoubtedly a nervous origin and the conditions of neurasthenia, themselves imperfectly understood, may well have their influence in its origination. It is also very possible that whatever interferes with the due processes of excretion may help to induce it or favor its development. It will certainly be of interest to notice in the future the coincidence of the disorder with enteroptosis, floating kidneys or any other abnormality of the abdominal viscera. Is its comparative frequency in women due to any degree to the abdominal displacements caused by corsets or tight lacing? Were this very largely the case it would seem that it ought to have been earlier recognized and far more prevalent in times past than would appear to have been actually the case from any records at our command. What actual or presumptive evidence is there that the thyroid functioning can in any way compensate for or counteract intestinal or renal auto-intoxication as is assumed by Dr. SCHWERDT'S theory? These and other questions are naturally suggested and need an answer before any one can fully accept his views. At best it is only a suggestion of one possible existing cause of the disease; the real nervous mechanism underlying and originating the disordered function of the thyroid, if we can accept that view as to its pathology, or the morbid state of the sympathetic system or of the brain itself, remains yet unexplained. The assumption of the existence of an auto-intoxication, which seems probable, is not enough to account altogether for a disorder that is so apt to suddenly follow nervous and emotional disturbance as is exophthalmic goitre; a special primary complication of some important portion of the central nervous system must apparently first occur. What this is, or even what it is likely to be found to be, is yet a question that remains to be answered.

Dr. SCHWERDT attributes to enteroptosis other disorders—scleroderma and myxedema—but in regard to these he apparently makes a less probable case. His paper has the merit of suggestiveness and of pointing out a line of inquiry that may possibly develop some addition to the sum of our knowledge of exophthalmic goitre.

SUICIDE BY SUGGESTION AND LIFE INSURANCE.

According to KRAFFT-EBING, a German woman who recently insisted on committing suicide at a certain date, was the victim of hypnotic suggestion by

her husband, who had insured her life for \$10,000, the policy terminating on the day of the suicide. It is rather astonishing, considering the tendency of life insurance companies to use all legal methods of avoiding payment of policies, that this plea has not been entered before. It is a perfectly valid plea, but of course the burden of proof would rest on the insurance company. Suicidal races like the Germans could be easily hypnotized into a state of susceptibility to suggestion as to date and manner of suicide. This would be difficult, however, in the English-speaking races when the subject is not insane, criminal or neuropathic. Many states of slight emotional depression, however, render the patient peculiarly susceptible to suicidal suggestions, of whose source the patient would be so entirely unconscious as to regard it as arising in his own mind or else hallucinatory in character. Cases have been observed in which melancholiacs had attempted suicide in various ways, accidentally or unintentionally suggested by persons in contact with them, but of whose suggestion they were unconscious as they ascribed the attempt at suicide purely to an impulse. It would be perfectly possible therefore in a melancholic patient to suggest suicide in a particular way and at a particular time without the patient being aware of the true source of the suggestion. It has happened that melancholiacs have had various ideas suggested to them, by an examination of whose source as connected with the examination they were totally unconscious, although they remembered the examination itself. From a forensic standpoint, the case of KRAFFT-EBING, is of peculiar interest, not merely as related to the possibilities of suggestion in hypnotism, but also of its possibilities in other mental states. As such suggestions would undoubtedly be criminal under the common law the accused would have the benefit of a reasonable doubt, which would throw the burden of proof very severely on those alleging the existence of the suggestion. For this reason it is probable that life insurance companies will not benefit very much by raising this plea in cases of suicide.

THIRTY-SECOND ANNUAL MEETING OF THE MICHIGAN STATE MEDICAL SOCIETY.

This meeting was held at Grand Rapids, May 13 and 14. About two hundred and fifty members were present. This society does its scientific work in three sections viz., medicine and obstetrics; surgery and ophthalmology; gynecology and abdominal surgery. The first section occupied one session in discussing preventive medicines in a series of five papers, each presenting some especial phase of the subject, followed by a discussion of the topics presented in the papers. The second section by a series of four papers discussed the nature and diagnosis, surgical and medical

management of cancer of the stomach. The section on gynecology by a series of four papers discussed uterine displacements. Besides these were many other papers in each section discussing varied topics, mostly practical in their nature, often of intense interest, frequently illustrated by a presentation of the actual cases, proving the results obtained. The interest was great and persistent in the work of each section, all the rooms provided for the meetings being filled to the overflowing.

Eighty and more new members were added to the rolls. The social arrangements made by the hosts of the society at Grand Rapids were in accord with the well known hospitality of the city, a reception on the night anterior to the opening of the session, brought the members into full touch with each other; a banquet to members and their wives on the evening of the first day, still further strengthened the bonds of fellowship.

The annual addresses were of especial interest; Dr. STRANGWAYS discussed "Our Profession; a Compound of Art, Science and Business" Dr. CARSTENS discussed "Specialists and Specialism;" Dr. SHURLEY analyzed "The present Status and Prospects of the Art of Medical Practice"; while the President, Dr. MCCOLL, gave a most interesting account of observations, made during a recent trip around the world, of the Plague in India. This part of the work of the Society was of unusual interest, giving opportunity to discuss topics out of order in the several sections or the general sessions.

Perhaps the most important action of the Society related to its modification of its methods of securing members. Formerly it has been accustomed to receive into fellowship no person not present at the meetings. Henceforth it will receive as members applicants who are not at the meetings, under the same conditions as those who are present. Formerly it mattered not whether an applicant was a member of a local society or not; henceforth members of local medical societies are received into fellowship at any time on the recommendation of the president and secretary of the local society, without reference to the Committee of admissions, or vote of the Society. This can be done at any time of the year, and without attendance at a regular meeting. Such action will strengthen the local societies, because their members when applying for membership, have only to pay their dues for the current year and agree to support the constitution and by-laws. All others have to be passed upon by the committee on admissions and be recommended by two members of the State Society, and receive a two-thirds vote of the Society at a regular meeting, sign the constitution and by-laws and pay their membership fee and annual dues. Henceforth every person will know that when the State Society recognizes a local medical society, it recognizes its membership as on an equal footing with

its own. To guard the State Society against the reception of unworthy members, the committee on admissions is given the duty of examining the local societies as to the fitness of their membership to a place with the members of the State Society.

It is believed that this act of trust and privilege, given the local societies by the State Society, will stimulate the formation of new societies in districts now without a local society, and will augment the membership of those now existing. Besides that, it is in accord with the practice in many of the States. Further, the Society directed the committee on admissions to take all possible steps to develop the formation of new medical societies in unoccupied fields, just as the adherents of religious or fraternal bodies seek to form new churches or lodges in fields of humanity not fully occupied. It is hoped that each other member of the Society will omit no opportunity to do the same sort of missionary work among medical men as they are able. The State Society offers especial advantages to the members of these societies beyond those given to outsiders, advantages attended with increased honor. It is believed that this notable enrichment will aid materially in the gathering of medical men regularly together, to discuss the science and art of their profession and strengthen the bonds of personal fellowship. The lack of these things, is the great element of weakness of the medical profession.

In short, the Michigan State Medical Society, has taken the first steps to develop local medical societies to the fullest extent under existing conditions. It should have been done a quarter of a century ago, but the fact that it has begun now greatly encourages its thoughtful members.

To further aid in the work of increasing the coöperation of the profession, it appointed a committee to study the question of establishing a journal of the Michigan State Medical Society and report at the next annual meeting. Many of the members who have given attention to this matter believe that such a journal could be started and maintained greatly to the advantage, not only of the State Society, but all the local societies, and every other medical organization, and all the interests of the profession.

Others are looking for more light, and the committee is expected to make such an exhaustive study of the matter, as to enable the society at its next meeting to act intelligently in the matter. After listening to the results of the study by a committee for a year, the Society decided that it was unwise to establish the regular meeting of the Society in any one city.

It thus appears that the most notable action of this meeting was its radical change in its relations to medical societies; the outcome of this action will be watched with interest by every friend of medical

organizations. There can be no question as to the correctness of the principles involved; the only question is respecting the vigor with which they are operated by individuals in the Society. If every member does what he or she can to promote their fullest development, the profession of Michigan will develop far more rapidly than in the past; it will be able to secure a unity of thought and action upon topics which have a common interest.

The officers elected for the ensuing year were: President, Dr. J. B. Griswold of Grand Rapids; Vice-presidents, Drs. E. L. Shurley, Detroit; E. W. Davis, Saginaw; G. C. Huebner, Ann Arbor and C. B. Burr of Flint; Secretary, C. H. Johnston of Grand Rapids; Treasurer, W. G. Henry of Detroit; Members of the Judicial Council, A. W. Alvord, Battle Creek, J. E. Emerson, Detroit, Perry Schurtz, Grand Rapids.

The next meeting will be held in Detroit, with Dr. E. S. Sherrell as Chairman of the Committee of Arrangements.

SURGICAL OPERATIONS IN THE DAILY PAPERS.

Since medicine and surgery became established upon a scientific foundation certain distinctions have served to indicate to the general public the line of separation from charlatanism. To make such distinction the methods of advertising in the public prints common to quacks and nostrum venders have been interdicted on the part of the regular medical profession. In fact this is the chief criterion by which the public has learned to distinguish between scientific physicians and pretenders. Modern ingenuity in advertising as utilized by irregular practitioners and proprietors of patent medicines has so closely simulated ordinary reports of medical and surgical cases that the lay reader is often misled. This confusion is increased when regular physicians adopt the methods of charlatans to report so-called remarkable cases in the daily papers.

This vicious practice has been so frequently condemned by the medical press and by medical societies that it would seem useless to continue to animadvert upon the subject; but the eagerness of certain members of the profession to attract public attention oversteps at times all bounds of professional decorum and decency. In some instances this abuse is so often repeated that one might infer that a surgeon has adopted the practice of reporting every major operation he performs in the daily papers. Some common surgical operation is described in detail, headlined as a "Triumph of Surgery," a "Delicate Operation," "A Remarkable Case," etc., with exaggerated and sensational descriptions of ordinary surgical methods. The details, however, are usually sufficiently accurate to show that the source of reportorial information is in the surgeon himself, who seeks such notoriety as a "near cut" to public favor and patronage.

Apart from the position in which the profession as a whole is placed by such methods, the advertising surgeon is taking a most unfair advantage of his colleagues. The profession is scandalized by such conduct and should by a vigorous public sentiment condemn all such disreputable methods. When a physician or surgeon adopts the advertising methods commonly practiced by charlatans he is breaking down the barriers between scientific medicine and quackery and has no right to expect the respect and confidence of his professional brethren.

THE NEW YORK MEDICAL LEAGUE.

In another column will be found a letter from Dr. DOUGLAS H. STEWART setting forth the aims and purposes of this new creation. From it we gather that the primary and ulterior purpose of this organization is to put a check on and suppress hospital and dispensary abuses and encourage physicians to more actively participate in those affairs, municipal or State, which concern their own interests. It is most extraordinary what it has already accomplished in its three months' existence. Its membership now numbers over five hundred practitioners, and while other medical societies have contented themselves with passing ephemeral resolutions, the League has succeeded in passing a bill through the State Legislature of New York which strikes a crushing blow at the dispensary evil, and when it goes into effect, in November, many of the dispensaries in the State will necessarily go out of existence. There is, indeed, but little doubt, from what we have learned of its *personel*, that this organization of physicians will inaugurate a most radical revolution in the body-medical, and it is probable that it may even have branches in several of the progressive cities in the United States.

THE JOURNAL SPECIAL TRAIN.

Medical gentlemen from Illinois and vicinity, the Pacific Coast and the Northwest, who intend to be present at the great jubilee meeting of the ASSOCIATION, are invited to take the JOURNAL SPECIAL, which will go by the Pennsylvania Railway without change from Chicago to Philadelphia. The time limit of ten days is as long as granted by any other route. See advertisement in another column, and make no mistake. The JOURNAL guarantees the most perfect of modern railway equipment.

CORRESPONDENCE.

What Constitutes Readable Print? Satinized, Light-Reflecting White Paper Fatigues the Eye.

ST. LOUIS, Mo., May 15, 1897.

To the Editor:—I herewith send you a few crumbs in answer to your call for a discussion of the paper on which the JOURNAL should be printed, because I am convinced that it will be calculated to do good service by directing attention to

very important questions, which must be of great practical interest to the human race both in this and future generations.

The question of the size and form of printing type, and the color of the material for background, is not only of great importance to the comfort of adults, but it is of far greater importance to children and those who quite naturally look to the typographical and mechanical features of the JOURNAL for a model.

What constitutes readable print? The most readable print is that by which one may obtain the maximum of reading, with the minimum of injury to the sight.

It is first necessary to have a clear idea of the word, readable, as applied to the impression of type.

Letters upon paper can be read without fatigue only when there is a marked contrast between the letters and the ground. This contrast may be of tone, of colors, or both.

Contrast of tone is the most favorable condition for distinct vision if we consider white and black as the two extremes of a scale, comprehending the gradations from normal gray; in fact, black letters upon a white ground present the maximum contrast of tone, and may be read in a perfectly distinct manner without fatigue in diffused light. Indeed, all whose sight is enfeebled by age require the utmost contrast of tone. The word "tone" of a color is here employed exclusively to designate the various modifications which that color, in its greatest intensity, is capable of receiving from white, which lowers its tone, or of black, which heightens it.

The light we employ to supply the place of the sun changing the relations of color under which the same bodies appear to us illuminated by daylight, it is evident to us that if we neglected this difference of relation, it would give rise to error, because any assortment of colors favorable to read in diffused daylight, might be less so by artificial light; therefore we will put aside the most desirable of all papers, the pale brown—or the paper recommended to reduce the contrast of tone, having a brownish or yellow hue when the deep black printer's ink is used—for there are some mechanical difficulties attending the perfect execution of toned papers, as well as that of expense.

All are of course familiar with the effect produced by the maximum contrast of tone, that of black print with a satinized (glossy) light-reflecting white paper, giving the greatest stimulation of the retina, and consequent fatigue.

More important factors, perhaps, in the readableness of print than tone and color of the ink and paper, are the size of the type and its corollary, length of line, to which may be added the direction of the line across the paper.

That printed lines should not be much longer (not more than fifty letters) than are found in the JOURNAL, may seem of little importance to the general reader.

The popular prejudice in regard to the double columns on a page would be untenable, were it not that the same economy which restricts the amount of space also reduces the size of the type and crowds lines together. A double column page which is properly printed and divided, is most certainly preferable to the same amount of matter extending in a single line across an entire page. It has been accepted by oculists that type embraced by an angle equal to five minutes, is the smallest printed matter which can be recognized by the average normal eye. According to this formula, the smallest print a normal eye can readily distinguish at a distance of one foot is about 1.50 of an inch; at eighteen inches (the average distance at which a book is held by an adult), the smallest recognizable type would be about 1.32 of an inch. The normal eye should never be subjected for any length of time to a type smaller than twice this size, that is 1.18 of an inch, and it would be better after middle life to employ a type even a little larger than this.

The fact, however, that spectacles are now so commonly used, removes in a degree by restoring to the focalizing power the necessity of a larger type with advancing years.

Too coarse print—such as “English type” or “long primer”—is wearisome to the eye, as it requires more exertion of the rotator muscles which govern the movements of the eye, that is, for a given amount of matter; and especially is this the case when the breadth of the page is, as usually happens, increased so as to keep the just proportion of matter on a line.

The type must be of a size to maintain a just relation between the length of the line and the ideas to be conveyed by the printed matter, but not so small as to require an effort to decipher it, and these lines must not be long enough to cause fatigue by undue use of the rotators of the eye.

No print is readable enough to preserve the sight of those who in defiance of fixed natural laws subject their eyes to a greater or longer strain than that to which the animal economy is adapted.

Vision should be looked upon as a physical capability, just as well fitted to be recognized as a point of merit in our daily exercises, such as walking, bicycle riding, running or jumping, etc.

Résumé.—1. For reading: Heavy faced type in contradistinction to light faced, properly leaded, with spaced lines, should alone be employed.

2. A dead faced white paper (with a non-reflecting surface) has considerable influence upon the ease with which the act of vision is performed and therefore should be preferred.

3. A very light almost imperceptible yellow tint paper is recognized as the best, that known to paper-makers as “natural tint” from the fact that it contains no dye whatever and has been bleached only to a moderate degree; it has the color of unbleached cotton cloth. This paper, however, is expensive. A likely substitute made from wood pulp or straw can be had in some of the second class papers in a brownish or yellow tint with a dead or non-reflecting surface at a moderate cost.

Respectfully submitted, WILLIAM B. MEANY, M.D.
3907 West Belle Place.

Blackboards In Schools.

AUSTIN, TEXAS, May 14, 1897.

To the Editor:—In your issue of May 1, page 854, Dr. A. C. Corr says: “The blackboards ought to be clean black,” etc.

The color of school exercise boards is a matter of great importance, but has been strangely neglected. For from time immemorial, it has been a fact of common knowledge, even among uneducated people, that *black* is the worst of colors for the eyes; hence, it has long been a custom with tailors, to charge more for making a *black* suit of clothes, than for any other color. For many years we have given schoolroom hygiene much special study, and have long taught, by word and pen, that school exercise boards should *not* be *black*.

The best color for such boards is some shade of cream white, a dead surface of soft, mellow tint, varied in its degree of whiteness to suit the quality and quantity of light afforded.

The crayons for said exercise boards, for ordinary daily use, should be a clear sky-blue color; the extra colors, a canary orange and a clear dark green.

Q. CINCINNATUS SMITH, M.D.

617 Colorado Street.

Medical League.

NEW YORK, May 11, 1897.

To the Editor:—In answer to many inquiries about the New York Medical League, and hoping to set at rest many vague editorial surmises as to its purposes, I send you the following preamble from its constitution.

The objects of the League shall be:

1. To unite fraternally Doctors of Medicine, in good standing, for mutual protection and benefit, by advancing the interests of its members professionally, financially and politically.

2. By united action to secure the enactment of such laws as shall benefit the medical profession.

3. To influence Doctors of Medicine to be good citizens, in the highest sense of the term, and to urge upon them the necessity of taking active part in matters pertaining to State and local government and of voting at every election.

4. To collect evidence of hospital and dispensary abuses and to exclude well-to-do persons from medical charities, thereby securing proper care and attention for the worthy poor.

5. To secure the adoption of laws commanding the appointment by the courts of medical experts qualified for their work.

The League in its constitution and by-laws has provided with due care for all the necessary work to promote the aims above mentioned. You can readily see that there is nothing secret or underhand about the League, and its objects, being so worthy and timely, must commend it to the profession of the whole country. Granting that the present financial depression is shared by us, we must admit that the many and increasing abuses of medical charities enter largely into the vital question, Are the wages worthy of the physician? Heretofore we have suffered greatly in all matters pertaining to our profession because of lack of union, and this indifference to self-protection on the part of the physician the League seeks to remedy.

The class legislation against physicians is evidenced by:

1. The law in New York City that the president of the health board must not be a physician.

2. The exclusion of all men not connected with college faculties from all public hospitals, by the Commissioner of Charities.

3. The exclusion of all physicians from the Board of Charity Commissioners, which controls all the public hospitals.

4. The utter disregard of municipal authorities of all advice by physicians upon all questions of public hygiene.

5. The unsatisfactory position in which physicians are placed when called upon to answer malpractices suits, generally, as we know, originating in imagination and malice, if not plain blackmail.

The above statements are sufficient to warrant the formation and extension throughout this Republic of a League which shall ensure to the physicians equal rights, protection and strict justice. The motto of the New York Medical League is “Fiat Justitia, ruat Cælum.”

Yours sincerely,

DOUGLAS H. STEWART, M.D.,
Cor. Sec. N. Y. M. L.

“Medical Instruction of the Laity in the Lay Press.”

MILWAUKEE, WIS., May 17, 1897.

To the Editor:—I was considerably interested in the letter of Dr. Shastid published upon the subject of medical education of the laity. It must be admitted that the Doctor's idea is very clever and ingenious, but altogether impracticable for the following very simple reasons:

Doctors possess the same human nature as do other people, and it is altogether unreasonable to expect them to devote their time to writing articles unsigned and for no pay. Physicians, merely because they are more humanitarian than people of other professions, should not be asked to devote their time and talents for the medical education of the people without financial remuneration or fame. I might urge other objections to the Doctor's scheme, but the one mentioned is greatest, for it would be simply impossible to secure a good staff of writers who would write anonymously and for nothing.

This is not intended to detract in the least from the philanthropic character of the profession, for, while doctors may be expected to treat people for nothing, it would be unreasonable to expect that more time should be consumed in the production of scientific literary work, gratis. It would be short of impossible to get together men of acknowledged ability to further the scheme proposed by Dr. Shastid.

Very truly,
A. L. HERRON, M.D.

ASSOCIATION NEWS.

The Philadelphia Meeting.

It has been necessary to make certain minor changes in regard to the various places for Section meetings and also concerning the different hotels which have been placed upon the list by the sub-committee on Reception and Accommodation, of which Dr. de Schweinitz is Chairman. In order that this corrected list of meeting places and hotels may be in the hands of every member of the ASSOCIATION we republish it below.

All persons desiring to register at the meeting, if not delegates or permanent members, must bring certificates of membership and good standing in their State or County Medical Society.

The General Sessions will be held in the Main Auditorium of the Academy of Music, Broad and Locust Streets at 10 A.M. and close at 1 P.M.

Headquarters, Hotel Walton, Broad and Spruce Streets.

Registration Office in the lower corridor of Horticultural Hall, Broad Street below Locust.

Post Office in the outer vestibule of Horticultural Hall.

The Bureau of Registration and Post Office will open May 31st, at 1 P.M.

THE SECTIONS MEET AT 9 A.M. AND 3 P.M.

Practice of Medicine in the Broad Street Theater.

Surgery and Anatomy in the lower hall of Horticultural Hall.

Obstetrics and Diseases of Women in the Main Auditorium of Beth-Eden Church, corner of Broad and Spruce Streets.

Neurology and Medical Jurisprudence in the hall 1415 Locust Street, third floor, rear.

Ophthalmology in the northeast Banquet Room, tenth floor, Hotel Walton, Broad and Locust Streets.

Laryngology and Otolaryngology, Hall 1415 Locust Street, fourth floor, rear.

Materia Medica and Pharmacy, Hall 1415 Locust Street, third floor, front.

Diseases of Children, Hall 1415 Locust Street, second floor, rear.

State Medicine, Hall 1415 Locust Street, fourth floor, front. Dermatology and Syphilography in the Foyer of Horticultural Hall.

Physiology and Dietetics in the Banquet Hall of Hotel Stenton, Broad and Spruce Streets.

Dental and Oral Surgery in Parlor D, Hotel Walton.

COMMITTEE ROOMS.

The Executive or Business Committee in Parlor C, Hotel Walton.

The Judicial Council in the Ladies' Lower Parlor of the Academy of Music.

The Trustees in the Ladies' Upper Parlor of the Academy of Music.

The Nominating Committee in the Central Room, Hotel Walton, Broad and Locust Streets.

RATES QUOTED BY HOTELS TO DELEGATES OF AMERICAN MEDICAL ASSOCIATION, JUNE, 1897.

Hotel Walton, Broad and Locust Streets: \$3.00 and upward per day, European plan only.

The Colonnade, 15th and Chestnut Streets: \$1 and upward per day, European plan; \$3 and upward per day, American plan.

The Lafayette, Broad and Chestnut Streets: \$1 and upward per day, European plan; Table d'Hôte: breakfast 25c, to \$1; luncheon, 75c.; dinner \$1.25.

The Bingham House, 11th and Market Streets: \$2.50 and upward per day, strictly on the American plan.

Hotel Stenton, Broad and Spruce Streets: \$2 and upward per day, European plan; \$4 and upward per day, American plan.

The Continental, 9th and Chestnut Streets: \$3 and upward per day, strictly on the American plan.

The Windsor, 11th and Filbert Streets: \$1 and upward per day, European plan; \$2 per day, American plan.

The Stratford, Broad and Walnut Streets: \$1 and upward per day, European plan only.

Girard House, 9th and Chestnut Streets: \$2.25 to \$3 per day, strictly on the American plan.

Hotel Hanover, 12th and Arch Streets: \$2.50 per day, strictly on the American plan.

Aldine Hotel, Chestnut Street above 19th: special rates to members of the AMERICAN MEDICAL ASSOCIATION, \$2.50 per day on American plan; \$1 to \$3 on the European plan.

The price quoted in each instance is for one person only. Rooms commanding only the lowest price are naturally limited in number. It is especially desirable that each member intending to be present at the meeting shall personally, or by letter, make his arrangement with the hotel at which he desires to stop.

Department of Public Health.—There will be a meeting of the Special Committee on "The Department of Public Health," at the Hotel Walton, Philadelphia, at 8 o'clock, P.M., Monday, May 31, 1897.

U. O. B. WINGATE, M.D.

Chairman of Committee.

Executive or Business Committee.—The first meeting of this Committee will be held in Parlor C, Hotel Walton, cor. Broad and Locust Streets, Philadelphia, on Monday May 31, 1897, at 5:30 p.m. Subsequent meetings will be held at the same place and hour, unless otherwise ordered by the committee, for the consideration of matters referred to it by the ASSOCIATION, and for the transaction of business.

L. DUNCAN BULKLEY, M.D.,

Secretary of Committee.

BOOK NOTICES.

Diseases of the Eye, and Ophthalmology. A handbook for physicians and students. By Dr. A. EUGEN FICK, University of Zurich. Authorized translation by ALBERT E. HALE, A.M., M.D. Philadelphia: P. Blakiston & Co. 1896.

We have at the present time a number of such excellent works on ophthalmology by American authors that we should not think it worth while the trouble of translating a foreign work unless it possess some particularly striking merit to distinguish it from our home productions.

But this book can not lay any claim to such distinction. The phraseology is often very ambiguous; as for instance, in the explanation of the shadow-test, of which we have seen far better descriptions in American works.

The information on some of the more important diseases is very defective. To illustrate, in the treatment of granular conjunctivitis the author recommends the excision of the folds, which operation has long since been abandoned as irrational; but no mention is made of the expression of the trachoma follicles, though this method is recognized, in this country at least, as the most efficient treatment.

The only operation for entropion described in detail is the obsolete method of Gaillard's sutures, which the author himself pronounces useless; for he says: "I have seen so many failures after Gaillard's operation that I have abandoned the method."

But the most unsatisfactory part of the book is the treatment of the anomalies of refraction and the ocular muscles. It is evident the author does not lay as much importance upon accurate refraction work as American oculists do, nor does he seem to recognize the far-reaching influence of refraction and muscular errors upon the nervous system, for which conclusive proofs have been furnished by thousands of clinical observations in this country. The majority of American oculists we are sure, will seriously hesitate to regard as a trustworthy guide for physicians and students a book which contains statements like this: "Young persons with slight hyperopia (up to 2 D) can usually see well both near and far objects. They need no treatment."

Catarrhal Diseases of the Respiratory Passages. By J. M. G. CARTER. Pages 135. Chicago: E. H. Colgrove. 1895.

This condensed treatise on catarrhal diseases of the respiratory passages is a well written and interesting essay rather than a text-book, and practitioners will find it good reading, containing many valuable ideas and pleasing theories. The chapter on catarrhal rhinitis and pharyngitis is the consideration of the subject from the standpoint of the intelligent general practitioner, and the conclusions drawn from a large experience are both valuable and interesting.

Diseases of the Ear, Nose and Throat and Their Accessory Cavities.
By SETH SCOTT BISHOP, M.D., LL.D. Illustrated; pp. 496.
Philadelphia, New York and Chicago: The F. A. Davis
Co. 1897.

This condensed work covers a special field which has not been generally combined under one cover by American authors. The work is concise and practical and will be of undoubted value to general practitioners who must include this class of work within their field.

It is easily seen that the author is a close follower of the principles and practice of the great Politzer and that portion of the work devoted to diseases of the ear can only be spoken of with praise.

PUBLIC HEALTH.

Unfavorable Tidings of the Plague.—A dispatch from Bombay to the *Daily Mail* of London, May 14, says that the bubonic plague is ravaging the Cutchmandvi district. There have been 2,000 deaths in a fortnight, and half of the population have fled.

A Conflict of Benefits.—Bayonne, a suburb of Jersey City, N. J., is in arms against a proposed trunk-line sewer, fifteen or twenty miles in extent, with an estimated discharging capacity of 70,000,000 gallons per diem and at a cost of construction of about \$6,500,000. The object is to provide a drainage for the lower Passaic Valley and the city of Newark. The claim of the Bayonne citizens is that a nuisance would be created on their Newark bay shore, where there is no deep water of sufficient tide to afford relief. Besides they maintain that the Jersey Central drawbridge built on spiles across the bay would prove a barrier to the flooding away of the great volume of sewage. Engineers who advocate the project aver that the sewer in question might be advantageously continued across Staten Island into New York Harbor. Still all the parties to the controversy have not been called into counsel.

Administrative Aspects Regarding Pneumonia.—At the January quarterly meeting of the Michigan State Board of Health the question of the communicability of pneumonia and of public health duty in respect of the same was brought forward by Professor Fall, who mentioned that there had recently been brought to his attention an outbreak of pneumonia which tended to show the communicability of the disease. There were five cases with two deaths, which all seemed to have been spread directly, one after another, from preceding cases. That pneumonia is a germ disease has been demonstrated; that it is a dangerous communicable disease there is no question. It is now known that exposure to cold and to the germs causes pneumonia. There are at least two species of germs, either one of which causes pneumonia. Just which one was present in this instance was not ascertained. Probably, after a time, we shall be able to distinguish the different forms of the disease due to the different germs. But, before this can be done, physicians who have such outbreaks in charge must see that, from the germs present, cultures are made by some competent bacteriologist, and records must be made of the signs and symptoms, so that these may be compared with those in outbreaks due to the different germs. Pneumonia is a disease which causes many deaths in Michigan in every year; and while the State Board of Health has done much for the education of the people preparatory to its restriction, the board has not yet recommended isolation of patients as in diphtheria, scarlet fever and smallpox. It is anxious to collect all the information it can, bearing upon the modes in which pneumonia is spread, in order that, as soon as practicable, the best measures may be recommended for its restriction. Ballard's investigations at Middlesboro have pointed to a common cause, as sewer air accompanied with defective drainage, as being an agency in

the incidence of a pneumonic series quite as probable as the communicability from case to case. It is difficult without the closest inquiry to separate these two classes of cases. Pneumonia has been known to be "epidemic" in jails or other crowded institutions and the disease has sometimes been regarded as infective by some reporters, while others have traced it to some aerial contamination common to the inmates of the institution. One matter of clinical history of the disease that seems to militate against the theory of contagiousness is the fact that, so far as our knowledge is concerned, it has never been found necessary, in hospitals and asylums, to isolate the cases of pneumonia. It may have been done in some special instances, but if so, those instances have escaped our notice. There is room for much careful study in relation to the bacteriology and clinical history of the so-called "pythogenic pneumonia." One point in the administrative relations of the disease is apparent, namely, it is important that in all cases where communicability of pneumonia is suspected, the local health authority should be notified of the fact.

Sanitary Arrangement of Vermont School-houses.—In compliance with No. 102, Laws of 1896, the Vermont State Board of Health, hereby issues the following recommendations and regulations for "lighting, heating, ventilating and other sanitary arrangement" of school-houses. In the choice of a site for a school-house, its construction and furnishings, the following directions are to be observed as far as possible:

1. The site should be upon a slight elevation with soil dry and well drained.
2. If in a village, it should be at a point free from noises and unsavory odors.
3. If in the rural portion of a town, at a point free from violent winds.
4. As near the center of school population as possible.
5. Playgrounds should be provided for exercise and amusement.
6. In villages, or where there is a basement, play rooms can be arranged. In rural houses, without basements, a shed should be provided for exercise in inclement weather.
7. There should be plenty of pure water supplied for drinking purposes.
8. Buildings should be so located as to secure the best light.
9. Particular attention should be given to this in villages where the school-house is likely to be surrounded by other buildings.
10. Care should be taken when the building is of wood to make it warm. This can be done either by using thick building paper under the clapboards, or by filling the space between the outside boarding and the lath with clean dry sawdust.
11. The walls of the rooms should be light gray or buff color.
12. All doors should be hung to swing out, and in large school buildings proper fire escapes should be provided.
13. As forty pupils are as large a number as one teacher can well instruct, the rooms should be 32 x 28 x 12 feet high, giving from 200 to 300 cubic feet of air space and 20 square feet of surface area for each pupil.
14. The windows should be numerous, large enough, and so arranged as to give ample light to every part (and corner) of the room. The window space should be at least one-fourth of the floor space. There should be no more space between the top of the window and the ceiling than is required to finish the building, and the window sill should be four feet from the floor. The light should be arranged so as to fall upon the pupil from the left or left and back, never from the front. There should be curtains of a gray or buff color for all windows—two to each window—hung in the center of the window so that either the upper or lower half, or both, can be shaded.
15. If there is no cellar under the building, there should be a space of at least two feet from the floor to the ground, and there should be windows or openings in the underpinning so that there can be a free circulation of air.
16. If the corridors are used as coat rooms they should be well lighted and ventilated.
17. In rural portions of a town, there should be two out-buildings—one for girls and one for boys. They should be at least twenty feet from the school building and from each other, with a high fence between. Earth closets should be used with road dust, sawdust or ashes, so arranged that they may be easily cleaned. In villages where water is available, there should be a system of bowls, urinals, drains and sewers, constructed according to modern plumbing rules. Closets should not be placed in basements under schoolrooms.
18. Desks and seats. The height of the seat must correspond with the length of the legs below the knees. The seat may be horizontal or slightly curved. The back should be formed of a lower convex and an upper concave portion. A desk for writing should have an inclination of about 15 degrees. The desk

should be fitted to the pupil each year. A perpendicular line from the edge of the desk should project only slightly over the edge of the seat. 18. Blackboards should be placed opposite windows, never between, and should be of a dark lusterless color. Lessons placed on the board for pupils to copy are injurious to the eyes by reason of the rapid change of focus required from the distant board to the paper on the desk; hence, these should be avoided.

NEW INSTRUMENTS.

EXTEMPORE SPINAL CORSET FOR POIT'S DISEASE OF THE SPINE.

LOUIS KOLIPINSKI, M.D.
WASHINGTON, D. C.

I have for some years used an extemporaneous spinal corset in place of Sayre's plaster jacket and the expensive spinal supports of the instrument makers, which possesses some advantages and may at times be found useful to others who encounter chronic diseases of the vertebral column.

The corset about to be described I have found always adequate to relieve the indications presenting in these cases; pain and impaired mobility of the trunk and lower extremities and consequently it can be passed without question of fulfilling the requirements of a mechanical support.

To prepare the corset a pattern is first made by means of a newspaper and scissors, arranging the former in a manner to fit the thorax and abdomen so that below, it slightly overlaps the iliac crests, meets edge to edge in front and extends upward two inches below the clavicles. Semicircles are cut on both sides to allow free room for the axilla.

The material used for constructing the corset is the article called "Japanese splashier," in common use as a wall protection about a lavatory. The particular form of "splashier" is that of German manufacture and consists of slender round pieces of wood of the diameter of a common lucifer match. Two are sufficient for a child or a patient of average figure. The "splashier" is readily cut with scissors to the shape and size of the paper pattern. The inner surface of the jacket is lined with cheese cloth and the edges bound with broad tape. The external surface is further reinforced by transverse strips of tape four to eight in number, secured with stitches which are passed through and across the inner cheese-cloth lining. To apply the corset it is necessary to pad pressure spots which will be found along the spinal column, the armpits, the anterior abdominal wall, the hips and sometimes the mammary and sternal regions. Cotton or cheese cloth may be used hereto varying with the seasons.

The patient lies supine with the spinal column fully extended, the corset is slipped on and secured by means of three circular straps of leather or broad tape. The first one around the upper part of the jacket, the second about the middle and the third at its base. The last must bring the jacket snug in apposition with the iliac crests as the fixed point. The uppermost one is secured as tightly as the patient's respiratory freedom may demand, the middle one must be the most secure of all.

The corset thus designed fulfils the indications previously mentioned and has I believe some obvious advantages, which are, cheapness of material, lightness, elasticity, porosity and the fact that it can be made in a few hours by any female member of a family from the physician's verbal description.

MISCELLANY.

Correction.—"The Diagnostic Significance of *Enzymes* in Cyst Fluid," published in the *JOURNAL* May 8, page 885, was by mistake headed under the title of "Eczema!"

Warning!—Advertisers are cautioned that the program is copyrighted by order of the ASSOCIATION, that no advertisements appear in the official program and that any representations to the contrary are fraudulent.

Illinois State Medical Society.—The following were elected officers of the Illinois State Medical Society: J. M. G. Carter,

M.D., President; T. J. Pitner, M.D., Vice-President; J. T. McAnally, Second Vice-President; E. W. Weiss, Secretary; Geo. N. Kreider, Treasurer. Next place of meeting, Galesburg.

The Most Important Discovery.—The University of Würzburg accords the distinction of having made the most important discovery during the past three years to Professor Behring, for his diphtheria antitoxin, and has bestowed upon him a gold medal and a purse of 1,000 marks.

Good Assumptions for Hypothetical Questions.—Hypothetical questions may be framed, the supreme court of Colorado holds, *Courvoisier v. Raymond*, Sept. 21, 1896, upon the assumption that the evidence tends to prove certain facts, this assumption being within the probable or possible range of the evidence.

Ferratin is one of the new remedies recommended by the committee of revision for adoption into the new fifth edition of the Russian pharmacopeia (*Chemiker Zeitung*, 31, 1897). It is an organic iron compound, of albumin and tartrate of iron, forming a definite iron albuminic acid; it contains 7 per cent. of iron, is readily absorbable, does not constipate and has no untoward effects. On the testimony of its discoverer and others, it is identical with the natural ferruginous element of food, absorbable in the system and stored in the liver and other organs as a "reserve iron for blood formation."

Niemann's Tuberculosis Antitoxin.—Niemann states that he has succeeded in isolating an antitoxin from the serum of young goats that had been inoculated with increasing doses of a tuberculin prepared from a virulent culture of tubercle bacilli. From experiments on guinea-pigs, in which tuberculosis had been produced by inoculation, he claims to have demonstrated that his goat's serum contains an antituberculin. Animals showing tuberculous ulceration at the seat of inoculation, with tuberculous enlargement of the glands, were cured by inoculating them with the goat's serum, the ulcer healing and the glandular enlargement entirely disappearing. Niemann also obtained good results in the treatment of tuberculosis of moderate severity in human individuals. Under treatment the general condition of the patients showed marked improvement, the tubercle bacilli disappeared from the sputum, and the cough and expectoration considerably diminished. High elevation of the temperature rarely followed the injection of the serum, even in large doses, while albuminuria was never observed.—*Münchener med. Wochenschrift*.

Drugs in Department Stores.—The appellate division of the New York Supreme Court gave an important decision regarding the rights of department stores to sell drugs without the supervision of a registered pharmacist. The decision was in a test case brought by the Pharmaceutical Society of Kings County. The individual members of a firm had been found guilty in a police court of a misdemeanor in selling a bottle of paregoric and a bottle of quinin. Their conviction was affirmed by the county court, and its decision is now upheld by the appellate division of the supreme court, which denies the contention of the defendants that they occupy a position similar to that of wholesale dealers by selling medicines in original packages, and that hence they should not be required to make their sales under the supervision of a registered pharmacist. The court held that the law was devised for the protection of the community at large, and that serious damage may be done if the law is not strictly observed. Hence it appears that if the department stores desire to sell drugs they must do so through the instrumentality of registered pharmacists.

The Latest in Roentgen Photographs.—Kümmel has traced with the Roentgen ray the course of the Murphy button through the organism. Syndactylia in a child was successfully treated with information derived from paternal photographs. Stechow thinks the importance of this photography in army surgery can not be too highly estimated. Levy Dorn locates foreign bodies with extreme precision by passing a needle around the

part, held behind the fluorescent screen. The two points at which the shadow of the needle coincides with the shadow of the foreign body are marked on the skin. Repeating this in two or three different positions the position of the foreign body can be found exactly. Another method is by moving the light slightly and thus taking stereoscopic photographs. Max Levy reports that it is now possible to take photographs of the thorax and pelvis with an exposure of only thirty to sixty seconds. The time has been thus shortened by obtaining a more complete vacuum, laying a supplementary screen over the sensitive plate and by using specially prepared plates with the sensitive film twice and four times the usual thickness.—Congress of Surgery, Berlin, April.

In Nature of Hearsay Evidence.—In the personal injury case of *Thompson v. Manhattan Railway Company*, where it was desired to prove that the plaintiff suffered from an injury to the spine, the attempt was made to prove that fact, not by the testimony of the physician who had attended her, but from the treatment that she received. Such proof, the appellate division of the supreme court of New York thinks, was in the nature of hearsay. The treatment of the plaintiff for a particular disease, it maintains, was no more than a declaration of the physician that she was suffering from such a disease; and as the declaration would not be competent, the court holds, Dec., 31, 1896, that the proof of the treatment was not competent. Nor does the court think that the jury could infer from the particular treatment what the belief of the attending physician was, because, while the witness on the stand might have given the specific treatment for one ailment, the attending physician might have given it for another. Further, it says, had the attending physician been produced as a witness on the trial, the vital inquiry would have been what at that time he believed to be the nature of the injury to the plaintiff, not what had been his view or belief on that subject at any previous time. And for that reason, his previous belief of treatment would not have been competent, except on cross-examination.

Examining Physician only an Agent.—An examining physician employed by a life insurance company examined an applicant for insurance on January 30, and on February 4, returned to the company a certificate that he had found the insured to be in sound health. February 11, the company issued a policy containing the provision "that no obligation is assumed by this company prior to the date hereof, nor unless on said date the insured is alive and in sound health." It was subsequently contended that the company was bound by the examination made and reported by its examining physician, and that it should not be allowed to prove by another physician that the insured was not in good health when the policy was issued. But, aside from the possibility that the insured might have been in good health January 30 and not on February 11, the supreme judicial court of Massachusetts holds, *Gallant v. Metropolitan Life Insurance Co.*, decided October 23, 1896, that the examining physician was only the agent of the insurance company to make the examination, and report the result of it. He had no authority to make a contract of insurance for the company, in which the results of his examination should be conclusively taken by the company to be true. The company made its own contract, a part of which was as above. If, in fact, the insured at that time was not in sound health, the court therefore holds, the company was not liable on the policy, and this fact could be shown by any competent evidence.

The Effects of Small Caliber Bullets.—In an article under this title in the *Annals of Surgery*, January, 1897, Dr. Gwilym G. Davis of Philadelphia reviews the literature of this subject and discusses critically the various conclusions that have been reached by experimenters and observers. The effects produced by a bullet are penetrative or explosive. The former are directly proportioned to: The hardness of the projectile (non-deforming); the softness or elasticity and compressibility of

the tissues; the velocity of the bullet; the small size or frontage of the bullet and lastly its weight. An increased velocity produces increased penetration only to a certain extent because the resistance to the entrance and passage of a bullet increases in a more rapid ratio than does the penetration, so that a point is soon reached beyond which any additional velocity is expended laterally on the tissues. The lateral or explosive effects are proportioned to: The softness of the bullet; the hardness and non-compressibility of the tissues; the velocity of the bullet; its large size or frontage; its weight and in a slight degree its rotatory motion derived from the rifling. The lack of disabling power has been observed in every instance in which the small calibers have been used in actual warfare, as in Chili, where the 7.6 millimeter Mannlicher rifle was used; in some of the contests of the British troops with the half-savage natives of their Eastern possessions in which the 7.7 Lee-Medford was used; in the Chinese war in which the Japanese used the Murata rifle of about 8 millimeters; in the Abyssinian campaign in which the Italian troops were armed with the 6.5 Mannlicher-Caveano, and in the present Cuban rebellion in which the Spaniards carry the 7 millimeter Mauser. In the recent fighting in South Africa the British troops were unable, by their rifles alone, to stop the onward rush of the natives and it was only the opportune assistance of the machine guns that saved them from being overcome. The Italians in their campaign against the Abyssinians were not so fortunate. The disabling effect of their 6.5 bullet was so slight that it was thought the ammunition had been tampered with. Dr. Davis submits ten conclusions as the result of his study; 1. That the initial force of the bullet is an onward or a penetrative one. 2. That when penetration is impeded the onward force becomes transformed into a lateral one. 3. That explosive effect is only another name for lateral action, *i. e.*, outside the track of the bullet. 4. That lateral action is most marked in hard bones (the fragments being carried onward) and in organs containing water (bladder, brain, liver, etc.). 5. That practically the rotation of the bullet on its axis does not materially affect the character of the injury. 6. That the effect of gunshot wounds is not so severe on the living body as on the dead. 7. That the destructive power of the small caliber arm has been overestimated. 8. That its stopping or disabling power is less than that of larger calibers. 9. That wounds in future conflicts will be, as a rule, less severe and healing more rapidly, with fewer complications than has been the case in the past. 10. That less radical treatment will be required and conservatism will be followed by most brilliant results.

Detroit.

THE DETROIT MEDICAL AND LIBRARY ASSOCIATION at its regular meeting Monday, May 3, listened to a paper by Dr. Charles Douglass, entitled "Infantile Stools and Their Significance." The paper was discussed by Drs. Chapoton and Jennings.

THE DETROIT COLLEGE OF MEDICINE graduated eighty-one M.D.'s Tuesday evening May 4. This was the twenty-eighth anniversary of the college, which is in a prosperous condition. The damage done by the late fire to the main building is now being rapidly repaired. It being necessary to alter all the interior of the building, the corporation has added another half story.

AT THE COMMENCEMENT EXERCISES of the Michigan College of Medicine, held March 23, forty-seven gentlemen received their diplomas.

THE MEDICAL BILL which was before the Michigan legislature met its death. Dr. Edgar, a member of the House from Lenawee, amended the bill, but it was defeated in the House by eleven votes, a majority of the Wayne County (Detroit District) members voting against it.

Washington.

THE ANTI-VIVISECTION BILL REPORTED TO THE SENATE.—Senator Gallinger has reported the bill to regulate vivisection in the District of Columbia. The bill received the unanimous approval of the District committee of the Senate, and is a modification of the bill presented at the last session of Congress. He accompanies the bill with a very full report which discusses the subject for and against the bill from the evidence presented to the committee. He appends a most impressive list of names of some of the most influential people in the country, who favor and urge the passage of the bill. It is very plain that the efforts of the vivisectionists to defeat the bill have attracted unusual attention to this measure, thus arousing a large opposition from very prominent persons who evidently do not clearly understand the situation, but whose expressed wish and great numbers have influenced the Senate committee. (A timely

attack might yet defeat the measure.) The bill provides: 1. For the use of anesthetics in all painful experiments on living vertebrate animals, the so-called inoculation experiments, tests of drugs and medicines and cases of recovery from surgical procedure being expressly exempted from this requirement. 2. For the licensing of all experimenters by the District Commissioners, except those who are duly authorized officers of the government of the United States or of that of the District of Columbia. 3. For the prohibition of vivisection in the public schools and in exhibitions for the general public. 4. For the inspection of all places of experiment by inspectors to be appointed by the President of the United States.

MEDICAL SOCIETY.—At the meeting of the Society held on the 12th instant, the discussion of the essay of Dr. W. W. Johnston on "The effect of School Life on the Health of Children." Dr. Busey: The influence of premature school life on the health and development of children. Dr. S. S. Adams: Some of the causes of so-called school diseases found in the home. Dr. Kober: Many of the causes of so-called school diseases found in the school. Dr. Woodward: The sanitary condition and needs of Washington schools. The discussion was on motion continued to the regular meeting next week, when other members will speak on the subject.

MEDICAL ASSOCIATION OF THE DISTRICT.—At the meeting of the Association held on the 11th inst., Dr. C. Busey was unanimously elected the delegate to represent the Association of the District of Columbia at the meeting of the British Medical Association, to be held at Montreal. The following was adopted as a part of the by-laws of the Association and made binding on its members:

1. That every institution for medical charity shall require from every applicant for relief in a hospital or dispensary, a written certificate to be obtained as hereinafter provided. Emergency cases are to be excepted from the operation of this rule. 2. That such certificate be obtained from Physicians to the Poor, the Board of Associated Charities and any registered physician. 3. That cases of sick and injured persons found upon the streets, in the stations or elsewhere, who require immediate treatment, shall be carried to the Emergency Hospital, or the nearest hospital having an emergency service, or to their homes, if so directed by the patient or his friends. 4. That emergency patients shall not be detained longer in such institutions than the necessity of the case imperatively demands, but shall be discharged from the service and sent to their homes or to some public hospital as the patient may elect. 5. That members of this Association shall be entitled to the privilege of attending private patients occupying private rooms in any of the public hospitals of this city. 6. That in future the members of the Medical Staff of hospitals when attending medical or surgical cases in private pay-rooms shall insist upon proper payment for their services, except in the case of such patients who are clearly unable to pay for same. 7. That whenever the Medical Staff or a majority thereof of a hospital or dispensary resigns, and when after due hearing, this Association finds that the resignations were for just and sufficient cause, it shall be forbidden for any member of this Association to accept a position on the staff of said hospital or dispensary. 8. That whenever one or more members of the Medical Staff of a hospital or dispensary are dismissed, and when after due investigation, this Association finds that such dismissal was without just and sufficient cause, it shall be forbidden for any member of this Association to fill the vacancy created thereby. 9. That complaints made under Rules 7 and 8 shall be made in writing to the Standing Committee, which after due consideration shall report its findings to the Association.

THE PUBLIC SERVICES.

Army Changes. Official List of changes in the stations and dates of officers serving in the Medical Department, U. S. Army, from May 8 to 14, 1897.

Capt. R. R. Ball, Asst. Surgeon U. S. A. (Ft. Adams, R. I.), is granted leave of absence for one month, with permission to apply for an extension of two months.
 Capt. Nathan S. Jarvis, Asst. Surgeon, leave of absence granted is extended to July 1, 1897, at which time his resignation has been accepted by the President to take effect.
 First Lieut. Guy O. M. Godfrey, Asst. Surgeon, now on temporary duty at St. Paul, Minn., will proceed on the 15th instant to Ft. Yellowstone, Wyo., and report to the commanding officer for temporary duty with troops in the National Park during the season.
 First Lieut. Paul F. Straub, Asst. Surgeon, is assigned to duty with Troop C, Fourth Cavalry, during the season at Sequoia National Park and General Grant National Park, Cal.
 Capt. Merritt W. Ireland, Asst. Surgeon, is assigned to duty with Troop

K, Fourth Cavalry, during the season at Yosemite National Park, Cal.
 Col. William H. Forwood, Asst. Surgeon-General; Major Louis M. Maus, Surgeon; Capt. Rudolph G. Ebert, Asst. Surgeon, are detailed to represent the Medical Department of the Army as delegates at the annual meeting of the American Medical Association, to be held in Philadelphia, Pa., June 1 to 4, 1897.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the two weeks ending May 8, 1897.

Surgeon A. G. Cabell, ordered to the "Monongahela" May 15.
 Surgeon D. H. Morgan has been detached from the naval academy and ordered to the "Monongahela" May 15.
 Asst. Surgeon R. G. Brodrick, ordered to examination for promotion May 8.
 Asst. Surgeon F. C. Cook, detached from the "Vermont" May 8 and ordered to the "Wilmington" May 10.
 Medical Inspector J. C. Wise, detached from marine headquarters, Washington, May 15, and ordered to Columbus, Ohio, as delegate to the Association of Military Surgeons.
 Medical Inspector J. C. Wise, after duty at Columbus, ordered to the "Philadelphia" as fleet surgeon.
 Medical Inspector J. A. Hawke, detached from the "Philadelphia" on relief, and granted three months' leave.
 P. A. Surgeon C. H. T. Lowndes, ordered to duty at marine headquarters.
 Surgeon C. U. Gravatt, ordered to U. S. S. "San Francisco" (fleet) per steamer of May 22.
 Medical Inspector H. J. Babin, detached from the "San Francisco" on relief, ordered home and granted three months' leave.
 P. A. Surgeon G. T. Smith, ordered to the naval hospital, New York, temporarily, May 15.
 Asst. Surgeon M. S. Elliott, detached from the "Columbia" and ordered to the "Indiana."
 Medical Inspector J. M. Flint, ordered to examination for promotion, Washington, May 12.

CHANGE OF ADDRESS.

Brothers, S., from 93 to 244 Madison St., New York, N. Y.; Barbat, J. H., from 1412 Folsom St. to 700 Golden Gate Av., San Francisco, Cal.; Brown, H. L., from 800 Monroe Av. to 508 Congress St., Chicago, Ill.; Bouffeur, A. I., from 788 to 1178 Washington Boul., Chicago, Ill.; Booth, F. H., from 522 N. Sacramento St. to 857 W. North Av., Chicago, Ill.; Brauns, E., from 341 Roscoe St. to 11 Cleveland Av., Chicago, Ill.; Beach, W. M., from Pittsburg to 89 Arch St., Allegheny, Pa.
 Cook, J. C., from Hyde Park to The Kenwood, 47th St. and Kenwood Av., Chicago, Ill.; Clausen, J. J., from 1327 E. 8th St. to 1400 Summit St., Kansas City, Mo.; Conner, R. E., from New Florence to Hickory, Pa.; Cheahire, M. U., from 828 Congress St. to 195 S. Oakley Av., Chicago, Ill.; Devine, G. C., from 277 S. Lincoln St. to 430 S. Wood St., Chicago, Ill.; Dean, G. S., from 2486 Market St. to 1089½ Valencia St., San Francisco, Cal.; Davidson, Charles, removed office to Suite 1007 Columbus Memorial Building, Chicago, Ill.
 Greenebaum, E. C., from 357 S. Lincoln St. to 468 E. 42d St., Chicago, Ill.; Greenfelder, L. A., from 9000 Indiana Av. to 3500 Ellis Av., Chicago, Ill.; Gilbert, J. W., from Verona to Corinth, Miss.; Grinstead, J. F., from Chicago to cor. 4th and Washington Av., St. Louis, Mo.; Goodman, C. W. T., from 708 S. Michigan Av. to 508 N. Washington Av., Gadsden, Mich.
 Houston, Jas., from Swartz Creek, Mich. to 2d Av. and 20th St., New York, N. Y.; Hanna, C. W., from Zanesville to 807 Gay St., Portsmouth, Ohio; Hill, F. E., from 7 to 10 W. 9th St., Cincinnati, Ohio.
 Kaster, J. P., from Albuquerque, N. M., to Topeka, Kan.; Kirkbride, M. F., from Philadelphia, Pa. to Spring Lake Beach, N. J., P. O. Box 205.
 McDaniel, E. D., from Mobile to Camden, Ala.
 Peck, Geo., from 926 N. Broad St. to 840 Westminster Av., Chicago, Ill.
 Reynolds, Geo. W., from 815 Webster Av. to 1924 Arlington Pl., Chicago, Ill.; Russell, E. S., from Pittsburg, Pa. to Alliance, Ohio.
 Schaper, Chas. S., from Franklin to 1304 N. 8th St., Sheboygan, Wis.
 Van Velsor, Frances T., from 2480 Indiana Av. to 6059 Ellis Av., Chicago, Ill.; Wyeth, John A., from 27 E. 35th St. to 19 W. 35th St., New York, N. Y.; Wright, J. C., from 1330 27th St. to 2414 Kingman Av., Des Moines, Iowa; Wills, Wm. L., from 127 W. 1st St. to 306 Wilcox Block, San Francisco, Cal.

No. 22

ADDRESS.

"MEDICAL" LEGISLATION AND HOW TO OBTAIN IT.

The annual address of Section Three of the Illinois State Medical Society, delivered at E. St. Louis, Ill., May 20, 1897.

BY JOHN B. HAMILTON, M.D., LL.D.

PROFESSOR OF THE PRINCIPLES OF SURGERY AND CLINICAL SURGERY IN RUSH MEDICAL COLLEGE, CHICAGO.

Quantum animis erroris inest.—Ovid.

In these impatient days when science is aglow with the light of new discovery, the scientific mind naturally looks for sympathy and support from those following the same and kindred professions. The learned physician profoundly impressed by the wide vista which science has in so many ways opened to his view, can not but expect that the members of the other learned professions would concede his special knowledge and adopt general rules of action in conformity therewith, but to his utter disappointment he finds not only the legal profession but as well the Protestant clergy not only failing to see matters as he sees them but in many instances, arrayed in positive antagonism to his views, aims and wishes.

It is probable that the profession of medicine to fully receive that necessary sympathy and support must insist that the rudiments of medicine shall form a part of academical education, for as Blackstone has said "Sciences are of a social disposition and flourish best in the neighborhood of each other; nor is there any branch of learning but may be helped and improved by assistances drawn from other arts."

As laws are "rules of action prescribed by some superior, which the inferior is bound to obey," it is apparent that when that superior, as in this country, is the State or the Nation, the law must be equally binding on all, and that all have the same general interest in its application. That it shall contribute to the service of the public and benefit posterity should be the ultimate object of every public law.

It is too much the fashion to speak of medical legislation as the peculiar and special property of the medical profession and for their use, whereas in fact the general welfare of the people is the general object in medical legislation, sought to be attained in every instance, whenever it has been asked by this Society or kindred societies throughout the United States.

In an Illinois decision last year upon the question of the compensation of an expert witness, the Judge in referring to physicians applied the extraordinary epithet of "pampered children of the State" and actually spoke of the State Board of Health as having been created for their benefit. It is the public display of such misinformation and dense ignorance as this, that requires that proper academic education for all should include the elementary branches of medicine.

Had the learned Judge known only a little of col-

lateral science he would have known that the function of a State Board of Health is the prevention of disease, and the prolongation of human life. Had he known the actual facts in regard to the Illinois Board of Health, he would have known that almost the entire expenses of that Board are borne from the license fees of physicians and not from the State treasury, and so far from the State supporting the medical profession, that abused profession sustains that portion of the duty of the State. It is unfortunate that so little hygienic work is now performed by the State Board of Health, but that is the fault of the Legislature and not of the medical profession.

This Society through one of the ablest committees it has ever had, formulated a bill for the welfare of the people, so far as protection from the impostures of quacks was concerned. Able legal advice was procured, criticisms and comments from medical societies and individual members of the profession were solicited; the energetic chairman, Dr. Pettit spent time and money to interest medical societies, secure information and perfect the bill. It was introduced into the legislature and died without a struggle. The disgust of those of us who observed its demise, was not mitigated but only deepened when we also observed with what eagerness, not to say actual yearning, the bill legalizing "osteopathy" was welcomed by a willing senate, and we are informed that this bill positively sailed through both Houses of the Michigan legislature without meeting any obstruction or encountering any opposition.

Thus it is once more demonstrated that in the opinion of the law-making body, pains-taking labor in the acquisition of a profession is an unnecessary strain upon the human constitution, when by a short course of "osteopathy, as it is taught in Kirksville, Missouri," all restrictions upon practice may be thrown off and the "osteopath" clothed with the privilege of the State, go at once into practice.

What stimulating "incentives" were applied to the law centers of the Michigan legislature, may never be known, but that other quacks came to the financial aid of the "osteopaths" there is little doubt. Something more than an X-ray will be needed to develop the unknown quantity here.

In Iowa the osteopathy bill was promptly defeated. They have twelve physicians in the Senate of that State, and about half that number in the House.

The bill introduced by Dr. Hall in our legislature providing for professional secrecy, it was thought would pass; similar bills had passed in other States, and it was believed that no sane man would object to a measure which provided for the protection of the patient and the guarding of his secrets in all except criminal cases. It was not particularly in the interest of the doctor, but it was in the interest of the people; but a doctor introduced it, it was "medical legislation" and therefore doomed to defeat in advance. Had

some advertising quack proposed it, instead of regular physicians, its claims might have been better; but as it was it had no friends, and we are told that in committee an old lawyer with snowy locks and hands trembling with age wrought himself into a storm of passion in denouncing it. The mighty shade of Cicero was invoked in tragic tones to help defeat this joint production of man and the devil. The awe-struck committee, conscience-smitten for having for a moment dared to look at a bill introduced by a physician, hastened to perfect their record by disclaiming lot or part in the bill and jumping on it as one man. Then another bill was introduced providing for some better laws in regard to medical expert testimony; a sincere presentation of the merits of the case had been made by the Medico-Legal Society of Chicago; its framers had the advantage of the experience of the best experts in the State; but all to no purpose, except to add to the record of defunct bills.

In National legislation the only measure that has been successful was the medical practice act of the District of Columbia; that is not an ideal act, but it is probably the best attainable. Ohio, Indiana, Wisconsin and Iowa have new practice acts; all of them recognize factional medicine by name and thus perpetuates it. The committee of this Society, as I think, wisely acting in conjunction with the committeemen from the State Homeopathic Society omitted specific reference to any of the medical sects. The understanding was that in the composition of the board those sects should be represented, and it is apparent that the laws which do recognize sects have done much to keep up sectional lines; besides that, where will it end? Beginning with a statutory recognition of homeopathy and eclecticism, then passing on to physio-medicalism and now osteopathy. Can any human mind compass the infinite subdivisions of true and false science to which we may at last come? No, my brethren, if we must have sects and offshoots from legitimate medicine let us not perpetuate them by tamely consenting to have them entrenched and made everlasting by statute.

What good will it do to recite the annual failures? None, perhaps, except by continual presentation of the case to stimulate renewed effort in this campaign of education, as our friends the politicians say. That the people are indifferent in the matter is unfortunate, but the indifference is due to ignorance, not to wilful intent; whether we can say the same of our legislators is, I think, doubtful; in any event I think it safe to say that continued agitation is necessary. We shall gain nothing by waiting for our posterity to step into line. We should adopt the motto of the Silent Commander when he planted his guns in the wilderness, and ourselves "fight it out on this line if it takes all summer," and trust that in time the vibrations of the pendulum may bring legislation in our direction.

Let us recall the fads and crazes, some of them now dim with the changes of the past, while each had its meed of popularity. Suppose with the present views of those concerned with our legislation we had present with us the Perkinists, who with the same unblushing effrontery that now characterizes osteopathy, paraded the same certificates of miraculous cures and by personages of equally high rank, and yet we know that our fathers knew that these same tractors were bits of insensate brass, unanimated by

even an electric thrill. Perkins had, however, higher aspirations than he of Kirksville, Mo.; having conquered New England with skill and speed, he crossed the Atlantic and invaded the great city of London, where he soon set the fashion by the aid of the magic tractors. Lords and ladies vied with each other in the possession of the precious brasses, and when the faculty ventured to remark, *sotto voce*, that Perkins and his tractors were frauds and should not be recognized as methods of treatment by persons possessing average common sense, then the cry of bigotry, fanaticism and old fogy was raised; the American wit of the day, T. G. Fessenden, an American poet then in London, was employed to lampoon the Royal College of Physicians. This he did quite to the satisfaction of the Perkinists in a satirical poem entitled "Terrible Tractoration!! A poetical petition against galvanizing trumpery and the Perkinistic Institution, in four cantos, most respectfully addressed to the Royal College of Physicians by Christopher Caustic," one English and two American editions of this precious poem of ninety years ago are extant (a copy of which is in my own library), and on perusal I must say that the omnipresent Dr. Still has practically the same grounds for his opposition to the regular profession of today as Perkins had one hundred years ago; but who now mourns for Perkins, while "there are other pebbles on the beach." I suppose if he were here in the flesh we should be compelled to stand by while some able legislature enacted that tractoration as practiced by the immortal Perkins should, to use the language of the bone-o-paths, "not be considered as the practice of medicine within the meaning of the acts regulating the practice of medicine in the State of Illinois." And the Thomsonianism, with its alleged four elements, *earth, air, fire and water*; why does not the steaming ghost of its immortal founder arise and demand "recognition" at the hands of a compliant and awe-struck legislative body?

In reflecting upon these fads and impostures of the past, we can afford to smile at the temporary elevation of the impostures of our own time, knowing that the day will come when they will be numbered with the absent, and that "the dead and the absent are always wrong" by unanimous consent. But will medical legislation always be at cross purposes with the best interests of the community? Let us hope not. Let us reflect that we have two ways to be heard in the legislature, one is to make sure that we send friends to represent us in that body, and the other is to send physicians to the legislature and to Congress. Those in the active period of busy practice need not be sent, but those of mature years, whose experience in every day affairs would make their opinions generally valuable, and who have attained standing and dignity in the profession. I have in mind now two retired physicians, in my own city, yet in mental vigor whose ripe experience makes them welcome at any medical gathering, and are fully capable of taking hold of State questions and matters medical of medical legislation. Indeed the whole country would gain the benefit of their wisdom if they could be put in position to exercise it for the public welfare.

Shall the doctor go into politics? you ask. I say yes, if he can personally afford it and is of ripe experience. We may never hope to have correct medical legislation until we are either properly represented in the law-making body, or the community in general shall have elementary knowledge of medicine; the

latter is probably not practical in our day, and only the former course is open.

No sincere patriot need ever fear in this country to speak his political sentiments or to speak openly in defence of his principles so long as he is governed by pure and patriotic motives, by love of right, and by affection for his country and its flag. Virchow in Germany and Nathan S. Davis in this country have never hesitated to speak out when they thought the exigency demanded, and we have never heard that the people thought any the less of them on that account. Nor of Dr. Joseph Warren who made "incendiary" speeches on Boston Common, and fought in the line at Bunker Hill! Nor of Dr. Benjamin Rush, one of the Continental Congress and signer of the Declaration of Independence.

Put medical men endowed with such noble independence in the legislature and in the halls of Congress, trained by long practice and close contact with the people; they would consider the general welfare as above every earthly consideration. It is said that our profession does not and can not breed statesmen or orators, but let us recall that saying of William Winter, that "there is a better thing than the great man who is always speaking, and that is the great man who only speaks when he has a great word to say."

The acts of the members of the profession in the Iowa Legislature have demonstrated to the world the wisdom of the electors who sent them there.

MEDICAL PROGRESS AS INFLUENCED BY OPPOSITION.

Read before the Florida State Medical Association at Palatka, Fla., April, 21, 1897.

BY U. S. BIRD, M.D.
TAMPA, FLA.

The subject of this paper is *Opposition*, especially its results, as observed in the progress of the science and art of medicine. But it is unnecessary that we confine ourselves to a medical view of this subject. During every day its influence may be observed, if not experienced. And how various are its results! We have seen people driven to despair, even to the extent of self-destruction, by blind, ignorant opposition. People who stood ready to bless the world with the fruits of their genius, but who died, crushed by neglect and contempt, and the consciousness that those who spurned them, and not they themselves, were most injured. Such a predominating consciousness of one's responsibility to his day and generation may not possess every man, but some it does, and the world does not always recognize them, nor hardly realizes what it has done when it has quenched such a spirit. The path of advance is strewn with the remains of those who have succumbed to the pressure of a force greater than they could endure.

The history of the political life of every people is largely a record of apparently fruitless effort of a few against the resistless inactivity of the many. Every difference, insignificant or of international importance, is an instance of the generality of our subject. In every contest are represented two sides, both right to a certain extent, and the champions of one side must fail. Every war represents a sacrifice of lives and interests to a superior force. It is unnecessary that there should be any right in such cases. Both sides may be admitted to be wrong. But when an individ-

ual's allegiance has been won, the fact becomes apparent that he is working for a purpose, which, for the time, may mean every thing to him, and that his failure or success has a significance of its own, independent of extraneous circumstances.

Our every-day business life shows the same conditions. It may not be amiss to suppose that every improvement in detail, every advance in method, represents the life-work, and may be the apparently unsuccessful life-work, of a man. The list of business failures in any of our great papers is an instructive but melancholy illustration of our subject and its results. A most important part of our business world is represented by the mechanical arts and sciences. In this particular branch of work, opposition may, to a great extent, be defined as being ignorance of physical law as it is observed in the various materials with which mechanics have to do. In other fields, ignorance of human nature constitutes a large proportion of the opposition which is encountered. In no other department of our industrial world has there been greater improvement, showing a corresponding activity. Our patent office is deluged with devices of every conceivable description. Many a man has spent his life in trying to prove to the world the value of his idea or design, and given up in discouragement, when he was right.

The history of religion probably contributes more instances of apparently fruitless effort than any other subject at our command. So accustomed at times have devout people become to doubt and opposition, and their results, oppression and wrong, that they have attempted to find virtue in necessity, and pleasure in their trouble. Hence we find fanatics glorying in tribulation, not from high and pure motives, but from the delusion that there is virtue in suffering, independent of the high principles which may at first have led to it.

In the history of medicine we see that great achievements have been preceded by great sacrifices. Only great men are capable of great sacrifices, and yet such men are not always recognized. Men have striven in obscurity and neglect, and have succeeded in sowing a harvest to be reaped by others. But our profession is not behind others in recognizing the merits of its deserving members.

The efforts of Hippocrates, Aristotle, Galen, Vesalius and other patriarchs in medical history have received ample recognition. Their difficulties were such as few of us can comprehend, and their achievements are justly regarded with veneration. Harvey's trials and discouragements have given to his discovery an added brilliance. The glory of Jenner's achievement is not lessened because we know that while he was working to convince people of the great value of his gift to them, he was the most abused man of his time. Abominal surgery owes, in great part, its present development to the impetus given it by McDowell, who operated under unique and dangerous conditions. We are told that ignorance and prejudice threatened his life. To Sims we owe an important surgical operation, and the subsequent impulse given to that class of work. In his book he tells us of his work, pursued under difficulties and against opposition, apparently sufficient to discourage him. Pasteur, thinking and working independently of precedent and careless of ridicule, gave us bacteriology, a science which is taking an important place in relation to every department of medical and surgical work.

But it is unnecessary to enumerate at greater length. The instances given suffice for our purpose. An effort has been made to keep in view the fact that the various instances of progress noted have encountered opposition and repulsion. These isolated facts have been used to indicate an universal condition, a fundamental truth. Since we have to do with a condition which, to a greater or less degree, affects each and every one of us, it will not do to try to explain it away. It is a ghost which will not down. It may be well to inquire why every new fact, every attempt at progress meets opposition, not only among the insignificant and irresponsible, but among the ablest, the most progressive men.

In the first place, it may be repeated that there are two aspects to every proposition. Every fact, every circumstance, has associated with it modifying conditions which make a plausible positive or negative argument possible. By keeping this point in view while studying a subject important errors may be avoided.

Opposition may be included in two classes; reasonable and unreasonable. Unreasonable opposition may be disposed of in a few words, as being due to either jealousy or ignorance, or both. For our purposes it is unnecessary to inquire into these causes. But the other kind of opposition, reasonable opposition, merits our attention.

The most probable cause of reasonable opposition is a natural hesitation to adopt every novelty which may be presented. This hesitation is the result of experience. Repeated disappointments in ourselves and others, warn us to make haste slowly. A famous lyric poet is credited with saying in his haste, "All men are liars." While we may hesitate, for personal reasons, to accept so radical a statement, it is astonishing how many such people are met. Two instances will illustrate the idea as it is sometimes observed.

At a meeting of prominent surgeons one described an operation which he had performed, laying stress on a particular detail, to emphasize which he presented a specimen which he had removed. On inspection the specimen was found to be deficient in this very matter, thereby making the operator unpleasantly conspicuous, though the point was of minor importance.

Another instance illustrates the point in view under different circumstances. A surgeon while visiting the hospitals of our large cities, saw that the reports sent out from a certain institution were uniformly false. In these reports no reference was made to mild cases of sepsis, or other such complications following operations, thereby rendering their records of no value to those who might be working along similar lines.

In those cases, the errors, one unintentional, the other intentional, were made by men of acknowledged ability and high position. No reference is made in this connection to individuals whose countenances adorn the advertisements of cure-alls in the secular press, or to persons whose signatures are appended to eloquent testimonials to the definite effects of indefinite nostrums. Such facts make thinking people slow in reaching conclusions. In the medical profession this amounts to a conservatism which no man's authority is sufficient to break through. Positive proofs must accompany every claim to consideration. Herein is one of the most efficient barriers against

fraud. The consciousness that every detail will be sifted, criticised, examined, misconstrued, forces a man to do this for himself, whether he will or no. And in doing this, he works, laying the foundation of all excellence. Were it not for this conservatism every medicine vender, every theorist would have only to present a nostrum or a hypothesis, to receive universal recognition and endorsement.

As a modification of this hesitancy in accepting innovations, may be mentioned the fact that the simple presentation of a theory or an idea, stimulates opposition in some people. Having no knowledge nor clearly defined opinions concerning the point at issue they assume a negative position, which would seem to have been suggested by contact with the affirmative. Thus we see that either side of every question has champions, who appear to have been created by the emergency.

Another cause of reasonable opposition is found in mental bias of every individual. No two people comprehend equally the same details when viewing a landscape or a proposition. Looking at a specimen of architecture, some may be attracted by color, its various combinations and general effect. Others may notice particularly the various details of form and outline. Others may have a tendency to study the peculiar relations of parts to each other, and to the whole. Still others may look past color, form and architectural effect, to the probable cost. Every other person will not see a proposition as we see it. Every detail will have a different significance to every observer. One result of this fact is that this bias gives a direction to study and investigation, which, if followed far enough, leads to an abnormal mental condition, absurdity. Perception is distorted. Facts are made to conform to our conceptions. That which is desired is seen. If a remedy is sought for a disease, it is found. When found, every sick person is seen to have this disease, and every recovery is credited to the remedy. The natural protection from this danger is that every one has the same complaint to a certain extent, and, by persisting in riding his own hobby, limits the ability of any one to ride his hobby to his own, or another's hurt. As a result of this conflict of many opinions, truth is finally seen, and order arises out of chaos.

The different environments of individuals account for many differences of opinion. An operation or a therapeutic exhibition, which may be a matter of routine hospital work, may be practically impossible under certain conditions. An attempt to use them results in failure, partial or complete. Want of success leads to discouragement and doubt as to the value of such measures. This may not be good logic, but it is a fact, as many of us can testify, and as such merits our attention. Facts are not disposed of by a comment of the illogical.

Again, supposing that the conditions are practically the same, people have a preference for things to which they are accustomed. A surgeon performs an operation with greater dexterity and better results than the modification which another surgeon performs. A physician has better success with remedies with which he is acquainted by long experience than with the therapeutic suggestions with which medical literature abounds.

One of the most important, and probably least understood causes of differences in results, and consequent differences in conclusions, is in people. No two

individuals are exactly alike, and yet individual differences are difficult of determination and interpretation. It is impossible to say that a certain disease affects an individual exactly as it did affect, or will affect, another individual. There is a certain resemblance among the grosser details of disease which justifies a classification, but the more subtle points can not be included in such a generalization. The fact that it is so little understood would indicate it as a most convenient shield for the errors of incompetence and trickery. But, because a fact may be misused, it is not to be taken for granted that it is of no use. Further study and investigation may throw such light on idiosyncrasy as to make it an important aid in medical practice.

If my propositions are admitted to be probable, it would appear that opposition is not altogether a thing of evil. Undoubtedly in the practice of medicine, it directly accomplishes much good by protecting the profession and the public from imposition. This is only a negative effect. Its positive, or indirect results are far more important and beneficial.

There are few things so stimulating, so inspiring, as opposition. Without opposition there would be stagnation. Ambition is its legitimate offspring. Were there no resistance, no obstruction, there would be no honor, no reward. The great incentive to labor would be wanting. Duties would be performed carelessly or not at all. No one strives for what all may obtain. Difficulties surrounding an object enhance its value. In many instances the pleasure of overcoming difficulties, the consciousness of having accomplished something worthy of us, is a sufficient reward. The object sought becomes of secondary importance. We encounter opposition under circumstances which make it necessary for us to rise above ourselves to overcome it. By rising to the occasion we become better and stronger. We add so much to our mental and moral stature. To opposition we owe most of the great moral and intellectual trophies bequeathed to us by former generations. Some of them are evidences of that peculiar and obscure force known as genius. By far the larger number is due to the earnest, steady, enthusiastic efforts to overcome difficulties by representatives of that great mass of humanity known as "the people," "the common people;" more correctly the typical, the normal, the intellectually, morally and physically healthy people. People who have not been dwarfed by the demands of our social customs. Those are they who are able to overcome difficulties.

Opposition presupposes movement. Not till a body begins to move does it encounter resistance to its progress. Insignificance attracts no notice nor criticism. An intellectual or physical fact may be considered as stationary, inoperative until it arouses resistance.

The lesson to be learned from this is so obvious that it is needless to enlarge upon it. It appears unfortunate that our ideas should prove faulty, our plans fail under the rebuffs and discouragements of opposition. It must be unfortunate. Our ideas are adopted, our plans laid, because they represent right to us. It is no small matter to know that our conception of right was wrong, even in an insignificant detail. The principle is the same, in great and small things. If we do our part well we can not afford to ignore results. By giving them our attention, using them as object lessons, we may learn to avoid similar

errors and overcome similar difficulties, thereby appropriating the only good in a mistake.

In the instances of medical progress referred to, each one was distinguished by an important characteristic: each one was a fact, an intellectual and physical fact. The circulation of the blood, vaccination and bacteriology are no visionary theories. Investigation, study and examination can not destroy facts. The refining fire injures and destroys refuse, but not gold. The great workers in our profession try their facts with fire seven times hotter than they expect others to use. When they present an idea they feel that it can stand any test, for have they not used every test? If one has anything which will help to advance science and benefit humanity, the object of all science, let him prove it; be sure that it is something of value, not the premature fruit of a vain and indolent imagination. Knowing this, there need be no hesitation to present it because of expected opposition. If an idea is valuable, criticism will demonstrate it. Expecting discouraging resistance it should be prepared for. Every possible contingency should be provided against, every fault and deficiency removed, and an idea, an operation, a therapeutic suggestion, presented which will not need defense. Success may not come in a month, or a year, but facts, which are truths, will ultimately prevail, their success being in a great measure the result of opposition.

THE DELIRIUM OF SHOCK.

Read at the Third Annual Meeting of the American Academy of Railway Surgeons held at Chicago, Sept. 23, 24 and 25, 1896.

BY R. SAYRE HARNDEN, M.D.

SURGEON TO THE NEW YORK, LAKE ERIE AND WESTERN RAILWAY;
EX-PRESIDENT OF THE NEW YORK STATE ASSOCIATION
OF RAILWAY SURGEONS, WAVERLY, N. Y.

I have purposely substituted this title as the subject of my paper for the reason that "Traumatic Delirium," as announced in the program, does not apply to all cases of delirium accompanying shock, especially to those cases termed, unwisely I think, "hysteria." That many functional conditions following traumatism, or nervous shock, may be of that character I have no doubt, but I do not like the term and I am certain that in many instances the delirium of shock results from pure psychic shock and sometimes proving fatal, even when unaccompanied with any actual traumatism.

What is this peculiar psychic condition to which we briefly call attention? Has it ever been full and satisfactorily explained? It has seemed to me, from an extensive experience with surgical cases and a personal observation of many of them attended with this strange and singularly fatal element, that the subject is of considerable importance.

Some authors claim they have never observed recovery in any case of severe traumatism attended with this form of delirium, and this has been—up to a recent date—my experience. I have, however, met with cases of pure psychic shock, not traumatic, attended with what seemed to be or at least simulated closely the delirium of shock.

I will cite one case, an engineer, whose engine came into collision, knocking the cab into kindling wood. He jumped off and fell upon one knee in the gravel, slightly bruising the skin over the knee-pan. He stoutly asserted that his limb was crushed, and while they were conveying him home upon a stretcher, continually cried out, "Oh! go and get my leg," screaming at the top of his voice the same song without change

of tune or tone, and the sight of his leg or my argument and most emphatic assurances made no impression upon him. He appeared to be in terrible agony, his anguish so pitiful as to excite the crowds of sympathizing friends almost to frenzy. When I had satisfied his friends that he was not injured at all, and they began laughing at him, he sat up, took a careful survey of his limb and emerged from his delirium.

I do not deem it necessary for me to give a recital of numerous cases of this peculiar inversion or perversion of mentality. I wish, however, to cite a case of pure delirium of shock accompanying a severe and fatal traumatism. A man and his mistress were run over by an engine, picked up and carried into our elegant temporary hospital, the baggage room. The man died in a few moments, and the woman lying by his side with a severely crushed leg, seemed utterly oblivious of her condition or his presence; answered questions promptly and correctly, giving me her name, residence, etc., said she was "in no pain." "Oh, I am all right, doctor," sang merrily and chatted lovingly, as she seemed to think, with the husband she had dishonored and left, and seemed to be going rapidly over her happy married life, but with no allusion whatever to her paramour or her injuries, ignoring anything said to her upon either subject, and yet seemingly perfectly rational when asked her name, residence, etc. When asked if her limb hurt her, lifting and examining it at the same time, she answered very promptly and frankly, "No," and at once resumed her happy songs and loving chat. At that time she had no perceptible pulse and, in fact, died in a short time. This case is perhaps a fair illustration of the delirium of shock.

I will only impose upon your patience and credulity by quoting one more case, similar to the above, but with different result. In this case the man, age 22, was run over by a loaded box car, the flesh crushed and entirely torn from the bones of the leg and thigh up to mid third, requiring amputation in upper third. There was slight manifestation of delirium and utter oblivion, as in the case just mentioned, of his injury. He would look at the mangled flesh and denuded bone, and then without seeming to realize that he was seriously hurt, would ask me if I would have him fixed up in a few moments, so he could go home. There was no mental excitation in this case. The loss of blood was considerable, pallor, lowered temperature, pulse, etc., indicated a grave degree of shock, and in fact, this case was typical of many I have seen which have proved fatal, and I fully believe this one would have proved so, but for the modern heroic measures for the restoration of vitality. The intravenous saline injection, hypodermic injections of nit. strychn., nitro-glycerin, etc., and external heat were used, and this case, which I had pronounced fatal, made a nice recovery.

Now, gentlemen, I believe the other case—occurring some years prior—might have been saved in spite of the fact that she exhibited in more marked degree the delirium of shock, as her injuries were not apparently as severe as in the latter case. I have an idea that the modern treatment of shock may perhaps change materially the experience of surgeons as to the fatal indication of this form of delirium.

The delirium of shock met with upon the battlefield, with its attendant exciting environment, is in many respects similar to that observed in railway accidents. I have passed among the wounded after

some of the great battles in our late war, and noted numerous instances of this peculiar delirium. The "shock of battle" in itself produces delirium, as I well know. I was not conscious of a severe wound until my attention was called to it by others. The awful groans of the wounded and dying, of which the historian and poet tell us, were often mingled with the chattering and happy songs of the mangled and expiring soldier, and in both instances, as a rule, the victims were unconscious of any actual mental or physical suffering.

Intense and unquenchable thirst is usually, and invariably I might add, the greatest suffering experienced by the wounded. Who has ever yet satisfactorily defined or explained this awful thirst for water? What is the condition which checks the sufferer in his muttering or delirium, and prompts him to ask coherently, often imperatively, for water, thank the giver, and relapse into a condition of unconscious anguish? Is it dissolution, molecular disintegration of vital nerve centers, or a peculiarly disturbed and exalted mentality, akin to catalepsy or hypnotic suggestion? The functions of the brain seem sensible and exalted, often keen and brilliant. These cases certainly exemplify the fact, that severe traumatic conditions are not usually attended with much pain during the manifestation of shock; are they hypnotized by their terrible environment into a condition of anesthesia?

A very plausible explanation of the cause of serious and fatal shock, with its attendant symptoms of delirium, etc., seems to be the molecular disintegration of the nerve centers, or nerve fibrilla. The impaired respiration, diminished arterial tension, cardiac depression, musculo-cutaneous anesthesia, sub-normal temperature, etc., would certainly indicate this. Certain it is, the brain often retains its functions to the last, exalted and bewildered, it is true, but still the citadel of the mind, obeying its demands, even when the bodily functions are paralyzed and undergoing rapid dissolution, and acting with unusual rapidity.

I have often heard dying men give instruction as to the disposal of their effects, describing accurately where they could be found, and going into details that a lawyer would not think of, as though conscious that dissolution was rapidly approaching and yet apparently unconscious of their physical condition, or the nature of their wounds. It is a pitiful and strange scene to witness the dying look, keen and yet vague, brilliantly pale, almost phosphorescent; the bright, keen and shimmering eye; the hoarse and gradually fading voice; the imperative, pleading, pathetic demand for water! more water! as if its cooling influence might assuage the awful anguish. The poet exclaims:

"Death having preyed upon the outward parts,
Leaves them insensible; and his siege is now
Against the mind, the which he pricks and wounds
With many legions of strange phantasies;
Which in their throng and power to that last hold,
Confound themselves; 'tis strange that death should sing."

Charcot, Oppenheim, Strümpell, Guion, Thorburn, Dreschfield, Weir Mitchell and others seem to be exponents of the theory that hysteria enters largely into the element following traumatism in many cases, but others dissent from this view, and it seems to me wisely. I do not myself like the term "hysteria," especially when applied to such conditions.

In Georges Guion's work we learn that "many of

these disorders arise, not so much as the result of an immediate cause, but from the state of the nervous system being such that an exciting cause is able to provoke it to the manifestation of functional disorder."

Page, in his admirable work on railway injuries, claims that "these nervous disorders have their beginning in profound mental shock, and the cause will be found in the cerebral cortex, and that the mandate of the brain through the spinal cord is checked, as indicated by inability to protrude the tongue or move the limbs."

There is no doubt in my mind that the suggestion, or autosuggestion element, enters largely into these cases, and might properly be termed "traumatic suggestion," but for the fact that they are observed in cases of psychic shock unaccompanied with traumatism.

Railway accidents are usually attended with an element of severe nervous shock, not only to the injured, but to every one present. My experience has demonstrated, to me at least, that there are distinctive features in railway shock, and I believe the element of psychic shock is far more common in such accidents than in those met with elsewhere.

It was not my intention to go extensively into the discussion of shock, or to quote at any length the views of authorities upon the subject of the delirium of shock, but simply to call attention, briefly, to some points relative to the importance of this peculiar and usually fatal indication, believing that a more thorough examination and discussion of the subject at the hands of the learned gentlemen of this Academy might result in a better understanding and improved methods of treatment of the more severe forms of shock. The practical application seems to be that we should bend all our energies and efforts to overcome this element called traumatic shock, especially those cases attended with delirium, unless, indeed, the poet be right in assuming it to be dissolution or death.

I am frank to say that up to a recent period I have invariably given an unfavorable prognosis when this *well-defined* indication of grave element of shock manifested itself and did not feel warranted in resorting to measures for its relief when accompanying severe traumatisms.

DISCUSSION.

Dr. JAY—Delirium is a disturbance of the cerebral functions manifested by impaired action of the nerve centers, characterized by hallucinations.

Shock is the depression or grave effect produced by severe injuries, operations or strong emotions; a relaxation or suspension of the sustaining and controlling influence which the nervous system exercises over the vital organic functions of the body. It is the result of a profound impression made on the cerebro-spinal axis, either directly through the agency of an afferent nerve or through the circulating medium. There is a peculiar condition in which the manifestations of shock are due not to severe bodily injury but to purely mental causes. This variety of shock may be even more profound than that produced by bodily injury. The mental impressions produced by railway accidents come under this head; while the precise change which takes place in the cell structure of the ganglia of the cerebro-spinal system, to produce the delirium is caused by a change in cell relations produced by the shock, either bodily or mental, certainly seems plausible. It may be that the cell structures of the brain are unduly stimulated as in the delirium of intoxication, or from an anemic condition as in low grades of fever accompanied by delirium. A child will become delirious from mechanical irritation of the digestive tract

reflected through the spinal cord to the brain. In any and all forms of delirium there must be a change in the physiologic condition or the anatomic relation of the cerebral cell structures, and does it not seem probable that the anatomic relations of the cells have been temporarily changed; that the shock has disturbed the natural relations existing between the minute cells; any such disturbance of the cerebral cell structures must disturb or derange the mental processes, and the disturbance of the mental processes is the delirium? This disturbance of cell arrangement may be that the location or position or peculiar grouping together of the cell structure have been temporarily changed and the delirium will continue until the physiologic relations have been restored. Mental processes may produce this change in cell arrangement, and delirium follows. The part or organic structure involved must be the same, and similarly affected in all causes of delirium or else the mental processes do not have a fixed and definite location through which to make manifest their marvelous doings, or in which to record their wondrous achievements. In delirium the intellect or mind is not impaired, but the organic structure, through which the researches and investigations of the intellect are made known and in which they are recorded, are not in perfect condition to receive them, hence the wandering. Often this cell derangement is soon restored by rest and quiet alone. At other times help is furnished by medical aid or surgical assistance. Whenever or by whatever means this is accomplished the delirium has ended, the intellect commences where it left off, at the beginning of the delirium, and the individual is himself again.

Dr. COLE—Dr. Jay, who opens the discussion, has talked about everything but delirium of shock.

Dr. JAY—That shows how little you know about it.

Dr. COLE—That shows, Mr. President, how little any of us know about this subject. We know no more today than our forefathers did a hundred years ago about shock, and until some one gets ready to make an exhaustive and systematic explanation upon the different orders of animal kind we are not likely to. The French school, strange as it may seem, disclaims any such condition as shock and traumatic shock. I say strange as it may seem, because the French are of a neurotic temperament, and it is generally agreed that shock has to do primarily with the nervous system. We know that a snake's head may be cut off and they will live not only till sundown but perhaps several days; we know the same thing is true of other animals in the lower orders. Those of us in active practice know that the cases where we get what is called shock most pronounced are, as a rule, among patients of a nervous temperament, whether it is molecular changes, or whether it is as the French claim entirely due to the loss of blood—which claim to my mind is ridiculous because we have all seen shock where there was no excessive hemorrhage; whatever it may be, no one has as yet been able to determine, or give a satisfactory definition of shock. We see it in so many forms, including the delirium of shock which the author has so beautifully written about. It would be desirable if this Academy, representing an important branch of surgical practice, a class of surgical work where this element so largely predominates, could in some systematic way elucidate this subject.

Dr. REED—Just one point I wish to call attention to in this discussion. I do not propose to try to throw any more light on the question, but I do not think it is quite the right thing to allow the remark which our distinguished Fellow made, to go without a little check on it. I think the Doctor did not intend the meaning to be conveyed which seemed to be conveyed in that respect, and that is that shock was the result or might be the result of the shaking apart of the cells of the brain or the spinal cord. The point I wish to make is this, that while that has been advocated I do not think there is good reasonable ground on which to establish a theory that would carry it out.

For instance, a man is shot through the head—and I have seen more than one person shot through the head fall down and get up and walk off—and there is some shock, and the man gets well after all this. I saw a man in whom I am sure the cells were very much torn; he had a buzz saw cut his skull open from the occiput to a point between the eyes tearing out the sinus—and not a small buzz saw but a large saw—and that man got well to my positive knowledge and lived ten or twelve years afterward; and I made a postmortem—after his death, of course (laughter). The point I want to get at is this: There was a very marked disturbance of the cells of the brain, and yet that man did not have any marked shock, he did not have any delirium. I know another case that was hurt on a railroad in an accident near Loudenville, O., the whole side of the head was crushed in; that boy got up and in less than two minutes he walked two blocks from the engine leaving a part of his brain lying on the platform, and dripping over him, and he did not become delirious. I begin to think that the theory which the doctor did not qualify, is untenable ground, and we should be careful in taking such a position, first, because it is not tenable, and second, because we have "our friends, the enemies," ready to say that is the cause of all the spinal calamities we go into court with. I do not think it is right to take that ground which is dangerous and which has a foundation not absolutely tenable. I simply bring these cases up as evidence that it is not always, at least, shaking up the nervous system that produces delirium.

Dr. BRYANT—I am not a pathologist, but I have a friend who is a histologist and pathologist, and he tells me that all cells, nerve cells as well as others, eat, grow, reproduce and have motion; and as a pathologist he says shock is due first to lack of eating—nutrition; he tells me the loss of blood will cause shock, interfering with nutrition; anything, like joy, grief or fright, which will interfere with digestion will also cause shock—it interferes with the nutrition of the nerve cells—and that is as far as I can go in this matter; but I think that is correct, and perhaps time will prove it.

Dr. HARNDEN—I had thought perhaps I would elicit some information on the cause of the peculiar condition. I find I have failed in my object. I am satisfied we will not be able to find the cause, the peculiar condition. I do not think I have expressly stated in any part of my brief paper anything which explains the condition to my mind or to yours; I thought Dr. Reed was going to give an explanation, and he got the buzz saw started half way through the man's head, but I found he stopped the demonstration, and I stop too.

RELATIVE INSUFFICIENCY OF THE PULMONARY VALVES.

Read before the Chicago Pathological Society, Feb. 8, 1897.

BY ROBERT B. PREBLE, M.D.

INSTRUCTOR IN GENERAL PATHOLOGY AND CLINICAL MEDICINE AT THE NORTHWESTERN UNIVERSITY MEDICAL SCHOOL, CHICAGO.

I shall make no apologies for presenting to the Society the report of a case and a brief paper upon so rare a condition as insufficiency of the pulmonary valves and the rarer condition of relative insufficiency. If we would make accurate anatomic diagnoses of the commoner valvular affections, we must have some familiarity with the signs of the rare ones. I am confident that you will all agree that we should not content ourselves with the diagnosis, "heart disease," but should endeavor in all cases to make as detailed a diagnosis as possible.

Relative insufficiencies, that is, those due to enlargement of the orifices rather than to contraction of the cardiac valves, are now admitted by almost all clinicians. Those upon the two auriculo-ventricular orifices and the aortic orifices are well known and the recorded cases are very numerous.

The relative insufficiency of the pulmonary valves has received very little attention as yet, and the reported cases can be counted almost on the fingers of one hand. I believe, however, that when once the attention is directed to the subject, the cases will rapidly multiply, for many of the conditions which may in time cause a relative pulmonary insufficiency are common.

The literature of this subject may be dismissed very briefly. Cases have been reported by Stokes,¹ Kolisko,² Bristowe,³ Coupland,⁴ Litten,⁵ Chauffard,⁶ Gouget,⁷ each one and supported by autopsy. Pawinski⁸ in 1894 reported four cases, but only one went to autopsy some months after the diagnosis of relative insufficiency had been made, and no insufficiency of the pulmonary valves was found. Grawitz⁹ reports one case unsupported by autopsy, so that his case is not above question. Chauffard's case seemed well established clinically, but at the autopsy the pulmonary valves were competent to the water test. Barie¹⁰ in 1891 collected 58 cases of pulmonary insufficiency with 43 autopsies, and included in his list the cases of Stokes, Kolisko, Bristowe and Coupland. He evidently did not regard them as relative, for he questions the possibility of relative pulmonary insufficiency, although in a later article, 1895, he admits the possibility. The literature thus contains but six cases supported by autopsy.

Because of this very brief list we must infer much of the etiology and symptomatology by comparison with aortic and organic pulmonary insufficiency.

Because of the anatomic and functional similarity between the aortic and pulmonary valves, we are justified in the inference that conditions similar to those causing relative aortic insufficiency might cause relative pulmonary insufficiency if brought to bear upon the lesser circulation. The possible causes of relative aortic insufficiency are numerous, but they may be conveniently classified in three groups: 1, those affecting the aorta, altering its structure so that it is dilated more easily, as in acute aortitis, arterio-sclerosis; 2, those increasing the peripheral resistance, as in nephritis; 3, those dilating the left ventricle, as myocarditis.

By transferring this grouping to the pulmonary valve, we have:

1. Arterio-sclerosis of the pulmonary artery is uncommon and rarely reaches a high degree. There is no reason why it might not cause relative insufficiency of the valves.

2. This group of causes, namely, those increasing the resistance to the circulation of the blood through the pulmonary artery, is most important and includes many different diseases. Gourand¹¹ in 1865 drew attention to the possibility of relative pulmonary insufficiency resulting from emphysema, chronic bronchitis and indurative pulmonary processes. Coupland's case was secondary to emphysema, Bristowe's to emphysema and obliterative pleurisy. Stokes does not specify in his report as to the primary condition, but states in relation to the question that he has seen marked dilatation of the pulmonary artery in cases of emphysema.

Gouget's and Chauffard's cases were secondary to a combined mitral lesion. It is well known that these lesions cause an increase in the resistance to the pulmonary circulation, and there is no reason why the increase may not so dilate the pulmonary artery as to render the valves incompetent. The four cases reported

by Pawinski, and the one by Grawitz, were cases of mitral stenosis. From the clinical report we can not but agree with Pawinski's diagnosis, but the autopsies are wanting.

Litten's case was very different. The pulmonary artery was plugged by an embolus, an echinococcus cyst. The vessel was dilated to such a degree that the valves became incompetent.

Other diseases which might belong in this group are obliterative pleurisy, obliterative pericarditis, kyphoscoliosis, mediastinitis, aortic aneurysms and other mediastinal tumors, and all conditions which sometimes give rise to pulmonary embolism.

To these we must add the cause found in the case to be reported. When for any reason the left ventricle fails to do its work, the blood may dam back into the lungs and reach such a tension as to cause relative insufficiency of the pulmonary valves. This adds a large number of diseases, all those which can cause an increase in the resistance in the systemic vessels.

3. The third and last group, those affecting the myocardium, could as well cause relative pulmonary insufficiency as it does other relative insufficiencies.

The physical signs of relative pulmonary insufficiency do not differ essentially from those of an organic insufficiency. There is a varying degree of cyanosis, but often far less than one might expect. Sometimes there is a visible systolic pulsation in the second left intercostal space, and this may be so marked as to suggest a thoracic aneurysm. Over this same area there is often a palpable thrill, systolic or diastolic, or both. On deep palpation below the ensiform we can sometimes make out a diastolic thrill in the right ventricle.

Percussion shows that the cardiac dullness is increased to a varying degree to the right. The left borders of the heart are normal or nearly so, unless changed by some complicating condition. The dilated pulmonary artery often gives a retrosternal dullness extending to the left second intercostal space.

Auscultation shows a diastolic murmur loudest in the second left intercostal space, propagated down the sternum and outward toward the left clavicle and usually not audible over the auscultation point of the aorta. According to Bernhardt, the murmur is loudest during expiration. The murmur is quite similar to that heard in cases of aortic insufficiency, but is not propagated into the vessels of the neck. Its point of maximum intensity is not peculiar to it, for the murmur of aortic insufficiency is frequently loudest in the second left interspace. It is often accompanied by a systolic murmur, just as the diastolic murmur of aortic insufficiency is.

Friedreich in 1867 stated that there could be no doubt but that the same vascular phenomena occurred in the pulmonary circulation with insufficiency of the pulmonary semilunars, that occur in the systemic vessels in aortic insufficiency. These vessels, although removed from direct observation, still give rise to certain signs described by Gerhardt.¹² Gerhardt¹³ found that a manometer connected with the nose gave a tracing of the pulsation of the pulmonary artery. The tracing taken from a case of pulmonary insufficiency differed very greatly from those taken in the normal individual and in cases of aortic insufficiency, being higher and steeper and resembling the pulse tracing of aortic insufficiency.

Although we can not apply the stethoscope directly to the pulmonary artery, we still find traces of auscul-

tatory phenomena similar to those of the peripheral vessels in aortic insufficiency. Gerhardt found in five cases of pulmonary insufficiency two dull tones audible over the entire chest and similar to those heard over the brachial artery in cases of aortic insufficiency. Similar tones are heard over the normal chest close to the heart, but not at a point so remote as the outer border of the right scapula. Wide diffusion of these tones is not, however, peculiar to pulmonary insufficiency, for they are found also in well-marked cases of mitral insufficiency, where they arise in the pulmonary vein, and in cases of aortic insufficiency, where they arise on the aorta.

Pulsation of the pulmonary capillaries occurs just as it does in the peripheral capillaries in aortic insufficiency. Systolic intensification of the vesicular murmur during slow and deep inspiration in the portion of the chest near the heart has been known for a long time, but this phenomenon, called by Gerhardt an "audible capillary pulse" over remote portions of the chest, occurs only with the pulmonary insufficiency when the capillary pulse is derived from the pulmonary artery, with cases of mitral insufficiency when the capillary pulse is due to a retrograde wave of blood through the pulmonary vein, and in cases of aortic insufficiency when it is exactly comparable to the capillary pulse in the systemic vessels.

The second pulmonary tone may be present or absent.

These, briefly, are the physical signs in cases of relative pulmonary insufficiency. We will find in addition the signs of the primary condition.

The following is a brief clinical and postmortem report of a case, seen in Dr. Herrick's ward of the County Hospital:

German laborer, 42 years old, single and with negative family and personal history, except for an attack of gonorrhoea seven years ago. Never had rheumatism or any other illness. About two years ago ran four miles without special inconvenience, but the next day spat blood, and had palpitation of the heart for several days. About one year ago had an attack of weakness and shortness of breath. Present illness began some days ago with dyspnea, headache, vomiting, cough, precordial pain and edema of feet and legs.

Examination showed a well-nourished man, face flushed and slightly cyanotic, moderate dyspnea, edema; veins of the neck prominent, showing a negative pulsation, and at no time did they show the positive pulse characteristic of tricuspid insufficiency. Temperature normal. Pulse slow until just before death. Small amount of fluid in chest, later increasing to such an amount that the chest was aspirated, drawing off a pint and a half of serous fluid of specific gravity of 1009, and containing few red blood corpuscles. Chest and lungs otherwise negative.

Heart: Apex beat in sixth interspace in the anterior axillary line. Deep cardiac dullness to second rib above, and one and one-half inches to right of sternum and to the apex beat. Palpation showed over the apex a systolic and presystolic thrill. The pulse had the characteristics of the pulse of aortic insufficiency well marked; capillary pulse distinct. Auscultation at the apex showed systolic, diastolic and presystolic murmurs. At the base two diastolic murmurs resembling the murmur of aortic insufficiency, that is, soft, long drawn and blowing. One of these murmurs was transmitted downward from the aortic area toward the apex; the other downward along the sternum. The second pulmonary tone was wanting, as was also the second aortic.

The liver was enlarged from passive congestion.

The urine scanty, of high specific gravity, albumin with granular and hyaline casts.

The interpretation of the cardiac findings was not entirely simple. The shape and size of the cardiac dullness indicated an enlargement of both ventricles. The character of the pulse and the diastolic murmur at the base satisfactorily demonstrated an aortic insuf-

iciency, which accounted for the enlarged left ventricle.

The enlarged right ventricle was referred to a mitral lesion, either double or single. Relying mainly upon the presystolic thrill at the apex, the lesion was thought to be a combined mitral insufficiency and stenosis. Had there been only the presystolic murmur at the apex, it would have been interpreted as the presystolic murmur described by Flint in cases of aortic insufficiency. I have since learned that Schwalbe has found a presystolic thrill at the apex in a number of cases of aortic insufficiency without any accompanying mitral stenosis.

We had yet to account for the second diastolic murmur at the base, transmitted down the sternum, and for the absence of the second pulmonary tone, which, if there was a mitral lesion, should have been accentuated. Both of these could be easily explained by the supposition of a pulmonary insufficiency. This supposition was strengthened and confirmed when, after a few days' treatment, this murmur disappeared and the second pulmonary tone reappeared. The improvement was but temporary and the pulmonary tone was again replaced by a murmur.

The clinical diagnosis was aortic insufficiency, mitral stenosis and insufficiency, relative pulmonary insufficiency, parenchymatous nephritis, hydrothorax and passive congestion of liver.

After being in the ward a few weeks the patient died, and an autopsy was held four days after death.

The heart unopened weighed 1040 grams. Walls of both ventricles thickened, left ventricle 2 centimeters, right ventricle 1 centimeter. Aortic semilunars thickened, not more than two-thirds the normal size and incompetent to the water test. Pulmonary valves unchanged in structure, but are incompetent to the water test. Mitral valves thickened at the base, many vegetations. Orifice admits six fingers. Myocardium soft and friable, with scar in the interventricular septum. Tricuspid negative. Aorta shows atheromatous plaques. Liver of passive congestion. Kidney of parenchymatous nephritis.

Postmortem diagnosis: Hypertrophy and dilatation of the heart; aortic, pulmonary and mitral insufficiency, fatty and congested liver, parenchymatous nephritis.

The autopsy showed first that there was no mitral stenosis, so that our inference of mitral stenosis from the presence of the presystolic thrill at the apex was not warranted.

It is much to be regretted that the pulmonary orifice was not measured. The normal, according to Rauhing, being 67 millimeters in the male, measured in fifteen cases, and 63 millimeters in the female, measured in sixteen cases. Peacock's figures vary from these, being 90 mm. in the male, measured in sixteen cases, and 88 mm. in the female, measured in thirteen cases.

The water test as applied to the pulmonary valves is much more reliable than when applied to the aortic valves, for there are no coronary arteries through which the water may escape, and the difference between the blood pressure under which the valves close during life and the pressure of the water test is not so great as with the aortic valves.

From this case and the others so far reported, we must conclude that relative insufficiency of the pulmonary semilunar valves is possible, and inasmuch as the primary diseases which may cause this lesion

are common, we are justified in believing that this condition is not so rare as so far supposed.

ON THE PRODUCTION OF HYDROCHLORIC ACID IN THE GLANDS OF THE STOMACH.

BY J. A. WESENER, PH.C., M.D.

CHICAGO, ILL.

PRELIMINARY COMMUNICATION.

In *Medicine* of November, 1895, I showed that hydrochloric acid is secreted by the mucous membrane of the stomach and not formed by chemic action on the food products or fermentation. In these experiments I found a nearly constant relationship in the percentage of acid produced after each stimulation. Since then I have performed the same experiments upon three cases of chronic gastritis. In these cases free hydrochloric acid could never be detected with Boa's reagent, but upon quantitative determination of total chlorin before and after evaporation of stomach contents a difference of chlorin was found which gave about the same per cent. of volatile chlorid as was found in the cases of normal stomach, where free hydrochloric was always present.

This decomposition of chlorid was not syntonin, as the experiments were performed upon empty stomachs. This led me to believe that I was dealing with a very unstable organic chlorid, which when evaporated to dryness volatilized the same as free hydrochloric acid, but would not give Boa's test. On the strength of this observation I performed the following experiment:

1. Pure nucleic acid was obtained from three dozen thymus glands of sheep.

2. A syntonin solution was prepared; this contained .2 per cent. of egg albumin and .1 per cent. of hydrochloric acid; the acid was all taken up by the albumin.

Then before proceeding, the nucleic acid solution and syntonin were tested for free hydrochloric acid with Boa's reagent, to be absolutely certain that it was absent. To 5 c.c. of syntonin a saturated aqueous solution of nucleic acid was added as long as a precipitate was formed. (The precipitate is a nuclein proteid.) This precipitate was filtered out and the filtrate tested for free hydrochloric acid. Boa's reagent gave a positive reaction. The experiment was repeated several times, the results always the same.

On making a quantitative estimation of the chlorin, in the syntonin and after precipitation with nucleic acid, it was found that all the combined chlorin had been discharged as free hydrochloric acid.

About this time I had the good fortune of seeing a case at the laboratory which I must report as it will be the keynote of my theory, which I will state in the conclusion. The patient was a man who has suffered from chronic gastritis for several years. The first examination of the stomach contents gave the following: Reaction alkaline, free hydrochloric acid absent,

mucus abundant. He was given hydrochloric acid; three weeks later another examination was made. Reaction slightly alkaline, Boas' and Günzburg's reagent gave a reaction for hydrochloric acid. The red color which was produced was not as sharply defined as when free hydrochloric acid is present, but more of a diffuse red; furthermore, the reaction did not take place until the last drop was evaporated, whereas when the acid is present in a free condition, the color shows very soon after the heating is commenced. A quantitative determination of chlorin before and after evaporating the stomach contents, showed that a loss of chlorin always took place. From these facts I feel justified in saying that hydrochloric acid is never present in a free state in the glands of the stomach but always in combination with a proteid, and when this body is thrown off from the glands a decomposition takes place, giving free hydrochloric acid and a proteid.

The reason I have for this statement is:

1. In the cases of chronic gastritis that I have examined, there is a very unstable proteid chlorid (which is not syntonin), which when tested for free hydrochloric acid is negative, but when estimated quantitatively acts just like free hydrochloric acid.

2. I have shown what a powerful affinity nucleinic acid has for albumin and that when chlorin is in combination it is discharged as free hydrochloric acid.

3. In the one case of chronic gastritis a reaction was had for free hydrochloric acid, although the reaction of the fluid was alkaline to litmus, phenolphthalein and lacmoid. The acid could not have been there in the free state but must have been there in a proteid combination, which when heated very gently decomposed giving free hydrochloric acid.

4. That the nucleus of the cells in the glands of the stomach take up the chlorids from the blood and combines them with the pepsinogen and rennet zymogen; this combination remains intact in the glands, but when discharged decomposes into free hydrochloric acid, pepsinogen and rennet zymogen. The acid thus liberated first acts upon the albumins to form syntonin and then acts upon the zymogens and liberates them into an active state. I believe this assertion is correct for the reason that pepsin and rennet are very closely related to nucleinic acid.

FISH SLIME DISEASE.

Read before the Cape May County (N. J.) Medical Society.

BY EUGENE WAY, M.D.

PRESIDENT OF THE CAPE MAY COUNTY MEDICAL SOCIETY AND MEMBER OF THE AMERICAN MEDICAL ASSOCIATION.
DENNISVILLE, N. J.

The title of my paper is the name applied by the laity to a disease, which, owing to the location of our county and the occupation of a large number of its inhabitants, is frequently met with by the members of this Society, and undoubtedly by all physicians living near the seashore, but of which little or nothing has been written or published in our text-books.

The disease consists essentially of septicemic inflammation due to the entrance into the blood through the lymphatic system of the slimy exudation covering the fish of our bays and ocean.

The class of persons most liable to this disease are the hardy fishermen who follow the sea for a livelihood, and so well is the disease and its cause known to them that they have named it as above.

The poison causing this disease, in the majority of

cases, enters the system through an abrasion on the hands, usually caused by a puncture made by the fins of the fish.

The symptoms vary in degree according to the amount of poison entering the system.

In some cases there is only a slight swelling and redness at point of injury, or a small nodule forms which is annoying for a few days. In other cases painful abscesses form which are slow in healing, the patient, however, being able to go about but unable to follow his vocation.

In the severest type of cases met with there is after two or three days of general languor, a well-marked chill followed by fever and sweating. The point of injury becomes swollen, red and very sore and develops into a deep-seated abscess, the pain from which is excruciating and agonizing in the extreme. The chill or a chilly sensation recurs daily and fever becomes continuous, accompanied by vomiting and great muscular weakness, sometimes attended by delirium. The tongue becomes heavily coated and the skin usually sallow.

These symptoms continue with greater or less severity until the formation of pus, which occurs in from four to eight days, when they ameliorate, leaving the patient exhausted and often anemic. Secondary abscesses often form in the axilla, and congestion of lungs a not unusual and dangerous complication.

The prognosis is favorable as the disease is seldom seen except in fishermen, who are of necessity a hardy and robust set of men, but would in more delicate persons undoubtedly show a small percentage of deaths.

The treatment consists of removing the exciting cause of the disease, relieving pain and keeping up the strength of the patient.

The prophylaxis, which can seldom be applied, consists in at once washing the abraded or injured surface with fresh water and an antiseptic solution.

Purgatives at the beginning of the disease are a necessity in most cases and calomel in small doses is usually indicated during its continuance.

The strength of the patient must be kept up by quinin and iron and opiates freely administered.

When suppuration is established tincture cinchona comp., aromatic sulphuric acid and stimulants are to be freely given.

The abscesses which form must receive careful attention, early and free incision made and the position of the parts so arranged to favor the escape of the secretions.

Poultices must be freely used until the discharge of pus has nearly ceased, when carbolyzed cosmolin or an ointment composed of hg. cum creta two parts, cosmolin eight parts, should be applied.

Perfect cleanliness must be insisted upon and disinfectants such as acetanilid, creolin, carbolic acid or corrosive sublimate, unsparingly used throughout the disease.

Medical Caprice.—A prominent physician of India recently died from the bite inflicted by one of the deadliest of snakes; he had been making experiments with a view to the discovery of an antidote, and supposed he had rendered himself proof against the venom of snakes. One of the worst victims of rheumatism we ever knew was a man who had discovered a positive cure for that disease. The secretary of a notorious Cincinnati consumption-cure company died of tuberculosis. The former proprietor of the Lydia Somebody's great female nostrum is in her grave dead from the very diseases that her successors are indecently advertising against in the poorer class of daily papers.—*Massachusetts Medical Journal.*

SERUM THERAPY WITH REPORT OF CASES.

Read before the Tri-State Medical Society, St. Louis, Mo., April 7, 1897.

BY JOHN M. ALLEN, A.M., M.D.

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE IN THE UNIVERSITY
MEDICAL COLLEGE, KANSAS CITY, MO.

The announcement of the subject matter of my paper carries with it the idea that I would cover the field of serum therapy, but I shall confine myself to the use of antitoxic serum and its effects in diphtheria and phthisis pulmonalis.

The curative effects of antitoxic serum in diphtheria is now so well established that there is no need of argument or detail report of cases to establish its benefits in this disease to the medical profession. Hence I give only a summary of my cases. I have treated fifty-three cases of diphtheria without the loss by death of a single case. Forty of these cases were treated with serum only, cleanliness and good food. The remainder had had other treatment before I saw them. The complications which occurred among these cases were as follows: Hoarseness, seven; five of aphonia; two of toxemia; one of broncho-pneumonia resulting from the extension of the membrane into the bronchi; one case of paralysis. No operative interference was needed. In none of these cases of complication did I see them before the third day. All of the cases which I saw within the first twenty-four hours recovered without complication. Hence it is my opinion that cases seen thus early rarely have any complications.

My mode of administering the serum is to begin with a full dose the first day; two-thirds the next day; one-half the next day in mild cases. If the case is of malignant variety, I repeat full doses of serum every ten hours until improvement begins. Then lessen the dose, and give from two to four more. This repeated administration of the serum is based on the fact that the bacilli may be found in the fauces for several weeks after the membrane is thrown off.

It does occasionally happen that the larynx has been attacked a week or ten days after the membrane disappears from the fauces. But where the remedy is continued as directed above, the bacilli are either destroyed or are so attenuated as to lose their vital energy. It is my opinion that the serum has immunizing properties, because I injected it into seven children who were dangerously exposed to the disease. None of them had it. The dose used was full size.

I have treated four cases of phthisis pulmonalis with Paquin's antitoxic tuberculosis serum.

Case 1.—June 1894, Mrs. D., age 32, mother of one child, presented herself for treatment and I found her in the following condition: Hereditary tendency to phthisis, had gradually lost flesh and strength until reduced from 115 pounds to 75 pounds, in a period of about twelve months. Severe cough and expectoration for about last seven months. Sputum had been examined about four months before I saw her and found to contain bacilli tuberculosis. At the time of my first visit she stated that she had had hectic fever and colliquative sweats daily for some time. Temperature 103.5, respiration 37, pulse 98. Entire loss of appetite. Sputum under microscopic examination found to contain large quantity of bacilli. Auscultation and percussion located two spots in upper portion of right lung that were impervious to air. There was no evidence that the tissues had broken down.

I began the treatment with Paquin's antitoxic tuberculosis serum, giving ten drops by hypodermic injection, increasing the dose within three days to a dram, which was continued daily for 120 days. After

which for another 120 days it was given every other day. After this it was given three or four times a week for the remainder of the year. This treatment was supplemented by the following prescriptions:

R. Creosote	xxiv gtt.	130
Tr. cinnamom	ʒiv	16 00
Glycerin	ʒxx	80 00
Sig. Teaspoonful gradually increased to five teaspoonful three times daily before eating.		
R. Oil eucalyptus	ʒi	400
Oil cassia	ʒi	400
Creosote	ʒi	400
Oil tar	ʒi	400

Sig. Inhale in nebulizer frequently.		

By the end of the third week her appetite began to return, hectic fever ceased, cough and expectoration gradually ceased and in less than six months she weighed 120 pounds. From the end of the third month the bacilli began to be attenuated and continued to decrease in size and number until the end of the fifteenth month when none could be found in the sputum nor has there been any since. The points of dulness in the lungs have greatly decreased in size, but have not entirely disappeared.

Case 2.—July 1895. Unmarried lady, age 26; hereditary tendency to phthisis. Had been an invalid for five years, visiting many climates in search of health. When presented to me I found her in the following conditions. Extreme emaciation, loss of appetite, hectic fever, chronic diarrhea for the last fifteen months; pulse 110, evening temperature 103.5, respirations 45; auscultation and percussion revealed a large abscess in apex of right lung. Mouth covered with aphthae. Sputum loaded with bacilli. My prognosis was that she would not live sixty days. She was placed on the same course of treatment as Case 1. At the end of four weeks hectic fever had ceased. Her appetite had returned. Diarrhea very much better and entirely ceased before the sixth week. She steadily improved until the end of the fifth month, when a thrombus formed in the left femoral vein from which she died thirty days later.

Case 3.—December, 1895. There had existed for five years a tubercular deposit in the apex of the right lung. Childbirth caused it to rapidly break down. Microscopic examination showed tubercular bacilli. Began treatment and continued irregularly two months. This case was refractory to treatment from the beginning; therefore was not benefited and died at the end of five months.

Case 4.—March, 1896. Male, age 22, of good proportions. Had hemorrhages several times during the preceding year. Progressive emaciation; weight 130 pounds, appetite not good. Evening temperature 101.5; respiration 34. Auscultation and percussion indicated tubercular deposits at two points of upper right lung. Microscopic examination of sputum showed an abundance of bacilli. Began treatment as above and within three weeks patient began to improve, which continued without interruption until he was compelled to leave me, September, 1896. At this time temperature normal, respirations 22, weight 150, appetite good. Sputum contained attenuated bacilli. When last heard from he was at work on a ranch in Colorado.

In an analysis of the above cases it is fair to conclude that if this treatment was begun before the structures began to break down, it would be certainly beneficial and possibly curative. After abscesses have formed it is beneficial but probably not curative. Yet if the disease is not too far advanced in the second stage, many could be cured if supplemented by climate influences.

In estimating the curative value of the remedies used, the inhalation of germicidal remedies is certainly in the right direction; but alone they are useless. The creosote has for years had some reputation as a cure for phthisis. That it is beneficial, there is no question; but it is not curative, for the reason that it practically has no effect on the bacilli. This I have many times demonstrated by microscopic inspection of sputa in patients in my clinic at the University

Medical College of Kansas City, who had taken large quantities of it. Creosote is beneficial in two ways. 1. It reduces the toxins in the blood, thereby lessening or preventing hectic fevers and colliquative sweats. 2. In a very large percentage of cases of phthisis pulmonalis next to the lungs the most frequent structure involved is the duodenum with chronic inflammation and ulceration. This interrupts intestinal digestion and assimilation, also often by reflex irritation interrupts stomach digestion. Hence is the progressive emaciation in phthisis. Creosote stands at the head of the list as a curative remedy in this pathologic condition, thereby increasing the digestive and assimilative force of the person.

With these facts before me I must conclude that the active force in affecting the bacilli was the serum. The next question is as to the effects of the serum after entering the blood. On this point many theories have been advanced.

I abstract the following from an address delivered by Dr. William Carter, of Philadelphia, before the Pan-American Medical Congress, 1893. "That blood serum is a powerful and active therapeutic force is just now beginning to be recognized. Landois discovered more than twenty years ago that the mixing of the blood of different animals resulted in the destruction of red corpuscles." Recently Dr. Carter by experiment has established the globucidal property of blood serum beyond question. He has further demonstrated that the serum of some animals are destructive to the life of others. Mettall and Buckner have shown that the blood serum of certain animals which are refractive to certain diseases is highly destructive to the bacteria that caused the disease. This shows that there are other forces in the blood which are destructive to bacteria, besides that of Metchnikoff's theory of phagocytosis. It is also well established that animals naturally susceptible to certain diseases can be immuned to those diseases by injection of the blood serum of animals either naturally immune or rendered so artificially. That the injection of blood serum of immune animals after infection has taken place will destroy it and terminate this disease is true.

That serum has globucidal and germicidal properties is well established. Its globucidal effects can be well understood, but whether its germicidal effect be by actual contact or by destroying the entity upon which the germ lives and develops is doubtful.

In view of the fact that the life and development of the germ depends as much on its environments as that of the human family, and further that its life and development ceases as soon as the pabulum upon which it lives is consumed or destroyed, we deduct the idea that serum destroys this pabulum, thereby terminating the life of the germ. This is proven by the natural history of all the contagious diseases, first by their being self-limited, secondly by the fact that one attack in the majority of them immuned against a second, no matter how badly we may be exposed to the contagion. Indeed inoculation will not produce the disease. For no other reason than the entity upon which the germ lives and develops has been eradicated by previous attack. When serum is injected into the blood to immunize the person, it is done before there exists any germs in the blood; therefore, not for its germicidal effect. The only phenomena observed is a slight reaction attended with elevation of temperature. Hence immunity is nothing

more than the eradication of this entity upon which this germ lives and develops. I give as an example, smallpox. After the person has been immuned from the disease no difference can be detected by the microscope or otherwise between the immune person from smallpox and the one who has not been. The blood, the secretion and exhalation are exactly alike. I think this holds good in all germ contagious diseases. We see this exemplified in the following process of fermentation, acetous, venous, alcoholic. The bacterial ferment lives and develops as long as the fluid element contains the essentials necessary for its life, after which it dies and no further germ life can exist in this fluid. The same is true of all culture media.

Hence it is my opinion that the curative effect of serum is indirectly germicidal by destroying an entity, which is necessary for the life and development of the bacilli. This is manifested in the fact that after its use the bacilli becomes attenuated; and from the further fact that many of us do not possess this entity. Hence the bacilli can not develop in our structures.

A FEW NOTES ON SQUINT.

BY WILLIAM B. MEANY, M.D.

ST. LOUIS, MO.

It has long been known that hyperopes easily become the victims of exaggerated strabismus constituting squint; the disturbance between the two functions—accommodation and convergence—leading to this result. The accommodation is measured and recorded by the Nagels plan of metric angles—a plan which corresponds with the metric measurement of the accommodation.

An emmetrope looking at an object half a meter away would use two diopters of accommodation; he would at the same time converge to the same point, and thus convergence would be expressed by two meter angles, so that we record it thus: $A = 2 D$; $C = 2 m a$. If the object looked at be 20 cm. off, then: $A = 5 D$; $C = 5 m a$. The position of the p. p. (near point) and the p. r. (far point) of accommodation vary according as the patient is emmetropic, hyperopic or myopic; and in all, the p. p. and p. r. of convergence is much the same, whatever the state of refraction may be, and the amplitude of convergence is not reduced by advanced age.

The foregoing remarks show how much latitude must be allowed when considering the connection between the linked functions of accommodation and convergence. Therefore the hyperope for a given amount of convergence will have to call into play an amount of accommodation in excess of his convergence equal to the amount of his hyperopia. Now if accommodation does not exceed the positive part of his range of accommodation, he will be able to see clearly; this is the case in the lower degrees of hypermetropia, but in the higher degrees it will be impossible to harmonize these two functions which preside over binocular distinct vision. The amount of accommodation necessary for clear vision calls into action a greater amount of convergence than can be used for that particular distance, and convergent strabismus is the result.

I am aware that in thus considering the connection between accommodation and convergence, one is assuming that binocular fixation is a faculty which exists from birth, and not (as it might be considered) an acquired habit.

A hypermetrope therefore may find himself in this predicament—either he can see binocularly but indistinctly, or he sees distinctly with a loss of binocular vision. If the production of squint be due to a want of harmony between the two functions of accommodation and convergence, how is it that while some hypermetropes become the victims of strabismus, and others do not?

This is a question which it has always been difficult to answer satisfactorily, as much so now as in the past; the most probable explanation is that when one eye is inferior to the other in point of vision, it is sacrificed for clear and distinct monocular vision; so that any slight or trivial complaint—ulcers or nebulae—or even the covering up of one eye for a few days, an instance of which we have long been familiar as assisting in the development of concomitant squint. The squinting eye is often found to be amblyopic (at least 50 per cent.), and until A. D. 1880 (about) this amblyopia has been considered as the result of squint caused by suppression of the image in the squinting eye; the object of the suppression being the prevention of diplopia, which could not fail to be of great inconvenience to the patient; no evidence is forthcoming in support of this theory.

I know of no case on record in which the vision of both eyes was found good before the squint developed, one of them afterward becoming amblyopic. One is somewhat inclined to neglect taking the visual acuity of young children owing to the time taken up in endeavoring to get correct answers from them and the ease with which one can "estimate" (approximate) their refraction by other methods, such as retinoscopy or the ophthalmoscope, and by thus omitting the acuity of vision one diminishes the chances of finding cases in support or otherwise of this theory.

Is it not fair then to assume that the theory of suppression of the false image followed by amblyopia is quite acceptable as the one of congenital amblyopia.

While errors of refraction are important factors in the production of squint, has for a long time been generally agreed upon, yet the surgeon who neglects to keep strict account of the disturbed muscular functions will find the results of his attempts to correct the obliquity entirely negative.

Surgical interference for the correction of squint is a binocular proceeding and should only be resorted to after a study of each eye separately, and both as regards their reciprocal movements. A thorough consideration of the factors influencing the movements of the eye in the commencement will aid us materially in the treatment. The factors favoring convergence are, lowering of the plane of vision, fixing near objects, exercising of the accommodation; while the absence of fixation for near objects, raising the eyes, repose of accommodation by the aid of dark smoked glasses, the instillation of atropin, paralysis of accommodation, diminish convergence and favor divergence.

Every measure taken to reestablish binocular vision facilitates the cure in a strabismic subject. If for example a convergent squint having developed at an early period of life, be operated upon without first submitting the patient to a tonic treatment; orthoptic exercises and especially the stereoscope or the use of other well-known measures to further diminish the squint, we may expect not only a return of the original trouble, but it has been the experience of the past that prediction with almost a certainty of having an

over-correction often resulting in a disfiguring divergent squint, that may cause an endless amount of trouble to counteract.

By submitting a child to the therapeutic treatment as herein detailed, I have witnessed a squint of 30 degrees rapidly diminish to 15 degrees of convergence; having derived from therapeutic measures all the advantages they have furnished.

The following case may prove interesting, having been treated in the "old way."

A young man 19 years of age applied for treatment, as he stated it, for loss of sight in the right eye.

Ophthalmoscope examination reveals:

Left eye: Hyperopia total, 3.5. V = 1.

Right eye: Hyperopia total, 3.5. V = 0.

Right eye: Convergent strabismus apparent, 52 degrees.

Angle K (angle between the lens of fixation and the radius of the cornea which passes through the pupil) + 10 degrees.

Here we have a case with a total convergent strabismus of $52 + 10 = 62$ degrees; an exceptionally high degree.

Fields of fixation measured with perimeter:

Left eye.		Right eye.	
External.	Internal.	Internal.	External.
32	47	47	34
Instead of normal:			
47	47	47	47

It will be readily observed that the field of fixation is strongly limited to the outer side of both eyes; binocular vision absolutely abolished. It was found impossible to provoke the union of the two stereoscopic images or the simultaneous vision of such with the stereoscope.

A tenotomy of the internal and advancement of the external recti muscles was practiced in the right eye; the internal rectus muscle was found enlarged and exceedingly strong; the external rectus weak, narrow and flattened; a slight resection of the tendon was made. Atropin having been instilled, both eyes were securely bandaged, antiseptic dressings of mercuric bichlorid, 1 to 5000, being used. Both eyes were kept bandaged until the removal of the threads on the fourth day.

The eye operated upon was again bandaged, the opposite eye was left free and provided with its correcting glass + 6D. The fifth day after the operation the bandage was removed and a + 6D provided for the right eye.

The hyperopia proved to be of six diopters in each eye. On careful examination of the eyes a slight tendency to convergence persisted; the eyes were again examined on the ninth day after the operation and, instead of a total apparent strabismus of 62 degrees as existed before the operation, it was found to be one of 10 degrees only.

With a stereoscope furnished with convex glasses of 12 diopters for each eye, the patient unites the images when they are separated by a distance of 60 millimeters. Stereoscopic exercises were ordered and to be continued daily; after several days' use of the stereoscope, the patient having learned how to observe his optical impressions, indicates (one eye being covered with a colored glass) distinctly a monocular diplopia for each eye.

The two monocular images appeared to be very near each other, separated by six or seven centimeters when the object, a flame, is placed at a distance of five meters.

Twenty-eight days after this patient was operated upon the apparent strabismus had practically disappeared; with a colored glass a distant flame though first seen in homonymous diplopia, the patient quickly unites with the two images.

The binocular vision persists up to a one-seventh m. (14 cm.), so that with hardly a month's treatment he has obtained almost normal amplitude of convergence. $PC = 7\text{ m a}$; $RC = 0\text{ m a}$; $7\text{ A C} = \text{m a}$. The patient unites the stereoscopic images with a distance of 73 mm., which shows the increasing strength of the divergent power with simultaneous contraction of both external recti muscles.

Does not the foregoing history of this case illustrate that a success was possible only with a combined tenotomy of the internal and advancement of the external recti muscles, followed by orthoptic and stereoscopic exercises, as well as the correction of the existing error of refraction? I am quite sure the results would not have been the same had we dispensed with any one of the measures resorted to in the treatment.

Are the functions of the muscles of the eye of a chemical nature, or a mechanical one, or both? Is the solution to be had only in mathematical research?

There are other muscles of the body which act in concert in order to produce certain effects, those of the glottis for example, about which anatomists to this very day have held such contradictory and confused opinions. The muscles of the eye, however, are about as well understood as those of any organ of special sense.

I thought it well at this period of time to register, in a general way, some of the views on squint held by the ophthalmic surgeons in the early *eighties*, and to cite a case successfully treated in the "old way." Just where the "old methods" so radically differ from the "advanced" disquisition, as set forth by some writers of late with the suggestion of recent promulgation, we submit the foregoing observations chronicled from the period hereinbefore referred to, for your consideration.

3907 West Belle Place.

TAXIS IN INCREASED INTRA-OCULAR TENSION.

Read in the Ophthalmological Section of the Congress of American Physicians and Surgeons, May, 1897.

BY S. O. RICHEY, M.D.

WASHINGTON, D. C.

The principal arteries of the globe enter it posteriorly and pierce the sclerotic directly, limiting as far as possible resistance to the access of nutrient blood. On the other hand, the veins pass very obliquely through the sclerotic in channels varying from 1.5 mm. to 5.5 mm. in length and contain no valves distal to their junction with the ophthalmic vein. The intra-ocular vessels have no vaso-motor constrictors, and the tension of the eyeball depends upon the pressure in the extra-ocular arterial current¹; after death it is lowered. Given an abnormal propulsive force in the extra-ocular arterial current from any cause, and the increased influx of arterial blood raises intra-ocular pressure. So long as this influx does not exceed the ability of the venous system to remove it, the increased tension is within the limits of safety; but should there be any slowing of the outflow of venous blood, that is, a loss of balance between the influx and the efflux of blood, "a vicious circle" is at once

formed, which is more or less able to break itself, depending upon the less or greater violence and persistence of the general vascular excitement.

Unfortunately, from this point of view, the anatomic course through the sclerotic of the veins favors obstruction to the outflow of venous blood, they for a limited part of their length being parallel with the sclerotic and within its meshes; so that *any* increase of pressure within the eye must narrow their lumen and diminish the outflow. This in turn adds to the existing intra-ocular pressure, farther reducing the caliber of the veins, and resulting in edema of the surrounding tissues, conveying a false impression that glaucoma is due to a disturbance of intra-ocular secretions.

Venous stasis in chronic glaucoma, if not relieved, results in thrombosis and connective tissue hyperplasia, in addition to other recognized changes. The difficulties and uncertainties arising in the history and management of chronic glaucoma have their immediate cause in thrombosis of the choroidal veins, complete relief from which depends upon the length of time it has lasted, and the more or less permanency of the changes within the vessels from the presence of coagula; for organized tissue may have formed there, with final abolition of the vessels, of which no mitigation is possible.

Previous to organization of the coagula and obliteration of the vein, during stasis and even when thrombosis is recent, the flow of venous blood is favored, or the coagula may be broken up, passed into the larger vessels and re-dissolved by pressure upon the external surface of the eyeball in imitation of the normal interrupted pressure upon it of the eyelids, of the extrinsic muscles and their tendons, and that produced by the contractions of the iris, which here, as elsewhere, promotes the movement outward of the current within the veins, and is antagonistic to stasis. This proceeding² I suggested and described at the meeting in 1896 of the American Ophthalmological Society, under the name of *taxis*, because the movement of the fingers is the same as in reducing hernia. It is an imitation of a normal function adjusted to a condition of normal tension, and is necessary because this function of the lids and muscles requires aid in a state of high intra-ocular tension, which offers increased resistance to pressure. It should be cautiously practiced when the coats of the vessels are weak, to guard against intra-ocular hemorrhage, the risk of which is small, except when hemorrhage is imminent or has previously occurred. It will accomplish what may be achieved by operation, with the advantage that it may be repeated with the recurrence of venous stasis and increased tension, which is a chronic tendency in chronic glaucoma.

That a myotic stimulates the iris to the production of this kind of pressure; that a mydriatic favors an attack of glaucoma by paralysis of the iris, thus allowing an advance of the vitreous body and lens, and consequent increased intra-ocular engorgement and obstruction of the anterior channel of filtration; that iridectomy, the force of the extra-ocular circulation being lessened, acts by temporarily relieving pressure upon the surface of the veins, permitting them to disgorge themselves; that after iridectomy, malignant glaucoma, intra-ocular hemorrhage and failure of the anterior chamber to reform are caused by the per-

¹ Resistance of the eyeball to pressure is equal to 26 mm. Hg., and pathologically may reach 70 mm. (Norrie and Oliver, System of Diseases of the Eye, Vol. 1, p. 125.)

N. von Kries found arterial pressure in the capillaries of the hand when raised to be equal to 24 mm. Hg.; when the hand hung down, = 54 mm. (Physiology, Landolt and Stirling, 2d Ed., p. 151.)

² A paper on "Massage of the Eyeball as a Therapeutic Measure in Glaucoma," by Dr. G. M. Gould, to be read at the meeting of the AMERICAN MEDICAL ASSOCIATION next month, is announced.

sistence of undue *vis a tergo* in the extra-ocular arterial system, I am convinced.

This paper is an appeal to my colleagues to transfer their attention in glaucoma from the anterior channels of filtration to the fundus; from the relative amounts of secretion and excretion of the fluids of the eye to the influence of the vascular system, local and general; from a possible vicious circle in the anterior to a more rational vicious circle in the posterior section of the eyeball; satisfied that only thus will they find an acceptable solution of the many perplexing phenomena which have been observed in glaucoma.

ASTIGMATISM.

Read to the Western Ophthalmological, Otolological, Rhinological and Laryngological Association at St. Louis, April 8, 1897.

BY DUDLEY S. REYNOLDS, A.M., M.D.

Professor of Ophthalmology, Otology, and Medical Jurisprudence, in the Hospital College of Medicine, Medical Department of the Central University of Kentucky, Surgeon to the Ear and Eye Department of the Louisville City Hospital, and the Gray Street Infirmary, etc.

LOUISVILLE, KY.

This report is based upon the recorded observations of 4,686 persons, excluding as far as possible all cases of presbyopia.

I rely absolutely upon the stenopeic disc, and the test type of Snellen, illuminated always with parallel light, with the patient's accommodation completely suspended. This is the only method which I consider worthy of the confidence of either the patient or the practitioner.

Total number of cases of spherical error requiring correction	8450	
Number of cases with H. in one eye and M. in other	168	= 3282
Astigmatism H. in both eyes	380	
" H. Comp. in both eyes	254	
" H. in one eye only	292	
" H. Comp. in one eye only	185	
Mixed astigmatism in both eyes	54	
" " in one eye only	37	
Astigmatism M. in both eyes	76	
" M. Comp. in both eyes	89	
" M. in one eye only	44	
" M. Comp. in one eye only	57	
	1408	
Persons with H. Astigmatism in one eye and M. Astigmatism in the other eye	4	= 1404
Astigmatism of oblique axis	206	
" of different degree in each eye	154	
" at right angles in both eyes	167	
" in one eye only	555	
" of same degree and axis in both eyes	322	
	1404	
Total number of recorded cases	4686	

It may be interesting to observe that the mydriatic used in the first 576 cases, in which there were 113 cases of astigmatism, was sulphate of atropin. In the remaining 4,110 cases, in which there were 1,291 cases of astigmatism, the mydriatic used was the hydrobromate of homatropin. The manner of employing the latter has been varied; at first I used one grain to two drams of distilled water, dropping the solution into the eyes every fifteen minutes until four applications had been made. This method proving unsatisfactory, I doubled the strength of the solution, and employed it every five minutes until four applications had been made. In a large number of experimental observations to determine just when the accommodation is suspended under this method of using the mydriatic, I concluded thirty-five minutes to be the minimum, and fifty minutes to be the maximum time required to produce complete suspension of accommodation.

In the last 2,000 cases I have employed ten instillations of the homatropin solution, in the strength of one grain to the dram of water, the instillations being one minute apart. I find that complete suspension

of accommodation is almost invariably present forty-five minutes after the last instillation, and that the effects have begun to fade away at the end of an hour and a half. I have occasionally found it necessary to repeat the instillations, causing the patient to remain another half hour after the last, and in the repetition of the instillation, I deem four applications quite sufficient. I have never known a case, even in high grades of astigmatism, which would not finally succumb to the action of homatropin. I have, in twenty or thirty cases, found a third repetition of the instillation of the homatropin necessary. I use the same strength of solution, and the same mode of application in children and adults alike. I have never known constitutional disturbance to follow its use, excepting in three instances, two of these young ladies of very sensitive nervous organizations, and one a boy with phimosis.

The asthenopia has not always yielded promptly to the correction of the refraction, but in a large number of instances constitutional treatment has been necessary. Change of diet, and habits of life are most essential in nearly every case. The nature of the constitutional medication should always be determined after careful examination of the general condition of the patient. I find patients with severe asthenopia recover quicker under treatment when the use of the eyes for the purposes of study is interdicted, pending the general treatment. Most persons suffering from asthenopia, require better blood and more sleep. Unfortunately a great many have acquired drug habits.

Persons who take yeast bread, cooked fruits, and other forms of glucose, suffer necessarily from the pressure, upon the nerve trunks, of the abnormally increased volume of the lymph stream, aside from the gastric irritation which adds to the severity of the headache, induced by the over-taxed accommodation of the eye. Phenacetin and other drugs of this class, including the bromids, simply aggravate the patient's condition, and no amount of pains-taking care in the correction of the errors of refraction will relieve such cases. A great many young men whose nervous systems are disturbed by the toxic effects of tobacco, are alike troublesome to manage.

Correcting errors of refraction in the eyes relieves those cases of asthenopia found in persons of good general health only. Recovery in all other cases is contingent upon other means of relief.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY.

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.
TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

(Continued from page 982.)

VII.—THE RISE OF GERMAN SURGERY UNDER AUGUST GOTTLIEB RICHTER.

Frederick II; German poets and musicians; Kant; Social relations in the second half of the century; Surgery and clinical institutions at Göttingen; The life of Aug. Gottl. Richter; Richter as a surgeon, as a writer, as a teacher, as a physician.

At the close of the Seven Years War, Prussia became one of the great powers of Europe. Frederick the Great, at home and abroad, was considered the greatest commander-in-chief, to whom only a few leaders of former times could be compared. Europe's

armies were amazed at his mode of warfare and tried to imitate the strategy of the German armies. As grew the belief in the invincibility of their King, so grew the confidence of the Germans. For hundreds of years there had been no man among them who had so powerfully taken hold of their entire affairs. At last, after so many long years of profound depression and national misfortune, a star arose, to whom the Prussians could look up with pride. And that luminary was Frederick II., the only man whose popularity struck root in this prostrated nation and who evoked such worship among his people. Indefatigably active, plain and unpretending in appearance and having good common sense, he disdained pretense, mendacity and flattery, and showed great love of justice. His highest ambition was to conquer ignorance and prejudice, to enlighten mankind and ennoble its customs. Frederick II. was the practical genius of that century. Filled with great perseverance and patience, his orders proceeded from a well-considered political management; he always retained a statesman-like calmness, his infallibility and judicious reckoning. In spite of the way in which his people worshiped him, Frederick grew almost indifferent to the enthusiasm of his subjects in his advanced age; he became more silent and reserved, and at the decline of his life said that he was quite tired of governing slaves. The following is taken from one of his posthumous manuscripts: "During a king's lifetime, he is the idol of his court, the eminent sprinkle incense before him, the poets celebrate him in song, the public fear him, but little is he loved. When he is dead, the evil he has done lives after him, for the good has been interred with his bones." Thoroughly German as the King was, nevertheless the French nourishment and training he had received during the deplorable condition of German literature, were revenged by his great contempt for the golden fruits that home literary products reaped later. He absolutely ignored Lessing's "Minna von Barnhelm" and "Nathan"; he considered Goethe's "Goetz von Berlichingen" an *imitation détestable de ces abominables pièces de Shakespeare*. There can still be seen in the public library at Zürich, framed and covered by a glass, a letter written to Professor Müller on the publication of the "Nieblungenlied" by Frederick the Great, in which he says: "You have too great an opinion of these things. In my estimation, they are not worth a penny (einen Schuss Pulver), and do not deserve to be resurrected; I would not tolerate such trash in my library, but would throw it out." However, what did the genius of the German poet care whether the emperor and the kings took a personal interest in his art or not; his own strength carried him through. But Goethe thought that, with the appearance of Frederick the Great and the good results of the Seven Years War, the grand epoch in German poesy and the evolution of the national spirit began. The German became cognizant of his worth, and with this confidence of self Lessing exclaimed: Show me an abstract of the great Corneille upon which I could not improve. We can well understand the importance of these words, if we picture to ourselves the fact that the French literature entirely controlled the German mind in the first half of the century. The courts copied after Louis XIV., the aristocratic Germans took no notice of their countrymen, the poets and authors, but wrote and conversed in French, and the Parisian tailor had no less an influence on our good tastes than the Parisian Academy. Now

German literature began to rid herself of her foreign adornment. A golden age of German belles-lettres, music and science dawned, without encouragement on the part of a kind Medici or a gracious prince.

It is charming to see how, simultaneously with the breaking forth of the *genius of the German poet* and the enthusiasm aroused thereby, our sciences are likewise promoted also without the good will and favor of a sovereign. Since the year 1750 new blossoms of German poesy have been developing, which, even then, breathed of national sentiment. Soon thereafter a new era in surgery also dawned, of which August Gottlieb Richter was the leader, obtaining the professorship of surgery at Göttingen in 1766. If we consider the following twenty years when Richter, in the prime of his life, wrote his most important works, we first of all come across his surgical library, which, as it were, opened a new world for the German surgeon. Daring, only on account of similar success, to compare the appearance of polite literature (*belles lettres*) of this epoch with the above—not judging the importance of the writers concerned—we find that Herder, by means of his studies of Homer and Shakespeare, his Oriental and Spanish literary researches, greatly enlarged the literary horizon. Richter annihilated the itinerant rapture and cataract butchers with his great works on cataracts and ruptures. This extirpation of fungi which grew so exuberantly on German soil, has a parallel in Lessing's exertions to expose the errors of the French dramatists, who beguiled the German art with the severity of Aristotelic philosophy. If there was still a point on which the poet and the surgeon agreed, it was the positive, productive reviews which both were so capable of writing. At last, Richter's principles opened the road for the progress of the science of surgery. What did the poets do during the interim (1766-1787)? Lessing, who composed "Minna von Barnhelm" during the last year of the Seven Years War, now published "Laoköon," and his dramas, "Emilia Galotti" and "Nathan." Wieland published "Mercury," "The Abderites" and "Oberon," Herder, a "Journal in Art and Science," "The Opinions of the Nations" and his "Ideas on the Theory of the History of Mankind." Then followed Goethe, the most ingenious representative of our tumultuous and oppressive period, with his great works, "Götz von Berlichingen," "Werther" and "Clavigo;" toward the latter end of this period we also find the works of the favorite poet of the Germans, Friedrich Schiller. They are: "Die Räuber," "Fiesco," "Kabale und Liebe" and "Don Carlos." An antique work on the beauty of the Greek form and style was resurrected and revived by Winkelmann, but the views obtained therefrom had to be revised for the Germans before sculpture, architecture and painting derived any benefit from it. There was a new turning-point in dramatic art when the first German National Theater was opened by the Ackermann troupe and the famous actor, Conrad Eckhof, in 1767, and when the Wiener Burgtheater was established by the Emperor Joseph II., in 1776, the sole object of which was "the improvement of good taste and ethical culture."

And the *German composer of music* furnished another step in the grand progress of the Germans. For twenty years he had not been blessed with so much talent. Gluck was the founder of a new dramatic style. After "Alceste," appeared his opera, "Iphigenie in Aulis," which was performed in Paris in

1774, with immense success, and within two years was sung 170 times, giving the older French music the death blow. Then followed his "Armida" and "Iphigenie in Tauris." At the beginning of that period, many symphonies, quartettes and sonatas of Haydn, the conductor of the Prince Esterhazy Band, and of Mozart, were known. The latter's "Idomeneus," "Entführung" (The Rape), "Figaro," which was composed in six weeks, and "Don Juan," which outshone all the others, belong to this epoch. The youth, Beethoven, was just becoming known, and his performances on the violin and piano, as well as his free fantasias, astonished the public. What an abundance of brilliant, truly patriotic works of art were showered upon Germany, as from a cornucopia filled with blessings, in the short space of twenty years following the Seven Years War, and while formerly but a single genius adorned a century, now one jostled the other.

But the sciences did not lag behind the belles lettres, but were greatly revolutionized by Frederick the Great's maxim, "Freedom of thought." The period of enlightenment in Germany began with him and Joseph II. The priest had to submit and the boldest idea gained ground over the old productions in spite of him. Ancient customs and modes of thinking became obsolete, prejudices were conquered. It was no accidental event that, in Germany at this time, the great thinker Kant "created thoughts which threatened to overthrow the entire former views of the world with wonderful boldness." In 1781 appeared his criticism on "Pure Reason." His philosophy, with which he ascertained the origin and limits of the human mind, which never permitted the entire theoretical use of our reason to extend beyond objects of practicable experience, and which discarded all old-fashioned ideas and prejudices, had a great influence on all the sciences. Those who did not wish to be behind the times had to resort to his prescribed course of free, independent research. To this guidance the German sciences owe their greatest success. History and philology took a new upward flight with Johann von Müller, Niebuhr, Schlosser and W. von Humboldt; the old classics were given new life by Heine and Wolff. Kant's ideas were also transplanted into the natural sciences (Blumenbach and Sömmering); they did not, however, make any great, wide-spread progress, because the apprehension of simplicity and plain fact was lacking.

We will here make a few remarks on the social relations in the second half of the eighteenth century. This gave itself the nickname of the "Enlightened;" from all chairs of learning and from the pulpits, in society and in the workshops of the mechanics, sounded the word "Enlightenment," and yet contemporaries talked of our "disordered period, in which sense and nonsense, wisdom and ignorance, bigotry, superstition and incredulity, enlightenment and darkness, integrity and deception cross each other" (Baldinger, 1787). This is similar to what Scherr, in our times, terms a kaleidoscopic variety of contrasts as being characteristic of the eighteenth century. General prosperity was discernible throughout the various German cities; the houses were more comfortable and more spacious and had larger windows and bright stairs; the towns were embellished with walks and gardens; the merchants and the manufacturers were now the wealthy people of the city; the wounds of the Seven Years War had healed. The government

founded charitable institutions for the care of the poor and of the sick, placing physicians in charge; for the vaccination of the public in general and for the deaf and dumb, the latter the first institution of its kind established in Leipsig, in 1778, by Heinike. Among the places of amusement, which were few in number and not very expensive, the theater was the most popular. The wandering theatrical companies increased in number and the arrival of one of them was an event of great importance. In spite of the poor transportation and the few good high roads, there was more traveling done than in the middle of the century, and that oftener into the mountains, on account of the growing taste for nature's beauties. The middle class, occupying a position between the nobility and the laity, comprised the learned, the officials, clergymen, and the prominent merchants. This class, which was separated from the mass by its exemption from military services and which considered it a disgrace when their children, after having been given an education at school, fell into the hands of the recruiting officer, represented the best portion of national power. It was the training received at college that united these men and distinguished them from all others. While formerly at the Latin schools a pedantic, thoughtless method of teaching was pursued everywhere, now a knowledge of the life of the ancients and an intelligence of its embellishments were the essential factors of study. The young people had to do their own thinking. In short, a classical education was the aim of the middle-class youth. The great value of athletics for physical development became known, and we are proud to say that the same did not alone emanate from Germany (Guts-muths, 1793), but was also greatly cherished in our Fatherland. On the other hand the interests of the government and the most important affairs of the nation were still slumbering. There were plenty of honorable men, but sentimentality prevailed instead of virility. Who does not know the touching story of Klopstock, when he with his friends was at the cemetery and at the sight of the roses, the flowers of love, in contrast to the grave, became so agitated that they bought a bottle of wine and caroused at the cemetery in accord with the roses and graves. We have mentioned heretofore how Voss and his friends formed the "Göttinger Hainbund," a society of young poets who vowed their friendship under the sacred trees of the "Hain," increasing the sentimental feeling to the utmost degree. When Goethe's "Werther" appeared the tears flowed in torrents; à la Werther became the favorite habit of sentimental gentlemen, and Schiller's "Lotte" was the most famous type of woman of that period. On account of the dearth of political interest, there grew an uncomfortable condition of frankness among the educated. While the Revolution was going on in France, the muse was calmly being cultivated in Germany, revelling in her two greatest poets. Louis XVI. and Marie Antoinette beheaded in France, while "Reinecke Fuchs" was being composed in Germany; Robespierre's Reign of Terror and the "Letters on Æsthetic Culture of Man;" the battles at Lodi and Arcole at the time of the writing of Wilhelm Meister, Horen and Xenien; Belgium sided with the French, "Hermann and Dorothea" were being written in Germany; Switzerland and the Ecclesiastical States (Papal territory) were French, while "Wallenstein" materialized in German; the left bank of the Rhine belonged to the French,

her natural daughter though, the "Maid of Orleans," was being composed across the border; Hanover was occupied by the French, when "Braut von Messina" was being written in German; Napoleon was crowned Emperor when the work "Wilhelm Tell" saw its first light. The ten years during which Schiller and Goethe, bound by the tender ties of friendship, lived together, the ten great years of German literature, were the same years that France suffered from her Reign of Terror (G. Freitag). To adorn oneself with the finery of others for a short time results in an uncomfortable feeling, even if this little loan of remarks on historical culture are pardonable on the part of the surgeon. We will therefore return to our sciences.

The predecessors of A. G. Richter were at *Göttingen*, the objective point of activity. Soon after the founding of the famous "Lein Athen" by George II., the very learned body physician of the Bishop of Lübeck and afterward of the King of Sweden, George Gottlob Richter, was appointed head salaried professor of medicine, and A. von Haller second professor of anatomy, botany and surgery by Werlhof in 1736. Haller's achievements for science at Göttingen were extraordinary. In 1738 he founded the anatomy amphitheater, a botanical garden the following year and in 1750 a maternity hospital. He also established a museum of anatomic collections and a school for artists whose specialty was plants and animals. His purpose to erect a clinic failed, for these institutions were not thought necessary until after van Swieten's successes in Austria. In 1745 he founded a scientific journal which, edited by him in a most skilful manner was, next to the Jena literary journal for scientific contributions, the most important collections in Germany. Richter carefully looked over all matter handed in for his journal, willingly accepted knowledge from foreign nations and always used a simple style of expression. After he had constructed a plan for the formation of a royal society of sciences in Göttingen, the same was organized in 1751 and attained great renown under his superintendence as its life-long president. Haller had put aside poesy as his influence in that direction amounted to nothing. No periodical publication on poetry could succeed by the side of the scientific journal. During the ten years after the appointment of the above men, two other professors were added to the medical faculty: Segner, who taught natural philosophy and mathematics, and Brendel. Somewhere about the year 1750, when Haller went back home and Segner moved to Halle, Röderer was given charge of the anatomy amphitheater and the maternity hospital while G. Zinn taught botany, but at the same time carried on anatomy. In the following ten years beginning with 1760, when the old professors, with the exception of G. G. Richter, had passed away or accepted positions outside of Göttingen, four additional salaried professors were appointed: R. A. Vogel for chemistry, mineralogy, pathology, semiology and materia medica; Ph. Schröder, summoned from Marburg, obtained the third position in the faculty and read on general therapy to the students; Büttner taught therapy and botany; the fourth, Matthiä, who, tutored by Heister, occupied his time principally with historical works, wrote on Hippocrates and Quintilian, but translated also more modern writings (Winslow's Anatomic Treatise on the construction of the Human Body, Garengot's Treatise on Surgical Operations,

le Dran's Manual on the Extraction of Stones from the Bladder). Three extra (unpaid) professors, who taught during this period were: Murray, having charge of the botany, Wrisberg of the anatomy, and A. G. Richter, surgery. The professors had a great habit at that time of meddling with all the branches possible in teaching, A. Wrisberg, for instance, using certain manuals in his lectures. He taught anatomy and physiology according to Haller's manual, obstetrics according to Roederer's principles, legal medicine according to Ludwig, surgery according to Heister and Ludwig, ophthalmology according to St. Yves and osteology according to Böhmer's manual. In 1773 Baldinger arrived in Göttingen to teach general pathology and the natural sciences, but remained here only until 1782. During the time from 1780-90 there were besides Murray, Wrisberg and A. G. Richter four more salaried professors: Peter Frank, of pathology; Gmelin, of chemistry, pharmacy and mineralogy; Blumenbach, of physiology, comparative anatomy and natural history; V. Stromeyer, of general therapy and materia medica. The unpaid Professor Fischer had charge of the maternity hospital, and Arnemann delivered surgical lectures. Some of the later professors with date of appointment were: 1792, the obstetrician Osiander; 1800, Wardenburg; 1803, Himly of Jena, as director of the hospitals and in 1804 C. M. Langenbeck was appointed unpaid professor of anatomy and surgery.

But what was the *condition of surgery* and what *were the clinical facilities at Göttingen?* The auspices under which practical surgery began in Göttingen were poor: A. v. Haller accomplished nothing during the seventeen years he was employed here. About the year 1765 the following lectures on surgery were given by three of the professors: The first one by G. G. Richter, who read Boerhaave, the second by Vogel, who taught according to Heister's little "Surgery" and performed operations on cadavers alone, and the third one by Wrisberg, who taught Haller, Heister and Ludwig, as mentioned heretofore. The students were now and then given opportunities to accompany their teachers on their visits to the sick and in 1764 Vogel founded a sort of ambulatory clinic (collegium clinicum) where the sick of the poor people in the city and from the country came. Vogel's students accompanied him to his patients' bedsides, and Saturdays they took little trips with him into the country visiting the more important cases. The students kept a notebook on the patients referred to them and for defraying the expense of the medicines they made a contribution out of their own pockets every quarter year. When patients needed surgical attendance the university surgeon, Tolle, was summoned, who had then to follow Vogel's instructions. Since the year 1750, the surgeons of Göttingen have been united in a secret corporation and one of the professors was appointed over them as Praeses Collegii Chirurgici; this position was held respectively by Haller, Roederer, Schroeder and A. G. Richter, in the order named. Not until 1780 a hospital with fifteen beds for medical and surgical cases was founded. The idea was suggested by the Free Mason's Lodge, which made yearly contributions for its support, but from the very beginning the government furnished the greatest share. The patients received their hospital garb, board and medicines gratuitously; only for the wealthier sick a few rooms were reserved. A. G. Richter was appointed superintendent and

granted the right to use his discretion in admitting the most important of those sick who applied. Two hours of his afternoons were spent in visiting, and in attending the necessary operations. Some of his assistants were: Dr. Böhmer, Professor Stromeyer, who also gave clinical directions in the hospital, and later Wardenburg and Himly. The help consisted of one male and one female nurse and one servant. Every month the Göttingen surgeons took turns in performing the operations for nothing, and their pupils were admitted as free spectators. Students who attended the daily visits paid reasonable fees for the same and were allowed to perform operations. Theological students also practiced there, but aside from this, there was religious services on Sunday and on holidays. From the time of the opening of the hospital in May, 1781, up to December, 1787, 667 patients were enrolled.

About the period of 1788-90 several alterations were made in the clinical institutions. Vogel's ambulatorium was changed to a endowed public Clinical Institute under Baldinger (1773) and afterward successively superintended by Frank, Fischer and Oslander. The number of cases treated at the ambulatorium, about 500 yearly, corresponded to the small number of inhabitants at Göttingen. The "Chirurgische- und Krankenhaus" also underwent a change. When, in 1793, all the secret societies, consequently also the Free Mason's Lodge, were dissolved, the latter presented the establishment and 5,000 thalers to the government, which from that time on maintained the same alone. It remained under the direct supervision of A. G. Richter until 1797. Two years later two of the sixteen beds were given in charge of Professor Arnemann, while the rest were equally divided between Stromeyer and Wardenburg. In 1802, Oslander took the superintendency of the hospital, but in 1803 turned it as well as the management of the Ambulatory Clinic over to Himly, who was assisted by the surgeon Langenbeck. The two institutions were combined for the instruction of the students to great advantage. Why Richter resigned the direction of the hospital after having served seventeen years and why Himly was appointed with his approval, has never been known. Himly improved the hospital; when in 1809 it had become too small, he moved it into a three-story building with two wings (from Geismarthor to Stumpfenbiel) and increased the number of beds to twenty-eight. Loder, Sömmering, Stiebel, Heusinger, Chelius and the Hanoverians, Spangenberg, Wedemeyer, Holscher, and others were educated there. Afterward many good army physicians were procured from this school for the military hospitals of Hanover. In the year 1807 there were 220 patients treated at the Hospital and seventeen practitioners with twenty-six auditors (pupils) were on duty.

Besides the Royal Clinical Institute and the Hospital the following four private clinics were established one after the other in the city: 1. Arnemann's Surgical Clinic (1796), which he established on account of the great number of patients afflicted with sore eyes and ears, and that, at his own expense paying for the medicines needed by the poor, and accepting contributions only from the wealthy. Later the institution was endowed by the government. During the first five years 1,096 cases had been taken in for surgical treatment. From 1801 on, medical patients were also admitted and then a special hospital (Medical Surgi-

cal Institute) was founded for them, in which the members of the same performed the operations. 2. The Medical Surgical Clinic founded by Wardenburg in 1799. Here the auditors were also allowed to practice operations on cadavers, and were placed in the sections that belonged to A. G. Richter's department (Physikat). This clinic was united with the Academic Hospital in the following year, accepting 349 patients (270 medical, 28 surgical, 36 operative) during that winter, besides the regular hospital patients. 3. The clinic established by Professor Cappel and the private tutor Jordan in 1801. 4. The Clinical Institute for Surgery and Ophthalmology founded by Professor C. M. Langenbeck, who then resigned his position in the Academic Hospital. In Langenbeck's Institution which was endowed and presented with a building by the board of trustees, there were treated 290 patients during the first year, 18 cataract operations and six amputations were performed and was attended by 82 students. The number of patients increased so rapidly that the structure had to be enlarged and thirty beds were now needed. Dr. Seyde and Pauli, Langenbeck's right hand man, were his assistants, the latter since 1813 at this institution which was free to all. We thus see that Göttingen had fine and exceptional facilities.

And now comes *August Gottlieb Richter*. If we modern physicians put the question: What do we know of Richter's accomplishments and achievements and his rank in German surgery, we would be compelled to answer: As much as nothing. When the writer conversed with a practitioner of the modern school, whose office was generally filled with patients, on Richter, the only praiseworthy deed he knew of him was as the author of a valuable work on ulcers; but this was an error on the part of the colleague, who had mistaken Rust for Richter. My only knowledge of him at first was, that a certain kind of scissors bore his name, and that he had written a book on ruptures. Surely there are many colleagues who are today wandering about in this wilderness. With shame we must confess that we have no complete biography of the best surgeon of but one hundred years ago. We certainly do not care about an encyclopedic order of dates and it is about the same to us when and where Richter was born, and yet of our own flesh and blood we German surgeons ought to preserve with the feeling of deepest gratitude and piety, his memory. In order to obtain the following facts regarding Richter, the writer had to interview various ones of his contemporaries still living.

Richter was born April 13, 1742, in Zörbig (district Meissen) and Her Royal Highness the Princess Augusta Carolina, the Duchess of Saxony, was his godmother. His father, George Gottfried Richter, who married Christina Dorothea Feichmann, was a master of arts and philosophy, the prime minister and the superintendent of the school in Zörbig; a brother of the above mentioned George Gottlob was professor of medicine in Göttingen, and George Frederick, professor of political economy and moral philosophy in Leipsig. Richter's grandmother, Johanna Maria, née Pinckertin, prided herself on her ancestry dating back to the Burgomaster Lucas Pinckert in Meissen to the year 1507, ubi gens Pinxeria jam diu ante floruit. Presumably his uncle at Göttingen, who had no children and was a wealthy man (established a fund of 1,200 thaler to be used for scholarships), won over the young August Gottlieb to the study of medicine, for,

according to the family tradition, he ought to have become a clergyman. His father, grandfather, great-grandfather and all his ancestors up to the sixteenth century were pastors, and the last one of these known, Paul Richter, was ordained by Luther in 1545. It had become a proverbial expression that clergymen are blessed with a big family, and Richter's proved no exception; August Gottlieb's father had nine brothers and sisters, and he himself had five; one of his brothers became a minister in Hanover, another was counselor of the consistory of Anhalt-Dessau, and one of his sisters married a preacher.

Having been instructed by competent teachers and sufficiently prepared to enter the university, he began the study of medicine at Göttingen in 1760, during the war. So when a hospital was equipped for the wounded soldiers, the young student joined the managing physicians and was so enthusiastic that he spent almost all of his time there. Under these circumstances, it was not surprising that he had no fascination for the learned profession of his uncle. Probably from a motive to please him, not to satisfy himself, Richter wrote a Doctor-dissertation on "de prisca Roma," after studying four years. He publicly substantiated his views on Sept. 12, 1764, "with honor," and on the 17th of the same month, at the inaugural ceremony of the Academy, received his degree from his uncle, whereupon Richter, "with due propriety expressed the usual thanks from the cathedra." Only a few weeks later, so that he might teach, he wrote a work on his observations made in connection with a cancerous ulcer of the stomach, and he defended the same with the Livonian Pflug. In October he started on an eighteen months' trip at his uncle's expense, visiting the following cities: Strassburg, Paris, London, Oxford, Leyden, Amsterdam and Gröningen. Much of his time was spent in London, where he studied with untiring diligence at the Bartholomew Hospital under Percival Pott. Richter pronounced it a most excellent school. Pott distinguished himself then especially in the treatment of diseases of the eye and hernias; later his pupil followed in his footsteps. Richter seems to have continued his friendly intercourse with his teacher, to whom he dedicated the second part of his Surgical Observations. In Paris his principal instructor was Petit, who took the lead in surgery at that time; Levret also taught him. When 24 years old, June, 1766, he returned to Göttingen and immediately received the appointment as professor. In his opening address he supported Daviel's ideas on the extraction of cataracts. Soon after he held a discourse on the great advantage of combining surgery and medicine, of which union he himself was an illustrious example. His acquirements were thus fully in keeping with the expectations that he had studied the very best surgeons while on his trip—as remarks the scientific journal of which he afterward became a contributor. He now began his course of lectures; in 1767 he delivered a discourse on surgery according to Ludwig's system, then he read one on diseases, "which required the use of instruments and surgical operations," and gave a public talk on ophthalmology. During the following semester he gave practice lessons in operating on cadavers at the Anatomical Amphitheater. In June of 1771, he became a regular professor and founded a surgical quarterly.

(To be continued.)

SOCIETY PROCEEDINGS.

Annual Meeting of the American Surgical Association.

Held in Washington, May 4, 5, and 6, 1897.

TUESDAY, MAY 4.

The President, Dr. John Collins Warren, delivered an address upon "The Influence of Anesthesia on the Surgery of the 19th Century."

Dr. John Homans, of Boston, read a paper entitled "The Indications for and the Technique of Hysterectomy."

Dr. H. H. Mudd, of St. Louis, in discussing this paper, said that hysterectomy for fibroid tumors had a technique which was not uniform and which varied with the special indications. He expressed himself as especially gratified to hear that Dr. Homans discards the clamp. In his opinion, hysterectomy for suppurative peri-uterine inflammations should be strictly limited to a very narrow field of action. Vaginal hysterectomy for malignant disease is efficient and desirable for those cases where the disease is limited to the external os. The extension of carcinoma of the os is by infiltration of new tissue in two directions, first, along the vaginal tissue and, second, into the broad ligament. Most of the cases in which malignant growth begins in the body of the uterus should be subjected to abdominal hysterectomy as this is certainly the only method of operation where the uterus is secondarily involved. The greater number of cases of malignant disease which require hysterectomy have their origin in the os, and if presented early to the operator may be removed by the vaginal route. The preparation of the patient for those operations is in accordance with the general rule, but the author's preference is to have the patient anesthetized upon the operating table in order that the time necessary for the anesthetic may be as short as possible. The Trendelenburg position is much preferable, and the abdominal incision should be free enough to give room for rapid and accurate work. If the growth is soft and pliable, it should be cleaned with a curette, washed with sterile water, wiped with a gauze sponge and the firmer margins approximated by sutures.

After describing at some length the various steps of the operation, the question of the ligature was taken up and silk was advised to be used in securing the ovarian artery. It may be cut short or left with one end resting in the vagina. Hemorrhages should be well controlled by ligatures or by clamps. The author has discarded iodoform gauze in all cases where it comes in contact with the peritoneum, as he considers it a dangerous agent.

Dr. F. E. Lange of New York, stated that in his opinion the principal dangers in these cases were hemorrhage and sepsis, and he thought it a good idea to lay down certain general rules to be followed in approaching all these cases. All working in the dark should be avoided. The speaker has occasionally employed a crux incision in these cases and in some has made an incision above the symphysis pubis, but has found that in some of the crux operations, the fleshy portions do not offer enough resistance, and this is especially true where the patients have not been pregnant before the operation and become so afterward. In some cases such an extensive raw surface has remained after operating, that it has been necessary to use the apron of the large omentum in order to prevent the agglutination of the intestines. The para-vaginal or para-rectal incision has also been employed to good advantage, which consists of the separation of all the soft parts along the side of the rectum. The hemorrhage is considerable in those cases and it is well to secure the vessels as much as possible before they are cut. The advantage of this incision is that the floor of the pelvis becomes much more accessible. Provision against infection is also greater because the drainage takes place away from the peritoneal cavity.

Dr. Dudley P. Allen referred to an operation in which the patient is placed in the Trendelenburg position, the fibroid is drawn over the pubes and is separated from the surrounding structures with a pair of scissors. The uterus is divided from the bladder anteriorly by a few cuts of the scissors and the broad ligament is held between the thumb and finger. This operation up to the present time has been very successful.

Dr. Albert Vanderveer of Albany, said he agreed with Dr. Homans that when curetting and all intelligent lines of practice had been carried out without recovery for the correction of misplacement, removal of the uterus is the proper procedure. As to the method of removal, he declared himself firm in the conviction that if the vagina is normal or comparatively so, if the cervix, particularly the external os, is in a healthy condition, the abdominal or supra-vaginal hysterotomy gives the pa-

tient a degree of normal vaginal anatomical relations that is comforting and beneficial to her, in addition to giving the operator an opportunity to examine the pelvis from above, to relieve adhesions, to bring under positive observation the tubes and ovaries and if not healthy to remove them. On the other hand, if there be present decided cystocele or rectocele or prolapse of one or both ovaries, then the vaginal route is to be preferred. In his opinion, the clamp should be avoided in the abdominal operation. He regretted very much the fact that these cases are not brought to the attention of the surgeon before the disease is so far advanced, and referred to the various diseases to which the condition is ascribed, as, for example, supposed change of life or ill health from last confinement or miscarriage. Speaking of carcinoma, he considered an operation was called for when it was confined to the uterus and all suspected symptoms and indications had been confirmed by microscopic examination of specimen removed. When the uterus is not too large from invasion of the body by the disease, when there is no considerable fibrosis present and when no pregnancy beyond the third month complicates, the surgical route should be through vaginal hysterectomy. The presence of a fibroid does not necessarily mean an operation, as many patients suffer so little inconvenience that such a procedure is not called for and curetting will answer in a few cases. As to the combined operation, pan-hysterectomy the author considered that but few cases called for this procedure, but when it is done, surgeons should give themselves the benefit of a free abdominal incision. He objected strongly to taking away any more of the pelvic organs than was absolutely necessary if like good results could be secured by a less severe procedure. In his opinion, it was inadvisable to place a Jacques self-retaining catheter in the bladder after these operations.

Dr. J. William White of Philadelphia read a paper entitled "The X-Rays in Surgery." He divided the consideration of the subject, 1, in its relation to foreign bodies; 2, fractures and luxations, and 3, diseases of the bones and joints. He stated that foreign bodies in the cavities of the body could be located by a system of triangulation by means of successive skiagraphs having known relations to one another and to a fixed point on the surface of the body next the plate. Bullets in the cranial cavity have been located and removed and their recognition is easy in the majority of cases, while in the thoracic cavity, they can be located with reasonable accuracy in the trachea, bronchi, lungs or pleura. Rubber drainage tubes in the pleural cavity can not invariably be detected by the Roentgen method, as they seem to be more or less translucent to the rays. Detection of bodies in the esophagus continues to be very satisfactory, and the conditions of foreign bodies in the abdominal cavity are about the same as in the thorax. Bodies in the pelvic cavity can be found by taking skiagraphs with the patient in various positions. With regard to fractures of the skull, it is especially desirable that we should be able to recognize, *a*, fracture of the inner table; *b*, linear fracture, and *c*, fracture of the base. Up to the present time, there is no case on record of the first two having been done clinically, but it has been done experimentally with entire success. Skiagraphy will doubtless result very beneficially in the future in the prognosis and treatment of fractures and dislocations of the spine, and will no doubt give us great help in obscure cases of fracture of the sternum, scapula, clavicle and pelvic bones. On account of the movements during respiration, skiagraphing the ribs is especially difficult, but this movement can be much restricted by a fixed dressing not opaque to the rays. Fracture and luxation of the bones of the extremities can usually be readily demonstrated. Ununited fracture even in the presence of close fibrous union can be demonstrated with great accuracy. In disability following old fractures near joint, skiagraphy has been of the greatest help in determining the mechanical cause of the limitation of motion. Referring to the medico-legality of this matter and to the question of whether or not the patient has a right to demand as ordinary care that the medical attendant should have a skiagraph of the fracture taken, the author stated that at the present time he would unhesitatingly answer in the negative. There can be no doubt, however, that skiagraphs will figure largely in suits for damages in the near future. There is no doubt that a definite diagnosis will soon be possible in cases of diseases of the bones and joints and it is evident that skiagraphy has added to the precision of our management of many forms of these diseases. In various forms of cardiac disease, the fluoroscope is likely to be more useful than the skiagraph, as, in the case of organs in motion, the skiagraph can only give the net result during the period of exposure. Referring to the amount of exposure necessary, the author stated that this varies very much, and in the case of stone in the gall bladder, thickness of the abdominal walls and the depth of the calculi from the

surface played an important part. Renal calculi had been found and successful operations performed based on the skiagraph evidence, while vesicle calculi are more difficult to find on account of the super-position of the pelvic bone. Urethral stones has not yet been seen clinically, but seem likely to be easy of recognition. As to the possible therapeutic properties of the rays, they were first thought to be germicidal, but this has since been denied. The author stated that he had directed his attention to the cure of cancer with the rays and his hopes of success had been somewhat bolstered up by his experience, although as yet he had no results to report. In the meantime, he felt confident that no harm could come to the patient, even though the experiment should be unsuccessful.

DISCUSSION.

Dr. W. W. Keen of Philadelphia in discussing this paper, called attention to the importance of the medico-legal relations of the X-rays and mentioned a case showing the unreliability of skiagraphs as a means of diagnosis.

Dr. Charles B. Nancrede of Ann Arbor dwelt upon the importance of taking skiagraphs in various positions and quoted cases in support of his statement that one or even two or three pictures should not be used as a basis of diagnosis. He also stated that the fluoroscope will occasionally be successful where the skiagraph has failed and *vice versa*. He illustrated his remarks with several skiagraphs and mentioned that an apparatus costing \$50 would throw a spark seven and three-quarter inches and do all that was necessary in the majority of cases.

Dr. G. R. Fowler of Brooklyn dwelt upon the importance of taking in various positions and mentioned a case in which he was able to demonstrate in a perfectly sound limb an apparent deformity similar to that which existed in a previously injured limb. He also stated that the fluoroscope was often of use when the skiagraphs gave negative results, and laid great stress upon the possibility of defective skiagraphic plates.

Dr. M. H. Richardson of Boston showed a number of skiagraphs and laid great stress upon the medico-legal relations of the X-rays. He stated that a number of judges had signified their intention of admitting these pictures as evidence in suits of malpractice.

Dr. Williams showed a number of skiagraphs and also demonstrated an instrument for showing calculi in the bladder.

Dr. Christian Fenger of Chicago referred to a case in which search was made for a bullet in the cranium and in which the soft parts of the skull down to the bone subsequently died, presumably due to too long exposure.

Dr. Edmond Souchon read a paper entitled "Operative Treatment of Irreducible Dislocations, Recent or Old, Simple or Complicated."

The writer considers all the forms and varieties of irreducible dislocations and studies for each one, the operation performed, the difficulties and complications after the operation, the results immediate, the results remote, and formulates the conclusions as to the advantages of each. The study is based on 140 operated cases. The profound silence of text-books and also of special books on dislocations in regard to this most important subject renders this study most imperative and timely.

All irreducible dislocations recent, simple or complicated, with fracture, that were operated by reduction or resection have given good results with one exception, in which death does not seem to be due truly to the operation alone, but to a complication of shock, unusually severe at that.

Irreducible dislocations, old, simple and forward, operated by resection through an anterior incision, are the most frequent, fifty-six cases against thirty-three by arthrotomy and reduction. Results remote show a great mortality percentage in resections from injuries to the vessels, but this is unavoidable with special care. The fatalities in reductions are due to sepsis, now preventable. The disadvantages of reductions are necroses of the cartilages and of the bone of the head, calling later for sequestrations and resection.

This is probably due to the greater dissection, and denudations of the head and surgical neck necessary to reduce than to simply resect the head. Reduction is the more desirable operation of the two because it preserves the head and all the movements depending therefrom, but the necrotic consequences are serious drawbacks, as also ankyloses following sometimes the reduction. It should not be resorted to unless it can be done easily, without too extensive dissections, although it may be necessary to use hooks, levers and some curetting of the cup, as the cases reported show. The duration of the dislocation is immaterial; it is the condition of the parts that is all important. Recent irreducible dislocations have given as much if not more trouble to reduce than dislocations of months' standing.

The anterior incision is the route in all forward dislocations; almost all forward cases operated by the axillary route and the posterior incision have been unfavorable.

Cases reported as operated by subcutaneous section of fibrous bands, of tendons, of muscles and by osteotomy have given good results, but they are so few. It seems extraordinary that surgeons have not employed the method oftener; perhaps they have, but having failed, have not reported the cases. In considering the extent and density of the tissues binding down the head and surgical neck to the surrounding parts, as reported by operators, it is a wonder that these methods should succeed except in very selected loose cases.

Irreducible dislocations, old, downward, four in number; have all been treated by the axillary incision with the resection, *i. e.*, removal of the fractured head more or less loose in the axilla, with favorable terminations. In one case, however, the head was "pegged back" and reduced, with a good result. One downward dislocation (Desprès) was treated by osteoclasis, but it was a failure, no false joint forming. Yet there are cases on record of forward dislocation in which the bone was fractured near the head, or through the surgical neck during efforts at reduction and which yielded a fair enough result.

Irreducible dislocations, old and backward, in the adult, have been reported twice. They were operated by resection with a very ordinary result.

Irreducible dislocation, old, upward and operated, have not been found on record.

Irreducible dislocations, congenital, have been operated several times; they were old, backward dislocations. Two cases were operated by reduction; one case died, the other had to have sequestra removed, and then did well. Three cases were operated by resection, two with good results; the third one is not stated.

Irreducible old dislocations in young subjects or in old subjects are duly considered; also old dislocations double, *i. e.*, of both shoulders; also spontaneous or pathologic paralytic irreducible old dislocations.

The forms and varieties due to complications are fully treated and also the forms and varieties due to relapses or recurrences and to the sequels of the operations performed for irreducible dislocations and old, simple or complicated.

Dr. J. Ewing Mears of Philadelphia, referring to Dr. Souchon's paper, advised that the word "irreducible" should be dropped and the word "unreduced" should be substituted. The word irreducible is a term which can be applied when efforts at reduction are limited to manipulation, while the word unreduced would refer to dislocations which could not be reduced even by operative procedures. He suggested that some rule should be laid down as to when a fracture should be considered acute and when chronic. In all cases of recent dislocation of the shoulder which can not be reduced by manipulation and operation is considered advisable, he recommended an incision through the deltoid muscle as being probably the best method. He considered that disability and pain were the two indications for operative interference in old dislocations and mentioned that he had seen cases of old unreduced dislocations in which as much freedom of movement had been accomplished as was necessary for excision of the head of the bone without any bad effects resulting. In some old cases of dislocation he considered massage as being very advisable before resorting to operation. With regard to the relief of pain in these cases, he thought any operation that would relieve pressure should be performed and that that was a question that could hardly be discussed. He referred to an operation performed by himself in 1886 in which he did a subcutaneous section of the neck of the humerus in which the object was to form a false joint. Although the operation was successful as far as the relief of pain was concerned, upon the death of the patient one year later, examination showed that a false joint had not been formed, but union had taken place at an obtuse angle in such a manner as to pull the head of the bone off the axillary plexus. The tissues around the joint had been stretched to such an extent as to permit the head of the bone to almost return to the cavity of the glenoid.

Dr. Joseph Ransohoff of Cincinnati considered that operative treatment in uncomplicated dislocations of the shoulder of recent occurrence were so readily reducible under anesthesia by manipulation, that operative treatment very rarely came into the question, and that unreduced dislocations of long standing, as far as treatment is concerned, must be entirely determined by the degree of disability entailed. Where this is slight, the patient is enabled to gain a livelihood, and pressure symptoms are absent, particularly if the dislocation is one of more than two or three months' standing, the advisability of operative interference must be questioned; but pressure upon the vascular or nerve trunks was a positive indication for opera-

tive interference. The operations suggested and practiced for irreducible dislocation of the shoulder are, 1, subcutaneous division of the adhesions; 2, subcutaneous osteotomy of the neck of the humerus; 3, arthrotomy; and 4, resection; but the French surgeons alone advocate the first named, the last two being most frequently indicated. In old cases, even where reduction is accomplished, there remains where the head had been contained a large cavity bounded by firm fibrous walls and often lined with an imperfect serosa which closes with difficulty and affords a ready nidus for infection. The earlier that interference is practiced, the better are the end results. The immediate fatality following arthrotomy is very considerable. The present status of the question of operative interference in shoulder luxations may be summarized as follows:

1. Immediate operative interference is indicated when the ordinary methods by manipulation under anesthesia have failed.
2. In irreducible dislocations, operations should not be delayed until irremediable changes have taken place in the capsule and about the humeral head. In comparatively recent cases arthrotomy offers the best end results.
3. In old standing cases the conditions found must determine the choice between arthrotomy and resection.
4. In unrecognized dislocations of long standing, a year or over, only grave compression symptoms must be recognized as indications for interference.
5. Special attention must be given to the prevention of sepsis, since in a very large proportion of cases recorded sepsis has been either the cause of death, or, by the destruction of the humeral head or obliteration of the joint cavity, has frustrated the very object of the operation.

Dr. Owens of Chicago stated that his experience with cases of this kind was only three in number, the first of which was of the subcoracoid variety in which attempts at reduction were unsuccessful and it was necessary to cut down through the deltoid muscle into the joint. Caries, suppuration and necrosis set in and finally resection had to be done. Since this case, he had seen one which proved to be a dislocation of seven or eight weeks' standing, although it was said to be a fracture. In this case an incision was made through the deltoid muscle, which was enlarged with a probe-pointed bistoury, but it was still impossible to reduce it. The subscapular tendon was then divided and although nothing could be found which seemed to be holding the bone, it was still impossible to reduce it and a resection had to be done which was followed by excellent results. The third case was one of dislocation which had been overlooked and mistaken for a fracture, and in this case also manipulation failed. In performing Kocher's method of rotation of the arm outward, the upper end of the bone gave way. Its position was improved at once and the pain finally disappeared. In order to prevent union, and to make a false joint if possible, the bone was moved every day. Movement increased and considerable usefulness was secured, so that he was satisfied with this accidental result.

Dr. John D. Roberts of Philadelphia referred to one case in which, in attempting to reduce it, much bruising of the soft parts resulted, and it was necessary to postpone operative interference until this condition improved. Later he discovered that he had put the head of the bone on the brachial plexus, so that the patient was worse off than ever and resection was necessary. The patient succumbed from shock and hemorrhage within twenty hours.

Dr. L. McLane Tiffany of Baltimore saw no reason why cases of dislocation of the shoulder joint should be considered in a different manner from those of any other joint, and considered free opening a proper procedure. As to the time when a joint should be considered irreducible, no hard and fast rule could be laid down as the variation is too great. After the head of a bone is firmly fixed in its abnormal position, resection is the best thing to do, as a painless and useful arm will invariably result.

Dr. Souchon closed the discussion of the paper, and referred to the fact that even Dr. Kocher had fractured cases in his attempts to reduce dislocations, and one patient had died. He spoke against waiting too long before operating on these cases on account of the adhesions which so often occur. He considered the deltoid muscle the all-important factor in the operation, and particularly on account of the division of the filaments of the circumflex nerve and the resulting paralysis. He laid great stress upon the after-treatment, and particularly as to when it should be commenced, stating that this must be decided according to the case.

Dr. E. H. Bradford of Boston read a paper on "Tendon Anastomosis." Referring to the transplantation of tendons and tenoplastic surgery, he spoke of the good results which have followed the transference of one of the peronei muscles from one side of the limb and attaching them to a paralyzed

muscle on the opposite side to correct a deformity of the foot resulting from such paralysis. He also referred to the union of the anterior tibial and extensor longue pollicis muscles, to shortening of the extensor tendons of the foot and also of the tendo Achillis, as well as transplantation of the sartorius tendon. In cases of spastic paralysis, he advocated lengthening of tendons and muscular fasciæ in the popliteal space, in the groin, in the forearm and in the hand. He also showed diagrammatically a method of splitting the patella, of shortening a lengthened ligamentum patellæ and shortening a relaxed capsule. He stated that before transplanting a muscle one should prove by electricity that the muscle itself is alive and healthy and that the muscle to which it is to be attached is strong enough to do the work. He stated that excellent results have followed these operations, and demonstrated with photographs and drawing cases before and after operation.

Dr. John B. Roberts of Philadelphia referred to a case in which paralysis of the extensor of the fingers existed and in which a laceration of the common extensor was found. Upon attaching the piece of tendon of this muscle to the thumb, the hand was rendered practically as good as ever.

Dr. De Forest Willard of Philadelphia stated that in a number of cases in which he had employed similar methods, much improvement has followed.

Dr. Bradford closed the discussion by referring to a case of Dr. Dawbarn's in which the insertion of the ligamentum patellæ was transferred by chiseling off the tubercle to which it is attached, crushing a portion of the tibia and inserting the tubercle there.

Dr. John B. Roberts of Philadelphia read a paper entitled "The Surgical Treatment of Suppurative Pericarditis." The author advocated, as he had since 1876, the treatment of pericardial effusions in the same manner as pleural effusions, and stated that paracentesis was insufficient to cure suppurative pericarditis. Incision and drainage were essential, and should be adopted as soon as the diagnosis of pus in the pericardium was made. The diagnosis of the purulent character of the effusion was only determinable by exploratory puncture. This should be done at the upper part of the left xiphoid fossa close to the top of the angle between the seventh cartilage and the xiphoid cartilage. Pericardotomy should then be done after resection of the fourth and fifth costal cartilage in the manner described by the author. The operation was believed to be novel in some of its details, though others have recommended and operated by various forms of resection. This method was devised to avoid injury of the left pleura, which is nearly always a complication in the ordinary methods of puncturing or incising the pericardium. As a rule, empyema is liable to occur as a sequel of pericardio-puncture or incision in suppurative pericarditis. The prognosis is good in pericardotomy for pyo-pericardium. In a table of 26 collected cases 10 recoveries and 16 deaths were shown. This gave a percentage of recovery of 38.44. Of the fatal cases at least 9 were septic, and all the others which died had complicating lesions such as pleuritis or pulmonary, cardiac or renal lesions. The operation devised by Dr. Roberts consisted in raising a trap-door of the fourth and fifth costal cartilages and connecting the soft parts, and using the tissues of the third interspace as a hinge. The internal mammary vessels and left pleura are thus exposed and pushed to the left.

Dr. Charles B. Porter of Boston discussed this paper and gave the history of one case which was operated on in a manner similar to that recommended by Dr. Roberts. The result in this case was that after convalescence was established the patient was in excellent health, and was able to ride a bicycle a considerable distance without fatigue. With regard to the indications for the operation, it may be said with confidence that the percentage of recovery after its performance warrants the statement that it is indicated in all cases of purulent pericarditis. The author then referred at some length to the surgical anatomy of the pericardium, and said that the ideal operation was as far as possible, 1, to avoid opening the pleural cavity; 2, to open the pericardium opposite the point where drainage will remain good after the sac has contracted; and 3, to secure permanent and free drainage. He then detailed the steps of the operation, and referred to a number of cases of reported recovery from purulent pericarditis treated by incision and drainage. A number of charts and diagrams accompanied the paper.

Dr. J. McFadden Gaston of Atlanta, Ga., discussed this paper, and stated that discussions on this subject have lately inclined to more vigorous measures of internal treatment before using any means of mechanical evacuation, the reason being more urgent in pericardial effusions than in pleural effusions. It may be said that aspiration is not applicable to purulent collections in the pericardium and should be limited to serous

effusions. The author then referred to a number of medical publications in which references were made to this subject, and stated that the only means available for testing the character of the contents of the pericardium is the aspirator or the hypodermic syringe. If serum is found, it should be evacuated, and medication with such agents as have been found most efficacious in serous pleural effusions, but if a purulent collection is already present, the case required a resort to incision and drainage without any delay.

Dr. Dudley P. Allen of Cleveland, and Dr. G. R. Fowler of Brooklyn, also commented on this paper favorably.

Dr. Roberts closed the discussion by stating that he would add the cases referred to by the discussers to the statistics in his paper.

Dr. S. H. Weeks, of Portland, Me., read a paper entitled "Report of a Case of Removal of the Gasserian Ganglion." The author gave the history of the case as related by the patient himself and the only apparent cause for the neuralgia seemed to be excessive mental work. After describing at length the details of the operation, the speaker stated that the only marked symptom remaining is inability to call up or speak certain names. There seems to be a limited amount of aphasia, which has been present from the first but which is gradually disappearing.

Dr. G. R. Fowler of Brooklyn, stated that he knew the patient in this case personally and could vouch for his intense suffering previous to the operation.

He also reported that the two cases of ligature of the common carotid and of the external carotid performed to starve off the Gasserian ganglion which he reported to the society last year have remained free from a return of the disease.

WEDNESDAY AFTERNOON.

In conjunction with the Alumni Association of the Jefferson Medical College of Philadelphia, the Association unveiled the statue of the late Prof. Samuel D. Gross, M.D., near the Army Medical Museum. Dr. C. A. Mastin and Dr. W. W. Keen delivered addresses, the statue being presented to the United States Government by the former.

THURSDAY MORNING.

Dr. Dudley P. Allen of Cleveland, read a paper entitled "The Origin of Appendicitis."

The author considered that there are three factors which must have some causative relation to disease, first, a bend of the appendix itself; second, a stricture of the appendix on the proximal side of the inflamed portion, and third a great increase in thickening of that portion of the appendix distal to the point of flexure and stricture. The author dwelt at great length on the pathology of the disease, and illustrated his remarks with a number of drawings demonstrating the histology of the appendix, as well as with an actual appendix and also with a fetus showing the appendix *in situ*. In concluding his paper, the author summarized his conclusions as follows:

1. In the descent of the cecum from the right hypochondriac to the right iliac fossa, the position of the appendix with relation to the cecum becomes changed.
2. The bend thus produced may be sufficient to embarrass the passage of the contents of the appendix into the bowel.
3. To empty the appendix an increased effort becomes necessary on the part of the muscular coats.
4. The increased effort on the part of the muscles results in hypertrophy, amounting in the specimen presented to nearly five diameters.
5. Increased pressure at the point of flexure produces irritation and inflammation causing destruction of mucous membrane, and at length organic stricture.
6. The hindrance to the escape of mucus produces the repeated attacks of pain resembling colic.
7. When the escape of the contents of the appendix is no longer possible, either from the tightness of the stricture or because it is closed by a concretion too large to escape, distension of the distal portion may gradually go on to perforation, or if the distension be rapid and extreme to gangrene.
8. In some cases the inflammatory process may not cause perforation but terminate in destruction of the mucous coat, and final obliteration of the lumen of the appendix.

Dr. L. M. Tiffany of Baltimore read a paper on "The Technique of Cranial Surgery." The author dwelt at some length on the difference between traumatic and pathologic operations, the best way of gaining access to the brain, and the various methods of arresting hemorrhage. He also went into considerable detail concerning the recognition of the brain area presenting through an opening in the skull, the removal of intracranial structures and the closure of the wound.

Dr. W. W. Keen recommended Pyle's chisels for opening the skull and stated that no rule could be laid down as to the size

of the opening necessary, each case being a law of itself. He was not in favor of employing the dental engine in opening the skull for several reasons, but he was in favor of osteo-plastic operations in certain cases. He advised that the operation should be performed in two stages. The interval between each to be governed according to the special case.

Dr. Weir of New York discussed the question of hemorrhage and the various methods of controlling it. He has to a large extent given up the use of the chisel, and rarely resorts to osteo-plastic operations.

Dr. J. Parmenter of Buffalo preferred the gouge and hammer to the chisel, as he considers them less dangerous. He advised against the practice of palpating the intra-cranial structures and laid great stress upon the importance of cleanliness in these operations.

Dr. S. J. Mixer of Boston considered that no trephine should be over three-quarters of an inch in diameter and believed in the employment of extensive flaps rather than run the risk of having to enlarge the incision. He also suggested the placing of a piece of celluloid between the skull and the skin to prevent adhesion where the operation is performed in two stages. He thought the question of how much pressure the brain could stand, and how much compression was safe in the case of hernia of the brain were very important. He recommended the presence of a skilled pathologist when exploring the brain so that removed fragments might be immediately examined and their true nature determined.

Dr. Christian Fenger of Chicago read a paper entitled "Ureterectomy." The author stated that ureterectomy had been performed for, 1, tuberculosis; 2, suppuration in the dilated ureter; 3, hydro-ureter, non-infected dilated ureter. He referred to the operations as primary, secondary, total and partial. He considers a primary as one when the ureter is removed simultaneously with the kidney; a secondary operation when after nephrectomy the removal of the ureter of the same side becomes necessary, as total when the entire ureter is removed and as partial when only a portion of the ureter is removed. He gave four methods of operating, 1, transperitoneal; 2, extra-peritoneal; 3, sacral; 4, trans-vaginal.

Dr. A. T. Cabot of Boston saw no special advantage in transplanting the end of the ureter into the vagina, and he thought the discharge from the lumbar fistula quite as endurable as from the vagina. He advised that the ureter should be cut off as low as possible when it was tuberculous, stating that the remainder could be removed if necessary subsequently.

Dr. M. H. Richardson of Boston read a paper entitled "A Case of Fenger's Pyloroplasty for Intermittent Hydronephrosis." In this case it was only when pain and tenderness were present that the tumor could be felt, and it was supposed to be a distended gall bladder, but proved to be an enlarged renal calculus. After describing at some length the steps of the operation, the author stated that the patient made a good recovery and has no recurrence of the symptoms.

Dr. Richardson read a paper entitled "A Case of Chronic Intestinal Obstruction from Incomplete Volvulus of the Sigmoid Flexure." This case occurred in a man 47 years of age who had constipation alternating with watery discharges, and occasionally sudden pains. Upon opening the abdomen the sigmoid flexure was found to have a capacity of at least two gallons, and was so twisted upon the colon as to obstruct the fecal flow. After untwisting the colon it was fastened to the abdominal wall and the patient made a complete recovery.

Dr. H. Burrell and Dr. R. W. Lovett of Boston read a paper entitled "Habitual Dislocation of the Shoulder Joint." The author mentioned several methods of treating these cases, mentioned the way in which the X-ray and the fluoroscope acted in these cases and referred to two cases successfully operated upon.

Many other papers were read by title.

Chicago Academy of Medicine.

Regular Meeting held April 9, 1897, at the Leland Hotel.

Dr. William L. Ballenger in the Chair.

Dr. L. Blake Baldwin reported a case of "Erythema Multiforme Bullosum."

On February 2 I was called to see a young man 21 years of age, American, single. Family history: Father and mother both living, brother died nine years ago of phthisis, sister died one month ago of phthisis, another sister has been operated upon for tubercular glands of the neck.

Personal history: Patient has always been of slight weight, about 112 pounds. Suffering from infantile paralysis when 4 years of age which resulted in ankylosis of the ankle joint; the leg shows arrest of development. He has suffered from

attacks similar to the present one since his 8th year. They recur about once in eight months. Dr. Jaggard treated him for the first attack, which was diagnosed as herpes zoster. The attacks have been increasing in severity. Each one of these attacks has been preceded by a distinct emotional disturbance, the last one following the death of his sister, which created the suspicion that the exciting factor is a nervous one. He complained a great deal of pain in the joints about a week before each attack. The pain increases until eruption appears.

Present illness began about January 15. Complained of nervousness and irritability, which increased up to the time I saw him until he would cry with pain if you touched his hands or feet. He complained chiefly about a prickly and itchy sensation about the plantar surface of his feet and the palmar surface of his hands. Also that the skin about these parts felt as if some one was holding a hot iron about an inch away. Upon examination I found papules upon the palms of his hands and the soles of his feet. On the next day the ankles were covered with small papules, as were also the knees, the wrists and the lips. These enlarged so that they formed bullæ from a pinhead to a ten-cent-piece in size. The mouth and throat were next involved, the tongue having eight large bullæ upon it, and was so edematous that the patient could not articulate. The bullæ extended down his throat, covering the tonsils and induced painful respiration. The coverings of these bullæ were of a dirty, grayish-white color, rupturing early and leaving exposed the swollen, easily bleeding papillæ. The bullæ upon the lips and adjacent skin ruptured later and upon their site there appeared black crusts consisting of dried serous exudate and blood. Some of these bullæ were originally of a distinctively hemorrhagic character. There was evidently considerable irritation of the salivary glands, as the quantity of saliva approximated that in acute stomatitis.

The patient has had similar attacks of a less severe type since he was 8 years of age. They occur about once in eight months. Upon the strength of these symptoms I made the diagnosis of erythema multiforme exudativum bullosum, which diagnosis was corroborated by Dr. Baum. The local symptoms rapidly subsided upon internal administration of eliminatives, cathartics and 5-grain doses of sodium salicylate with $\frac{1}{2}$ grain ergotin every three hours. Locally no application was made, but an astringent wash composed of 1 dram of fluid extract of eucalyptus rostrata to a glass of water was prescribed: The patient was confined to the house for ten days. After the subsidence of the local eruption there remained a considerable amount of pigmentation, which is slowly disappearing. There are several interesting features about this case. 1, the frequent recurrences, always preceded by violent emotional disturbances, and the increasing severity of each successive attack; 2, the extensive involvement of the mucous surfaces of the mouth and throat. These latter mean a serious menace to the life of the patient, as shown in the reported case by A. Lanz (*Archiv für Dermatologie und Syphilis*, Bd. xix, 1887, p. 575).

This patient is neurotic, mentally irritable, has the general nervous and metabolic instability frequent in this type of patients. In this case the instability has expressed itself in digestive disorders, after severe emotional disturbances, which have resulted in such malassimilation that the local manifestations are the expression of auto intoxications, acting through the vasomotor centers.

Dr. William A. Posey—I agree with Dr. Baldwin's diagnosis in the case he has reported, and I mention this at the beginning because the question of diagnosis in these angioneurotic disturbances of unusual type is a very difficult one. The whole question of the angioneurotic dermatoses is an extremely interesting one, and every case illustrating a peculiar type is worthy of record. From the simplest to the most complicated forms of these dermatoses there is the widest divergence. At one end of the scale we have such simple disturbances as macular erythema and urticaria, next in grade to these we find the ordinary forms of multifiform erythema—the papular and tubercular and circinate erythemas, then the bullous and vesicular erythemas; and at the other end of the scale we meet those most peculiar and striking diseases, pemphigus and dermatitis herpetiformis. I think there is a drift of opinion among dermatologists to the view that all of these are clinical manifestations of very closely related pathologic processes, and I believe they all deserve to be classed in one pathologic group. Such a case as Dr. Baldwin has presented tonight is peculiarly interesting as showing a transitional type of these conditions. Such a case, with its emotional disturbances and other evidences of marked nervous instability, presents many differences from the average case of erythema bullosum. On the other hand, while in its nervous symptoms it strikingly suggests to one the graver forms of these disturbances, like der-

matitis herpeticiformis, it certainly could not be classed as a case of that disease. Indeed, I think such a case has its chief interest in the fact that it presents a transitional type. I agree with Dr. Baldwin that it is probably a toxemia. The patient, I infer from Dr. Baldwin's remarks, has pulmonary tuberculosis, and I imagine that the toxemia in the case is of tubercular origin. There is a peculiar form of erythema associated with tuberculosis, namely, the indurated erythema of Bazin, in which tubercular gummata occur. I mention it here because it is of tubercular origin and to express the opinion that it belongs to an entirely different class from those erythemas like the case under consideration due to the presence of toxins.

Dr. William L. Baum—The question of erythema multiforme is one that interests dermatologists and most general practitioners. Cases of this type present clinically interesting features, mainly on account of the frequency with which the diagnosis is not made. As for its etiology, we know but little. It is my belief that the vast majority of cases are due to an irritation of the vasomotor centers. This irritation may simply be the result of a predisposition in the system itself, or it may be due to a reflex irritation from the absorption of some of the products of digestion. All of us have undoubtedly not only seen in others but in our own persons have experienced a sensation of distress following a hearty meal when something has happened to us, causing unpleasant emotional disturbances. If such conditions arrest the ordinary process of digestion, we must expect in certain individuals that there will be a greater amount of resorption of partially digested food products which in themselves not only act as irritants but as powerful poisons to the system. So, in cases like this, where there is a pre-existing defect in the nervous system and the system generally, it is no small wonder that such irritation should be excited and produce these disastrous consequences. This case is interesting in view of its frequent occurrence, as the Doctor has said, and in view of the fact that sooner or later by progressive recurrence it will become a formidable disease for the individual. When I saw the case in connection with Dr. Baldwin the patient had a large number of bullæ which had broken down in the mouth. The tongue was so edematous that the patient could hardly close his mouth and the bullæ extended upon the posterior walls of the pharynx as far down as could be seen. There are a number of cases on record of the extension of these processes so as to produce partial suffocation, and there is no doubt but that such cases may have occurred without having been reported. Another feature is this, that if these violent disturbances can take place upon the mucous membrane of the mouth and throat, it is but reasonable to suppose that they also occur upon the mucous membranes in the deeper lying structures, and this is one feature frequently found associated with these attacks. For instance, in a case in which I have noted a number of recurrent attacks of erythema multiforme, I have also noticed that the patient had always coincidentally a very violent ileocolitis. This ileocolitis was not, as was first supposed, due to infection with the bacillus coli communis, but was evidently due to an irritation of the vasomotor centers, because the patient had hemorrhages from the bowels and has passed large mucous casts from the intestinal tract. I should look upon this as being eminently a vasomotor disturbance occurring in patients whose system had been previously undermined, and not so much to the general toxemic condition *per se*.

Dr. James G. Kiernan—One point that impressed me with regard to the case narrated by Dr. Baldwin and that is, on the one hand, the defect shown in the predisposition to tuberculosis (it being a congenital or hereditary defect) and, on the other hand, the factor of emotional disturbance. It is a very striking thing when you study the untoward effects of drugs which depend in no small degree on the two predisposing factors which make up the etiologic moment, namely, the constitution of the individual, as narrated, and the constitution of the patient at the time the drug is administered, that you notice in all the classes which play a part on the general system through the nervous and alimentary systems one uniform, or practically uniform untoward disturbance. In almost all of those you will find a simple erythema or an erythema resembling that which has been described as bullæ. Furthermore, if we take the untoward effects which have been from time to time reported by observers in connection with the use of the antitoxins, whether the streptococcus antitoxin or the diphtheria antitoxin, we will find no small number of cases which in many respects resemble the case described by Dr. Baldwin. Now, it seems to me, that in dealing with this subject we have to consider, in the first place, the predisposition; in the second place, the condition of the individual at the time the disturbance occurs; thirdly, the exciting cause and the vicious circle

which is produced by all three, as Dr. Baum has put it. Undeniably in that class of cases in which we have erythema with bullous disturbance and the other conditions that occur with the insane, we will find so-called membranous enteritis in not a few cases. There are probably not a few cases in which the general condition is demonstrable as connected with some emotional disturbance, while the exciting cause of erythema also is connected with that emotional disturbance. It seems to me, therefore, that in dealing with these conditions we should take into account the general nervous state of the individual, as well as the disturbance of the gastro-intestinal tract and the liver and the resultant auto-intoxications. While it is true that auto-intoxication will play a large part in not a few of these cases, still there are a large number of others in which the vasomotor disturbances, directly traceable to a condition of emotional overstrain, can be proven to exist. The question is of considerable importance from the standpoint of orthotherapy, especially since we are more and more observing the untoward effects of drugs.

Dr. W. X. Sudduth—The remarks of the preceding speaker brings up the question of emotional states for consideration in connection with the case reported. The question arises, what is immunity? What is intoxication, and what are the conditions that favor intoxication? I have at the present time a case under treatment that has given me an excellent opportunity to study the effect of the emotions in intoxications. A sinus, following a surgical operation, of some four or five months' standing, at the present time secretes pus periodically; at other times it is in good shape, and the periodicity is dependent upon the emotional condition in which the patient periodically finds herself, and we can exactly prognosticate the condition that will result following the emotional disturbance. On the other hand, what is it that gives immunity from infection? Why is it that physicians, priests and nurses go among epidemic diseases and in the main escape infection? And why is it other people are taken down with epidemics when they come? Why is it people panic-stricken are the first to come down? I attribute it to the fact that the emotional disturbance changes the secretions of the body, making them good culture media. I have seen experiments made in the hypnotic state with tests for anesthesia, when hatpins were taken from the hats of women in the audience, run through the cheek, and through the biceps muscles, and yet have never seen infection follow. In all cases the affirmation went ahead, "this will not hurt you." The patient was disarmed of fear and had immunity from infection. And these are surely points we must consider in these forms of disease. This particular case I speak of, where a recurrence of suppuration had invariably followed on the part of the patient to entertain fear or a fearful result to herself, just as sure as she anticipates that condition of mind she has a recurrence of the discharge of pus. I have seen this in so many cases, that to me it is positive evidence that the emotions play an important part in the matter of infection, and also in producing immunity. A hopeful, joyous, happy frame of mind gives immunity; whereas a fearful or even apprehensive state of mind tends to change the fluids of the body so as to permit of infection.

Dr. James G. Kiernan—It seems to me, in limiting the principle of auto-intoxication in the way it has been done, the fact is ignored that is very frequently essential, that auto-intoxication precedes toxemia, and that after all the limitation is a little too narrow in regard to the general question of etiology.

With reference to the question of immunity, incidentally raised by Dr. Sudduth, there is very little doubt but that the general tropho-neurotic condition of the patient plays a part, and may be dependent upon an emotional state. Kasperek, whose observations were published about two years ago and have been verified by experiments since, tried the old experiment of Brown-Séguard of making a section of the sciatic nerve on one side in a rabbit, and then injecting the ear on the opposite side with various pyogenic bacteria. Some time after, a given time being allowed, the rabbit was killed. The side on which the section had been made, which would produce certain tropho-neurotic conditions, was found to be the seat of very grave and large abscesses, but the side on which the sciatic nerve was healthy was found to be free from abscesses. It would seem, therefore, from this demonstration that the tropho-neurotic states play a part in the predisposition to microbic invasion on the one hand and their interactions also play a part in producing immunity on the other.

Dr. Fenton B. Turck—I simply wish to object to the indiscriminate use of ascribing the conditions to toxemia. In the first place, to prove the existence of toxemia we are obliged to find the toxins. In the next place, we must determine the origin of the toxins. Thirdly, we should endeavor to determine the excretion of the toxins. The work of determining

toxemia by examinations of the urine, as has been done by Bouchard, on animals, is faulty, because the urine varies at different times, and the degree of concentration of the urine present is not accounted for in connection with the experiments and the conditions existing. An examination of the material taken from the stomach, has been carried out by myself, but this also is a source of error, for the variations that occur physiologically would in the same way mar the perfect scientific work of determining the exact toxicity of the contents. An examination of the blood would probably offer better evidence, in that if the toxins are found circulating in the blood and we can produce an action upon the animal, it is more conclusive evidence that toxemia exists. Van Gieson has carried out some very interesting pathologic experiments upon animals and has found the effects of toxins upon the neurons, showing parenchymatous degeneration of the cells of the cortical area. Now in this we are nearer determining the question of toxemia.

Concerning the question of toxemia from the intestinal tract something is definitely known, yet in the absence or exclusion of toxemia from the retention of metabolic products, it offers a very interesting study. But, at present, we are in no position to generalize and to make sweeping statements that a certain case is one of toxemia. It would be interesting if, in some of these cases, we could take the urine, the stomach contents, the fecal excreta and blood and by combined biologic and chemic methods examine them until something more accurate is arrived at. This is being done now, and I think it is better for us to make statements with a little caution, and, at the same time, await future results. At the time when bacteriology was first presented to us, all manner of diseases were ascribed to various forms of bacteria, and every time a postmortem was made and a certain microbe was found, the microbe was ascribed as the cause of death. The result was that our literature was filled with statements that were untrue, and had to be retracted; so that, at present, in reference to toxemia it is safer for us to be cautious in making statements. I would not like to say in a paper like this, before a scientific body, that this or that case was one of auto-intoxication without first having made experiments to determine the presence of toxins. I believe this can be done by withdrawing blood from patients and thoroughly examining it, as well as from examinations of the urine at different times, and withdrawal of the stomach contents in these cases. The poisons thus extracted can be injected into animals and results obtained.

Dr. William A. Pusey—I want to do some more protesting, and this time it is to take pronounced exception to Dr. Turck's statement that we can not scientifically attribute a condition to toxemia until after we have found the toxins either in the fluids or tissues of the body. It would be a happy day for medicine if the chemic and biologic means at our disposal would admit of such exact analyses. But in the present state of our knowledge I believe that most of those who are familiar with the uncertainties of analysis of highly complex organic products will admit that the actual determination of most of the toxins are problems at present beyond us. On the other hand, the determination of toxemias by indirect evidence is in many cases capable of the strictest scientific accuracy. For example, we have an urticaria in a patient after eating tomatoes or strawberries; we must wait until the infinitesimal quantity of toxin that is causing the trouble can be determined before we accept the position that such a condition is a toxemia? Or take another patient, with constipation, who develops urticaria; clean out the bowels thoroughly and his urticaria disappears; does it shock any of our ideas of scientific accuracy to decide that such a case is a toxemia? Or, take almost any of the drug eruptions—most of which develop after the ingestion of what is an infinitesimal quantity of the toxin when the total weight of the body is considered—and what inference is more absolute than that the resulting disturbance is due to the presence of the peculiar toxin? Indeed, in contrast to Dr. Turck's position, I would maintain that the determination of a toxemia can be far more accurately made from indirect evidence than can be done by a direct examination of the tissues and the fluids of the body. The position taken by him neglects the fact that the compositions of the human tissues and fluids are exceedingly variable; that we are not agreed among ourselves yet as to what are normal and what are abnormal constituents; and that the analyses made by competent investigators are often wide apart. Such being the case, I would maintain that Dr. Baldwin's determination of the existence of toxemia by inference is the accurately scientific position, and I am willing to assume the position, in contradistinction to Dr. Turck's, that a toxemia can in most cases be better established by indirect evidence than by the methods of technical examination which we have at present at our command.

Dr. William L. Baum—Since I have been one of the habitual users of the term auto-intoxication, it is perhaps incumbent upon me to come to its rescue, which has been so energetically attacked both by Dr. Sudduth and Dr. Turck. Dr. Sudduth's position in regard to auto-intoxication is an untenable one, for the reason that he leaves out of consideration the pre-existing chemic change already present, and a physiologic action may become a perverted one simply through a chemic change, and for that reason belongs to the class of toxemias or auto-intoxicants, because it is not what a patient has taken into his system that produces intoxication *per se*, but the chemic condition of the individual already present.

Dr. Turck's position is entirely untenable. A number of years ago (I think it was in 1888) in making some examinations I came across a number of reports of medico legal cases. One of them was a case of so-called strychnia poisoning in which a chemic examination had been made by an Italian chemist. It was shown that goose meat, which had undergone putrefactive changes taken internally, produced symptoms similar to strychnia intoxication. I would like to know if perchance we were to give one grain hypodermatic injection of hyoscyamin, it would produce an intense toxic condition, and perhaps prove fatal. How would you demonstrate either by an examination of the contents of the stomach, the condition of the blood, or of the feces that this grain of hyoscyamin is present? It only requires a small quantity of chemically altered tissue to have a physiologic action which is akin to that of some of the most powerful poisons; we know that these can produce chemic conditions of which the chemist or biologic student has no knowledge. How to look for these conditions, how to find them, is beyond the province of chemistry.

Dr. Baldwin—I have nothing to add in closing the discussion, except that it might be interesting to remark that the case I have reported went to his business on the 15th of February. He weighed himself on that day and was 109 pounds. He weighed himself again day before yesterday and was 121 pounds. He has been taking three quarts of milk a day and nine drops of arsenic.

Medical and Chirurgical Faculty of the State of Maryland.

Ninety-ninth Annual Session, held April 27 to 30, 1897.

(Concluded from page 991.)

SECOND DAY.

Dr. Ruhrah, physician in charge of the Pasteur Institute of the City Hospital, opened the discussion on "Rabies." He spoke of the preventive treatment of rabies. This institute has been opened twelve days and has six patients. The disease is very common where there are no dog laws, but where there is a high dog tax and careful supervision there are few cases of hydrophobia. The incubation period is about ten weeks, although it can be as short as two or three. In one case it is 18 months. Deaths in three weeks are rare. Of the cases which were reported about 47 per cent. of those bitten developed the disease. Men have a greater mortality than women, and children the greatest of all. Eight per cent. of suspected cases developed. When the wound was immediately cauterized the mortality only reached 33 per cent. of the 47 per cent. mentioned above, while in the uncauterized they reached 80 per cent. In the department of the Seine mortality of hydrophobia was 25 per cent. the first year in the Pasteur institute and 16 the second year. The virus gets into a part of the central nervous system so that in preparing virus a rabbit is inoculated from a rabid dog. Pasteur's idea was to make a modified form of the disease.

Dr. Wm. H. Welch then said that in drawing conclusions it is well to remember that such a disease as hydrophobia exists. This is unquestionable. Mistakes occur but the disease has characteristic symptoms. Inoculation in animals in series is a positive pathologic proof of the existence of the disease. The state of mind has nothing to do with the matter nor the element of fear, not more than syphilophobia can cause syphilis. The method of treatment rests on a complicated experimental basis which is just as satisfactory as is the treatment of diphtheria. The best way of finding its value is by the statistical method; there is no other which is so valuable for this purpose, and thus we show that the method is efficacious. It is not a sure cure, failures occur but are not numerous. The case which dies between the time of the bite and fifteen days after the beginning of treatment should not be counted in the statistics. The percentage or mortality is from 1 to 3 or 4 per cent. Those bitten through the clothing are often not dangerous. The mortality of those bitten on the head without treatment is from 80 to 100 per cent; under

treatment, 5 to 6 per cent. From 1886 to 1895 there were seven-teen deaths from bites on the head and face at the Pasteur institute, or 1.34. From 1890 to 1893, 135 persons were bitten on the head and face by rabid dogs and were treated with no deaths, not including those who died within less than fifteen days.

Dr. N. G. Keirle then explained very thoroughly how a dog was judged to be rabid both by the contents of his stomach and the bacteriologic examination of his spinal cord.

Dr. J. B. R. Purnell of Easton then made some remarks on this subject also.

Dr. C. Birnie of Tarrytown thought there was no doubt about the efficacy of the treatment.

Dr. John Morris did not believe that there were so many cases of hydrophobia, and thought that the discussion of the subject rather did harm in cultivating fear among the people. The paper was further discussed by Drs. Kemp, Goldsmith and Norment.

Dr. H. B. Jacobs then read a very elaborate paper on "Early Spinal Syphilis with the Brown-Séquard Paralysis." This was discussed by Dr. Geo. J. Preston.

Dr. J. W. Humrichouse of Hagerstown reported eight consecutive cases of laryngeal diphtheria successfully treated with intubation and antitoxin. These cases were not malignant. The membranes were small and toxic symptoms were not marked, but in every case he was obliged to perform intubation in order to avert death from stenosis of the larynx. It was the diphtheritic toxins which threatened life through the local lesions in the larynx. The mild character of the disease is due either to the type of the epidemic or to the use of antitoxin. He does not believe the cases would have done so well without antitoxin. The ages of the patients were from 16 months to 7 years. Bacteriologic cultures were not made. The small dose usually was 1,000 units and the large 5,000.

Dr. William T. Watson then read a paper illustrating the value of "Bacteriology in Preventing the Spread of Diphtheria." Physicians are very philanthropic, doing everything possible to prevent or cure disease and thus cut off the sources of their prosperity. He related several cases in which the bacteriologic examination showed the presence of diphtheria organisms in the throats of children who were in all other respects apparently free from the disease, and therefore he had had great trouble in convincing the mother, who depended on her own efforts for her support, that she must keep each child from school and herself from intercourse with her neighbors. In several cases he found the families had become discontented with bacteriology and also with their doctor for not sooner destroying the germs. They could not understand that children who had never been ill enough to be off their feet were a source of danger to the community for several weeks. This led him to ask the question, how long the bacteria of diphtheria might remain in the throat and mouth of persons apparently well since recovered from diphtheria. In looking over the work of Dr. Herman M. Biggs of New York he found that in a large number of cases collected the bacteria were found in persons anywhere from seven days to nine weeks after recovery, and these bacteria were in many cases virulent at the longest period. He thinks that general circulars should be issued by the health authorities to parents who can be made to clearly understand the possibility of the danger on this infection after this disease.

Dr. S. K. Merrick, in discussing these papers reported a case of diphtheria in an adult 56 years old. It was a case of laryngeal diphtheria, which gradually grew worse and when the edema rendered the attack dangerous antitoxin was used. It began with a small patch on the left arytenoid. The case recovered.

Dr. T. A. Latimer has used antitoxin in thirty cases with only one death and in many instances he used it early without waiting for a diagnosis by culture tests. Further remarks were made by Drs. Gardner, W. R. Stokes, Harlan, Humrichouse and Watson.

Dr. William Royal Stokes, Bacteriologist to the Health Board of Baltimore, then read a very interesting paper on "Microscopic Examination of Milk." He briefly reviewed the methods used in the municipal laboratory in examining milk. When the milk examined was from one cow, or even when it was a mixed milk from many cows it was centrifugalized for some minutes and then the sediment was spread out on a glass and strained. If many pus cells were found the specimen was rejected; but if there was only one or two pus cells in the field the specimen was passed. Often the milk from one cow whose milk was healthy was contaminated by milk from other cows.

Dr. J. C. Hemmeter then read a paper on "Food Adulteration." He spoke first of beer adulterations and said that the beer made in Baltimore was especially free from adulterants,

while the imported beer was not so good on account of the salicylic acid put in to preserve it during export. The water of Baltimore was especially good and contained very few organisms. He had examined a great many oysters and had failed to find any typhoid or pathogenic bacteria. He thought that the tidal waves of the Chesapeake Bay and lack of contaminated water kept the oysters free from a diseased condition.

Dr. Morris then said in reply that the examination of beer was not difficult.

Dr. Osler referred to the report published a few years ago in the *Lancet* on the Munich beer.

Dr. Charles O'Donovan then read a paper on "The Treatment of Gastric Ulcers after Hemorrhage." Gastric ulcers which tend to recover and in which the hemorrhage gradually decreases need no medical treatment; but those cases which recur and seem to grow worse should be treated surgically.

Dr. Samuel Theobald then reported 100 cases of "Cataract Extraction." He reviewed 100 of his consecutive cases of cataract showing his method of treatment and his results. This paper was discussed by Drs. Woods, Harlan, Randolph, Bernstein, Funck and Theobald.

At the evening session the various committees reported and the officers for the ensuing year were elected.

THIRD DAY, 12 NOON,

Dr. Harry Friedenwald read an interesting historical sketch on "The Early History of Ophthalmology and Otology in Baltimore." He said that as early as 1805 reference was made to licenses for oculists in Baltimore. Dr. Pierre Chatard, who came from France in his early life to Baltimore in 1797, was a prolific writer and contributed articles on diseases of the eye. Other writers, such as Dr. Wm. Gibson, Dr. George Frick, Dr. Cohen, Dr. Jameson and Dr. Harper show that the diseases of the eye and ear received very early attention in Maryland. In fact, Dr. Frick's book was the first to appear in English on the subject in Baltimore, and the third in the English language. This paper was discussed by Dr. Randolph.

Dr. R. L. Randolph then read a paper on "Pathologic Eye Specimens," and showed some beautifully executed water colors on the pathologic condition of the eye ground. He also showed specimens embedded in glycerin jelly according to Priestley Smith's method. This paper was discussed by Dr. Reik.

Dr. Reik then read a paper on "Exhibitions of Eye Specimens" and exhibited eye grounds mounted in glycerin jelly and showed some beautiful and normal specimens.

Dr. E. J. Bernstein then read a paper on "Prevention and Treatment of Ophthalmia Neonatorum."

Dr. R. L. Randolph said it would be interesting to hear from the obstetricians on this point.

Dr. Wilmer Brinton said that in his lying-in hospital he followed the method of Credé and in 800 cases he had 27 cases of ophthalmia neonatorum with no deaths. He rarely had occasion to use his method in private practice unless under very exceptional circumstances.

Dr. J. S. Fulton said he thought too much stress was laid on the connection between ophthalmia and gonorrhoea and referred to two cases of midwives who had been fined for not reporting cases. He thought the assumption that all cases of ophthalmia in newborn children came from gonorrhoea was wrong and kept many persons from making complaints.

Dr. R. Percy Smith of Sunnybrook, then read a paper on "Fracture and Dislocation of the Vertebral Column." He exhibited a case in which a heavy weight of 550 pounds had fallen on the back of a man and had both fractured and dislocated his vertebral column and injured his skull. The patient is able to go about and his recovery is remarkable.

Dr. J. E. Stokes then read a paper on "Two Cases of Anteparturient Asphyxia," which was discussed by Dr. Tiffany.

Dr. Frank Martin then read a paper on "Joint Tuberculosis Treated by Iodoform Emulsion." He reported several cases of severe joint tuberculosis on which he operated by first opening the joint, scraping off the tuberculous part and packing with iodoform gauze. The case had recovered. In answer to Dr. Taylor he said that the motion was not restored, but the fact that he had arrested the disease justified him in the operation.

Dr. Robert W. Johnson read a paper on "Two Cases of Gastrostomy and one of Gastro-enterostomy." He exhibited one of his patients entirely well. She was a young girl who had severe vomiting before the operation of gastrostomy, and that after the operation she had never vomited, and now considered herself well. In one case he recovered a long bonnet pin. This case of gastro-enterostomy died.

Dr. Hemmeter referred to this cured case as one in whom he

had used the electric light of the stomach, showing that the dilated condition of that organ extended below the symphysis.

Dr. Winslow said he had never had any success in operating for gastro-enterostomy, but he hoped to have better luck as his operations increased in number.

Dr. R. Tunstall Taylor made some remarks on the "Plaster Jacket vs. the Steel Brace," and showed five children who were undergoing treatment for Pott's disease. He thought that the plaster jacket gave good support when the curvature was below the seventh cervical vertebra; above that point the steel back brace was best. This paper was discussed by Dr. Smart.

Dr. Hiram Woods, Jr., read a very elaborate paper on "Suppurative Otitis Media with Symptoms of Sepsis and Intra-Cranial Disease," with recovery under mastoid operation and removal of polypi. He showed the importance of attending to certain running diseases of the ear which appear harmless but which in reality were dangerous.

Dr. Reik said that there was great necessity for good work in otitis media. He had seen a great many cases in which physicians had advised them to let the running ear alone. This is not right. For this reason too many cases come to the specialist too late for treatment. They need treatment early.

Dr. Hodgdon asked if there were any symptoms of meningitis.

Dr. Woods said that two cases were acute and seemed to be primary mastoid disease. This is very rare. There were no original symptoms observed, except slightly in one case where pain might have been from other trouble, but it disappeared with drainage, which does not occur in meningitis. He does not believe that these ear troubles are neglected as much as they used to be.

EVENING SESSION, 8 P.M.

"Does Medicine Advance?" This was the subject of the annual address, which was delivered by Dr. David W. Cheever, Emeritus Professor of Surgery at Harvard University. He said that the prime object of medicine was to prolong life, to relieve suffering and to prevent and cure disease. People lived longer than they used to, pain is more remediable. Many diseases can be prevented or avoided, but can we say that more sick people are cured. He then went over the various branches of medicine and gave a historic survey of the advance in medicine and concluded finally that medicine had made advances along every line. At the conclusion of this address the banquet was served.

FOURTH DAY—DAY SESSION, 12 M.

"Models of the Original Chamberlen Midwifery Forceps." Dr. J. Whitridge Williams then gave a demonstration of some models of the original Chamberlen forceps. He spoke of the early professional life of Peter Chamberlen and his son and their connection with the barber surgeons of London. By permission of the Royal Medico-Chirurgical Society of London Dr. Williams was allowed to have made models of the original models of these forceps. In some the blades were connected by a piece of tape, while in others there was a mortise lock. He showed how Chamberlen tried to sell these in Paris and in Amsterdam and exhibited one pair. He called attention to the fact that there was very little difference in the shape of the blades of the forceps of the present day from those originated by Chamberlen at the end of the 16th century.

Dr. J. H. Branham then related a "Case of Complete Hysterectomy of the Uterus and Vagina During Confinement."

Dr. George W. Dobbin, Resident Obstetrician, Johns Hopkins Hospital, then related the "Frequency of Contracted Pelvis in the Obstetrical Service of the Johns Hopkins Hospital." He gave a careful record of the obstetric cases in the Johns Hopkins Hospital and showed the importance of practicing pelvicmetry on all cases, without regard to any other conditions. These statistics have been of great assistance to them in their work, but allowances had to be made, from the fact that many of the cases were of the negro race.

Dr. Wilmer Brinton said that Drs. Dobbin and Williams deserved great credit for their excellent work on this subject at the Johns Hopkins Hospital. For the past three or four years he has kept account of the measurements of the cases coming under his care in his hospital and he had about three hundred measurements to report. It must be remembered that in the Maryland General Hospital 60 per cent. of the women were negroes. Of the 120 cases delivered there, three were high forceps cases, and the antero-posterior measurement of all were under 4 inches.

Dr. L. E. Neale said that he thought that each case should be treated on its own merits, and that while he carefully measured each case in his own hospital he thought that a great many other conditions could be taken into account also.

Dr. J. Whitridge Williams said they simply recorded these

for future work and he had no intention now of drawing conclusions, as the cases treated were too few in number. He hoped that all the members delivering women would take pains to measure their cases carefully. By this method he had discovered several cases of osteomalacia.

Dr. T. C. Gilchrist then read a paper entitled "The Common Contagious Diseases of the Skin as met with in School Children and How to Prevent Them." He said that ringworm of the scalp was one of the most frequent and dangerous diseases among the school children of Baltimore. It occurs in three forms, all of which he has found in two orphan asylums which he has lately visited. No child that has this disease should be allowed to go to school, and no child should be allowed to go to school who has dandruff or head affection unless it can be proved that ringworm of the scalp is absent. The disease is very hard to cure and not easy to diagnose. The short hairs, when the hair breaks off and little ends appear above the scalp give cause for suspicion. Another disease common among school children is pediculosis and pustular eczema. The proper treatment is to kill the nit with petroleum and the eczema will recover itself. Impetigo contagiosa is also another disease common among school children, and last of all, tinea favosa. Schools should be inspected against these diseases, and as in New York, so in other cities, immigrants with these contagious diseases should not be allowed to land. Scabies is another common disease. All these diseases are preventable and curable and should be more carefully looked after by those interested in the health of school children. Dr. Gilchrist also showed a case of pityriasis rubra and a case of alopecia areata, the latter of which was evidently, in his opinion, a case of myxedema, which he had treated with thyroid extract, 2½ grains at dose.

Dr. Mischeau thinks that often children in private schools are affected by these diseases, and related a case of a child taken to be very clean and who had, in spite of every kind of treatment, a continuous case of ringworm.

Dr. Brush asked if the first case presented had any nervous disorder, as he had had several cases of pityriasis rubra in his insane asylum.

Dr. Osler asked if the hair did not always return after the use of thyroid extract. This had been the case with his experience. He also said that he thought the girl was rather young to have myxedema.

Dr. L. G. Smart asked if 2½ grains was the usual dose of thyroid extract. He always began with 5 grains and kept it up unless there was digestive disturbances. From this small dose he obtained no reaction.

Dr. Blake asked whether the falling out of the hair had any connection with the pain.

Dr. Gilchrist said, in conclusion, to Dr. Brush, that the man was not nervous, and that otherwise was entirely well. He had used the thyroid extract in 5 grain doses and had found it too large, and got excellent results from 2½ grains.

"Caries of the Skull," was the subject of a very interesting paper by Dr. H. H. Biedler. He also exhibited a specimen.

"Some Diseases of Worcester and other Counties," was the subject of a paper by Dr. J. B. R. Purnell.

"The Spread of Tuberculosis Among the Russian Jews in this City," was the subject of a paper by Dr. J. E. Gichner, who as the attending physician to the Hebrew Benevolent Society had ample opportunity to study tuberculosis among that class. He found that each year the cases of pulmonary tuberculosis seemed to be increasing very markedly, and he attributed it in part to lack of cleanliness and to the unhealthy manner of living of the people. This paper was discussed by Drs. Canfield, Schaeffer, Brinton, Mischeau, Biedler, Osler, Blake, J. T. Smith and Gilchrist.

"Rupture of the Aorta," was the subject of a paper by Dr. W. G. Townsend, who showed the picture of a pathologic specimen.

"Uric Acid Diathesis in Children," was the subject of remarks made by Dr. Frank D. Sanger, who exhibited several specimens of the kidney showing uric acid alkali petris of the kidney and in the ureters.

Dr. Charles M. Ellis of Elkton was elected president for the ensuing year.

Chicago Ophthalmological and Otological Society.

Regular meeting held at the Victoria Hotel, April 13, 1897.

Dr. Montgomery in the chair.

There were twenty-one members and visitors in attendance. The minutes of the last meeting were read and approved. Dr. K. K. Wheelock of Fort Wayne was elected a member. The

secretary read the applications of Drs. A. E. Bulson, Jr., of Fort Wayne, and E. A. Lawbaugh of Chicago.

Dr. Ware showed a colored boy, 9 years of age, on whom one year ago there appeared a swelling at the outer upper angle of each orbit. These swellings increased rapidly in size, so that they became about three-quarters of an inch long, projecting forward and downward, dislocating both lachrymal glands and causing complete ptosis of both lids. The patient was first seen about a month ago and a diagnosis of specific periostitis made. Under large doses of iodid the swellings rapidly decreased, so that at present they can hardly be felt. There was no pain at any time in the course of the disease.

Dr. Colburn opened the discussion on "Muscular Asthenopia" by reporting four new cases of chorea treated by tenotomies.

The first case is a girl of 10 with a hyperphoria of 4 degrees and exophoria of 30 degrees, which was corrected by operation. Four weeks after the operation the patient was well, and has been so since.

The second case, a girl of 26, had chorea of three months. Operated on twice and cured.

The third case, a boy of 5½, which improved by the correction of 2½ D. of astigmatism, but chorea remained on using the eyes. No operation was done in this case.

Fourth case, a boy of 10, with marked degree of astigmatism, the correction of which cured the chorea.

The doctor reported four new cases of epilepsy, all of which were cured. He thinks that of the different heterophorias hyperphoria is far more important in the causation of muscular asthenopias than insufficiencies of the lateral muscles. His statistics showed a large percentage of asthenopic cases due to troubles with the extrinsic muscles, and his results have been very satisfactory.

Dr. Haight reported two cases, one with 4 degrees and the other 12 degrees exophoria, both of which were cured by operation.

Dr. Coleman had in years past operated a number of times for muscular asthenopia, but had found the results of operations so very uncertain that he had practically given it up, confining himself only to those cases that have diplopia. He found many cases in his own experience and in that of others where, after the muscular error was completely corrected, it had returned in from one to three months, and no amount of operation was able to permanently correct it. He had also found that the methods of testing for heterophoria were very unsatisfactory and uncertain.

Dr. Hotz reviewed 61 cases in his own practice, 10 with hyperphoria, 21 with esophoria and 30 with exophoria in which operations had been done with satisfactory results. He found that hyperphoria was most often the cause of symptoms. He had found that exercising the muscles after the manner of Gould was of no value in these cases.

Dr. Gradle thought that less than 1 per cent. of all cases of asthenopia had any relation to muscular troubles. He had found many people without any symptoms with marked degrees of muscular trouble. The only cases that he had thought important were those where there was what was formerly called a latent squint, but these cases did not have true asthenopia, but they have diplopia. Dr. Gradle considers that muscular asthenopia is merely an expression of one of many symptoms in a neurotic person, and he does not believe that balancing the muscles by operation is the best method of treating such cases.

Dr. Colburn, in closing the discussion, referred to the fact that it was not sufficient to test a patient's muscles with the eyes directed straight ahead. It was of great importance in many cases to test the muscles with the eyes in a different position.

On motion, the Society adjourned.

C. P. PINCKARD, M.D., Secretary.

SELECTIONS.

Amebic Abscess of the Liver, with Perforation of the Inferior Vena Cava.—Flexner (*American Journal of the Medical Sciences*, May, p. 553) reports two cases of amebic abscess of the liver, together with the only other one that he was able to find recorded in the literature, in which secondary perforation of the inferior vena cava resulted. One of the cases occurred in a man, 51 years old, in whom the diagnosis lay between abscess and neoplasm of the liver, with a leaning in favor of the former. An exploratory operation was undertaken, but it was not

until the aspirating needle was introduced in the right sixth interspace in about the anterior axillary space, passing through the diaphragm and about 5 cm. of the liver substance, that it entered a cavity from which about 20 c.c. of a brownish pus-like fluid, having the appearance of anchovy sauce, was evacuated. Portions of the sixth and seventh ribs were resected, the pleural cavity shut off by means of gauze and the diaphragm incised, and the peritoneal cavity protected in like manner. On the following day the liver was incised and between 1000 and 1500 c.c. of fluid similar in appearance to that aspirated evacuated. A large drainage tube was introduced and the wound was packed with iodoform gauze. The patient did well for eleven days after the second operation, when there occurred a copious hemorrhage into the wound and death soon resulted. Examination of the fluid aspirated on the first day showed no well preserved cells, but only granular debris. In the contents of the abscess evacuated at the operation were found a number of actively motile bodies with the characteristics of the ameba coli.

Postmortem examination disclosed in the right lobe of the liver a funnel-shaped cavity near its anterior edge, 5 cm. from its superior border. In its widest part this cavity measured 4 cm. in diameter, and led directly into a cavity in the substance of the right lobe of the liver the size of an orange. This second cavity at its deepest part measured 10 cm. in its greatest diameter. Across its upper portion ran the inferior vena cava, and at a point 2 cm. from the superior border of the liver it was occupied by a thrombus that half-filled its lumen. On removing this thrombus two perforations, one the size of a split pea, the other of a poppy-seed, were disclosed, leading directly into the cavity in the liver. For a distance of 5 cm. the adventitial coat of the cava was in contact with the abscess and assisted in the formation of its posterior boundary wall. The right lobe of the liver contained numerous additional abscesses of varying size. The intestines were free from ulceration, but several pigmented and depressed spots were present in the large intestine; and in the ileum, about 50 cm. above the ileo-cecal valve, there was a puckered area 1 cm. in diameter. Microscopic examination of sections from these parts showed, however, the normal structure of the mucosa. No evidence of previous ulceration was made out. Each lung contained an embolic abscess. Examination of the fresh contents of the abscess at the autopsy showed living amebæ in moderate numbers. Several varieties of bacteria were also present. The smaller abscesses and necrotic areas contained streptococci in pure culture. The pulmonary abscesses also were of streptococcus origin.

The second case occurred in a man, 45 years old, who had had recurring chills and fever, followed by profuse sweating. Subsequently cough developed, with blood-streaked expectoration, which later assumed the appearance of anchovy sauce and contained, in addition to pus cells, red blood corpuscles and epithelial cells, distinctly motile amebæ and crystals believed to be bilirubin. The fecal matter obtained by the rectal tube did not show amebæ. There was no history of dysentery. While under observation the patient was seized with sudden pain on the right side and immediately complained of dyspnea and oppression. Fulness and immobility of the right chest were noted on examination, with increased vocal fremitus and percussion flatness. Resection of the sixth rib on the right side permitted of the evacuation of a large quantity of pale-brownish pus. Subsequently amebæ were found in the discharges obtained by means of the rectal tube, and later diarrhea set in. The patient, however, grew progressively more and more feeble and death took place.

Upon postmortem examination the right lobe of the liver was found to contain a large abscess communicating directly, through the diaphragm, with a cavity in the lung. The abscess was bounded posteriorly, in addition to the thickened capsule of

the liver, by the adventitial coat of the inferior vena cava, into which it had ruptured at the point of entrance of the hepatic veins. The cava, beginning at a point just above the rupture, contained an occluding, partly decolorized, firm and adherent thrombus, which extended upward and projected into right auricle, about one-third of which it filled. Some of the main hepatic veins contained thrombi, which were firm and decolorized in the upper and red and soft in the lower portions. The small intestine showed only congestion and a few small areas of ecchymosis, chiefly in the mucous membrane. The large intestine, on the other hand, was the seat of many ulcers, which for the most part did not reach the size of a bean. They were in the mucous membrane or at most projected very superficially into the submucosa. They were quite regular and smooth, not undermined, and were covered with a sticky pus-like material. The majority were in the cecum and upper colon; they were fewer and well separated in the sigmoid flexure and rectum. The fresh material taken from the abscess common to the liver and the right lung contained many living amebæ. The left lung contained many small abscesses, presumably of embolic origin, and the left lobe of the liver two or three, of which none was larger than a split pea. In none of these were amebæ found. They, as well as the large abscess, contained cocci in clumps. Bacteriologic examination revealed the presence of staphylococcus pyogenes aureus in these situations, as well as in the blood of the heart and organs generally.

It is pointed out that the special features of interest in the cases reported are the existence of an amebic abscess of the liver in the first in the absence of intestinal lesions, and the probability in the second of the intestinal lesions being secondary to the hepatic and pulmonary abscess, perhaps through the biliary passages and the bile.

Surgical Significance of Gallstones.—Dr. F. Lange, before the Johns Hopkins Hospital Medical Society, offered the following as the outgrowth of a large experience in the treatment of hepatic calculus. In operating, his preferences have led him to entirely abandon the longitudinal incision, but, according to the proposition of Corvisart and the experience of other surgeons, as reported in the *Hospital Bulletin*, he further said, "I do exclusively the operation parallel to the border of the ribs. Correspondingly to the thickness of the abdominal wall, this incision must occasionally be a very large one. A very great difficulty must occasionally be met with through the smallness of the liver. It is a mistaken idea that in consequence of stagnation of bile the liver must be enlarged. On the contrary, I have had the experience that in occlusion of the common duct of long duration, probably through the influence of pressure, an atrophic condition of the liver tissue will take place, and occasionally the liver will be concealed high up behind the ribs and this may cause a great deal of difficulty in consequence of the high and deep position of the field of operation. I have taken, in eight of these cases, to excising the adjacent cartilages of the ribs, and I should like to commend that. It facilitates the operation very much. On the other hand, the enlargement of the liver may be a great hindrance, and, especially in fat and plump persons of short build, it may be quite difficult to get down to the common duct. In one of the cases I was unable, in spite of the excision of the ribs, to get effectually down to the point of the trouble, and not until I had pulled the liver as far as I could out of the incision, almost one-third of the liver substance being brought outside of the abdominal wall, was I able to easily get to the cystic and common ducts. It was the case in which I was obliged to open the cystic duct at two different points and, besides that, the common duct at the usual place about the middle of its course. In the cases of acute inflammation it is necessary, wherever one has reason to presume that the neighborhood of the gall bladder is infected, to keep everything as

much as possible open and give entirely free outlet for the peritoneal secretions. At the same time I always drain the gall bladder with a long tube with the view of having a siphon action upon the secreted gall, and this will act very effectually. Occasionally a blockade will take place through mucus or blood clot, and then it will be necessary to change the tube or make a cautious washing through it. I should advise against the injection of any irritating antiseptic solution into the gall bladder. I have observed that occasionally this fluid will cause distressing symptoms, attacks of colic, probably because it may get into the common duct and the hepatic duct and irritate. I only use saline solution or boiled water. I have always found that the bile itself was an antiseptic agent. After a short time the amount of purulent secretion is insignificant, and the healing of the abdominal wounds, although constantly in contact with the bile, is mostly uneventful and without any untoward symptoms.

"About stones in the liver substance I have no practical experience. I have once found a stone in the liver after it had perforated the walls of the gall bladder, but I have not had any experience with stones in the liver that have formed in the gall system above the hepatic duct. It is a fact that these stones will occur, that occasionally quite extensive casts of stone formation will take place in the gall system. I will not mention comparatively frequent uncomplicated cases, where we have to deal with dilated gall bladders and stones, and where the surgical treatment is comparatively simple. I never do the operation in two sittings. I find that it is entirely safe to operate in one sitting. I have always aspirated as much as possible the contents of the gall bladder through a thick aspirating needle, protecting as cautiously as possible the surroundings to guard against infection.

"I think that in some of my cases I have reason to assume that there is some valve action, especially in one case of stone in the common duct of small size. The patient had had an attack of gallstone some three months before this attack with jaundice lasting several weeks, most likely because of obstruction from this stone, which was solitary, as judged by its very round, regular shape. Probably after a time this stone shifted back and later on again caused obstruction together with an infection. This we saw not uncommonly in cases of obstruction of the common duct. Even if the stones are ball-like or rounded, at intervals a certain amount of bile will get into the gut. It is almost characteristic that if, in prolonged jaundice, at intervals the condition of the feces and the urine points to the passage of a certain amount of bile through the duct, we have probably to deal with obstruction from stone. Regarding the drainage of the common duct I have tried everything; I have left the duct entirely opened, and I have sewed it up with the insertion of a small drainage tube into the lumen of the duct, and I have sewed it up entirely. In cases where the common duct is healthy I think it preferable, if it can be done, to sew up the duct entirely. If there is reason to assume that there is obstruction beyond the stone I should prefer to drain, and I do this in such a way that I insert a small drainage tube from the wound in the common duct and pack gauze around it. This gauze (iodoform gauze boiled in glycerin) I leave in for five or six days. The tube I leave for a sufficiently long time to secure the proper outlet of any secretion as long as it exists. In draining a gall bladder I pack the gauze around the tube and leave the opening comparatively large for the reason that, at least the inflammatory cases, the surface of the gall bladder is such that it will necessitate some thorough cleansing and local treatment for a limited time. There will be clots of blood or shreds of tissue or inspissated mucus which might easily obstruct. I mostly remove this tampon in two or three days, and give the inside of the gall bladder an additional thorough washing and cleansing. Besides this we have either sewed the peritoneum to the

surface of the gall bladder where there is no infection outside of it, or we have packed around the circumference of the gall bladder in such a way that even if some of the contents of the bladder escape it is not likely to cause a spreading inflammation. A very serious complication that has led to fatal issue in several of my cases of advanced cholemia, is an inclination of the patient to bleeding. Three of my cases I have lost from secondary hemorrhages. Two of these cases were complicated with malignant disease of the pancreas. Necropsies were not made, and I can only say that I felt in the region of the head of the pancreas a resistant hard mass which I took for a malignant affection. Lately, Professor Riedel, a surgeon who has perhaps worked more in gall surgery than any other man living, has published cases in which he is inclined to assume that occasionally these apparent malignant thickenings of the pancreas may be but inflammatory thickenings, and he mentions one case which seems to be beyond any doubt. In an elderly gentleman, in whom the operation was abandoned, assuming that this was a case of cancer of the pancreas, the stones merely were removed. A fatal issue was awaited, but the patient lived for years and became healthy and strong, and there could be no question about his not having malignant disease. He assumes that through the presence of stones an irritation is kept up in the pancreas, and that this irritation, after the removal of the stone, may cease and the condition improve. I have lost one of these cases by the separation of the Murphy button after establishing cholecystenterostomy. The patient had had up to that time small hemorrhages from the inside of the gall bladder. I had purposely kept the gall bladder open, stitched to the abdominal wall, because I had the impression that this would probably be a case of bleeding, and in order to tampon and make counter pressure I kept the gall bladder open and was able up to the tenth or eleventh day to check the bleeding, but after the separation the patient had a profuse hemorrhage into the large intestine and succumbed to anemia."

PRACTICAL NOTES.

A Sensitive Test for Sugar.—A test tube of ordinary size is filled for about half an inch with hydrochlorate of phenylhydrazin in powder; then acetate of soda in powder or small crystals is added for another half inch. The test-tube is then half filled with urine and boiled over a spirit lamp, the powders passing into solution as soon as the liquid is heated. After the urine has reached the boiling point allow it to boil for two minutes. The tube is left in the stand, and examined again some time afterward. If sugar is present a yellowish deposit forms, which under the microscope is seen to consist chiefly of beautiful needle-shaped crystals of a bright sulphur yellow color. The crystals are often found after the urine has been standing for half an hour; but after boiling the tube we have generally placed it in the test stand, and not examined the deposit until at least six or eight hours afterward. If no sugar is present, only brownish amorphous globules or yellowish scales are found. The test when thus carried out is very sensitive; a diabetic urine so diluted with water as to contain only 0.015 per cent. of sugar gave no reaction with Fehling's solution and no indication of sugar by the fermentation test, but with the phenyl-hydrazin test showed a distinct deposit of long yellow crystals.—*Dublin Journal of Medical Science.*

Successful Suture of a Penetrating Wound of the Heart.—At a recent meeting of the German Surgical Society Rehn (*Deutsche med. Woch.*, May 6, 1897, Suppl. p. 88) reported the case of a man 22 years old who was stabbed with a knife in the left chest and came under observation in a most unfavorable condition, with dyspnea and cyanosis, almost pulseless and covered with blood. A wound was found in the left fourth intercostal space.

The area of cardiac percussion dulness was increased to the right; the heart-sounds were clear. On the following day the condition of the patient had improved, but the area of cardiac dulness had increased. On the third day the condition had grown worse, the pulse failing and the respiration becoming greatly accelerated. The area of cardiac dulness had increased still more and the patient appeared moribund. Operation was now decided upon and an incision was made in the fourth intercostal space, the fifth rib also being divided, and the pericardium exposed. When the wound in this sac was enlarged a large clot was encountered and an incised wound of the right ventricle 1.5 cm. long was found. No blood escaped during systole and it was possible to compress the wound with a finger without embarrassing the action of the heart. Three silk sutures were introduced during diastole and the hemorrhage ceased. The pleura was irrigated with saline solution and together with the pericardium packed with gauze. Immediately after the operation pulse and respiration were better. The surgical progress of the case was complicated by purulent pleurisy necessitating later reopening of the pleura. Except for slightly increased activity of the heart the condition of the patient was an excellent one seven months after the accident.

Plaster Bed for the Treatment of Scoliosis.—Jagerink has secured gratifying results with his plaster bed in treating twenty patients, mostly adults, some 25 years old, all with advanced scoliosis. They sleep in this bed all night and remain in it several hours a day. The plaster cast reaches from the top of the head nearly to the knees and is strengthened with iron bands. A slit is cut on each side of the spine corresponding to the points of the greatest curvature, through each of which a broad band is passed and fastened to an iron support projecting a foot or two above each side. These flat bands are gradually tightened until they exert considerable pressure upon the curvatures, while the head of the bed is raised, which stretches the spinal column. Full directions and cuts are published in the *Ztschrift. f. Orthop. Chir.*, Vol. v, No. 1, in which he recommends it in the warmest terms.

Lucas' Balloon Dilator for the Cervix Uteri is an hour-glass shaped balloon of inelastic and very strong rubber tissue distended with water. The concave top of the balloon receives the head and its pressure deepens the concavity, as the water within is forced by the pressure out into the other part in the vagina. This is considered an important advantage of this balloon as it favors correct presentation and does not alter it, which is one of the dangers of the Champetier balloon. Lucas believes that it will be found extremely useful in cases requiring prompt evacuation of the contents of the uterus, also in hemorrhage from placenta previa and in deformed pelvis.—*Jour. de M. de Paris*, January 31.

Success of Osmic Acid in Neuralgia.—Franck reports thirty-four cases completely cured in seventy-seven, some truly remarkable cures after years of suffering and the failure of other remedies and surgical intervention. He uses Chapiro's formula: Osmic acid, 0.1 gram; aq. dest., 6 grams; glycerin, 4 grams. Keep in black flasks. Usual amount injected, 0.01 gram.—*Nouv. Remèdes*, February 8.

Test for Peptone in the Urine.—As trichloroacetic acid precipitates the albuminoids, a concentrated solution of trichloroacetic acid added to an aqueous solution dissolves the albuminoids, while the peptone remains on the filter undisturbed. The addition of copper sulphate to the peptone residuum then produces the typical biuret reaction.—*St. Petersb. Med. Woch.*, No. 4, 1897.

Value of Somatose as an Anti-Emetic.—Lutaud calls attention to the peculiar and powerful anti-emetic action of somatose, with which he has promptly controlled a number of cases of rebellious vomiting in pregnancy, and prevented vomiting after chloroform narcosis. He adds that there is apt to be diarrhea when more than four teaspoonfuls a day are taken.—*Jour. de Méd. de Paris*, April 18.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the Association living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, MAY 29, 1897.

THE OCCASIONAL EXCITANT ACTION OF THE
BROMIDS.

The occasional untoward effects of the bromids, especially in certain epileptics, which were the subject of editorial comment in the JOURNAL last year at the instance of a paper read by Dr. S. WEIR MITCHELL, were again brought up before the Association of American Physicians at their recent session at Washington. Dr. H. A. HARE read a paper giving the results of inquiries made by him, in which he stated that these effects were well known to asylum physicians generally and that there already existed a considerable literature upon the subject. In the discussion doubt was apparently thrown upon the statements he had gathered from asylum physicians, which were held to have an insufficient basis; the bromid merely diverted the attack, it was hinted, but did not cause it, and presumably the idea was intended to be conveyed that its connection with the violence it was said to induce did not really exist.

It is not an important matter whether the bromids act by suppressing the ordinary outlet of the irritability in the fits or by some special excitant action of their own in particular cases, or whether the effects apparently due to the drug are caused by individual idiosyncrasy or not; the real question is, are they the result of its administration? As to this there seems little doubt, though the fact has been ignored or overlooked by some very prominent neurologists. This is the

more remarkable when it is known that these effects were mentioned in one of the earliest elaborate studies of the action of the drug, that of VOISIN, who reported several pronounced cases of bromid mania. It was later noticed expressly or incidentally by ECHEVERRIA, HAMMOND, STARK, and others, and in a discussion in the American Neurological Association, in 1881, Dr. J. S. JEWELL suggested the possibility that a certain proportion of the epileptics in asylums probably owed their commitment to attacks due chiefly or entirely to the administration of bromids, and Dr. SPITZKA expressed the opinion that 25 per cent. of them were thus liable. There seems to be very little doubt as to the accuracy and thoroughness of the earlier observations, and the very general recognition of the phenomenon by asylum physicians is corroborative. It appears to be a clinical fact that has been recognized by alienists in this country, while it has been overlooked both in observation and in the medical literature by some very prominent specialists.

Most of these instances of the evil effects of the bromids have been observed in cases where the potassium salt was employed, but whether there is any essential difference between them as was suggested in the discussion of Dr. HARE's paper is a yet unsettled question. There is some reason for the belief that it is the drug and not the suppression of the epileptic attacks which it induces, thus cutting off the natural outlet of the nervous irritability, which is responsible, at least in some cases. There is also evidence and a general probability that with moderate doses these effects are rare with any of the bromid salts; and that their lack of observation of late years may be due to the excessive bromid medication formerly employed. There is still, however, room for caution in regard to the administration of these very valuable agents, which when given in excess or injudiciously employed are by no means altogether harmless drugs. It is well that such a high therapeutic authority as is Dr. HARE, has taken up this subject and given his findings to the profession.

PROFESSIONAL INCOMES.

The average annual income of a metropolitan lawyer has been quoted as being \$800, but the *New York Herald* of May 16, makes that of the "Gotham" physician to be \$1,630. One who possibly may have inspired the interview stated in the article that his practice brought him \$10,000 each month, while another with a much clearer conscience said he was happy when he received \$100 in the same time. For prudential reasons both these unnamed brothers under the aegis of "the Code" teach us nothing of their money-making methods, and thereby incur none of the risks of that "competition" just now so much talked of by politico-economists. With the accord of modesty to the poorer exemplar let us think of an

income of \$120,000 a year with the long line of office patients jostling over each other at \$10 per somersault, and then be deaf to the coarse imprecations of the baffled tax-gatherer who ever flits through the "borough of Manhattan."

Verily we can not believe that our sister city, whom we always sincerely respect, can spare enough from the throngs about her well-appointed charities to support a medical prodigy who has so opened his books to a voluntary receiver. We confess to the view usually entertained by the biographers of rich physicians that more is due to "judicious investments" than to adroit advertising. Moral: Let us avoid the shoals of commercialism and enjoy the peace of the country practitioner who can steal a day or two for the philosophies of life beyond ear-shot of the "dull and sickening thud" of statistics such as these. Meanwhile let us not forget that our brother with so fashionable a practice may be posing before a glass for a grander rôle in the near future. He may prove to be a Paracelsus with much trimmed abilities.

THE MEDICAL TEMPERANCE ASSOCIATION.

This Association of medical men, whose special purpose is the study of alcohol and its effects on the body, hold their annual meeting in Philadelphia at the same time as the AMERICAN MEDICAL ASSOCIATION. Organized six years ago with Dr. N. S. DAVIS of Chicago, as president, and composed entirely of members of the AMERICAN MEDICAL ASSOCIATION, they hold an annual meeting for the election of officers at the same time and place. For several years they have read papers on the alcoholic question in the different Sections of the MEDICAL ASSOCIATION. For three years the Section on State Medicine has welcomed them. Some of the members have read papers in the Sections on Practice, Neurology, and Surgery, and the impression and interest created has been excellent. No moral or ethical side is discussed, and the topics are purely scientific and medical. This Association has grown to nearly a hundred and fifty members, all of whom are interested in the study of alcohol as a medicine and food, and who are trying to ascertain the facts as they appear to each one personally and in their separate fields of practice.

An English association, called the British Medical Temperance Society, has been organized for over twenty years, with the same purpose and plan, and composed entirely of members of the British Medical Association. They have an annual breakfast, and discuss alcohol at the table freely and frankly. Leading medical men attend these breakfast occasions, and speak for or against alcohol as a medicine with great freedom. This Society now numbers over five hundred members, and is considered an important annex to every meeting of the British Medical Association. The American society has not been able to rouse up

so much personal interest in the profession, and yet by its numerous papers every year, the subject has been kept quietly before the profession. Many physicians not members of this Association seem anxious to hear all the papers read, and some very interesting discussions have followed the reading of these papers.

The committee of fifty organized in New York a few years ago for the investigation of the alcoholic question, has followed some of the same lines marked out by this Association, and with much boasting reached the same conclusions. The impression has been created that they were doing the only real scientific work in this country. Most of these papers read in the Sections of the ASSOCIATION have appeared in the JOURNAL and have passed unobserved, except by those interested.

The sneers of some wise persons who thought this subject settled beyond further question, at this Association "as a set of cranks" unworthy of notice, have not been heard lately. In reality the medical side of the drink problem is as urgent and important a topic in medicine as any other. We shall never be able to understand it until the entire profession takes it up seriously, and studies it as this Association is doing, by short papers on the clinical aspects of alcohol in every-day observation.

The annual meeting will be held in the hall of the Section on State Medicine on Thursday, June 3. Dr. CROTHERS, of Hartford, Conn., is the secretary.

SYSTEMATIC COLD BATHING IN THE TREATMENT OF TYPHOID FEVER.

In his oration delivered on the occasion of the recent unveiling at Washington of the monument of the late Prof. SAMUEL D. GROSS, Dr. W. W. KEEN, in contrasting the numerous statues erected to the memory of statesmen and warriors with the few erected to honor the memory and the services of medical men, opportunely pointed out that "peace hath her victories no less renowned than those of war." In exemplification of this fact we need but refer to the conquest of smallpox through vaccination and to that of diphtheria by the antitoxin. There died recently in the seclusion of his home in Germany a modest provincial practitioner of medicine to whom the world owes a debt of gratitude of which it appears scarcely to be cognizant. For more than thirty years ERNST BRAND of Stettin labored zealously and unselfishly in deed and in word for the systematic employment of cold bathing in the treatment of typhoid fever and he was fortunate enough to live sufficiently long to enjoy the reward of seeing the principles he advocated and the methods he recommended adopted throughout the whole civilized world, with the result of saving from five to ten lives in every hundred submitted to the therapeutic measure that bears his name.

One may search in vain through the pages of history for the names of greater benefactors of their race than those of JENNER, of BEHRING and of BRAND. The time has happily passed when the prophylactic value of vaccination, the utility of the cold-bath treatment of typhoid fever and the therapeutic efficacy of the antitoxin of diphtheria could be made subjects of discussion. Each of these agencies has been established upon a foundation so strong as to be secure from attack by fanaticism and ignorance. The results obtained in the German and French armies from systematic cold bathing in the treatment of typhoid fever and the favorable statistics reported by HARE from Australia, as well as by numerous clinicians in various parts of the world, have done much to surround with confidence a measure that often seems cruel, sometimes unnecessary and occasionally harmful. In the United States BARUCH in especial deserves commendation for his persevering and consistent advocacy of the cold-bath treatment, while WILSON and OSLER have shown its value in hospital practice and SIHLER its practicability in private.

Among the largest individual statistics contributed to the now very considerable literature upon the hydrotherapy of typhoid fever are those of HARE of Australia, who now publishes (*Medical Record*, May 8, 1897, p. 656) the figures from the Brisbane Hospital for a period of fifteen years, during the first five of which so-called expectant treatment was employed in the treatment of cases of typhoid fever and during the remaining ten systematic cold bathing according to the method of BRAND. These statistics show that from 1882 to 1886, prior to the employment of cold bathing, there were among 1,828 cases of typhoid fever 271 deaths, a mortality of 14.8 per cent. The highest mortality in any year of this period was 17 per cent., the lowest 13.3 per cent. From 1887 to 1896 cold bathing was employed systematically and there were treated 1,902 cases, with 143 deaths, a mortality of 7.5 per cent. The highest mortality of any year of this period was 11.6 per cent., the lowest 1.3 per cent. The mortality was thus just halved. Omitting the cases treated during the first six months of this period, when the method was but imperfectly carried out, there were 1,731 cases extending over a period of nine and a half years, with 122 deaths, a mortality of scarcely more than 7 per cent. Dividing these cases into three equal groups of 577 each, the mortality was respectively 7.5 per cent., 6.9 per cent., and 6.9 per cent. Among the whole 1,902 cases 56 deaths were due to intestinal perforation, 2.9 per cent.; 23 were due to intestinal hemorrhage, 1.2 per cent.; and 64 were due to other causes, 3.1 per cent. As compared with the statistics of previous years these figures show no noteworthy change in the proportion of deaths due to intestinal hemorrhage and perforation, while the reduction in the mortality in consequence of bathing

is due to a diminution in the number of cases fatal from causes other than perforation and hemorrhage.

Under expectant treatment the mortality had been higher among females than among males, while under the cold-bath treatment this relation was reversed. The foregoing statistics include all cases of typhoid fever admitted to the hospital during the period specified; independently of the gravity of the case and of the plan of treatment pursued, and thus they exhibit the results secured in the most unfavorable light possible. The facts here briefly narrated surely require no elaboration. They are eloquent in their suggestiveness, and none will gainsay the justice of the claim that the man who devises the means of saving an additional seven of a hundred threatened lives is deserving of the gratitude of his fellow-men during life and of having his memory perpetuated in tablet of bronze or carving of stone equally with the greatest military commander, the most distinguished inventor or the most intrepid discoverer.

QUININ A HARMFUL REMEDY IN MALARIAL HEMATURIA.

Considering the very frequent occurrence of that alarming complication of malarial infection, malarial hematuria, in certain parts of the United States and its study in these regions as carried out by capable practicing physicians (and also in Greece where this symptom is also commonly met with), it is a remarkable fact that the writers of text-books and "Systems of Medicine" are able to give us so little information concerning the disease from a pathologic standpoint and that they persist in recommending the use of quinin for its relief. A lack of knowledge of the pathologic process underlying this condition is perhaps the excuse for this distinctly erroneous and harmful therapeutic statement. Doubtless in the majority of instances the author of a text-book, or article in a "System," simply quotes the mistake made by a previous writer and so perpetuates the error. Of the recent writers who commend the use of quinin in malarial fever may be named LOOMIS, who states that quinin is indicated in all forms of paroxysmal hematuria or hemoglobinuria; and TYSON, who believes that if quinin does not stop a hematuria that the hematuria is not malarial but due to other causes; and we find in the last edition of FLINT'S "Practice," edited by HENRY, the use of quinin is urged in this affection. In the editorial additions of F. C. SHATTUCK to STRUEMPPELL'S "Practice" the statement is made that the hemorrhagic form of malarial fever "demands cinchonism." Finally in THAYER'S admirable article on malarial fever in the "American System of Practical Medicine," edited by LOOMIS and THOMPSON, this author, while recognizing the fact that some persons have protested against the use of quinin in malarial hematuria, lends his influ-

ence to its use by saying that this adverse view, "is not held by the majority of observers." If he had said writers instead of observers, his statement would be correct, but the majority of *observers* are arraigned against this use of quinin. A review of the journals which represent the views of southern practitioners will reveal the fact that the most of them assert the harmfulness of quinin in such cases and of those who condemn this plan of treatment may be mentioned MEEKS, who writes in the *Therapeutic Gazette* for May. In this article, written by a physician of large personal experience with this affection, the injurious effects of quinin are emphasized. His conclusions are supported in this country by a collective investigation carried out by HARE in 1892 and published in the same Journal for July of that year. Thus out of 155 replies sent out to discover the views of physicians residing within the area shown by the United States Census to have a mortality of over seventy per cent. HARE found 19 experienced physicians who regarded quinin as useful in malarial fever and 28 who considered it harmful, while 12 experienced physicians believed it to cure malarial hematuria 27 asserted that this drug was capable of producing this symptom. PLEHN in the *Deutsche Medicinische Wochenschrift*, 1895, Numbers 25, 26 and 27, asserts that quinin will produce hematuria in many cases of malarial fever and that cases of malarial hematuria treated without quinin recover more rapidly than those who receive this drug. These statements are strongly supported by earlier writers than those just quoted, particularly in Greece where malarial hematuria is remarkably commonly met with. Thus KARAMITSAS of Athens has recorded seven cases of this character, the patients consisting of one female and six men. These cases he had under his personal observation and he records others reported to him. Two of his patients were medical men and he was able to produce hematuria in them again and again by the use of quinin. It is a notable fact that these patients did not have hematuria in the malarial attack if quinin was withheld. RIZOPOULOO asserts that the use of quinin in some cases will give rise to all the signs of a bilious hematuric malarial fever. TOMMASELLI has recorded similar cases. PAMPOUKIS and CHOMATIANOS also record cases of hemoglobinuria in persons both non-malarial and malarial and caused by quinin.

The following cases reported by KARAMITSAS also show that hematuria may be produced in an attack otherwise non-hematuric by quinin.

The patient, after irregular meals, arose October 14 with much anxiety, a headache and slight lumbago, but without fever. Two hours after noon some fever came on, with slight chills. The temperature rose toward evening to 38 degrees C., the pulse to 100; the tongue was a little dry, and covered with a white coating; there was thirst, heaviness of the cardia,

headache, especially in the frontal region. They gave him soda lemonade. About two hours after midnight the fever diminished, the temperature became 37.5 degrees, but the other symptoms remained in the same condition. In the morning (October 15), as the patient had no evacuation for two days, he was given a decoction of tamarinds with manna, which was followed by evacuations. The temperature toward noon was 37 degrees; except for extreme lassitude, the patient felt no other discomfort. Three hours after noon came a fever without chills, more severe than the day before. The temperature rose little by little to 39.5 degrees. Insomnia and fever existed during the entire night. About three hours after midnight the temperature descended to 38 degrees; then the patient began to take quinin; he took, up to seven o'clock in the morning, 20 grains, 5 grains an hour; an hour after the first dose, he felt much weakness, heaviness, with pains in the lumbar regions, and a desire to urinate. He passed shortly after copious urine of a red-black color. Let us observe that during the paroxysm and before having taken the quinin, there was ordinary febrile urine.

The weakness became still greater, also the painful heaviness in the lumbar regions. Two hours after having taken the lost dose of quinin, he had again bloody urine. For twenty-four hours his urine always presented a red color, but little by little it became lighter and less bloody, and the morning of October 17 had a normal color. The patient felt no indisposition save weakness. He was very pale, and his conjunctiva was during two days of a yellowish color, which disappeared little by little.

Aside from the fact that nearly all Greek writers of today believe the malarial poisoning renders the patient peculiarly susceptible to the hematuric influence of quinin, additional evidence can be adduced showing that quinin is harmful in the great majority of cases of malarial hematuria. In the first place the drug is never given except in very full doses in this affection and these doses are capable of irritating the kidneys, which, in many cases of acute malarial infection, are acutely inflamed, and in chronic malarial disease are generally seriously impaired in their functions. In this connection reference may be made to the valuable research of ATKINSON of Baltimore and the researches made by the Tri-State Medical Society of Alabama, Tennessee and Mississippi, which found nephritis in all cases of fatal malarial hematuria.

RALFE states that renal changes undoubtedly occur, although in some instances these may be due to cold and damp rather than the malarial poison, and ATKINSON has shown that malarial nephritis is tubal and diffuse, and that the inflammation is most marked in the neighborhood of the glomeruli. KIENER and KELSCH also describe a hemoglobinuric hyperemia as occurring during an acute attack of ague in which the

organs are intensely congested. The cortex is cloudy from blood-coloration, the glomeruli are prominent and red, and the pyramids redder still. Finally, in this connection we may cite the facts stated by THAYER as follows:

The grave damage which the kidneys may suffer in certain acute malarial infections, either from the direct action of some toxin produced by the hematozoa or from the presence in the circulation of injurious substances, due indirectly to the action of the parasite, is most strikingly brought to one's notice in the intense acute nephritis which may follow malarial hemoglobinuria. The kidney, however, rarely escapes a certain amount of damage in any severe malarial infection. Thus, out of 284 cases analyzed by HEWETSON and the author, albumin was found in nearly one-half, while severe acute nephritis was present in 4 instances. The nephritis following malarial fever is usually a mild acute, diffuse process similar to that observed in any infectious disease. In some instances, as stated in the section on malarial hematuria, the course may be rapid and fatal; in the majority, however, the prognosis is favorable and complete recovery occurs. It is not impossible that, in some instances, a fatal chronic diffuse nephritis may owe its origin to the malarial poison; however, definite proof of this is as yet wanting. There is nothing absolutely characteristic, clinically or pathologically, in these instances of malarial nephritis.

GUYOCHIN (*Action Physiol. et Thérap. de la Quinine*, Paris, 1872) has reported cases of genito-urinary irritation after the use of quinin, and FAGINOTI reports a case in which there was pain in the urinary passages, and the discharge of a few drops of blood on urination. MONNERET has seen positive hematuria follow its use, and RIVET (*L'Union Médical*, Nov. 1, 1884) has observed vesical spasm and hematuria after an ordinary dose of the drug. DASSET (*Bulletin de Thérapeutique*, xv, 248) reports the development of hematuria with retention of urine from cystic irritation due to quinin; and CACHERE (*New Orleans Journ. of Medicine*, October, 1869) records two cases in which hematuria followed the use of quinin. One of these, a boy of 13, had profuse hematuria after the dose of 10 grains, and a girl of 7 years was affected similarly whenever quinin was used. STILLE states that quinin irritates the urinary organs and if any part of this tract is diseased, the disease is aggravated.

An argument which may be well adduced in support of the use of quinin in malarial hematuria is the fact that this drug is undoubtedly a specific for the cure of ordinary malarial infection by reason of its destructive effect on the plasmodium. While at first sight this reasoning is cogent, in reality it is not so, for the hematuria is the result of a pathologic process produced by the infection and arises either from the sudden setting free of large amounts of hemoglobin in

the blood or because of degenerative vascular changes in the kidneys. To give quinin therefore to relieve an attack of malarial hematuria is to "lock the door after the horse is stolen" and its use will give the engorged and over-worked kidneys only the additional labor of eliminating the drug. If quinin is used at all in such cases it should be used as a prophylactic against future attacks and be given after the hematuria has passed by.

To denounce the use of quinin and offer no other plan of treatment is not the intention of this editorial. The use of copious draughts of pure water to flush the kidneys, hot applications to the loins, chloroform spirit given internally and the use of purgatives to unload the bowels and relieve the liver are indicated. Further, it was proved by the collective investigation of HARE, already referred to, that hyposulphite of sodium is to be regarded as a most useful remedy in the dose of 20 to 40 grains every four hours. A calomel purge is universally recognized as useful and tincture of the chlorid of iron seems to be of value if clinical reports can be relied upon.

PRESIDENT MCKINLEY WILL ATTEND.

We are advised by Dr. HOBART A. HARE, Chairman of the Committee of Arrangements, that President MCKINLEY has formally accepted the invitation to visit the meeting of the ASSOCIATION and will be present Wednesday morning. To prevent crush all members must show registration cards at the door for admission.

THE JOURNAL SPECIAL TRAIN.

Medical gentlemen from Illinois and vicinity, the Pacific Coast and the Northwest, who intend to be present at the great jubilee meeting of the ASSOCIATION, are invited to take the JOURNAL SPECIAL, which will go by the Pennsylvania Railway without change from Chicago to Philadelphia. The time limit of ten days is as long as granted by any other route. See advertisement in another column, and make no mistake. The JOURNAL guarantees the most perfect of modern railway equipment.

CORRESPONDENCE.

Food for Diabetics.

NEW YORK, May 18, 1897.

To the Editor:—The articles of Dr. Edward L. Munson in the current numbers deserve attention. It would be better for the profession if the serious chronic diseases were more fully noted and published. I can not fully agree with the Doctor in his deductions, and must put the evidence that has been presented to me against his, and with the evidence which is to come, we will all finally get at the truth.

In an experience more or less closely connected with seven cases of diabetes, I have seen a mortality of about 50 per cent. The treatment has been the use of the best of beef, broiled in the form of steaks, or with the white fibrous connective tissues

removed (which glue connective tissues ferment), and the lean muscle pulp broiled over a good live bed of coals, so that the resultant cake of meat would be of a dark brown color on the outside, and when opened reddish but not raw in color. This served on a hot water plate, properly seasoned with pepper, salt and butter as desired; and if in making the lean muscle pulp, it is not touched directly by the hands, and the cake of meat before broiling is made an inch and a half deep, and not too tightly pressed together, and care taken in broiling to turn often, this resultant cake of meat will be very palatable, and the patient bear the same for a long time. If the beef animal has been over-driven before death, or has been poorly fed, the beef is not good, and will be livery and gelatinous, and ferment in the alimentary tract.

If a patient can eat starches and sugars without their fermenting and adding to the sugar, I allow them to have such, but my plan of treatment has been to stop the fermentation of any kind of food in the alimentary tract, because such fermentation produces carbonic acid and other paralyzing gases, and these gases act directly on the liver, and help to increase the production of sugar. Again, American morphologists have shown for over thirty years that starches and sugars promote alcoholic and acetic acid fermentation in the stomach and bowels. These facts have been confirmed by German chemists. Victor Hugo, in 1862, in his great work "Les Misérables," called attention to the kinship of consumption and diabetes, and to the rôle that sugar and sweets play in acid fermentations, and as a cause of these two diseases. In 1888 I was in Kentucky attending the annual meeting of the State Medical Association. Some of the Louisville doctors were criticising another because he had made a diagnosis of consumption in a case of diabetes, as he had found the tubercle bacilli in the expectoration. I questioned my father, Dr. Ephraim Cutter, afterward about the matter, and he said the diagnosis was correct, as the two diseases may coëxist. It has been my experience to see the sugar increased and the patients made worse by their "spreeing" on sugars and sweets. The hardest thing I have had to contend with has been the adverse circumstances surrounding the patients as to their money matters, and the worry incident to such has helped to cause death. As to prognosis: a young woman in 1888 with not a large percentage of sugar, is living today. I do not know what her condition is, but she is living, and I judge in fair health.

In 1885, as a student, I saw a case in my father's office of a man with enlarged heart, diabetes and Bright's disease; the triad of stigma of albumin, casts and fatty epithelia being present in the urine. This man I again saw in 1890, when he consulted me, my father being in Europe, for a nervous condition he was then in. There was no evidence of Bright's disease or diabetes. A case of a young man in our care three years ago, whose specimens ran up to 1060 and were heavily loaded with sugar, who also had occasionally present the stigmata of Bright's disease, and whose liver dulness extended up the back and side over twice normal dimensions, was tremendously improved by living closely on beef with but little vegetable food. He was greatly hampered in his money matters, could not earn any money, had a wife and young child, and he would occasionally go a-spreeing as to his food, and go into jellies, sweets and fruits, with the result that he would be appallingly sick and nearly die. This case, however, died after two years in Denver of diphtheria. I do not care to go into other details as to patients now, but I must call attention very specifically to one point. It has been considered by the profession for years that beef causes uric acid conditions which lead to coma and death. Now, I feed beef in chronic cases because it has all the chemic elements necessary to nourish the body, and if good beef is rightly prepared, it digests easiest, and can be borne longer as a single article of food than any other element I know of. I do not believe in keeping any patient down to

one article of food unless absolutely necessary, but nine-tenths of my work is the handling of chronic cases of diseases, and with some of them I examine specimens of urine from 100 to 200 times in a year. I never have yet seen uric acid, coma and convulsions caused by beef, and I have seen specimens of urine which would deposit full of nitrate of urea on the addition of nitric acid. If my experience in this line was limited to one or two cases, and but a short time, my opinion would be worthless.

Finally, I hope that Dr. Munson and others will give us more of the evidence which they have in the handling of this most serious complaint.

Yours sincerely,

JOHN A. CUTTER, M.D.

Association of Acting Assistant Surgeons U. S. Army.

In reply to a letter concerning the status of this organization, we have the following letter from Dr. Parker:

GROVELAND, MASS, May 12, 1897.

To the Editor:—Replying to your letter, in which you state, as Dr. Shradly and others have done, that "a society which has no time of meeting can not be said to have any pronounced standing," I would state that our Association is fast going to pieces. Acting assistant surgeons no longer exist in the army. The new generation of army medical officers do not know of them except by hearsay. The brave deeds of the acting assistant surgeons have nearly been forgotten. There is no one brave enough and unselfish enough to plead for them. The AMERICAN MEDICAL ASSOCIATION has heard their cry, but has never helped them. Each year our notices have many which are returned with the simple word, *dead*. Our members have toiled hard and faithfully and spent their money generously, but no one in Congress will aid them, so one by one they lose interest and drop out. Of the eighty members remaining only a few can be found in Washington, still less in Philadelphia and New York. To come together would be a tremendous expense, as they are scattered from the Atlantic to the Pacific, from Dakota to Mexico (one member in Mexico). We meet at the call of our president, but can not obtain a quorum, and yet at these late days it is a pleasure to have some form of organization and to continue an effort for right and justice. The acting assistant surgeons have never been appreciated as they deserve to have been. They did magnificent service in the war. Hamilton, Flint, Agnew, Hunt, Morton, Shradly and many others served as such. Since the war almost all the dangerous field service in Indian campaigns was most willingly and faithfully performed by them. Deeds of heroism like that of Dr. Porter on the Custer battle field have been recorded. Will you not allow us the pleasure of legitimate organization, even if we can not meet *every* year? Will you not say a kind word for us and encourage a meeting worthy of the good men and true? I know you would hate to refuse. Hoping to hear favorably, I am, dear doctor,

Sincerely yours, WM. THORNTON PARKER, M.D.

Are Coal-tar Derivatives Incompatible with Mercury?

HOT SPRINGS, ARK., May 15, 1897.

To the Editor:—I am interested in the above query. Some years ago, soon after the introduction of the coal-tar derivatives as antipyretics, I yielded on several occasions to the inclination to prescribe what would seem a reasonable dose of calomel, soda and acetanilid, and in every instance noticed on the part of the patient an alarming distress. The toxic symptoms in each case being a marked gripping of the bowels and an elevation of temperature followed by an alarming asthenic condition. I gave up the idea of combining calomel and acetanilid, until recently I was again tempted to use it in the case of a child 3 years old suffering with a gastro-intestinal dis-

order. Convulsions returned more severe with intense pain in bowels, increased tympanites and tenderness, the child dying from exhaustion. I do not think the dose killed the child, for it was almost in a dying condition when I was called to see it; but I am certain that the fateful combination caused a return of symptoms with increased severity. J. C. MINOR, M.D.

Seborrhea and Alopecia.

MILLEDGEVILLE, IND., May 1, 1897.

To the Editor:—I see in the JOURNAL that it has been announced from the Pasteur Institute that M. Sabouraud has established the fact of the identity of the microbe in seborrhea and alopecia. I was very much disappointed by not finding the remedy. Could you tell me in the JOURNAL something that will destroy the microbe and stop the disease? Respectfully yours,
J. S. SHIELDS, M.D.

ANSWER—Sabouraud now supplements his discovery of the identity of seborrhea and alopecia (JOURNAL, April 24, page 801), with the results of his research into the causes and mechanism of ordinary baldness, which he summarizes as follows: 1. The specific microorganism of fatty seborrhea introduced into the hair follicles produces there four constant results, sebaceous hypersecretion, sebaceous hypertrophy, progressive papillary atrophy and the death of the hair. These phenomena resulting from the seborrheic infection occur both on the glabrous and hair-covered portions of the body. 2. The vertex is the chosen seat of the infection on the scalp, and chronic fatty seborrhea is therefore the cause of the loss of the hair, which constitutes ordinary baldness. This follicular seborrheic infection is not only indispensable to the evolution of baldness, and baldness does not develop without it, but the same seborrheic infection continues intense, pure and permanent until the baldness is completely and definitely established. 3. Ordinary baldness is therefore a specific microbial affection with distinct characteristics. He adds that these statements are the results of three years' pain-taking research, which he describes more fully in the *Ann. de Derm. et de Syph.*, March, 1897. The therapeutic indications in alopecia and baldness are, therefore, the remedies which have been found effective in seborrhea, especially sulphur.

Acromegaly.

ONEIDA, N. Y., May 24, 1897.

To the Editor:—In your issue of May 22, page 986, Dr. Osborne reports a case which in nearly every particular was like one I had nineteen years ago this month. A man aged 69 years had the disease upward of twenty-five years, and had been able to do light farm work, and had received but very little medical treatment during the whole period. I was first called to see him April 9, 1878, when I found him suffering from general edema, more marked in lower extremities, difficult breathing, irregular action of heart, etc.

In the condition I found him it was difficult to diagnose the case, myxedema from acromegaly. The usual remedies in such cases had but little effect, only palliative, and he died on May 5, being confined to his bed only about one month. Owing to the absence of friends, I did not get a postmortem examination till about eighty hours after death. I found hypertrophy of nearly all the bones throughout the body. Thyroid gland was very large, and the heart weighed three pounds and three ounces.
H. W. CARPENTER, M.D.

The Portable Sterilizer.

DENVER, COLO., May 17, 1897.

To the Editor:—I am pleased to waive any claim of priority for developing or presenting the principle of the "Compact Portable Sterilizer" illustrated in your issue of May 1, and regret that unfamiliarity with the publications of Dr. Carl

Beck in regard to his sterilizer made it necessary for me to work this instrument out for myself, and that I should appear to claim that to which I am not entitled.

I shall feel that my labor has not been wasted, however, for it has resulted in giving me a most satisfactory instrument, one I believe to be in a number of essential details a great improvement upon that described by Dr. Beck; the lamp, stand and absence of wire screens and baskets being among them. Its extreme simplicity is one of its best features.

HORACE G. WETHERILL, M.D.

Excessive Doses of Opium.

SAC CITY, IOWA, May 24, 1897.

To the Editor:—I am collecting material for a paper on excessive doses of opium in children, either administered as medicines or taken accidentally. Any readers of the JOURNAL who may have seen such cases in their practice, or met them in any other way, will confer a great favor by sending me an outline of the case with prominent points. In all such cases proper acknowledgment will be made and due credit given.

Yours very truly,
CALEB BROWN, M.D.

ASSOCIATION NEWS.

The Philadelphia Meeting.

PHILADELPHIA, May 24, 1897.

To the Editor:—The arrangements are thoroughly completed for the reception and accommodation of those of the profession who expect to attend the semi-centennial meeting to be held in Philadelphia June 1. The Committee of Arrangements has every reason to believe that visitors will be satisfied with the meeting places which have been prepared for them and we are ready to entertain as many of the profession as may honor us by their presence. I append to this letter the latest information in regard to the Section dinners. It is earnestly hoped that all those who belong to Sections, or who intend to belong to Sections, will write to the gentlemen whose names are attached to each notice of a Section dinner, engaging a plate. It will also interest those of the profession who intend bringing their families with them, to learn that an exceedingly active and competent committee of ladies has undertaken to see that all visiting ladies are thoroughly entertained during the hours that the members of the ASSOCIATION are busy in the general meetings or in the discussion of scientific subjects.

Everything promises a most enjoyable meeting and the only thing that the Philadelphia Committee requires now to make the meeting in every way a success is the large attendance which we have been hoping for since it was decided that Philadelphia was to be the meeting place for 1897.

In the name of the committee I desire to earnestly urge all readers of the JOURNAL to make special effort to attend this meeting, which I am sure will be a memorable one in the annals of the ASSOCIATION, largely because of the unusually good scientific program which will be presented in the various Sections.

Yours very truly,
H. A. HARE, M.D.

SECTION DINNERS.

Section on the Practice of Medicine.—Dinner at the Aldine Hotel, Chestnut above 19th Street, at 7 P.M. \$3 per plate. Notify Dr. J. H. Musser, 1917 Chestnut Street, Philadelphia.

Section on Surgery and Anatomy.—Dinner at the Bellevue Hotel, Broad and Walnut Streets, at 7 P.M. \$3 per plate. Notify Dr. Orville Horwitz, 1115 Walnut Street.

Section on Obstetrics and Diseases of Women.—Dinner at Hotel Walton, Broad and Locust Streets, at 7 P.M. \$3 per plate. Notify Dr. Milo B. Ward, Hotel Walton.

Section on Ophthalmology.—Dinner at Hotel Walton, at 7 P.M. \$3 per plate. Notify Dr. G. E. De Schweinitz, 1401 Locust Street, Philadelphia.

Section on Diseases of Children.—Dinner at the Bourse, 5th Street between Market and Chestnut Streets, at 7 P.M. \$2

per plate. Notify Dr. Alfred Hand, Jr., 211 S. 17th Street, Philadelphia.

Section on Laryngology and Otology.—Dinner at the Stenton, Broad and Spruce Streets, at 7 P.M. Notify Dr. E. L. Vansant, 1909 Chestnut Street, Philadelphia.

Section on Materia Medica and Pharmacy.—Dinner at Willow Grove Park. Take care at Broad and Locust Streets, after the session on Tuesday. Notify Dr. Frank Woodbury, 218 S. 16th Street, Philadelphia.

Section on Neurology and Medical Jurisprudence.—Dinner at the Aldine Hotel at 7 P.M. \$3 per plate. Notify Dr. Chas. K. Mills, 1909 Chestnut Street, Philadelphia.

Section on Dermatology and Syphilography.—Dinner at Hotel Walton at 7 (?) P.M. \$3 per plate. Notify Dr. M. B. Hartzell, 3634 Chestnut Street, Philadelphia.

Section on State Medicine.—Dinner at the Aldine Hotel at 7 P.M. Notify Dr. Elmer Lee, 103 State Street, Chicago, Ill.

Section on Dental and Oral Surgery.—Dinner at the Aldine Hotel at 7 P.M. Notify Dr. E. Talbot, Columbus Memorial Building, Chicago, Ill.

Dinner of the American Medical Editors' Association will be held at the Aldine Hotel, 19th and Chestnut Streets, at 7:30 P.M. \$5 per plate. Apply to Dr. Judson Daland, 319 S. 18th Street, Philadelphia.

There is but One Official Program.

NEW YORK CITY, May 21, 1897.

To the Editor:—Replying to yours of the 19th inst., we were approached by a plausible gentleman pretending to represent the AMERICAN MEDICAL ASSOCIATION bearing with him documents apparently proving that he was authorized to take advertisement for the official souvenir program, and upon his assurance as a man of honor that this was the official program we placed contract for one-half page space. Now that we are advised that the official program published by the ASSOCIATION will be issued by you, and will contain no advertisements, we shall refuse to pay for the space contracted for and shall also refuse to consider all propositions hereafter emanating from any source for space in any official program. This is the third time we have been bitten, and the last. Such proceedings on the part of unauthorized individuals do more harm to the AMERICAN MEDICAL ASSOCIATION than its officials probably estimate. Very truly yours, SHARP & DOHME.

President McKinley.—It is officially announced that the President of the United States will be present at the Wednesday morning session of the ASSOCIATION.

Department of Public Health.—There will be a meeting of the Special Committee on "The Department of Public Health," at the Hotel Walton, Philadelphia, at 8 o'clock, P.M., Monday May 31, 1897. U. O. B. WINGATE, M.D. Chairman of Committee.

Executive or Business Committee.—The first meeting of this Committee will be held in Parlor C, Hotel Walton, cor. Broad and Locust Streets, Philadelphia, on Monday May 31, 1897, at 5:30 p.m. Subsequent meetings will be held at the same place and hour, unless otherwise ordered by the committee, for the consideration of matters referred to it by the ASSOCIATION, and for the transaction of business.

L. DUNCAN BULKLEY, M.D.,
Secretary of Committee.

SOCIETY NEWS.

Ohio State Medical Society.—The fifty-second annual meeting was held in Cleveland and in many features was decidedly successful. The total membership is nearly 900 and about one-third were in attendance. The society took action on the proposed amendment to the State medical laws which provides for the establishment of boards of examiners independent of college faculties. It met with considerable opposition especially from Cincinnati college representatives and at one session the resolution was tabled. But the sentiment of the decided majority could not be thus silenced and on reconsideration the

opposition was overwhelmed by the strong arraignment of the college authorities and the manifest endorsement of the provisions of the amendment. Three hundred and twenty-five participated in the annual banquet of Thursday evening. Dr. Dan Millikin, the prince of post-prandial orators, presided and it was demonstrated that this form of entertainment can be made a most potent factor in cultivating the fraternal spirit, in the noblest profession, and securing recuperative relaxation.

It was demonstrated that the Ohio society has outgrown the one section method of presenting papers. Out of an average attendance of 250 there are about 100 who are interested in all kinds of papers. The remaining 150 drift in and out according to what papers are under discussion and thus add to the confusion. Profitable discussions can not be had unless there is close attention. Aimless and useless discussions are tolerated in our State societies to the extent of driving the best men from attendance. The brightest thoughts of the keenest minds can be aroused under the influence of convention enthusiasm as in no other manner, and it becomes the duty of the officials to so arrange surroundings that these scintillations of brilliant intellects will be received, appreciated and recorded.

Dr. W. H. Humiston of Cleveland was elected president; Dr. T. Clarke Miller, Massillon; Dr. Geo. Mitchell, Mansfield; Dr. D. H. Brinkerhoff, Fremont; Dr. E. H. Hyatt were elected vice-presidents; Dr. Jno. A. Thompson of Cincinnati, secretary; Dr. H. M. W. Moore, Columbus, asst.-secretary and Dr. James A. Duncan, treasurer. The society is to meet in Columbus in 1898.

Washington State Medical Society.—The eighth annual meeting of the Washington State Medical Society was held at Spokane, Wash., Tuesday and Wednesday, May 11-12, 1897. The following officers were elected for the ensuing year: President, J. B. Eagleson, Seattle; first vice-president, J. J. McKone, Tacoma; second vice-president, D. G. Russell, Spokane; secretary, F. H. Coe, Seattle; treasurer, J. W. Bean, Ellensburg. Seattle was chosen as the place for holding the next meeting.

Montana State Medical Society.—At the annual meeting of this society, held at Helena, the following officers were elected, viz: Dr. G. T. McCulloch of Missoula, president; Dr. B. F. Sandon of Neihart, first vice-president; Dr. C. M. Chambliss of Bozeman, second vice-president; Dr. B. C. Brooke, secretary; Dr. W. M. Bullard, corresponding secretary. The meeting next May will be held in Missoula.

PUBLIC HEALTH.

Secretary of Illinois State Board of Health.—A meeting of the new Illinois State Board of Health was held at Springfield May 24. Dr. J. A. Egan of Chicago was elected secretary, vice Dr. John W. Scott of Springfield, term expired. Dr. Julius Kohl of Belleville was elected treasurer. The board adjourned to meet the last Tuesday in June. It will be recalled that Dr. F. W. Reilly was some time since offered reappointment as secretary, but declined in order to retain the assistant health commissionership in Chicago. Dr. Egan has a splendid army record and gained his appointment in the Chicago Health Department by competitive examination. He is a young man of more than average ability, and is well equipped for his new position.

Hawthorne's Experience in India.—Julian Hawthorne, who was sent to India to describe the scenes of the famine and of the bubonic plague, returned to New York on the steamship *St. Paul* May 22. "The only other correspondent I met in India," he said, "was one from the Reuter News Agency. I spent only thirty days in India, a fortnight in Bombay and a fortnight in the famine district among the native villages. Millions of Hindus and Bengalese died from starvation, and the govern-

ment figures represent one-sixth of the actual deaths from the plague."

The Virginia State Board of Health.—The term of office of the State Board of Health appointed in 1893 expired in March. Their successors appointed the following as members of the State Board of Health for the next four years: Drs. Rawley W. Martin, Lynchburg; Vernon G. Culpepper, Portsmouth; Hugh M. Taylor, Richmond; Landon B. Edwards, Richmond; Paulus A. Irving, Richmond; Lewis E. Harvie, Danville, and J. H. Neff, Harrisonburg. The latter two are new members of the board, succeeding Drs. Robert J. Preston of Marion and Paul R. Carringer of the University of Virginia, who retire. The *State Bulletin* says: "While we welcome most cordially the newly appointed members, Drs. Harvie and Neff, yet we part most regretfully from our old friends, Drs. Preston and Barringer, both of whom are prominent and distinguished in their special work in the profession, and have been useful, suggestive members of the board."

There were in London during 1896, 135,797 births, 83,511 deaths and 79,738 marriages.

Influenza and diphtheria are reported on the increase in London.

NECROLOGY.

CHARLES R. NELDEN, M.D., Bellevue Hospital Medical College, 1864, died May 2 in Stanhope, N. J., aged 55 years. During the war he was a medical cadet, U. S. A., from 1862 to 1864, after which he served a while as an acting assistant and surgeon. He conducted a pharmacy in connection with his practice for twenty-five years and was well known in Sussex County. The cause of his death is given as locomotor ataxia.

CORNELIUS OLCOTT, M.D., died May 2. Born in Jersey City, N. J., Jan. 21, 1828, he was of English descent. In 1849, soon after his graduation from the New York University Medical Department, he took up his life residence in Brooklyn, N. Y., and at once strongly identified himself with its sanitary interests. With the exception of his service as a volunteer surgeon at Fortress Monroe and during the Fredericksburg campaign, he devoted himself to private practice, but without resigning his position on the surgical staff of the Eastern District Hospital. He was also President of the Greenwood Lake Association. He leaves a widow and a son, Dr. Charles A. Olcott.

ROBERT ROSKOTEN, M.D., of Peoria, Ill., died May 8, aged 81 years. He served in the armies of Germany, France, Portugal and the United States; was a profound scholar, speaking several languages fluently. His medical education was acquired at the universities of Halle and Jena. Becoming involved in the revolution of 1848, he was forced to flee and came to the United States. At the breaking out of the Civil War he was one of President Lincoln's first appointees on the board for examination of army surgeons, afterward going to the front and attaining rank of brigade surgeon. Injuries received at Shiloh compelled him to leave the service.

N. P. PEARSON, M.D., an old resident of Chicago, died at his home May 6, aged 72 years. He received his medical education in his native country, Denmark, coming to Chicago in the 50's. For a number of years he was Danish consul in that city and stood high in the estimation of the people.

TRAILL GREEN, M.D., Easton, Pa., died April 29, aged 84 years. Dr. Green was a graduate of the University of Pennsylvania and afterward professor of chemistry in Lafayette College. In 1841 he accepted the chair of natural sciences in Marshall College, and for half a century was a member of the American Association for the Advancement of Science, and became the first President of the American Academy of Medicine, as well as being a prominent member of many other scientific bodies.

C. E. CRANE, M.D., Green Bay, Wis., died May 8, aged 71 years. He was surgeon in the army during the rebellion, afterward President of the Brown County Medical Society, and from 1874 to 1879 mayor of Green Bay.

JOHN CRESSWELL, M.D., who died lately at his home in New Bethlehem, Clarion County, Pa., was a graduate of the Cleveland Medical College, 1857. By his death this community has lost an upright citizen and the medical profession a devoted member. That the evidence of our affection for him may live when we too have gone, we recommend that the following be recorded in our minutes:

WHEREAS, Death has removed from us Dr. John Cresswell, an old and faithful member of our society,

Resolved, Dr. Cresswell by his exemplary life, both as a physician and as a citizen, was endeared to us all; always honorable in his intercourse with his confrères and always kind and sympathetic to the sick and afflicted.

Resolved, We regret his death and mourn with those who are dear to him, but submit in sorrow to his last call.

Resolved, That a copy of these resolutions be sent to the family of the deceased, a copy to the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, and a copy to each of the papers in Clarion.

W. M. CLOVER, M.D.,

I. J. WIREBACH, M.D.,

R. S. WALLACE, M.D.,

Committee.

CHAS. L. BLAKESLEE, M.D., of South Windsor, Conn., died May 2, aged 34 years.—E. C. Bright, M.D., Mt. Sterling, Ky., died at his home May 4.—Geo. W. Burdett, M.D., a graduate of the Dartmouth and Harvard medical schools, at Worcester, Mass., May 10, aged 76 years.—J. J. Ikirt, M.D., East Liverpool, Ohio, May 18, aged 70 years.—Henry Wilson, M.D., Oberlin, Ohio, April 24, aged 56 years.—Robert L. Hartman, M.D., Independence, Pa., April 24, aged 66 years.—Franklin Wayne Entrikin, M.D., Findlay, Ohio, May 13, aged 67 years.—Hugh F. McNairy, M.D., superintendent of the Lakeland Asylum, Frankfort, Ky., May 12.—Joseph R. McLean, M.D., Scranton, Pa., May 5.—Benjamin Eddy Cotting, M.D., for fifty-five years curator of the Lowell Institute, Boston, died May 22, aged 75 years. Dr. Cotting was consulting surgeon to the Boston City Hospital, a fellow of the American Academy of Arts and Sciences, and held diplomas of membership in medical societies in Rome and Athens.—Noah Torrey, M.D., South Braintree, Mass., May 9.—Joseph W. Cushing, M.D., Boston, May 9, aged 60 years.—Frank J. Gould, for twenty-three years clerk of Rush Medical College, Chicago, May 21, aged 53 years.—Alexander J. Mullen, M.D., Michigan City, Ind., May 4, aged 40 years.

MISCELLANY.

Dentistry a very Ancient Profession.—A floating clipping has reached us that Dr. Geist-Jacobi of Frankfort, Germany, has written a history of dentistry from 3700 B. C. to the present time. According to this it is known that there were men practicing the profession of dentistry in Egypt at least 5,000 years ago.

Would Lister Approve?—The Hungarian government permits women to study medicine if they so desire, but one of the professors of the University of Budapest has recently proclaimed that he has something to say in the matter. Of the five women now studying medicine there, one has a remarkably fine head of hair, which the professor of surgery says must come off before she can be permitted to attend his clinics. The reason that he gives for his prohibition is that "wool carries infection."—*Medical Review*.

Precocious Parturition.—Dr. Floyd Young reports the following unusual case from Chilhowie, Virginia. A young white girl, aged 10 years and 2 months, daughter of respectable parents, gave birth to a fully matured child weighing three pounds. The parents seemed to know nothing of the condi-

tion of the little woman, and on the night of her confinement they thought she was suffering with colic, hence sent for no physician, and knew no better until they heard the cry of the child. The girl was well developed in every respect, having menstruated regularly since she was 2 years old. The baby was not allowed to nurse and only lived a few weeks.—*Bulletin of the Virginia Health Board.*

Suicides in Times of Financial Depression.—It is stated as a fact that in 1890 the number of suicides was 2,040, in 1891 3,531, in 1892 3,860, in 1893 4,436, in 1894 4,912, in 1895 5,759, and in 1896 6,420, and these all occurred in the United States. What relation has this to the general business depression, and the consequent inability to provide for the family, if any, and is the same increase shown during other times of financial depression? The records of insurance companies ought to be particularly interesting as to these statistics. Among those who have considered the subject the incontestable policy is blamed very largely for the enormous increase in self-destruction.—*Medical Examiner*, April.

Liability of Physician Making Examination for Third Party.—Where a physician undertakes to examine a person, and to report whether he is diseased, the supreme judicial court of Massachusetts holds, in *Harriott v. Plimpton*, Oct. 21, 1896, that he is bound to have the ordinary skill and learning of a physician, and to exercise ordinary diligence and care. If he fails, and the person examined is injured because of his want of such skill and learning or his want of such care, he is answerable in damages. The fact that the purpose of such examination is information and not medical treatment is, in the opinion of the court, immaterial. But the breaking of a marriage engagement of the person examined, in consequence of a wrong diagnosis, the court considers too remote a damage to sustain an action. Whether the physician has used ordinary care, learning and diligence is, upon the evidence, for the jury to determine. When the physician's subsequent conversations with third parties on the subject of the examined person's condition are had under circumstances which justify him in communicating the information, the court further holds that the absence of express malice is a defense to an action for slander.

Alcoholic Fermentation Produced by the Fluids of the Living Cells.—By crushing yeast cells and compressing the crushed cells with a pressure of 400 to 500 atmospheres, E. Buchner has obtained a clear, yellow fluid containing over 10 per cent. of solid particles, largely albumin. After filtration, which eliminates every vestige of the living cells, the fluid displays the extremely important property of producing alcoholic fermentation, namely, converting glucose into alcohol and carbonic anhydrid. "These results are the complete refutation of the hitherto accepted ideas that fermentation is only associated with the presence of the living cells, and opens new paths for biologic and bacteriologic investigations, by which pathology and possibly also therapeutics may benefit." Buchner claims priority over Koch in this mechanical crushing process, which is the basis of Koch's new tuberculin. His description of the process was published last January. He also states that he offered to patent it for the firm now manufacturing the tuberculin, who refused after long deliberation.

Doctor's Bills as Expenses.—In actions for personal injuries, in order to recover for medical attendance and similar items, the supreme court of Nebraska says, in *Golder v. Lund*, March 3, 1897, that it is necessary for the plaintiff to show two facts: First, what expense he actually incurred; and, secondly, that it was reasonably incurred. It is not the reasonable charge for medical services which he may recover, but the expense to him of such services, not to exceed their reasonable value. But in order to recover in such an action for expenses of medical treatment, the court further holds, it is not necessary to prove

by the record that the physician rendering the services was licensed to practice under the statute. Proof that he practiced as a physician raises the presumption in actions between third parties that he was licensed to do so.

A Contemptible Misrepresentation.—The New York *Medical Record* of May 22, 1897, contains the following:

Dr. John B. Hamilton, formerly of the Marine Hospital Service under Surgeon-General Wyman, has gone to the Illinois Northern Hospital for the Insane at Elgin, to assume the duties of superintendent. We understand that, while abandoning his extensive surgical practice in Chicago, he will still be retained as editor of the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*.

Dr. Hamilton was formerly the head of the Marine Hospital Service and from 1879 to 1891 Dr. Wyman served under him. From 1891 to 1896 he was a surgeon in the Marine Hospital Service stationed at Buena Park, near Chicago. Elgin is just beyond the border of Cook County, only a short run by rail. Dr. Hamilton does not abandon anything. It is pleasant to know from the *Record* that he will be retained as editor when the Trustees meet again, and it is to be hoped that Messrs. Wm. Wood & Co. will retain Dr. Geo. F. Shradly for at least another year. It has lately been suspected that some lineal descendent of Ananias, with an exaggeration of the family traits, was temporarily occupying Dr. Shradly's stool.

The Illinois Health University Ousted.—The supreme court of Illinois affirmed, April 3, 1897, the judgment of ouster in the quo warranto proceedings, brought on the relation of the attorney-general, against the Illinois Health University. The latter was incorporated, under the laws of Illinois, April 16, 1895, "for the education of teachers in the science of health and the true art of healing; and fitting men and women for the rights and duties of citizenship, and of conferring upon such teachers, when duly qualified, such diplomas, such degrees or certificates of qualification, as may seem proper and just to the officers and faculty of the institution." The supreme court, speaking through Mr. Justice Carter, says that there was sufficient alleged in the information filed by the attorney-general to show that the "University" had assumed and usurped powers, privileges, and franchises not conferred by its charter; that it had not in good faith carried out the object for which it was incorporated, but was engaged in the fraudulent business of selling medical diplomas to, and conferring the degree of doctor of medicine upon incompetent persons, for gain; that it did not conduct a medical school, college, or university, and that its pretended business of educating teachers in the science of health and in the true art of healing, and of fitting men and women for the rights and duties of citizenship, and of conferring upon such teachers, when duly qualified, such diplomas, such degrees or certificates of qualification, as might seem proper and just, etc., was a mere pretense. It is not consistent with the public policy of a State which enacts stringent laws for the preservation of the public health, and for the protection of its people from quacks and ignorant pretenders to a knowledge of the science of medicine and surgery, continues the court, to authorize or permit a pretended health university to turn any one, whether known or unknown, qualified or unqualified, into a doctor of medicine, armed with a diploma and degree as one qualified to heal the sick, who may answer its prescribed list of questions and pay its prescribed fee. The charter of a corporation is the full measure of its power, and, if any doubt arises out of the language employed in such charter, such doubt must be resolved in favor of the State. By demurring to, instead of answering and denying the charges in the information, the court adds that it stood admitted that there was a wilful misuse and abuse of the powers conferred on this corporation, and a prostitution and perversion of its corporate powers to objects and purposes for which no certificate of incorporation could be properly issued, and which would be against the policy of our laws. It was a clear abuse of the liberal privileges conferred by our incorporation laws for the Illinois Health University to make use of them for the purposes set forth in the information. And for such abuse and misuse, the supreme court holds, its charter might and should be revoked.

New York.

THE CRAIG COLONY OF EPILEPTICS.—Governor Black of New York State has signed the bill appropriating \$126,600 for the Craig colony of epileptics. The State Board of Charities, who have been clothed with ample powers, believe that the colony will be in time self-supporting since it is largely an agricultural institution, with nearly 1,800 acres to its credit. The claim is that the above-named appropriation will benefit some six hundred dependents now waiting for the improvements.

THE NEW BELLEVUE FACULTY.—The professorial staff of the recently combined University and Bellevue Colleges of New York city has been formed by choice from some of the old timber from both schools and by the importation of some from the outside. Of the latter, Prof. J. G. Adami from the McGill College of Montreal is to occupy the important chair of pathology; he was formerly an instructor at Cambridge University, England. Dr. Austin Flint takes the subject of physiology. Dr. E. G. Janeway will give clinical instruction; Dr. LeFevre will serve as secretary. The other members of the faculty, so far as has been announced, are Dr. H. M. Biggs, public medicine and infectious diseases; Dr. J. D. Bryant, applied anatomy and clinical surgery; Dr. I. S. Haynes, practical anatomy; Dr. H. P. Loomis, materia medica and therapeutics; Dr. W. T. Lusk, obstetrics; Dr. W. M. Polk, gynecology; Dr. A. A. Smith, medicine; Dr. L. A. Stimson, surgery; Dr. W. G. Thompson, medicine; Dr. R. A. Witthaus, chemistry, physics and toxicology, and Dr. G. Woolsey, anatomy. Emeritus professors—Drs. R. O. Doremus, A. E. McDonald, C. I. Pardee, L. A. Sayre, W. H. Thomson and H. G. Piffard. Assistant professors—Drs. J. C. Edgar, J. F. Erdman, F. W. Gwyer, E. LeFevre, J. A. Mandel, G. T. Stewart and I. Sickles. Clinical and special professors—Drs. S. Alexander, G. Bacon, F. H. Bosworth, C. S. Bull, C. G. Coakley, E. B. Dench, F. S. Dennis, E. D. Fisher, A. Flint, Jr., J. A. Fordyce, C. F. McDonald, P. A. Morrow, W. P. Northrop, H. D. Noyes, C. E. Quimby, B. Robinson, R. H. Sayre and J. E. Winters.

Washington.

DR. RALPH GALLINGER'S PROMOTION.—Dr. Ralph E. Gallinger, son of Senator Gallinger, who spent the past year in the French Hospital in New York city and the Emergency Hospital in this city, has accepted an appointment as house officer in the Boston City Hospital, and is now at his new post of duty.

ILLEGAL PRACTITIONERS FINED.—During the past month three illegal practitioners of medicine have been fined and ordered to stop operating in the District of Columbia.

MEDICAL SOCIETY.—During the past month some very interesting work has been done in the medical society, viz.: Dr. Kober read a paper entitled "The Relations of Predisposition and Heredity to Disease;" Dr. James Kerr "Nephrectomy for Malignant Disease," case and specimen; Dr. Lamb "Hydatidiform Mole," case and specimen, Dr. D. K. Shute "Heredity with Variations;" Dr. A. A. Snyder "Esophagotomy for Removal of Foreign Body," case and specimen; "Appendicitis," case and specimen; Dr. Lamb "Spina Bifida" case and specimen; "Cerebral Hemorrhage," Dr. Bovee, specimens showing complicating tubal and ovarian suppuration; Dr. Wm. W. Johnston, "The Effect of School Life on the Health of Children." This latter was a most valuable paper showing the work which had been done in this direction in foreign countries and its neglect in this country. The paper was fully demonstrated by charts showing percentages of relations of different diseases with respect to age, sex, kind of study and varied defects.

GARFIELD HOSPITAL.—Dr. W. W. Johnston has resigned from the staff of the Garfield hospital and criticises some recent acts of the Board of Directors.

CENTRAL DISPENSARY AND EMERGENCY HOSPITAL.—Dr. Wm. P. Carr, Professor of Physiology in the Columbian Medical College, has been elected a member of the attending staff.

Colleges.

THE NEW YORK UNIVERSITY MEDICAL DEPARTMENT held its fifty-sixth annual commencement at Carnegie Hall May 2, and will reopen October 1 under the name of the New York University Bellevue Medical College. The number of graduates was 103 and they are the last of the three-year-course men. Medals and prizes were distributed and the speakers duly emphasized the importance of hard work.

At the annual commencement of the Woman's Medical College of Kansas City, April 22, three young women received diplomas.—The degrees conferred by the University of Buffalo (N. Y.) April 27, in the department of medicine, number seventy-four.—Niagara University has just graduated ten new doctors.—The New York Medical College and Hospital for Women had seven young women graduates this year.—The class of 1900, College of Physicians and Surgeons (N. Y.), recently presented Prof. C. F. Chandler with a loving cup in token of his twenty-five years' service in the college.—The graduates of Albany Medical College, at the recent commencement numbered 60; those of Jefferson Medical College 164, of the Medico-Chirurgical College, Philadelphia, 66; of the Medical College of Virginia 33, with 15 more from Georgetown University and 24 from the Columbian University, Washington, D. C.—Stephen Smith, M.D., a graduate of the College of Physicians and Surgeons (N. Y.) and professor of surgery in Bellevue Hospital, has donated 1,500 volumes to the medical library of Syracuse University.—Twenty-eight young women received diplomas from the Woman's Medical College, Philadelphia, May 19.—Among the twenty-two graduates from Howard University Medical Department May 10, were six young women.

Hospitals.

According to the twenty-fifth annual report of Roosevelt Hospital, New York city, the number of patients during 1896 was 3,118. The daily average was 140, and the number treated in the accident room, but not detained, was 5,128. A training school of nurses was established November 16 and the private patients' pavilion opened two days later. The expenses have been considerable, and an appeal is made for additional contributions. Meanwhile charter applications for the hospital and dispensary of the Pasteur Institute, as well as for St. Bartholomew's clinic, have been denied by the State Board of Charities. The reasons given for the refusal in the case of the latter are that the "vicinity is fully supplied with institutions for medical relief of the sick poor, and that the policy of the board is to discourage unnecessary increase of charities of this kind, etc." The motto adopted seems to be "Divide and conquer."

The net proceeds of the festivities in Los Angeles, Cal., attendant upon the Queen's Diamond Jubilee, are to go to the Good Samaritan Hospital of that city. It is believed that \$4,000, the amount necessary for a new wing, will thus be raised.—An addition to the Monte Vista (Colo.) Hospital, costing \$2,000, has been decided on.—The new buildings of the Plant System Hospital, Waycross, Ga., have just been opened to patients, cost \$45,000.—Between June 1 and Oct. 1, 1896, about 4,000 children were given the benefits of La Rabida Sanitarium, Jackson Park, Chicago. During the six months that this old convent was open the management paid the car fares of more than 1,500 people who otherwise would have been prevented from enjoying the benefits of La Rabida. The work will begin again June 1.—During the year ending April 1, 1897, Augustana Hospital, Chicago, cared for 938 patients; two-fifths of these without cost.—The new annex to Michael Reese Hospital, Chicago, cost \$13,000, was recently opened. It was the gift of Jacob Rosenberg.—In 1896, 2,104 patients were admitted to the Alexian Brothers' Hospital, Chicago. The new buildings 307 x 226 feet exterior, are now in process of construction.—The Victoria Diamond Jubilee Association of Chicago, invites contributions toward the endowment of hospital beds in Chicago, in celebration of the sixtieth anniversary of Queen Victoria's reign.—An addition to the gynecologic department of the Johns Hopkins Hospital, costing \$10,000, is under construction.—Elizabeth T. L. Warren, late of Brookline, Mass., has bequeathed property to the value of

\$65,000, for the establishment of free beds in the Massachusetts General Hospital.—The building fund of the Eastern Maine General Hospital has been increased to \$20,000 by a gift of \$200 from Mrs. T. N. Egery of Bangor. This puts the hospital in the way of receiving larger sums which were conditionally promised.—Charles H. Senff, Whitestone, L. I., has donated \$10,000 to the Flushing (L. I.) Hospital.—St. Joseph's (N. Y. City) treated 1,331 indoor patients in 1896, and 2,956 outdoor cases.—The Kelly donation to St. Vincent's (N. Y. City) is \$50,000.—The Mount Sinai Hospital (N. Y.) reports 3,106 patients admitted in the year 1896, while the dispensary treated 33,694.—St. Margaret's Hospital, Pittsburg, is almost under roof. Mr. J. H. Shoenberger bequeathed \$250,000 for the building alone, his entire bequest for hospital purposes being \$800,000.—Mrs. Felix R. Brunot, Pittsburg, has notified the board of foreign missions of the Protestant Episcopal church, that she will build and endow, in any part of China which they may select, a hospital for lepers. She prefers Shanghai.—The old Pennsylvania Hospital (Phila.) was founded by members of the Society of Friends, and was the first general hospital in the country to open its clinics to women medical students.—The Baltimore Hebrew Hospital and Asylum Association receive \$200 by the will of the late Solomon Katzenberger.—After June 1, the Stormont Hospital, Topeka (Kan.) will cease to be a hospital for women, and admit general cases.

Societies.

COLORADO STATE MEDICAL SOCIETY.—The twenty-seventh annual convention of the Colorado State Medical Society will be held in Denver June 15, 16 and 17. Thirty-two names are on the program and a large attendance is expected.—The one hundred and sixth anniversary meeting of the New Hampshire Medical Society was held May 24 and 25 at Concord.—The annual meeting of the Berkshire district medical society was held in Pittsfield, Mass., April 29. The following officers were elected: President, Henry Colt, Pittsfield; vice-president, M. M. Brown, North Adams; secretary, L. C. Swift, Pittsfield. The society has a membership of forty.—The Middlesex county medical society held its one hundred and fifth annual meeting at Haddam, Conn, April 23.—The New Mexico Medical Association convened at Albuquerque May 12.—The fifty-third annual meeting of the American Medico-Psychological Association was held in Baltimore May 11 to 14.—The Iowa State Medical Society held its forty-sixth annual session at Marshalltown May 19 to 21.—The regular quarterly meeting of the Illinois and Iowa Medical Society took place at Rock Island April 22.—The Kansas Medical Society closed its annual meeting at Topeka May 14.—The Detroit Medical and Library Association recently adopted resolutions urging the passage of the Michigan Medical League Bill.—Detroit will be the next place of meeting of the Michigan State Medical Society, which met May 13 and 14 at Grand Rapids.—The physicians of Piatt County (Ill.) have recently organized a Piatt County Medical Society.—The semi-annual convention of the Minnesota Valley Medical Association convened at Mankato May 11.—The Central District Medical Society of Missouri met at Sedalia May 6 and the Southwest Missouri District Medical Society at Springfield May 13.—The following recent conventions in New York are noted: Cattaraugus County Medical Society, at Salamanca, May 11; Madison County, at Oneida, May 11; Onondaga County, at Syracuse, May 11; Orange County, at Goshen, May 4; Orleans County, at Albion, May 12; Oswego County, at Oswego, May 11; Westchester County, at White Plains, May 7; Utica Medical Library Association, Utica, May 12.—The one hundred and sixth anniversary of the New Hampshire Medical Society was celebrated at Concord May 24 and 25.—The Ohio State Medical Society closed its annual convention at Cleveland May 21.—The seventh annual session of National Association of Military Surgeons convened at Columbus, Ohio, May 25.—The Logan County Medical Society met May 14 at Bellefontaine, Ohio; the Union Medical Association, at Salem, May 6; the Guernsey Co. Medical Society at Cambridge, May 11.—The annual session of the Pennsylvania Medical Society convened at Pittsburg May 18.—The sixty-fourth annual meeting of the Tennessee Medical Society was held May 11, at Nashville.—Cameron, Texas, entertained the Brazos Valley Medical Association May 12.—The Franklin County Medical Society met at St. Albans (Vt.) May 11.—The fifty-first annual convention of the Wisconsin State Medical Society closed, at Racine, May 7.—The Southwestern Kentucky Medical Association held its semi-annual session at Paducah May 10.

THE PUBLIC SERVICE.

Army Changes. Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from May 15 to 21, 1897.

Capt. Edward C. Carter, Asst. Surgeon, leave of absence granted is extended two months.
Major George W. Adair, Surgeon U. S. A. (Washington Bks., D. C.), is granted leave of absence for one month.
Capt. Charles E. Woodruff, Asst. Surgeon, is relieved from duty at Ft. Sheridan, Ill., to take effect June 1, 1897, and ordered to Ft. Custer, Mont., for duty.
First Lieut. Powell C. Fauntleroy, Asst. Surgeon, is relieved from duty at Ft. Niobrara, Neb., to take effect upon the arrival at that post of Capt. Philip G. Wales, Asst. Surgeon, and ordered to Ft. Robinson, Neb., for duty.
First Lieut. Charles Lynch, Asst. Surgeon, is relieved from duty at Ft. Robinson, Neb., to take effect upon the arrival at that post of Lieut. Fauntleroy, and ordered to Ft. Sheridan, Ill.
Lieut.-Col. William E. Waters, Deputy Surgeon-General, will be relieved from duty at Columbus Bks., Ohio, on July 15, 1897, and will then proceed to his home, where, at his own request and for his own convenience, he is authorized to await retirement.

PROMOTIONS.

To be Asst. Surgeons with rank of Captain after five years' service: First Lieut. Champe C. McCulloch, Jr., Asst. Surgeon, May 5, 1897; First Lieut. Frederick P. Reynolds, Asst. Surgeon, May 5, 1897; First Lieut. Isaac P. Ware, Asst. Surgeon, May 5, 1897; First Lieut. Robert S. Woodson, Asst. Surgeon, May 5, 1897; First Lieut. Madison M. Brewer, Asst. Surgeon, May 5, 1897; First Lieut. George D. De Shon, Asst. Surgeon, May 5, 1897.

CHANGE OF ADDRESS.

Angear, J. J. M., from 482 W. Lake St. to 143 S. Western Av., Chicago.
Bell, S. D., from Pinehurst, N. C., to Butler, Pa.
Berry, Wm. F., from Nellisville, Wis., to LaFayette, Ind.
Blair, P. B., from Chicago, Ill., to 274 E. 5th St., Winona, Minn.
Bower, C. L., from 26 S. 18th to 1837 Vine St., Philadelphia, Pa.
Chandler, F. C., from 1817 to 1236 Noble Av., Chicago, Ill.
Cleveland Medical Gazette from 837 Superior St. to 812 Prospect St., Cleveland, Ohio.

The Journal of the American Medical Association

VOL. XXVIII.

CHICAGO, ILL., JUNE 5, 1897.

No. 23,

ADDRESSES.

THE AMERICAN MEDICAL ASSOCIATION; ITS PAST, PRESENT AND FUTURE.

President's Address, delivered at the Semi-centennial Anniversary Meeting of the American Medical Association, at Philadelphia, Pa., June 1, 1897.

BY N. SENN, M.D., Ph.D., LL.D.
CHICAGO, ILL.

The AMERICAN MEDICAL ASSOCIATION was born at the dawn of a great era in the history of medicine. Only a few years before its organization was effected anesthesia, which has robbed the operating room of its greatest terrors, came into general use and at once opened up new fields of usefulness for the surgeon. The new science of bacteriology, upon which is based our modern views regarding the etiology and prevention of disease, has been founded and firmly established since that time. The principles which govern the present treatment of wounds conceived by the immortal Lister and developed to the existing state of perfection by a host of his enthusiastic followers, have revolutionized the practice of surgery during the last quarter of a century. Normal and pathologic microscopic anatomy are recent acquisitions to our knowledge of living tissues in health and disease. Aseptic midwifery is the direct descendent of aseptic surgery and has secured for the lying-in-woman the same protection against puerperal complications, as the employment of aseptic precautions will prevent largely the occurrence of suppuration, sepsis and pyemia in the treatment of the injured and patients requiring operative treatment. Anesthesia and asepsis have created visceral surgery. Our knowledge of chemistry and physiology has been vastly increased during the last fifty years by thousands of earnest and devoted students in possession of improved instruments and apparatuses for accurate investigations. During the same time great strides have been made in the practice of medicine and the preparation and methods of administration of drugs. In the light of many of these recent advancements we have at least learned that disease is influenced for the better by aiding and assisting, rather than by combatting and opposing nature's resources. Translumination of the body by the wonderful Roentgen ray is the last and most important addition to our diagnostic resources in medicine and surgery. In these stirring events which have startled the medical world in such rapid succession during the last half of this century many members of our ASSOCIATION, dead and living, have taken a prominent and often leading part. In looking about for an appropriate subject for my address at this meeting I have deemed it expedient to utilize my time and this unusual opportunity in discussing as briefly as possible "The AMERICAN MEDICAL ASSOCIATION, its Past, Present and Future."

This is a day of rejoicing to the medical profession

of the United States. We celebrate today the semi-centennial, the golden jubilee of the AMERICAN MEDICAL ASSOCIATION. You have come here from all parts of the Union to do honor to this festive occasion. It is appropriate that you should have selected Philadelphia as the place of meeting at this time; it was here that the organization of our ASSOCIATION was completed half a century ago. Philadelphia is near and dear to every American citizen, as it is the birthplace of the greatest and most prosperous nation in the world. It is here that on July 4, 1776, the most precious document in the possession of the American people—the Declaration of Independence—was signed, read and approved by the representatives of a people who craved for freedom, liberty and independence. It was here that the sweet music of the liberty bell was first heard, the reverberations of which reached from the Atlantic to the Pacific, and from the Great Lakes to the Gulf of Mexico, and which has continued and will continue to echo and reëcho over our vast and free country for all time to come. It is a source of congratulation to every and all honest and progressive practitioners of medicine that that document, which was the means of planting a free government upon the virgin American soil and creating a new nation, was signed and heroically defended by America's greatest physician—Benjamin Rush. The blood struggle for independence by a united patriotic people and its great success culminated in the foundation of the great Republic of the United States which in time gave the medical men an opportunity to establish American medicine upon a free American soil. It required a long time after the permanency of our government was assured for our professional ancestors to appreciate this opportunity and to take the necessary steps to secure adequate facilities for our young men to obtain a satisfactory medical education in this country and to create a medical literature of their own. Foreign text-books were used and European universities continued to be the Mecca for American students who sought a higher medical education. The country was new, its resources limited, its inhabitants represented different customs and nationalities, and the number of qualified practitioners limited. It is, therefore, not surprising that the organization of the profession, the establishment of institutions of learning and the foundation of an American medical literature met with many difficulties which it required years to correct and remove. Philadelphia has a special charm for every practitioner of medicine who has the interest and welfare of his profession at heart, as it has been, and still remains, the center of medical education and medical literature in this country, besides being the birthplace of the AMERICAN MEDICAL ASSOCIATION.

The members of the medical profession of this city, with Benjamin Rush at its head as a noble and inspiring example, have always been loyal to the

cause of a united profession, advanced medical education and the foundation of an independent American medical literature of the highest merit. In coming here today from the most remote parts of the United States in such vast numbers you are performing a duty you owe to the city so memorable in the history of our country and its medical men, who have taken such a conspicuous and active part in the development of American medicine and surgery. We are assembled here today to commemorate the work of a group of earnest men, patriotic American citizens, who took such an active part in uniting the medical profession of this country by bringing into existence and active operation the AMERICAN MEDICAL ASSOCIATION. Most of those who were helpful in laying the corner-stone of this great national institution have gone to their reward; few are left to tell the tale of the early struggles, frequent disappointments and final triumph. Of those who have been permitted to live long enough to witness the celebration of the semi-centennial, four names are familiar to you all, Nathan S. Davis of Chicago, Alfred Stillé of Philadelphia, J. B. Johnson, St. Louis, D. F. Atwater, Massachusetts. Davis, the father of the ASSOCIATION; Stillé, its efficient and faithful Secretary for many years. These two names have illuminated the firmament of American medicine for half a century, and they will continue to shine brighter and brighter as the ASSOCIATION increases in influence and membership. Honor to these men. A monument of marble or bronze; resolutions of thanks printed upon white satin and framed in precious metal would be but a feeble expression of the gratitude we owe them for their work so unselfishly rendered in founding and maintaining this ASSOCIATION. Their greatest satisfaction must remain in having been instrumental in launching the ship, steering it through many a storm with resolute determination and firm hands safely into the semi-centennial harbor, clearing it and handing it over in splendid condition for another generation to manage. While our hearts are full of gratitude toward the few surviving founders of the ASSOCIATION, we must not forget the labors of the many who have joined the silent majority. Hundreds of former members of the ASSOCIATION have performed important duties, written scientific papers, and by their work and example have distinguished themselves sufficiently to have their names written upon a tablet to be placed in the Memorial Hall of the future permanent home of the ASSOCIATION.

History.—Time does not permit to give a full history of the ASSOCIATION from its foundation to the present semi-centennial year, but I regard it as a duty to the ASSOCIATION to give a brief account of the motives that animated its founders and to call your attention to a few of its early members whose worth stands out in bold relief in its early history.

The founders of the AMERICAN MEDICAL ASSOCIATION were deeply impressed with the dignity and responsibility of our profession. They had for their object to secure by united action a higher standard of medical education, a more general diffusion of medical knowledge and the creation of a respectable medical literature. The motives which incited them to action are well shown in the utterances of two of the early Presidents. At the Baltimore meeting in 1848 Dr. Chapman, the President, alluded to the necessity of the members of the profession to work in harmony and unity to secure a more uniform and higher stan-

dard of medical education and to preserve the dignity of the profession as follows: "From slumbers too long indulged, the profession has at last awoken, and shaking the poppies from its brows, is recalled to a sense of what is due to itself and the obligations it owes to preserve its heritage, to be transmitted to posterity unsullied and without detriment or loss. Excited by this generous impulse it comes forward in the majesty of its might to vindicate its rights and redress its wrongs. To no other tribunal does it deign to appeal for these purposes. No mean petition of grievances, or supplicatory memorial for relief, or more immediate addresses to popular feeling to engage its favor shall sully our proceedings. We have in a spirit becoming our just pride trusted, and will, I hope, continue to trust our cause exclusively to the clear heads, the warm hearts and strong arms of the host enlisted in its service. We do not want, nor will condescend to accept any extraneous assistance. Confiding in our own resources, we shall through them maintain the struggle till conducted to victory and triumph." The implicit faith in the work of the ASSOCIATION entertained by Dr. Chapman and the results obtained have been fully realized during the past fifty years of its existence. At the same meeting the President-elect, Dr. A. H. Stevens, pointed out the power and influence of a united profession in the following beautiful and truthful language: "Our profession, gentlemen, is the link that unites science and philanthropy. It is one of the strongest ligaments that binds together the elements of society. It teaches the rich their dependence, and elevates the poor to a sense of the innate dignity of their nature. Its aim is to add to the comfort and the length of human life."

Animated by such noble sentiments the founders of the ASSOCIATION commenced and finished their task with a spirit of unselfishness and a keen sense of responsibility and devotion to their important mission. The idea of organizing a National Medical Convention originated in the New York State Medical Society and was discussed for the first time at the meeting in 1844. The main object of the promotion of this project was the elevation of the standard of medical education, and consequently the betterment and advancement of the whole profession. The needs of such a step were very apparent at that time. The wonderful increase of the population of the New Republic by immigrants from all parts of the civilized world required a rapid increase of medical men. New medical colleges sprang up in rapid succession in different parts of the country, and the rivalry between them made it impossible to effect a change for the better without strong influences brought to bear upon them from without. Young men began the study of medicine without even a common school education, and had no difficulty in obtaining a diploma upon attendance of two courses of lectures of four months each. All students attended the same lectures with limited or no hospital and clinical facilities. To the thoughtful medical men of that time it was plain that such a condition of things would soon result in lowering the practice of medicine to a trade instead of elevating it to the dignity of an art and science. Quackery in its worst forms prevailed, the services of the honest physician were undervalued and his standing in the community, compromised on all sides by his less conscientious competitors with and without diplomas. The founders of the ASSOCIATION had in view, to effect through

their combined influence a higher standard of preliminary education of those who should enter upon the study of medicine, lengthening of the college terms and better qualifications for the degree of Doctor of Medicine. All this had to be gradually accomplished without any legislative aid. Such radical changes in our system of medical education could only be attained by our persistent efforts in the course of time, but during the fifty years of the existence of the ASSOCIATION they have been wrought and perfected to an extent far beyond the most sanguine expectations of its most enthusiastic founders. The ASSOCIATION during this time has accomplished much more than what it was originally designed for. Through its influence nearly all of the medical colleges have adopted a systematic graded course of instruction combined with ample hospital, clinical and laboratory facilities. Besides all this it has brought the members of our profession in the various sections of our vast country in close touch and intimate social relationship so beautifully described by one of its distinguished and most active members, the late Dr. Bennett Dowler, who in an editorial on this subject said; "As a social and professional *reunion* of kindred spirits and great minds, its memories afford perennial delight. It has given impetus to the progress of medical polity and science; it exercises moral suasion, rather than that of authority; it has brought together a bright constellation of intellect, cemented the bonds of friendship among good men and true, and it will leave a luminary track of light in the moral firmament of the Æsculapian heavens throughout the expansion of the Republic."

History has demonstrated the necessity of associated action in advancing the interests of the arts and sciences, commerce and the learned professions. The origin and the success of the AMERICAN MEDICAL ASSOCIATION have demonstrated the full meaning and force of this statement. Individual efforts accomplish but little in the correction of long standing and widely disseminated evils. In 1835 the faculty of the Medical College of Georgia proposed the holding of a convention of delegates from all the medical colleges of the Union. This proposition met with little encouragement on part of the remaining medical schools, and the first movement which contemplated a convention of delegates, not only from all the medical colleges, but also from the regularly organized medical societies throughout the New Republic, was made in the Medical Society of the State of New York, at the annual session in February, 1839. At this meeting, upon motion of Dr. John McCall, it was decided to hold a National Convention in the city of Philadelphia in 1840. The movement did not meet with sufficient encouragement to carry out the desired object. In the meantime the cause of medical education received a new and vigorous champion in the person of young Dr. N. S. Davis. He was born in the State of New York, Jan. 9, 1817. Until 16 years of age he assisted his father in managing a farm. After receiving the limited advantages of a rural-district school training he attended for six months Cazenovia Seminary. With this scanty preliminary education he entered upon his professional studies at Fairfield, in the old College of Physicians and Surgeons of the Western District of New York and graduated with the class of 1837, being then but a few days over 20 years of age. Endowed with a logical mind and great power of discrimination he became impressed during his college life with the importance of a systematic graded course of in-

struction. His attendance upon lectures was arranged with such an object in view and he is probably the first graduate of an American Medical College who enjoyed the benefits of a graded course of instruction, which was arranged by himself and not by his Alma Mater. Ever since his graduation as a member of the American medical profession and as a teacher he has been an ardent advocate of systematic graded medical instruction, and the medical college which he later founded was the first one in this country to formulate and carry out his ideas. At the time he entered upon the practice of his profession in New York the Medical Society of that State was fostered and guided by Dr. John Stearns. Almost from the beginning of his professional career Dr. Davis became a leader among his colleagues, and a strong advocate of much needed reforms in medical education.

Between the years 1830 and 1845 the number of medical colleges in the United States nearly doubled. As there was no concerted action between the schools and the profession this rapid increase of competing schools furnished a formidable obstacle to the cause of improved medical education. Two courses of lectures from thirteen to sixteen weeks were usually required. Dr. Davis served as a delegate from Broome County in 1844, and at once entered upon his life work in agitating the necessity of concerted action to elevate the standard of preliminary and medical education. He introduced a series of resolutions to that effect and was appointed Chairman of the standing Corresponding Committee, to which the resolutions were referred. The following year the subject was again discussed *pro* and *con*, but many of the delegates from the medical schools placed themselves on record as being opposed to such radical changes as proposed by Davis and others. It was at this meeting that Alden March privately suggested to Davis that the objections which were made might be possibly overcome by calling a convention of delegates from all the colleges and thereby inducing the institutions of the several States to act in harmony. A preamble and resolutions for the formation of a National Convention were then immediately prepared and read by Davis. Few of those present and who took part in the discussion which followed were of the opinion that it would be possible to carry the movement into effect. However, a committee of three, composed of Davis, Peter Van Buren and McNaughton, was appointed. The Chairman immediately entered into active correspondence with the officers of the colleges and medical societies and received unexpected encouragement from sources least expected. The animosity manifested toward the ASSOCIATION came principally from the representatives of the medical schools, many of whom were opposed to extension of the lecture term to six months and a higher standard of preliminary education. The medical colleges which openly refused coöperation were those in New York and Boston. It was decided to hold the National Convention in the College Building of the New York University on the first Tuesday in May, 1846. Dr. L. Ticknor in the meantime suggested the advisability of organizing out of the National Convention a permanent National Medical Society. The National Convention was held at the appointed time and was attended by nearly one hundred delegates, representing sixteen different States. Dr. Jonathan Knight, professor of surgery in Yale College was elected President. After completion of the organization of the Convention Dr. Gunning S. Bedford

presented a resolution to adjourn *sine die*, asserting that the Convention did not represent a sufficient number of States. As the mover of this resolution was a member of the faculty of the medical school in which the Convention met, his open opposition came as a great surprise. The motion was lost by a vote of seventy-four to two, the latter being cast by the mover of the resolution and his colleague Pattison. A committee of nine was appointed to frame propositions for discussion and action. Of the propositions presented by the committee the first provided for the organization of a permanent National Medical Association, the next two recommendations related to preliminary and medical education, while the fourth suggested the framing of a code of medical ethics. A number of committees were appointed for the purpose of completing the organization next year and to place the ASSOCIATION at once into working order. It will be seen that the most violent opposition to the organization of the AMERICAN MEDICAL ASSOCIATION came from New York and it, therefore, does not appear strange that years later, after the ASSOCIATION was completed and had demonstrated by the work done and influence exerted, that it was in this same State that a part of the profession rose in open rebellion and seceded. The meeting in Philadelphia in 1847 was held in the Academy of Natural Science, May 5, when the organization of the AMERICAN MEDICAL ASSOCIATION was completed. It was attended by two hundred and fifty delegates, representing more than forty medical societies and twenty-eight colleges, embracing medical institutions in twenty-two States and the District of Columbia. Jonathan Knight was reelected President. Harmony characterized this meeting. The report on Medical Ethics made by Drs. Bell and Isaac Hayes was full and explicit and was unanimously adopted. In the preamble preceding the Constitution, the purposes for which the ASSOCIATION is organized are declared to be "for cultivating and advancing medical knowledge; for elevating the standard of medical education; for promoting the usefulness, honor and interests of the medical profession; for enlightening and directing public opinion in regard to duties, responsibilities and requirements of medical men; for exciting and encouraging emulation and concert of action in the profession; and for facilitating and fostering friendly intercourse between those engaged in it." The sentiments contained in the preamble show that the founders of the ASSOCIATION were infused with a spirit of enthusiasm and energy regarding the future welfare and usefulness of their profession and laid a wide and firm foundation upon which to build the temple of American Medicine. At this meeting committees were appointed representing the different departments of the healing art which were expected to report at the next meeting. The articles of the Constitution were adopted without much discussion and only a few amendments. The Convention then resolved itself into the AMERICAN MEDICAL ASSOCIATION, and the committee to nominate officers made a report which was unanimously adopted. Dr. Nathan Chapman headed the list of officers. The permanent organization of the ASSOCIATION gave a new impetus toward the formation of State medical and local societies, which soon became auxiliary to the National ASSOCIATION and excited a spirit of scientific investigation throughout the Union. The membership increased very rapidly. At the meeting in Baltimore the following year four

hundred and ninety-two delegates were registered, of which number two hundred and sixty-six were in attendance, representing the United States Army and Navy, twenty-four States and the District of Columbia. The annual meetings were held with regularity and with increasing attendance, until the great War of the Rebellion drew a line between the North and South, which temporarily parted the profession. The firing upon Fort Sumter brought on the greatest war the world ever witnessed, which for five long years made the earth tremble and saturated our soil with the blood of those engaged in the deadly conflict. Accounts of battles and rumors of battles filled the columns of our newspapers and furnished the all-absorbing subject of discussion in the home circles, business places, offices, the pulpits and at the seat of war. The brave men in blue and gray fought with a determination that could only be inspired by a sense of conviction of the justice of their respective cause, and born of a spirit of patriotism that has always typified the American citizen. Our profession took an active and honorable part in this terrible contest. The medical schools on both sides became almost depopulated, as many of the students shouldered the musket and hurried with the improvised armies to the bloody scene. The medical officers of both armies, composed mostly of men with a ripe experience as practitioners, but entirely ignorant of the many details required of military medical officers, ministered to the sick and wounded with an efficiency and devotion that challenged the admiration of the world. No armies ever enjoyed to a greater extent the blessings of military surgery. The services rendered by civilians so suddenly pressed into military life did much to mitigate the horrors of the many battlefields, and are remembered with gratitude by many of the surviving scarred and maimed veterans. The work done by the medical officers on both sides will always occupy an honorable position in the annals of military surgery, and in the history of our own country it will remain as a bright spot, a shining star during its most trying ordeal, when the very foundations of our Government were trembling from the desperate attacks of an honorable, well-meaning but misguided enemy.

The ASSOCIATION voted to meet in Chicago in 1865. The War of the Rebellion interrupted the meetings until 1865, when it was practically over, and after a number of adjournments, the ASSOCIATION met in Boston in May, 1865. It required repeated and continued efforts on the part of N. S. Davis to secure a meeting at this time, as the chairman of the Committee of Arrangements was strongly in favor of adjournment for another year. This meeting was attended by two hundred delegates. The only thing which savored of war and which showed the intense excitement which still prevailed and which caused a serious discord was the expulsion from the ASSOCIATION, without trial, of Dr. Montrose Pallen, an alleged sympathizer with the South and who then resided in Canada. Dr. Pallen was charged with the most unreasonable and heinous crime of introducing smallpox among the people of the North and East. In spite of earnest protests by a number of more cool-headed delegates, he was expelled without trial. Seventy of the delegates entered protest against this hasty and unwarrantable action. As the only redeeming feature in this unpleasant episode in the history of the ASSOCIATION, I find that after the close of the war Dr. Pallen

was exonerated and reinstated at the next meeting, which was held in Baltimore in 1866. After the close of the war the delegates from the South at once resumed their attendance, the most cordial relations were restored and many of the largest and best meetings have taken place in Southern cities. The attendance has increased steadily and the influence of the ASSOCIATION has been felt throughout the Union and has extended far beyond the limits intended by its founders. The ASSOCIATION is now in a healthy, vigorous condition, a precious and responsible heritage of its founders. Its membership now consists of nearly nine thousand physicians. The responsibility of its officers and members increases with every additional advantage it offers. Its influence for good will increase with every new membership. Every regular physician practicing his profession owes a duty to the ASSOCIATION, and the least he can do is to join its ranks. There is no reason why, in the course of ten years, our membership should not increase to fifty thousand. It is my duty and your duty to bring within its folds every respectable physician of our acquaintance. Increase the army of regular conscientious physicians, secure concerted action and be helpful in inciting among its rank and file a spirit of scientific investigation, and you discharge a part of the duties imposed upon you by the founders of the ASSOCIATION.

MEDICAL EDUCATION.

One of the principal subjects in view of the founders of the AMERICAN MEDICAL ASSOCIATION was to effect a much-needed reform in medical education, looking toward a higher standard of preliminary preparation, lengthening of the lecture course and a systematic graded course of instruction. These objects have been nearly attained and largely through the influence of the ASSOCIATION. Nearly all of our medical schools, large and small, now require four years' attendance, of eight months each, of a systematic graded course, and with few exceptions furnish adequate laboratory and clinical facilities. Our printed transactions from the beginning of the ASSOCIATION until the present time are loaded down with matter pertaining to medical education. This mission of the ASSOCIATION is about fulfilled. We have medical schools that are on a par with those of the older nations. There is no further excuse for our medical students to seek foreign universities to obtain a thorough medical education. Some of the very best practitioners of the United States are men who graduated in our own schools and who have never left their native soil. It requires no stretch of imagination to predict with certainty that our country will become the center of medical education within twenty-five years and our medical institutions will be sought by foreign nations, as they will in the course of that time furnish facilities for teaching far in advance of those of any other country. Our medical schools are not tampered by politics and they are undergoing a rapid evolution by acquiring unlimited financial resources and by the ceaseless activity, the wide-awake, energetic and enthusiastic practitioners who by hard work, frequent intercourse with representative medical men at home and abroad become model practical teachers. The next function of the ASSOCIATION, as far as medical education is concerned, lies in another direction—post-graduate education.

MEDICAL SOCIETIES AS POST-GRADUATE INSTITUTIONS.

We are all aware of the fact that the best medical education obtainable anywhere is but the entering wedge, the foundation for a broader practical education needed at the bedside, which occupies a lifetime and which is never completed. The diploma from any college is but an evidence that its possessor is prepared to enter with understanding upon this post-graduate study of medicine. The recent graduate has but a faint idea of the limitation of his knowledge when measured with the rigid requirements at the bedside. The successful progressive physician is, and remains, an earnest steady student. He enters at once upon a course of post-graduate instruction in an institution which he never leaves and from which he can never expect to graduate. It is and must be one of the principal functions of medical societies, National and local, to receive the young practitioner and direct and supervise his post-graduate work. The medical societies, large and small, are the legitimate and proper post-graduate medical schools. The polyclinics and post-graduate medical schools, which have recently appeared upon the field of medical institutions and which had their origin in this country, have done good work in furthering the objects and directing the ambitions of the progressive practitioners, old and young. They have fostered and favored specialism, and have as often retarded as advanced the true interests of the science and art of medicine and surgery. They never did and never will take the place of the medical societies as post-graduate institutions for the enlightenment and advancement of the great mass of practitioners. Post-graduate medical education must be systematic, graded, continuous and not spasmodic. Is it not true that many city, village and country doctors, after a few years of active practice, tired of the monotony of their work and the severe exactions placed upon the general practitioner, seek one of our post-graduate institutions, after a term of two or three months, receive their certificate printed upon the finest sheepskin, signed by forty or fifty professors, most of them themselves recent graduates and next appear upon the surface as full-fledged specialists? I am willing to accord our post-graduate medical schools a field of genuine usefulness, but they can never take the place of medical societies in imparting and supervising post-graduate instruction. Rational post-graduate work consists in the reading of the current medical literature, in mastering the contents of modern text-books and monographs, the diligent use of the microscope as a means of scientific investigation and as a diagnostic aid, in acquiring and maintaining an adequate practical knowledge in interpreting disease from a bacteriologic standpoint, and a regular attendance of the meetings of medical societies, local, State and National. Not a single day should be permitted to pass without absorbing something useful from the mass of medical literature or the study of some specimen, histologic or pathologic, under the microscope. Application and practice will soon initiate the intelligent seeker of knowledge into a systematic course of study. The fruit of such individual efforts belong to the medical profession and should be brought into the proper channel through medical societies or the medical press. Every recent graduate should affiliate himself with the local, State and National societies, and the time and money spent in attending their meetings will be well invested. He should always be an

attentive listener, and as time and opportunity present themselves, an occasional contributor. There are at present two apparent prevailing evils regarding medical societies as educational institutions; too many societies and too many papers. The multiplication of medical societies of all kinds has gone on with unwarranted speed, and the *furor scribendi* that is prevalent at the present time is unparalleled in the history of medicine. Specialists have their own societies, all of which are doing excellent work. There can not be too much said in favor of city, county and State medical societies, all of which should be in affiliation with the AMERICAN MEDICAL ASSOCIATION, which is now and always will remain the recognized representative body, the final tribunal of the American profession. The organization of district and sectional medical societies is of questionable utility, as these societies detract from the attendance and scientific work of the National associations, and the State and county medical societies. Medical societies are especially intended for scientific work. The great majority of doctors who attend the meetings, do so for the sole purpose of receiving or imparting knowledge. There are, however, men who attend these gatherings from less pure and unselfish motives; they are the political doctors, the wire-pullers who are always on their feet making and discussing motions, offering amendments to amendments, often to the great consternation of the presiding officer and the detriment of the scientific work of the society. These men appear more for the purpose of being seen and heard, to kill time rather than to promote the legitimate work of the society. Every society contains more or less of this morbid material. These men come early and place themselves on record at the very first possible opportunity; they seldom read papers or take part in the discussion of scientific subjects. Some of them have been mayors, aldermen, or if fortune smiled upon their political career, perchance, members of the State legislature. They know something about parliamentary law and are anxious that their more timid and less informed colleagues should know it. The general meetings of the ASSOCIATION have on many occasions resembled more a political caucus or a stirring debate in the Senate or House of Representatives than the calm proceedings of a scientific body. Many valuable hours have been consumed by discussing subjects that should never have appeared. Our constitution and by-laws have undergone so much mending that even those best informed would find it difficult to tell what is old and what is new. Let this part of our work be referred to appropriate committees who take the necessary time and pains to inform themselves correctly and in a calm deliberate way make the necessary recommendations to the society. Let us in the future devote our whole time to scientific work and not tempt the patience of those who come for that sole purpose by the prolonged discussion of business and executive topics that can be done much more satisfactorily in the committee room than the general sessions of the ASSOCIATION. To make medical societies a proper and useful training-school for the practitioner, young and old, the scientific work must be done in a systematic manner. The young graduate with a practical experience dating back two or three years should not feel called upon to appear in any of our sections and occupy our time by relating wonderful cases or a series of daring surgical feats. His maiden efforts belong to the local society, the smaller the better. After a training for

five years or more he is then qualified to serve the State medical society in an active capacity, preparatory to his entering the working ranks of the AMERICAN MEDICAL ASSOCIATION at the expiration of six or ten years of active practice. By taking such a course he is adopting a systematic course of post-graduate education and instruction which will slowly but surely bring success and recognition. The ephemeral reputation which occasionally rewards early literary efforts on high-sounding subjects is frequently followed by a depression from which it is difficult to recover. It is the slow growing solid oak, and not the slender poplar that reaches out early for the sky, that offers the greatest resistance to wind and storm. The young physician will do well to select subjects for his early literary work from the primary branches of the science of medicine, anatomy, physiology, histology, chemistry, pathology and bacteriology and reserve his efforts in writing on practical subjects until he has acquired sufficient experience to speak authoritatively. By pursuing such a course he will interest and instruct his older colleagues and command their respect and admiration at the very threshold of his professional career. One of the glaring faults of the medical societies of the present day as teaching institutions is the presentation of too many papers. A bulky volume of transactions is no indication of the value of the work accomplished. The papers should be few, concise and thorough, the discussions free and general. It is usually more difficult to discuss a paper intelligently than to write it. It is seldom that in a prolonged discussion the remarks remain limited to within the legitimate limits of the subject under consideration. To discuss a paper properly requires careful preparation. Off-hand statistics must be regarded with suspicion. A sense of honesty should compel participants to report their unfavorable as well as their favorable cases, and to record their mistakes as well as their successes. Embellished, painted statistics, too prevalent at this time from ambitious operators, are dangerous traps and should be scrupulously excluded from the current medical literature. Honesty in medicine, as elsewhere, is always the best policy and will be amply rewarded at the proper time. Clinical reports are valuable when properly made; harmful and misleading when based on superficial observation and written from memory instead of from an accurately kept case-book. The results of postmortem examinations should be given with the same candor as the clinical history and the reasons which lead to the diagnosis and the treatment pursued, as it often furnishes the last argument in favor of or against what was surmised or done for the patient during life.

Scientific work of the Association.—The published transactions and the volumes of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION are a mine of information for the general practitioner as well as the specialist, as they contain valuable contributions to medical literature, embracing all the departments of the healing art and the allied sciences. Many of the contributions have found a permanent place in our general literature and must be referred to by authors who write on the subjects of which they treat. It is a source of regret that many of the most important and interesting papers read during the early history of the ASSOCIATION have been buried in the volumes of the transactions. The value of these compendious volumes are as a rule underestimated by medical literary men, and are not consulted and quoted with the

frequency they deserve. No other works contain a more accurate report of the early history of anesthesia. Indigenous medical botany receives well-merited attention. Endemic and epidemic diseases which prevailed in this country at that time are discussed by the most prominent and competent medical men. Surgery is ably represented by a number of the most distinguished surgeons of that period. From the very beginning of the ASSOCIATION hygiene and sanitation were given a prominent place in the proceedings. Anatomy and physiology received more attention then than now. During the early history of the ASSOCIATION the scientific work was done by committees and the reports were read and discussed in the general sessions. The reports were comprehensive and long. W. T. Wragg made the first report of the Committee on Medical Sciences in 1848, which occupies fifty pages of the first volume of the transactions, and embraces the current medical literature of that year in a condensed clear form. The same year the Committee on Practical Medicine reported through their Chairman, Joseph M. Smith, "On the Contagions and Infectious Epidemics." The report was quite a lengthy one and deals largely with the etiology and pathology of typhoid fever. In the same volume the Committee on Surgery gives a detailed account of Brainard's work on the "Treatment of Spina Bifida and Serous Effusions by Tapping and Injections of Tincture of Iodin;" and a very interesting treatise on "Anesthetic Agents."

A special and comprehensive report on "Anesthetic Agents, Their Mode of Exhibition and Physiologic Effects," by J. R. Bigelow, contains the most authenticated account of the early history of anesthetics and some practical suggestions how they should be administered, which are the safest guides today. The members of the Committee on Obstetrics discussed the "Use of Anesthetics in Labor." Their conclusions are summed up as follows: "The committee do not think it important to express an opinion as to the comparative value of sulphuric ether and chloroform in obstetric practice. While the latter is more convenient, the former is probably more safe, owing to the fact perhaps that it is not cumulative in its operation. They are both efficient and either may be employed at the option of the accoucheur." The Committee on Medical Literature, headed by Oliver Wendell Holmes, gave short abstracts of the more important articles published in the medical journals of the United States during that year and of the works on medicine and surgery by American authors and translators. N. S. Davis writes the report of the committee on "Indigenous Medical Botany," which includes the botanical description, medical properties and uses of *Lycopus virginicus*, *Hamaelis virginica* and *Cimicifuga racemosa*. Adulteration of drugs is treated by T. O. Edwards.

In the second volume Dr. James Wynne makes the "First Report of the Committee on Public Hygiene," which covers 223 pages. In the same volume Francis C. Porcher read the "Report on the Indigenous Medical Plants of South Carolina," which occupies 250 pages and includes a description of 319 plants and their medicinal uses. It was soon found that these lengthy reports, although extremely valuable, did not meet with the requirements of the profession. Consequently, at the Charleston meeting, the standing committees were abolished upon motion of Dr. Isaac Hayes, and upon motion of Dr. G. B. Wood it was

Resolved, that a committee of seven be appointed to take into consideration the arrangement of committees for future action, and to report as soon as possible. In accordance with the action of this committee the future scientific work of the ASSOCIATION was to consist of discussions of special subjects selected for the next year. The committee also recommended the appointment of a Committee on Volunteer Communications which should be authorized to award a prize of \$50 for each of the essays approved by it, not, however, exceeding five in number in one year. The action of the committee led to the appointment of twenty-seven special committees. This arrangement proved satisfactory for a number of years, when the rapidly increasing attendance made it necessary to do the scientific work in sections representing the different departments of the healing art, adding new sections for the study of special branches as specialism asserted itself. This plan has proved eminently adapted for the needs of the general practitioner, as well as the different specialists. A vast amount of valuable material is brought to the different sections annually by many men, who, at the same time, take an active part in the proceedings of societies devoted to special work. Most of the prominent men in the profession attend our meetings annually and are always sure of bringing the fruit of their labors and product of their pen before an appreciative audience. Our section work is improving from year to year, and has done much toward creating and moulding the medical literature of this country.

Prize essays.—Literary work in this country is appreciated only by the profession, and the only prospective reward is a consciousness of a duty performed and the recognition it may receive from the profession. Government recognition, such a strong stimulus to hard work in many of the countries abroad, is out of question here. For the purpose of stimulating original research the AMERICAN MEDICAL ASSOCIATION during the first few years of its existence took the necessary steps to establish prizes for meritorious literary productions. The origin of awarding prizes for essays was by the following resolution offered by Dr. Alfred Stillé, while Chairman of the standing committee on medical literature at the annual meeting in Cincinnati in May, 1850:

"Resolved, that the sum of \$100 raised by voluntary contributions, be offered in the name of the ASSOCIATION, for the best experimental essay on a subject connected either with physiology or medical chemistry, and that a committee of seven be appointed to carry out the objects of this resolution; said committee to receive the competing memoirs until the first day of March, 1851, the author's name to be concealed from the committee and the name of the successful competitor alone to be announced after the publication of the decision."

The Treasurer's report at the next meeting showed that \$50 had been paid in through Dr. A. Stillé and \$50 through Dr. F. G. Smith; and at that meeting, Charleston, S. C., May, 1851, the first prize was awarded to Dr. John C. Dalton, his subject being "On the Corpus Luteum of Menstruation and Pregnancy." The prize in 1852 was awarded to Austin Flint, who wrote "On the Variations of Pitch in Percussion and Respiratory Sounds, and Their Applications to Physical Diagnosis." The successful competitor the following year was Washington L. Atlee, who presented a notable paper on "The Surgical Treatment of Cer-

tain Fibrous Tumors of the Uterus Heretofore Considered Beyond the Resources of Art."

In 1853 Walter J. Burnett presented a paper on "The Cell, Its Physiology, Pathology and Philosophy, as Deduced from Original Investigations, to which is added its History and Criticism," and received the coveted prize.

The following year the prize was awarded to Daniel Brainard, the most distinguished surgeon at that time of the great and distant West, for his classical paper: "An Essay on the Method of Treating Ununited Fractures and Certain Deformities of the Osseous System." Among the remaining prize essays, the one on "Resection of Joints," by Culbertson, is entitled to special mention for its thorough exposition of this subject and its statistical value.

Prizes were annually offered in the name of the ASSOCIATION until 1880, when at the annual meeting in New York, all previous regulations awarding prizes were abolished and a new system for awarding prizes through the agency of the several sections was adopted. Since that time no essays have been offered and no prizes awarded.

It will be seen from what has been said, that the prize essays of the AMERICAN MEDICAL ASSOCIATION take a high place in American medical literature, and it must appear plain to everyone that the practice should be resuscitated. Authors and investigators should be encouraged in their work. The awarding of medals and prizes will encourage the younger members of our profession to apply their talent and energy in a proper direction. The recognition by the American profession of the merits of a literary production is a source of greater satisfaction to the author than the gratification afforded by the intrinsic value of the prize.

I would recommend as the greatest stimulus to original research the awarding of an ASSOCIATION gold medal for the best essay on any subject pertaining to the healing art. The gold medal to be offered by and at the expense of the ASSOCIATION. I would suggest that one side of the medal should bear the bas relief of the father of the ASSOCIATION, Dr. N. S. Davis, and the name of the AMERICAN MEDICAL ASSOCIATION; the other inscribed with the name of the successful competitor, the date of the award, with an Æsculapius staff in the center. The ceremony of awarding the medal should be in public on the last day of the meeting of the ASSOCIATION, preceded by an appropriate speech by the presiding officer. The competitive essays should be placed in the hands of a special committee on prize essays three months before the date of the meeting in the same manner as was customary in competing for prizes in the past. It is time that the profession of this city, the home of the distinguished Benjamin Rush, should do something substantial to commemorate his memory. They can do nothing better than to establish at once, before this meeting adjourns, a Rush Memorial prize to be awarded for the best treatise on any subject relating to the science or practice of medicine. This city has the enviable reputation for its distinguished, enthusiastic and wealthy physicians, and I am confident they need only to be reminded of this late obligation to their most eminent colleague of the past to step forward and subscribe the necessary fund of five or six thousand dollars. I am sure if Benjamin Rush had a voice in this matter he would prefer such a monument to one of marble or bronze. I trust that

in the near future every section will establish an annual prize. If this is done we may expect a rich harvest of the most valuable contributions to indigenous medical literature.

American medical literature.—During the early history of our country students and physicians had to depend upon foreign authors for their text-books. With the Declaration of Independence came a sense of responsibility to our representative medical men to create a literature of our own. The first timid attempts consisted in translating or editing foreign books. The great evil of this then, and to a certain extent even now too general a practice, did not escape the good sense and keen eye of one of the early members of this ASSOCIATION, whose name has become a household word throughout the civilized world—Oliver Wendell Holmes, who alludes to this subject in the following plain but significant language: "It can not be denied that the great *forte* of American medical scholarship has hitherto consisted in 'editing' the works of British authors. The committee are not disposed to disguise the fact that this business has been carried on in a very cheap and labor-saving fashion. A tacit alliance between writers and publishers has infused the spirit of trade into the very heart of our native literature. The gilt letters of the bookbinder play no inconsiderable part in the creation of our literary celebrities. Sometimes the additions by the 'American editor' have been real and important, often nominal and insignificant." Dr. S. D. Gross, the Nestor of American surgery, and the foremost medical author this country has produced, raised his voice against such a parasitic literature at the meeting of the AMERICAN MEDICAL ASSOCIATION in 1850 by offering the following preamble and resolutions, which were unanimously adopted:

WHEREAS, The interests and dignity of the medical profession of the United States, as well as the true spirit of patriotism and a love of independence, demand that we should use all proper and honorable means for the establishment of a National Medical Literature, and

WHEREAS, We have hitherto paid too blind and discriminate a deference and devotion to European authority;

Resolved, That this Association earnestly and respectfully recommend to the medical profession generally, and to the various medical schools in particular, the employment of native works as text-books for their pupils, instead of the productions of foreign writers.

Resolved, That the editing of English works by American physicians has a tendency to repress native literary and scientific authorship, and ought therefore to be discouraged by all who have at heart the object contemplated in this preamble.

Resolved, That this Association will always hail with satisfaction the reprints in their original and unmutated form, of any meritorious works that may emanate from the British press.

At this same meeting Dr. G. B. Wood spoke upon this subject and said, among other things: "Our literature will start forward at a rate that will probably astonish the world as much as our profession in the arts, in wealth and in all the comforts of life. It will have the advantages, moreover, of conformity with our institutions. It will intertwine itself with the popular feelings, convictions and habits, imparting to them consistency, strength and durability; growing with their growth, at once giving and receiving support, and, above all other means, adorning, ennobling and strengthening the natural character."

The utterances of these three eminent members of the AMERICAN MEDICAL ASSOCIATION were made at a time when our ASSOCIATION was passing through the stage of infancy, and yet how forcible and positive is

the language pleading for an undefiled, pure American literature. Largely through the influence of this ASSOCIATION their wishes have been realized. Foreign works edited by American authors are becoming fewer year after year, while books written by American authors have nearly displaced English text-books in our college and physicians' libraries. Today the best text-books for students and the safest guides for physicians and surgeons are those written by American authors. We have every reason to take a just pride in the rapidly growing and high standing of our American medical literature. Our foreign colleagues will soon be compelled to acknowledge our literary independence and to recognize more fully the pen-products of American authors. The time is coming and is near at hand when we will be in a position to pay our indebtedness to them and their predecessors with compound interest, and they will follow to a limited extent our example in the past and commence to edit and use American text-books. Let us stimulate the awakening and growing interest of American authors by creating the necessary funds for a number of prize essays and the future distinction and preëminence of American medical literature will be assured.

Journal of the American Medical Association.—

One of the potent agencies in the hands of the members of this ASSOCIATION to place American medical literature upon a sound basis is our official organ, the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION. It should be and already has become the mouthpiece of the American medical profession. It depends for its support, not upon a wealthy publishing firm or drug house, but upon the profession upon which its existence and maintenance depend. It has only one object in view, the advancement of the science and art of medicine and surgery. Its editor is chosen not for his influence to secure a large subscription list, but for his abilities to manage the JOURNAL for the benefit and betterment of the American profession; in other words, not so much for his business as literary attainments. The JOURNAL has become a permanent institution. It has passed through the trial stage; it has become a power for good in the land. It required years of discussion, preambles and resolutions before the ASSOCIATION abolished the publication of its Transactions in volume form and decided to journalize its proceedings together with the papers read in the general and section sessions. The first suggestion to publish a journal was made by Dr. J. B. Flint of Kentucky at the Richmond meeting in 1852, who gave notice of a proposition to amend the Fifth Article of the Constitution, "So as to provide that, instead of the annual volume of Transactions, the ASSOCIATION may establish and maintain a quarterly journal to be a medium for the publication of the proceedings, and of the most valuable contributions of its members; an organ of resolute and impartial criticism, and an efficient exponent and advocate of the views of the ASSOCIATION on medical science, education and ethics."

It required years for this proposition to come into effect, and when finally, largely through the efforts of N. S. Davis, the Society voted to journalize its Transactions, many had serious doubts as to the ultimate outcome of the new enterprise. At the earnest solicitations of the Board of Trustees, Dr. Davis consented to become its first editor, and placed the JOURNAL upon a sound basis. He was followed by J. H. Hollister and J. C. Culbertson, both of whom labored earnestly and faithfully in the trying editorial chair.

The present editor, Professor John B. Hamilton, assumed the responsibilities of the office with an ability and confidence born of thorough preparation and long practice. He took charge of the JOURNAL at a time when it was in a critical condition. He was well prepared for the duties of this position by nature and education. His long and successful career as a public officer, his keen knowledge of human nature, his good judgment and power of discrimination, his classical education, his intimate acquaintance with the history of medicine and his long experience as a teacher of pathology and surgery, had amply prepared him to manage successfully and edit with ability the official organ of our ASSOCIATION. You are familiar with what he has accomplished. The number of subscribers has been increased threefold, the JOURNAL has been increased in size and greatly improved in quality. Under his editorial management it threatens to become in a few years a dangerous competitor to the *British Medical Journal*, which it will soon equal in the number of subscribers and perhaps in influence. The JOURNAL deserves our undivided influence, as it is the organ which strengthens the ASSOCIATION and binds together in one great brotherhood its members, and its columns are largely devoted to the medical literature of our country, of which it has become its foremost exponent.

Code of Ethics.—At the time the AMERICAN MEDICAL ASSOCIATION was organized the profession of our country was in a most trying condition. The standard of medical education was at the lowest ebb. Of preliminary education there was none. Quackery in all forms was rampant, and no restraints to practices of all kinds by legal enactment. Those who had at heart the elevation of the profession had to make some provision in singling out from the incongruous mass the men who were entitled to professional recognition and public confidence. This was done by the founders of the AMERICAN MEDICAL ASSOCIATION by framing a Code of Medical Ethics, which was called for in the preamble introducing the Constitution. The Code of Ethics was framed by a Committee of seven with Dr. John Bell as Chairman, and was adopted in 1847 without discussion and by an unanimous vote. The Code is liberal in tone, lofty in its sentiments. It requires nothing of its devotees but what would be most willingly subscribed to, observed and carried out by anyone who has the true interests of his profession and his patients at heart. Its language is closely akin to that of that great book, the authority of which but few have the audacity to doubt. The language is that of Percival and our own Benjamin Rush. It is a document which is the backbone and corner-stone of the AMERICAN MEDICAL ASSOCIATION. It is the very foundation upon which the ASSOCIATION is built. It is the rock of Gibraltar upon which all attacks have foundered. Remove it and the AMERICAN MEDICAL ASSOCIATION will be no more; let it remain, and it will continue to grow, flourish and exert its influence for good for all time to come. No changes in the Code have been made whatever since its adoption, except the addition of Section or Paragraph 2, under the head of "Duties for the Support of Professional Character," second division of Code. That addition originated from a charge against admitting delegates from the Michigan State Medical Society on account of the Society having elected as one of its delegates Prof. E. S. Dunster, who was represented as engaged in teaching and giving certificates to students in the Medical Department of the

Michigan University knowing them to be intending to practice an "irregular exclusive system of medicine." The charge was made near the close of the annual meeting in 1877 and referred to the Judicial Council, but too late for the latter to investigate and report at that meeting. At the meeting in 1878 the Judicial Council made an explicit report, declaring that the Code of Ethics contained *no provision* touching the subject under consideration. After much discussion, the members of the Judicial Council were appointed a special committee to report such an amendment to the Code as would cover the subject. Accordingly, at a later stage of the same meeting, the committee reported a paragraph to be added to the first section of the second division of the Code, under the head of "Duties for the Support of Professional Character." But the President decided that amendments to the Code of Ethics must be subject to the same rules as amendments to the Constitution, and the ASSOCIATION acquiesced in his decision. Consequently the proposed amendment or addition to the Code was laid on the table until the next meeting, which was held at Atlanta, Ga., May, 1879. At that meeting the amendment was taken from the table and briefly discussed, and again laid on the table until the next annual meeting. The next meeting was held in New York, June, 1880, and the amendment to the Code seems to have escaped attention until near the time of final adjournment, when, on motion of Dr. Foster Pratt of Michigan, it was postponed and made a special subject for consideration at 10 o'clock of the second day of the next meeting, which was held in Richmond, Va., May, 1881, and at the appointed time the proposed amendment was taken up, and it was discussed in opposition to Dr. E. S. Dunster and H. O. Marcy, when further consideration was postponed until 12 o'clock the next day, at which time it was taken up and advocated by N. S. Davis and opposed by Dr. Dunster, and again postponed until the following morning, when a substitute was offered by Dr. J. S. Billings, seconded by Davis, which was adopted by a three-fourths vote of the ASSOCIATION. (Trans., Vol. xxxii, pp. 38, 39.)

It is evident from the lengthy and complicated proceedings necessary to make this unessential addition to the Code of Ethics, that the American profession fully endorses the action of the Committee which drafted it, and are unwilling for any alterations or additions to be made. The Code has fulfilled the purposes for which it was intended, and will remain a *noli me tangere* for generations to come. I am sure that this feeling will prevail at the centennial celebration fifty years from now, and that our successors will be grateful to us for handing it down to them in an un mutilated form.

Rush Monument.—I have mentioned Benjamin Rush in this address in various connections, but I feel constrained to refer to him once more regarding a movement initiated by Dr. A. L. Gihon to erect to his memory a suitable monument in the City of Washington. The City of Washington is embellished and graced by many statues of the men whose lives are part of the Nation's history. The services of Presidents, heroes and patriots have been commemorated by the erection of statues of marble and bronze, the gift of an appreciative and grateful people. Law and science have been recognized in a similar manner by the erection of monuments or costly oil paintings to the memory of the leaders in the legal profession, and the exponents of science and art, as a token

of respect by the legal profession and the devotees to art. Religion and philanthropy are represented among the group of statues as an evidence of gratitude to representative men who devoted their lives to the church and the welfare of the needy. It is only recently that the disciples of Hahnemann have erected a beautiful statue to the memory of the erratic renegade of the regular medical profession, the founder of a medical sect who originally attributed nearly all disease and suffering to the acarus scabiei, and pretended to cure disease by producing a duplicate with high potency dilutions and triturations. What have the people done to immortalize the name of the greatest physician this country has ever produced, the man who had the honor and courage to sign the Declaration of Independence? Nothing, absolutely nothing. Is it not time that the AMERICAN MEDICAL ASSOCIATION should take hold in earnest to correct this wrong and remove from the medical history of this country a blemish that has been permitted to remain too long? Can we afford to let this semi-centennial celebration go by without securing sufficient funds to erect a suitable monument to the memory of Benjamin Rush? No! a thousand times no! The time is at hand to act and not to talk. Dr. Gihon has labored incessantly for a number of years in this worthy cause, but he has not met with the encouragement he had a right to expect. In 1884 he introduced a resolution at the annual meeting which was held in Washington, which had for its object the appointment of a committee to report at the next meeting as to the advisability of erecting a monument to Benjamin Rush in the City of Washington, as commemorative of the part taken by the profession of medicine in the establishment of the Republic of the United States. The resolution was unanimously adopted, and the President, Austin Flint, appointed a committee of seven with Dr. Gihon as chairman. This committee reported favorably upon the proposition at the next meeting, which was held in New Orleans. It was the desire of the committee that the statue should be completed and dedicated with appropriate ceremonies coincident with the meeting of the International Medical Congress at Washington in 1887. It was originally resolved that the necessary funds for the erection of the monument should be obtained by subscriptions limited to \$1, from each physician and student of medicine in the United States, and by voluntary donations of such additional sums as might be tendered by persons interested in the work. The burden of work in accomplishing this purpose has been consigned almost exclusively to the shoulders of the enthusiastic and energetic mover of the proposition—Dr. Gihon. Year after year he has addressed the members of this ASSOCIATION in the most earnest and eloquent language, pleading the cause which has possessed his body and soul. He has written thousands of letters and spent a small fortune in purchasing postal stamps, and what has been the result of his thirteen years of faithful endeavor in accomplishing a task that ought to have been performed before this ASSOCIATION was born, the erection of a monument to our immortal patriot-physician, Benjamin Rush? He only asks \$40,000, and of this sum, by constant appeals in this ASSOCIATION, State medical societies and the medical press, he has received up to date less than \$4,000. It has been well said that "Dr. Gihon deserved to have a monument himself for his efforts." But Dr. Gihon's labor is an unselfish one; he looks for no other reward than the con-

sciousness of having done his duty. What he does want, however, is that the profession sustain and aid him in this noble enterprise. No wonder he has often been discouraged, his patience has been severely tried, and it is time that we should hasten to his rescue. The necessary funds should and must be raised during the present session, or at any rate during the semi-centennial year. Loosen your purse strings and let the people of this country know that the profession is loyal to one of its greatest lights. See to it that the capital city will soon be graced by a magnificent statue of the idol of the American profession, the patriot-physician, and one of the greatest benefactors of our country—Benjamin Rush.

Prominent deceased members of the Association.—I have incidentally alluded to a number of the founders and prominent members of our ASSOCIATION. On an occasion like this it is appropriate to mention additional names of deceased members who took a most active interest in its organization and proceedings. Time does not permit to enumerate the names of all who deserve a permanent place in the memories of those who have enjoyed the privileges of the ASSOCIATION since their time. Among the physicians the following merit special mention:

Askew, H. F.	Griscom, John H.
Arnold, Richard B.	Hartshorne, E.
Bowditch, H. I.	Haxall, R. W.
Bache, Franklin	Holmes, Oliver Wendell
Blatchford, Thos. W.	Ives, Eli
Bartlett, J. K.	Johnson, H. A.
Brodie, Wm.	Jones, Joseph
Bowling, Wm. K.	Jackson, Samuel
Butler, S. W.	Lindsley, J. B.
Beck, John B.	Lee, Chas. A.
Bell, John	Mendenhall, Geo.
Clark, Alonzo	McNaughton, James
Comegys, C. G.	Palmer, A. B.
Chapman, Nathaniel	Pitcher, Zina
Clymer, Meredith	Parish, Isaac
Cooke, James	Smith, Francis Gurney
Dunn, Theophilus C.	Swett, John A.
Delafield, Edward	Stewart, F. Campbell
Drake, Daniel	Stearns, John
Dixon, Samuel H.	Thayer, Samuel W.
Elliott, Elsworth	Toner, Joseph
Francis, J. W.	Van Dusen, Harmon
Flint, Austin	Wood, Geo. B.

Anatomy and physiology are well represented by

Dalton, J. C.	Horner, Frederick
Draper, J. W.	Wistar, Casper

Of the surgeons who made a deep impression on American surgery and who fostered the AMERICAN MEDICAL ASSOCIATION, the following brilliant array of names grace from time to time the proceedings of our ASSOCIATION:

Agnew, D. Hayes	Norris, G. W.
Brainard, Daniel	Pope, Chas. A.
Buck, Gordon	Pancoast, Joseph
Briggs, W. T.	Pancoast, Wm.
Bigelow, A. J.	Parker, Willard
Carnochan, J. M.	Post, Alfred C.
Campbell, Henry F.	Richardson, T. W.
Dawson, W. W.	Stevens, Alex. H.
Eve, Paul F.	Smith, R. N.
Gross, S. D.	Stone, Wm.
Gross, S. W.	Smith, H. H.
Hamilton, F. H.	Wolcott, E. B.

Hodgen, John T.	Warren, John C.
Knight, Jonathan	Watson, John
March, Alden	Watson, A. B.
McDowell, Joseph W.	Wood, James R.
Mussey, Reuben D.	Yandell, D. W.

A number of the members of the AMERICAN MEDICAL ASSOCIATION have done pioneer work in the development of rational gynecology, and the names I shall quote now are frequently met with in text-books on diseases of women here and abroad:

Atlee, Washington	Drysdale, Thos. M.
Atlee, John L.	Goodell, Wm.
Byford, Wm. H.	Kimball, Gilman
Batthey, Robert	Lente, Fred D.
Dunlap, Alexander	Sims, Marion

American obstetrics was advanced and honorably represented by

Barker, Fordyce	Meigs, Chas. D.
Channing	Miller, Henry
Elliot, G. D.	Storer, D. Humphrey
Hodge, Hugh L.	White, J. P.
Howard, W. T.	

Richard J. Duglison, treasurer of the ASSOCIATION for a number of years, is best known as the author of a medical dictionary which has served a useful purpose to students and physicians for half a century. Isaac Hayes, one of the most influential members of the ASSOCIATION, was a distinguished oculist and editor of the *American Journal of the Medical Sciences* for many years. I might continue to enumerate the names of additional illustrious members of our ASSOCIATION, but enough has been said to show that much scientific work has been done by many distinguished members of our profession through the AMERICAN MEDICAL ASSOCIATION. The AMERICAN MEDICAL ASSOCIATION has been a post-graduate medical institution in which most excellent work has been done, the influence of which has extended far beyond the limits of our own country.

I have attempted to give you a brief account of what has been accomplished by the AMERICAN MEDICAL ASSOCIATION during the first fifty years of its existence, but it is impossible to estimate the benefit derived by the thousands of members who have attended its meetings, men who have contributed little or nothing, but who have been attentive listeners, and who never failed in returning to their homes with knowledge increased and renewed enthusiasm in resuming their responsible and onerous duties. At each meeting new friendships have been made and old ones renewed and more firmly cemented. One of the pleasant and attractive features of our annual meetings is the free social intercourse between the members, coming as they do from all parts of the Union. The social element of our gatherings should be encouraged and I know of no better way in which to foster it than to establish a new departure by making provision and establish the custom of making arrangements for the evening of the second day of our meeting for an

Association dinner.—The Committee of Arrangements are always severely taxed in procuring suitable entertainments for the members at each annual meeting. Much time and money have been spent for this purpose and all of us can testify to the lavish hospitality extended year after year by the local physicians and public spirited citizens. The evening receptions have been enjoyable and conducive in bringing the

delegates and members in closer contact. But I am sure you will all agree with me that they can not take the place of an ASSOCIATION dinner in making strangers friends and in affording the best possible opportunities for an interchange of ideas and experiences often of much more value than in listening to the reading of a scientific paper. Let us relieve our Committee of Arrangements of the greatest burden of their work and take the necessary steps to become independent, as far as our social enjoyments are concerned, by gathering around the festive board at our own expense. Section dinners have been a failure and should be abolished. Let us have a dinner where the sturdy country physician can sit with his more nervous and excitable colleague from the city, where the surgeon can meet the physician, the physician with the specialists of all kinds, that is, an easy, informal commingling of the different professional elements. Occasions like these could not fail in strengthening the ASSOCIATION and in diffusing knowledge not obtainable in any other way. The great medical societies in England and Germany have followed this custom for years, and the annual dinner is always looked for with anticipations of pleasure and profit. Let us imitate their example and I am confident we shall never regret the departure. It will not be difficult to furnish a mental feast for the guests by a number of well chosen toasts to be responded to by some of our members and representative men from the clerical and legal profession. Medicine, law and theology, the three great learned professions, have many things of common interest, and a closer acquaintance and relationship will prove of mutual benefit to all.

Annual addresses.—The scientific work in the general sessions is largely limited to the reading of addresses on medicine, surgery and State medicine. These addresses, as a rule, are carefully prepared and are always listened to with interest. The Chairman of each Section prepares an address which he delivers at the opening of the section over which he presides. A distinction should be made in designating the work done in the general sessions and in the different Sections, and I would respectfully suggest that the addresses delivered in the general sessions should be known as orations, instead of addresses, and the persons delivering them as orators, to still further distinguish them from the Chairmen of the Sections and their work.

Evening demonstrations.—It has occurred to me that the third evening of each session should be devoted strictly to scientific work of a special character. It seems to me that nothing would prove more profitable and attractive than a lecture on bacteriology, histology, normal or morbid, illustrated by magic lantern pictures from photomicrographs, projected upon a screen. The lecturer should be chosen by the Nominating Committee from year to year. We have an abundance of men well qualified for such a task within the ranks of our ASSOCIATION. A lecture of this nature, with numerous illustrations, would secure a large attendance and would be one of the means of keeping our members informed of what pure science is doing for the healing art.

Permanent home of the Association.—One of the present needs of the ASSOCIATION is a permanent home, with an editorial office and press room, for its official organ, a hall for the meetings, at least every three years, which could also be utilized for the meet-

ings of local societies, a library room for American medical literature, and a memorial hall for paintings, busts of distinguished members of the ASSOCIATION, and a room for a collection of indigenous medical plants and surgical instruments, the invention of American physicians and surgeons. The site for such a home should be decided by vote of all members of the ASSOCIATION. The present financial status of the ASSOCIATION justifies the taking of the necessary steps to bring such a project into effect at an early date. I am sure the profession of the city that will be honored by becoming the site of such a wonderful institution will contribute liberally toward erecting and maintaining it. Such a modern Æsculapian temple would soon become the Mecca for those in search of American medical literature, and a rich storehouse for everything pertaining to the medical history of this country.

A glimpse of the future.—Fifty years of steady growth has made the AMERICAN MEDICAL ASSOCIATION strong. It has passed the experimental stage; it has done a great deal in advancing and diffusing medical knowledge, and in the prevention, alleviation and cure of disease. It is the recognized final tribunal which directs and controls all other medical societies and medical educational institutions. It is the final Court of Appeals to which the regular practitioners and the public can look with confidence for the enforcement of a pure discipline and needed protection. It is the highest post-graduate medical institution in this country which without tuition provides a course of instruction annually of a scientific and practical character, well adapted for the busy practitioner, from which everyone returns with a firm determination to do more and better work. It is the great bond of fraternal union which binds and cements together the physicians and surgeons and devotees to special departments of medicine and surgery. The ASSOCIATION has done much for the profession and the people in the past, it can and will do more in the future. The organization is now completed and in excellent working order. We can devote in the future all of our time to scientific and practical work. The increase in membership during the last two or three years is unparalleled in the history of the ASSOCIATION. An awakening interest in the usefulness and prosperity of the ASSOCIATION is noticeable on all sides. The papers read in the sections and the discussions are becoming better from year to year. The fiftieth birthday of the ASSOCIATION will give a new impetus to the work and growth of the ASSOCIATION. It is difficult to foretell the possibilities of the second half of the first century of the existence of the ASSOCIATION. It is, however, safe to predict that when the first centennial celebration will be held in this city fifty years from now, the membership will have increased from 9,000 to 75,000 or 100,000, and our official organ at that time will be recognized the world over as the most enterprising and best medical journal. Few, if any, who, constituting my audience today, will live to see that day to bear testimony of the proceedings, festivities and incidents commemorating the first semi-centennial. The President who will then occupy this Chair and who probably at this time is laboring with his lessons in arithmetic, spelling, geography and grammar in some public school will then review the work of the ASSOCIATION for the first century, and may we trust from the records we shall leave behind that he may adjudge us faithful

servants in the cause of science and humanity. Taking up the thread of history from this day he will chronicle inventions and discoveries of which we have now no conception. The literature of today will be as old and useless as that of fifty years ago. We have the satisfaction of have been permitted to live and labor at a time when the science and practice of medicine and surgery were undergoing a complete revolution. We are now laying the cornerstone and are slowly but surely building the foundation for rational medicine and surgery. The work of the next fifty years will no doubt contribute much toward making what has been sought for ages in vain, the rendering of medicine and surgery exact sciences. The American profession will contribute liberally toward accomplishing this object.

In conclusion, let us implore Almighty God to shower the richest blessings upon the AMERICAN MEDICAL ASSOCIATION and the labors of all and every one of its present and future members. May it please Him who, during His earthly career, went from place to place as the Great Physician to heal the sick and maimed, through His boundless mercy and tender sympathies for suffering mankind, to so guide our lives and labors as to imitate His inspiring example in relieving suffering and in adding to the happiness of our fellowmen.

RECIPROCITY IN MEDICAL LICENSURE; A PLEA FOR INTERSTATE INDORSEMENT.

Presidential Address before the National Confederation of State Medical Examining and Licensing Boards, at its Seventh Annual Meeting, held at Philadelphia, Pa., May 31, 1897.

BY WILLIAM WARREN POTTER, M.D.

EXAMINER IN OBSTETRICS, NEW YORK STATE MEDICAL EXAMINING AND LICENSING BOARD, BUFFALO, N. Y.

For the second time it becomes my duty to assume the functions of presiding officer over the deliberations of this Confederation, and I beg at the outset to offer you my best thanks for this renewed mark of your favor.

Since our meeting at Atlanta last year the Confederation has suffered beyond measure in the death of Dr. Perry H. Millard, of St. Paul, one of its most able and useful members. Since the death of Dr. Rauch, I know of no one whose counsel has been so necessary to our welfare and of none whose devotion to the interests of the organization has been greater. It was my sad privilege to visit him at Johns Hopkins Hospital only a month before his end and then, though feeble in body, his clear and active mind was busy with the affairs of this Confederation; and especially with the report of the committee on minimum standards which he, as chairman, hoped to make at this meeting. But his final summons came on Feb. 2, 1897, when this accomplished physician and useful citizen passed to his immortality. "His spirit was twenty, his years were fifty, but, alas! his body was eighty. Farewell."

At our meeting last year it seemed proper to explain in considerable detail the objects of this organization in order that there might be no misunderstanding as to its purpose. For some time previously the medical schools, or at least some of them, had looked with oblique eyes upon our movements, fearing possibly that we might be scheming to interfere with their prerogatives in the educational field. At first, too, some of them were inclined to criticise the provision

made in most of the States that teachers in medical colleges shall not be eligible to appointment on examining boards. The wisdom of this proviso, however, must be apparent to every thinking man. No one disputes the fact that there must be absolute impartiality in the examinations; but how could this prevail if college teachers were made members? Obviously, one college would be jealous of another, and there would be no end of criticism and contention over the work as well as the representation on the boards; especially so in those States in which there are several schools. It was further alleged in some quarters that none but teachers were competent to prepare questions or mark answers. The absurdity of this suggestion has been abundantly proven. As a matter of fact the test of the State examination is different from that applied to undergraduates. The State examiners must by a few well chosen and comprehensive questions in each topic determine a man's general fitness to practice the science and art of medicine. They must so frame the few questions they are permitted to ask and which there is but scant time to answer so as best to develop that fact in a general way. On the other hand, teachers having been in close relationship with their pupils for three or four years merely examine upon the subjects in which they have given instruction; they often ask categorical questions or those admitting of incomplete answers—a defect that is expected to be supplied in answer to the next question, in further elaboration of the subject, which is easily understood to follow. This method is quite right and proper in a teacher's relation to the pupil or the candidate for the doctorate degree, but not admissible from our standpoint. Here each question must be clear, comprehensive and complete in itself, not susceptible of being answered by "Yes" or "No." Ours is, or should be, essentially a post-graduate examination.

In order to test this matter I have asked teachers in a few instances to submit groups of question; but I have found them, speaking generally, not adapted to the State test although quite satisfactory to ask at pass examinations or of candidates for the doctorate degree. A State examiner will soon acquire the skill of asking the sort of questions best adapted to his work, especially those that will best test the quality of instruction the candidate has received. Once this important knowledge is obtained his services become of incalculable benefit to the State and he should be retained as long as he will consent to serve.

Another fear of the schools was that the high standards would empty their benches or that there would be such a diminution of pupils as to materially deplete their incomes. Quite the contrary has been the fact. Bellevue, at New York, graduated a larger class this year than in some years past and its lecture rooms are reported to have been full. The College of Physicians and Surgeons (Medical Department of Columbia University) has found it difficult to provide room for its overflowing classes. In the city of Philadelphia, which since an early day has been a center of medical education, the schools are full even to embarrassment. In Buffalo the University Medical College never had so many matriculates nor so large a graduating class as this year; and so it is wherever high standards have been adopted. The explanation is not difficult; students want the best; it costs them no more in the end and serves them much more satisfactorily in their early struggle for recognition and professional favor,

as well as in maintaining a high position in later years.

It was made apparent at our meeting last year that the examiners compare favorably in education and *personnel* with the professors with whom we were assembled in joint session; and I hardly think it likely that we shall again hear the challenge, given probably more to cover a retreat than a mask an advance, "Who shall examine the examiners?" The answer, were one necessary, is not difficult to find; for the self-same authority that examines the examiners will no doubt find it an agreeable duty likewise to examine the professors.

No! there is no disagreement between the college faculties and the State examining boards, for it has been clearly demonstrated that they are friends. Their interest are common and their objects one. They must not be drawn into antagonism by the indiscreet utterances of a few misguided though well meaning persons. Each is working in separate yet contiguous fields and all are striving for the same purpose, namely, to obtain the best possible equipment for every man and woman sent out over this broad land to practice the profession of medicine.

There is then less occasion for extended remark now than heretofore, as I have already intimated; hence I shall address myself to the discussion of a single topic; one, however, of paramount importance.

INTERSTATE EXCHANGE OF LICENSES.—THE PROBLEM.

There are at this moment two questions pertaining to State control of medical practice that seem to tower above all others in the minds of many physicians, which demand our most careful attention and challenge our deliberate judgment. The two are, however, so inseparable that in reality they may be considered as integral parts of one subject and discussed together. I refer to, 1, minimum standards of requirements to enter upon the study of, acquire a diploma in, and obtain a State license for the practice of medicine; and 2, to the interstate indorsement or recognition of licenses so that, under prescribed rules, a licensee of one State may be permitted to practice in any other State in which he may seek a temporary or permanent residence.

It goes without saying that an exchange of these official courtesies between the States "is a consummation most devoutly to be wished" by every friend of State control in medicine. It is one of the principal objects that this Confederation is laboring to accomplish. It is at the same time one of the most difficult problems thrust upon us for solution. No one can deny the fact that it is pleasant to contemplate a time—I trust in the near future—when we may have a National registration bureau where every legally qualified reputable physician may be recorded, and when all physicians whose names appear on this register and whose licenses are properly indorsed by the registrar, may pass from one State to another in the practice of their profession and in the enjoyment of all the privileges thereto appertaining. But how is this to be established with celerity and with justice to all concerned? The ideologues who were chiefly interested in the agitation of the question of reciprocity of licensure, assert that unless an interstate exchange is arranged, and that speedily, the whole system of State control in medicine will go to the wall. Whether this is given out in the nature of a threat or a prediction I know not, but there are indications that lead me to

suspect the former. These men I believe are, for the most part, specialists who spend the vacation months at summer resorts, watering places, or on comfortable farms that their plethoric purses have secured in States more or less remote from their homes. They expect to make a snug sum from consultations and office patients during the vacation season, but do not relish the idea of being compelled to "undergo the nuisance of examinations" as they characterize it, in the States they have chosen for their holiday practice. They are frequently men of influence who seek to prejudice their medical friends against the system, by pointing out what they are pleased to term the injustice of applying the State laws in their cases, and then proceed to air their grievances in the columns of medical journals as a court of last resort. While I have no doubt that the denial of reciprocity now and then works hardship to deserving men who perchance must change their residences, but can ill afford to spare the time and money to take a new examination, I yet fail to see wherein the class of men first above referred to and who prate the loudest about it are deserving of special sympathy. They can well afford to submit to an examination in the States where they pass a profitable and easy summer; moreover, I am unable to discover any injustice in compelling them to comply with existing laws. Shall a State require of its own citizens a compliance with its practice laws and at the same time grant to the well-to-do summer specialist exemption from their operation? As the State laws, for the most part, forbid discrimination against the inhabitants of each, there is both a moral and a legal bar to such exemptions.

EQUALITY OF STANDARD A BASIS FOR RECIPROCITY; THE OBSTACLES.

The only equitable basis upon which reciprocity can be established that appears both feasible and practicable, is that of equality of standards for admission to the study and practice of medicine. This implies an equalization of the preliminary requirements of medical students and a uniformity of applying the tests; a uniform period of collegiate training including uniformity of methods of teaching; and, finally, an absolute similarity in the methods of conducting State examinations and granting licenses. A minimum standard of preliminary qualifications is important to agree upon. This ought to be done in a uniform manner by all the States for the sake of the good name of our profession even if there were no other cogent reasons demanding it. American medicine ought not to be disgraced any longer by illiterate physicians; hence illiterate students ought not to be admitted to our medical schools. If we can not agree upon any other question we ought to demand this much as a united profession.

What, then, shall be the minimum limit of education below which a student of medicine shall not be accepted? No more important question awaits answer but it is one on which, I am sorry to say, there is much diversity of opinion. If a man's mind has not already been disciplined to the extent of acquiring a good English education before he takes up the study of medicine, it presents a sorry foundation upon which to engraft a knowledge of such a multiform science and art. It is far more important, in my view, to agree upon a reasonably conservative standard of minimum requirements than it is to insist upon extending the terms of medical teaching to four years;

since it is better to teach three years of medicine to a well-trained mind than to demand four years' training of an illiterate student. I hope this cardinal principle can be definitely settled to the satisfaction of all the States at an early day.

But let us pass to the next topic, namely, uniform periods of collegiate training. Here, fortunately, there is less diversity of opinion, thanks to the good work of the Association of American Medical Colleges. Under the stimulating influence of the American Academy of Medicine, well seconded as I believe by this Confederation, we find a public sentiment fast settling to the conclusion that four years is quite short time enough in which to acquire the proper training and knowledge to fit one for the doctorate degree. It must be remembered that it is required nowadays of the undergraduates to pursue courses in anatomic, physiologic, chemic, biologic, pathologic and bacteriologic laboratories, and to undergo training in medical, surgical and obstetric clinics. Add to this the necessary didactic and recitative courses besides training in special techniques—microscopy, ophthalmoscopy, laryngoscopy and the like. With all these, besides much other information that must be acquired, and who shall say that four years is too long a time to devote to college work? It would be interesting in this relation to trace the progress that has been made in the last quarter century in the various departments of medicine; but this is as familiar to you as to me. You know how the complexity of the present age with its rapid transit and instantaneous methods of communication, has correspondingly increased the assaults by the enemies of health that are multiplying with such marvelous rapidity. To meet this complexity requires a mind more deeply and broadly cultivated; preparations for receiving and utilizing medical instruction must be increased and lengthened. As our cultivation develops our immunity from disease lessens, hence our vigilance and efficiency must be greater, our period of preparation longer, and our training increased in length, depth and breadth. It is therefore, with pleasure that we observe and heartily approve the good work of the Association of American Medical Colleges that is arranging the curricula in such a manner as will be adapted to the environment of the present day. In this relation it would also appear essential that methods of teaching should be reduced to a degree of uniformity that heretofore has not been attained. With a universal establishment of four years' courses in American medical colleges, it will become appropriate for them to grade their curricula to as near a common level as may be consistent with surrounding conditions. Methods of teaching in all the laboratory departments could easily be conducted on a scale of similarity that would make them practically uniform in all colleges.

The third condition to be standardized is one that immediately concerns this Confederation and it becomes us to deal with it in a most thorough-going manner. The first step toward equalizing methods of applying the separate examination for license in the several States, it seems to me, is to bring the examiners together on the subject. If they can be made to agree upon questions concerning their all-important function, then we have gone a long way toward establishing uniform methods. If, however, they differ in opinion as to the application of the principle in the several States, then the prospect for speedy adjustment presents a more discouraging view. The first

point that offers itself is so plain that I am sure no one will attempt to dispute it. The foundation principle of a separate examination for license to practice, is that it shall be applied to all with absolute impartiality; there must be no exceptions to the rule—no exemptions. While it is true that a law on this subject can not be made retro-active and that all legal practitioners at the date of its passage must continue to be so recognized, yet all others must be examined; and so the work must continue from year to year. Another inflexible rule that ought to prevail is that a diploma from a registered school should be demanded as a passport to the State examination. The logical conclusion is that a State examination is supplemental and consecutive to that of the schools, and that it should be refused in all cases where applicants are not holders of legally obtained diplomas from registered and recognized colleges. If this rule were scrupulously enforced it would deprive medical college faculties of grounds for any further opposition to State control. If, on the other hand, any of the State examining boards are permitted to examine undergraduates for license, it enables them to set up a standard of their own, which is antagonistic to the underlying principle of State control and, I fear, subversive to the best interests of reform in medical education. When the duties of medical examiners are reduced to the mere question of determining the qualifications of such individuals as legally constituted schools shall turn over to them with M.D. degrees, they will have served the whole purpose for which they have been created. It is understood that there must be a uniform system of recognizing and registering the medical schools in the several States.

With the foregoing principle once settled the minor details of standardizing State medical examinations for license could be more easily arranged. A uniform system of propounding and marking questions becomes desirable. For instance, if it could be agreed that ten questions in each department or topic should be asked and that each answer should have a possible value of ten points; and, further, that the total possibilities of the examination should be fixed at 100 points maximum and 75 points minimum in each topic, we could easily approach uniformity in this part of our work. The only remaining important question would be as to the valuation of the answers. This necessarily will always vary in degree, since the personal equation of the examiner enters somewhat largely into its outcome. It is a well-known fact that some examiners are inclined to a high, others to a medium, and still others to a low valuation; but with experience and an interchange of opinion on the subject this factor would soon be reduced to an exiguity that would render it comparatively unimportant.

LEGISLATIVE ENACTMENTS.—THE SOLUTION.

These, then, are the essential steps toward reciprocity; these are the obstacles to be overcome before it can be accomplished. The remedies lie in legislative enactments and these, speaking generally, are of slow development. Nevertheless, with a healthy public opinion once aroused on the subject legislative bodies will soon take heed and adopt adequate measures to overcome defects. The newer States are likely to fall into the front line sooner than the older ones that already have imperfect laws. Public opinion moves faster, and I had almost said in a sounder fashion, as we travel toward the Occident. This in some respects

is no doubt true. Montana, for instance, stands at the forefront in all of its requirements for State license. Minnesota, too, has been a pioneer in the movement for advanced standards and has one of the best laws. Moreover, we may expect those States east or west, north or south, that as yet have no laws relating to medical practice, taking heed of the necessities arising under present conditions and profiting by the experience of those States that have preceded them in relation to State licensure, will soon enact laws that will meet all the conditions of the present day and which will satisfy the most idealogistic views.

At present twenty-seven States demand separate examination for license to practice medicine. In fifteen of these a legally obtained and possessed diploma is the first condition imposed; without it a candidate can not be admitted to the examination. It only remains for these States by statutory enactments to bring their preliminary requirements to a common level, and then for their several examining boards to agree upon uniformity of methods, when, lo, the question of reciprocity is solved! A license granted by one of these States will then be valid in all others of this class, upon proving identity, character and the payment of whatever fee may be imposed. With reciprocity once accomplished between these States, the others one by one will soon afterward establish themselves on the reciprocity basis in self-defense, if for no other or better reason.

Those who most loudly and persistently demand interstate indorsement aim their criticisms at the examining boards, holding them responsible for all their woes; whereas, as a matter of fact, the examiners have nothing whatever to do with the question. They are simply agents of the States to administer the laws as they find them and can not change the practice in regard to reciprocal interchange of registration. The statutes in every instance with which I am familiar merely permit the acceptance and registration of licenses issued by other States where the standards are at least equal in all respects to those of the State issuing the license. This means, if it has any significance whatever, that in all preliminary requirements, in collegiate training, and in State examinations, one and all, there must be an equality and a uniformity of standards before licenses can be accepted for registration in a reciprocal manner.

The precise language of the New York statute on this subject is as follows: "Applicants examined and licensed by other State examining boards registered by the regents as maintaining standards not lower than those provided by this article . . . may without further examination, on payment of \$10 to the regents and on submitting such evidence as they may require, receive from them an indorsement of their licenses or diplomas conferring all rights and privileges of a regent's license issued after examination." This principle was reaffirmed in an amendment to the practice law passed March 21, 1896, in the following terms: "New York medical schools and New York medical students shall not be discriminated against by the registration of any medical school out of the State, whose minimum graduation standard is less than that fixed by statute for New York medical schools."

As many other States have enacted statutes fashioned after that of New York, containing this particular proviso, and as still other States hold to the same provision in effect, it is easy to understand how pow-

erless the examiners are in the premises. These demands of the restless and migratory doctors must be taken to the State legislative halls and there made known if relief is expected. Meanwhile, the members of this Confederation may assist in bringing the matter about more speedily by acquainting the legislatures with the difficulties to be overcome and by urgently recommending the adoption of such amendments to existing laws as will meet and remove the present defects.

My object in discussing this subject in detail is to place the examiners right before the country in regard to it and to divert further criticism against the delay of reciprocity into the proper channel.

PROGRESS DURING THE YEAR.

During the past year attempts have been made in nine States and Territories to establish medical examining boards, in four of which efforts have been successful. Those that have joined the list with practice laws are: The District of Columbia, Idaho, Indiana and New Hampshire. The laws of New Hampshire, District of Columbia and Idaho make a diploma from a registered school a requisite to enter the examination. In Indiana the law is modeled somewhat after that of Ohio and is a substantial beginning in a State that has sadly needed protection from charlatans and medical pretenders. So in the academic year just now about to close there has been substantial gain in the direction of State control, even if some important States have fallen "just outside the breastworks." These no doubt will re-form their lines and come to the attack another year with full promise of success. If four States and Territories are added to the list each year, in a short time we shall be able to rejoice in a professional rehabilitation that will compel the admission of the American licentiate to the best medical standing wherever civilization exists.

It seems important in view of the present condition of State control that the committee on minimum standards appointed last year shall be continued as a standing committee of this Confederation, with enlarged powers that shall include the question of reciprocity. I desire to invite your attention to the publication of a brochure entitled "State Requirements for the Practice of Medicine; a Guide to the Qualifications and Methods of Procedure to enter upon the Practice of Medicine in the United States," by Dr. Charles McIntire of Easton, Pa. It constitutes the Bulletin of the American Academy of Medicine for February, 1897, and is by far the most complete publication on the subject yet issued. If secretaries of boards had paid more attention to requests for information the book would have been absolutely accurate up to the date of its issue; as it is, it is surprising how much Dr. McIntire has been able to furnish of value. Every State examiner and especially every secretary should be supplied with this guide and it should be placed on file in all public libraries.

QUESTIONS OF PUBLIC HEALTH ARE INVOLVED.

To return for a moment and finally to the special subject matter of this paper, permit me to say that in any event and under all circumstances the honest and earnest friends of reciprocity may be sure of the active and zealous coöperation of this Confederation in all reasonable efforts to establish it. In most of the States where State license is now required the struggle to obtain even imperfect laws has been prolonged

and the contest has been exasperating as well as fatiguing. Every possible influence has been brought to bear on legislatures to prevent even a conservative recognition of the principle. Nor is this all; after laws have been passed making a good start in the direction of this reform the State medical societies, through whose influence, speaking generally, the measures have been adopted, have been kept constantly on the defensive at legislative hearings and otherwise to prevent amendments to existing statutes that would weaken or tend to destroy their usefulness.

These proposed amendments generally have their origin in spite, malice, caprice or vengeance, and should always be regarded with suspicion by legislative bodies. It will be a happy day for the friends of State license when legislatures can be persuaded to turn a deaf ear to all amendments that are proposed outside of State medical societies or State boards of medical examiners. This would save much time to members of legislative bodies and give security of feeling to the medical profession. If legislators could be made to appreciate the fact that public health interests are involved in the question of State license; that every attempt to weaken the principle is a blow at public sanitation, and that higher standards of medical education mean better health for the people, then perhaps it would be easier to obtain and maintain the necessary laws to protect the commonwealth against that kind of ignorance, superstition or super-refinement that always lurks in the environment of quackery.

Traveling and advertising quacks, christian-science and faith healers, clairvoyant and spiritualistic mountebanks—these and every other kind of pretender that panders to the ignorance and superstition of the people, leeching their money and sapping their vital force, ought to be no longer tolerated by enlightened communities; and if legislatures would lend a willing hand these villainous enemies of public and individual health and prosperity may soon be disposed of in a fashion becoming an intelligent and progressive age.

284 Franklin Street.

HAS THE MILK LABORATORY COME TO STAY?

Address of the Chairman delivered in the Section on Diseases of Children at the Forty seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY A. C. COTTON, A.M., M.D.
CHICAGO, ILL.

Probably at no time in the world's history has the subject of infant feeding received so much attention as at present. The results of bacteriologic research and experimentation have of late given direction to the observations of some of the brightest minds of the profession, and the recent revival of interest in pediatrics has been due to the suggestions of the *preventability* of the disorders of the digestive tract of infants and children. It is not strange, then, that our recent literature teems with contributions on the subject of infant feeding. Some of our would-be teachers are dogmatic and precise in the presentation of their methods, while others are satisfied with the assumption of a merely suggestive attitude toward the subject, while still others present the plea of empiricism and point to results which they do not attempt to explain except upon the ground

of experience. But amid all these conflicting theories and opinions, whether based upon chemic, physiologic, natural or empiric reasons, each new theory or procedure is met with the assertion, "I told you so long years ago," which simply goes to verify the old adage, "There is nothing new under the sun," even in regard to the feeding of infants. Meanwhile statistics show, with here and there an exception, perhaps due to our more modern ideas of hygiene, that the high rate of infant mortality still exists as of yore; "the voice of wailing and lamentation is heard throughout the land—Rachel weeping for her children and refusing to be comforted, because they were not." Among the many conflicting statements of the learned physiologist, the expert chemist, the trained bacteriologist and the experienced empiricist, a cursory glance reveals *three* quite well defined classes of infant feeders, viz.: 1, those who regard the early infant as belonging to the carnivora; 2, those who would place the nursling of the human species among the grammivora, and 3, those wise old experimenters, who seeing in the early young the same dietetic requirements universally attributed to his adult progenitors, place him beyond question in the omnivorous class.

"Follow the teachings of nature," says one; "the sustenance drawn from the maternal font is purely animal food, and when that font is prematurely dried the substitute must be obtained from animal sources, preferably the elaborated product of a lactiferous gland, those being preferred which in the constituents of their product most nearly resemble that furnished by nature." The mother's milk is analyzed, the percentages of fat, lactose and proteids determined, and the dogmatic assertion proclaimed that as cow's milk somewhat closely resembled breast milk, cow's milk alone shall be recognized as containing the necessary constituents for infant food. Immediately some sage rises in his place and solemnly says, "I told you so," and echo catching up the words, they reverberate back along the vista of history until it dies away in the old legend of "Romulus and Remus" suckled by a wolf before the days of ancient Rome. Meanwhile the infants die. The bacteriologist comes to our relief, with his demonstration of myriads of *microorganisms* with which the cow's milk swarms, and informs us that heat will *kill* the disease germs and we must *sterilize* our milk. Again the voice, "I told you so. I boiled my milk long years ago." Up springs the chemist and says by boiling you lessen the food value of the milk by coagulation of its lact-albumen and the devitalization of its most absorbable portion. The bacteriologist upon appeal shows us how to rid the emulsion of its active pathogenic bacteria by submitting it to a temperature *below* the boiling point. But still the infants die and the curdy stools persist and stimulate the chemist to show us not only the excess of the indigestible casein in cow's milk but its peculiar tendency to the formation of *dense curds* under the action of gastric acids. Then comes the physiologist with his *predigestants*; and the extra-gastric peptonization of the offending caseous constituents is in vogue. Once more the echo, "I told you so long years ago," even crossing the Atlantic from the realms of the Sultan, pointing to the fermented preparation of matzoo; from the steppes of Russia with its kumyss, and from the plains of Tartary with their kaffir grains. Next comes the swarm of *cerealists*, who, while admitting the indigestibil-

ity of amylaceous substances in the infant stomach, claim that by partial conversion (by the malting process or by heat) of the starch of cereals into sugar we can furnish the baby with proper alimentation for all the requirements for his full development. Grains are plenty and flour is cheap and commercial instinct eager for gain and the land is flooded with "baby foods" as the best substitutes for mother's milk. Again, "I told you so" is heard echoing until we learn that from the beginning of history *parched cereals*, powdered and in the form of decoctions, have been used under the name of "baby pap."

"Cane sugar is a poison to infants," declares the physiologist. In refutation of which statement the matron of every Southern and Western cabin points to the lusty nursling contentedly mumbling his "sugar tit" while developing strength and stature like the mammoth weeds of the generous praries. Still in the crowded districts of the metropolis the infant mortality repeats its figures with sickening regularity and the persistent anemias and mal-nutrition of the puny rachitic or scorbutic progeny is charged to the use of the exclusive vegetable or animal diet.

Then clinical experimentation in infant diet, with all its variations and alternations between cow's milk, animal extracts, vegetable decoctions and cereal jellies is inaugurated, and the hoary headed rises up among us and gravely claims "It was thus I did eons and eons ago." Says one theorist, "raw milk is poison;" says another, "boiled milk is indigestible;" says another, "starch is indigestible;" still another, "cereals are unnatural;" again, "cows milk even if freed from its pathogenic bacteria is ill adapted to the stomach of the human infant because its constituents do not bear the same proportion to each other of similar constituents of breast milk." Then are we told to so regulate the relative proportions of the constituent parts of the natural emulsion of the cow's mammary gland as to most nearly approximate the relative proportions of the normal constituents of the product of the maternal breast. "It is as plain as day," said he, "for chemic analysis shows us the average composition of cow's milk to be, sugar 4.50, fat 3.75, albuminoid 3.76 (casein 3.00, albumin 0.76); while the average composition of mother's milk is, sugar 6.50, fat 4.13, albuminoid 2.00 (casein 1.00, albumin 0.55)." The difference is seen in this that cow's milk is acid while mother's milk is alkaline, that cow's milk contains less fat, less sugar and more albuminoid substance than mother's milk. We will regulate cow's milk by rendering it alkaline—a voice from out the solemn past murmurs, "I used lime water years ago." We will add more sugar—the same voice, "We have always sweetened the baby's food." We must diminish the percentage of the proteid substance to get rid of the offending casein. The ancient practitioner mournfully suggests, "I have always diluted the milk with three parts water the first two months, two parts water the next two months, with one part water for the fifth or sixth months, and out of the distant past comes the hollow murmur of "wine whey, rennet whey, cream and water, and the mortality was just the same."

Next, science declares we will separate this cow's milk emulsion into its constituent parts and then we will *reassemble* them in definite and exact proportions, so that our *new* emulsion shall resemble a good average breast-milk, and we will patent the process and call it a "milk laboratory." Then says the old prac-

itioner, "For many long years have I employed that procedure by allowing my cow's milk to stand for hours in a deep, narrow jar until gravity should cause the casein to precipitate and the fat to rise; then carefully skimming the cream, I have with delicacy siphoned off the upper one-third of the milk. With this cream, this upper one-third, plenty of milk sugar, an equal quantity of sterilized water, some aqua calcii and perhaps a pinch of salt have I attempted to approximate mother-milk, but I neglected to patent the process, and the infants died, or their teeth developed slowly or their bones softened and their stools were still curdy."

But, says science, the idea of the milk laboratory is not to secure a uniform product which shall most resemble the average breast-milk, but to furnish different emulsions to meet the *especial requirements of individual cases*. The old practitioner replies, "there is nothing new in this idea; from my youth up I have practiced these precepts. I have increased the fat to attenuate the curds, increased the sugar to correct constipation, also the fat for the same purpose, decreased the solids by addition of water and added cereals to *harden* the bones." What, then, fellow-workers, is the benefit to be derived from the milk laboratory since it brings with it no *new ideas*?

I believe the advantages lie in the direction of *more exact manipulation, greater precision, greater accuracy in the keeping of records*. In fact, the milk laboratory already begins to assume the same relation to the dietitian that the well equipped pharmacy has so long borne to the therapist. The busy pediatrician of today can no more depend upon nurses and mothers for the regulation of the infant's food than for the preparation of therapeutic agents from the crude drugs. A definite prescription for the regulation of the necessary constituents of a liquid food to be compounded by a competent manipulator aided by all the requisite paraphernalia for carrying out the physician's idea in the *demand of the hour*. I believe the *milk laboratory* has come to stay. As far as I can learn all my Chicago brethren who have used our milk laboratories are agreed upon this subject.

The brilliant successes recorded by Dr. Rotch, obtained with modified milk through the Walker Gordon Laboratory of Boston, have stimulated the profession and given a new impetus to the study of infant feeding. We are securing through the milk laboratories at Chicago very gratifying results, of which, I trust, the profession will hear more at an early day. The facility for exact experimentation stimulates closer observation in our efforts to perfect nutrition in the infant. And although one may say nothing new has yet come of it, I believe the future is full of promise. That the efforts of the practitioner through the milk laboratory must be confined to the manipulation and regulation of cow's milk alone, is a mistaken idea that in some way has been associated with the early discussion of this subject. On the contrary, in the milk laboratory the advocates of the employment of cereal products in infant feeding find their best facilities for testing and demonstrating the value of their theories. It was my intention to present two lines of experimentation which have interested me of late at the Chicago Laboratory, but as this paper is already long I will merely mention them, trusting that at a later day they will meet with a worthy exposition.

Your former chairman, Dr. Christopher, and your

present representative, have of late been incorporating in some of their prescriptions for milk mixtures definite quantities of cereal jellies as expressed by percentage of starch. The ingenious experiments of Dr. Leeds of Hoboken, demonstrating the difference in coagulability of the casein between cow's milk and mother's milk, have stimulated our efforts to still further eliminate the casein without reducing the percentage of proteid substances. This we are attempting to do by replacing a large part of the rejected cow proteid with egg albumin. It has been claimed that egg albumin rendered the mixture unstable and that it could not be protected by Pasteurization because of its ready coagulability. We have not found these obstacles to the use of egg albumin to be insuperable, and are today employing the egg to replace the lact-albumin with satisfactory results. At my suggestion, our prescription blanks have been arranged for the addition of egg albuminoids when deemed advisable.

The milk laboratory, I believe, has come to stay.

ORIGINAL ARTICLES.

THE RELATION OF DISEASES OF THE SKIN TO GENERAL CONDITIONS.

Read before the New York Academy of Medicine, April 1, 1897.

BY L. DUNCAN BULKLEY, A.M., M.D.

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL; CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL, ETC.

The modern division of the practice of medicine and surgery into many specialties has been a natural and legitimate sequence to the marvelous development of the science and the art of healing which has been made in late years. The sum total of medical knowledge in various lines has now become so great and extended that few if any can hope to compass and apply it to all satisfactorily in a lifetime; and the development of specialism in the medical profession (as in many other branches of science) has both contributed to this development and has facilitated the practical application of knowledge and experience along many lines. The advances which have been made in connection with medicine and surgery, largely by specialization of work, compare favorably with those obtained in other lines of human activity, even in this age of steam and electricity.

But, on the other hand, all thoughtful men must recognize that in this minute subdivision of thought and practice, and in the enormous aggregation of medical knowledge there is a lack of coordination in its practical application which at times results disadvantageously to the patient. Minute and concentrated attention to separate and individual lines of thought and practice has too frequently resulted in a narrowness of thought and practice, which has prevented the physician from properly recognizing, appreciating and applying many of the broader principles of medicine, which are so often of the utmost importance.

This is especially apt to be the case in connection with diseases of the skin, and yet in almost no branch of medicine is the error more serious; and the error has unfortunately spread from the specialist to the general practitioner, until lesions on the skin are now too often regarded as special and local affairs, quite unconnected with disorders of the general system.

The reasons for the neglect of internal conditions of the system in the practice of dermatology are not

difficult to discover. Much of the work in this branch has, of late years, been done by those who have devoted themselves to it exclusively, almost from their first graduation; they have had little or no practical experience in general medicine, and as their interest and study has been largely concentrated on the lesions visible on the skin, other broader relations of medicine have naturally become less distinct. The feeling that the skin affection is a local one is also largely shared and fostered by patients, who constantly urge that they are in perfect health, and only desire the removal of the local disease which gives them annoyance. Thus, it happens that more and more attention is localized on the portion of the body that gives offense, and varied local applications are used with more or less satisfactory results, and subsequently recommended to others. The profession is thus taught to look upon local measures as the only important feature of treatment.

It must be granted, however, that clinical experience often seems to give considerable support to the errors thus begun. For undoubtedly, very much can often be accomplished by correct and proper local treatment, and the cessation of this or that eruption under local applications does often seem to warrant belief in their great efficacy. On the other hand there is certainly often danger of error in this judgment. For it is possible, and indeed probable that very frequently the local or other exciting cause which produced the eruption has passed away, and thus the local lesion which was left yields readily to local treatment while the general systemic condition which predisposed thereto still remains; the skin then readily succumbs to a renewed irritant and the eruption recurs again and again, until the conditions of system at the bottom of it are removed. This is well illustrated by syphilis, where local mercurial or other treatment may be successful in removing local lesions, which will reappear again and again until the actual disease is overcome by proper constitutional treatment. In certain instances, as in herpes zoster, the eruption is quite self-limited, and so naturally ceases under any proper local application. How readily could a perfectly ignorant person be deceived on seeing the rash of scarlet fever, measles, chicken pox or variola cease after local treatment; the same error could occur in regard to eruptions excited by certain drugs, as quinin, belladonna, copaiba, etc., after the administration had been suspended.

But belief in a general local pathology and treatment for all diseases of the skin finds a still further support in the fact that there are certain lesions of the skin which are of a purely local nature, and yield readily to local measures alone. Such, for instance, are certain hypertrophic and atrophic diseases, and some new growths, as also the lesions caused by various local irritants and those produced by animal and vegetable parasites. But even in many of these very careful medical study will determine features or elements where the broad principles of general medicine should be applied. A striking illustration of this is found in ringworm in children, which will persist and luxuriate in those of weak constitution or exhausted by mal-nutrition, and yield much more readily when proper internal measures are instituted.

Finally, recent science has been claiming for the class of microbes an important place in the local causation of skin lesions. But it is more than ques-

tionable if, in many instances which have been claimed, they are more than accidental elements, or even the result, instead of the cause of the diseased process. In some instances, at least, it seems highly probable that the parasites generate and operate only because the soil is suitable and has been previously rendered so by other causes which can and should be removed.

I can not more forcibly illustrate my conception of the relations between local pathology and general causes than by reference to some facts in nature. For a long time it was unknown as to what was the real cause of a certain condition or disease in peach trees called "yellows." It is a disease which attacks the leaves, causing them to become yellow and fall off; the life of the tree is thus impaired, no fruit is produced, and before long the tree itself may die. Careful study finally demonstrated that the disease was caused by a fungus parasite invading the leaves, and thus arresting their vital action. Many and varied local remedies were thereupon advised, and much ingenuity expended upon methods of spraying the trees with various solutions destructive to the parasitic growth. While these means are all effective for a time in some cases, in other instances they fail to save the trees, while in many if not most trees the disease recurs again and again, requiring repeated and frequent applications. Finding local treatment to be but temporary and often ineffective, attention was then paid to other and more general points relating to the life and nutrition of the trees, and now, at the present time the best authorities advise, not the local treatment to the leaves, but improved nutrition to the tree, especially in the way of phosphates to the roots, even though it is yet recognized that the disease on the leaves is parasitic. The increased vitality of the tree enables it to resist the inroads of the parasites which, attacking first the leaves, finally destroyed the life of the tree itself.

At my country home I have a large *virgouleuse* pear tree which each year has borne a very great number of pears. But when about half grown the fruit becomes attacked by a fungus which thickens and hardens the skin of each pear, and they soon crack and dry up, so that hitherto for many years there has never been a single good pear ripened; the fruit is hardened with deep fissures, and never more than half grown. Finally, I began to systematically reduce the number of pears which were allowed to remain on the tree, removing a third or half of them when they were the size of a walnut, and before showing much signs of the parasite. The result was remarkable. A very great improvement occurred in the remaining fruit, which resisted the parasite very markedly, some of the pears attaining large size and ripening without being cracked and split as formerly. Another year I shall carry the process still further, removing a larger portion of the fruit very early, and the resulting vigor in the remaining portion will enable those that are left to resist the parasite still better. Thus we see the fruit yielding to the attack of the parasite when the strength of the tree was weak from overbearing and resisting it when a lessened quantity of fruit allowed greater vigor to be expended upon each pear.

One more illustration. On a very bad, hilly and stony field on my farm, which had run entirely to red sorrel and brambles, my farmer sprinkled a considerable quantity of wood ashes thickly across one corner.

In the following spring this portion was covered with a beautiful carpet of white clover, it forming a striking contrast with the rest of the field, although no clover seed was sown. This clover was reproduced for several years until the fertilizer was exhausted, when the weeds again gained the ascendancy and have remained in possession of the spot. We see here that with proper nourishment the clover seeds, which are everywhere present, grow luxuriantly, while with impoverished soil plants of a lower order assert themselves. All are familiar with the growth of moss, both upon dead and dying trees and upon those in poor damp ground, and shut in from sunlight, and how it disappears when the best conditions of life are secured; the mistletoe on the oak flourishes when the soil is damp and on the highest branches, where vitality is least.

Illustrations could be multiplied indefinitely to show the resisting power of health over the germs of disease, and yet the principle seems to be applied very little in diseases of the skin. They seem to be regarded on all sides as something peculiar and distinct from other maladies and subject to different pathologic laws. My plea is that the specialist and general practitioner should look at them more as other diseases are considered, namely as being largely evidences of lowered vitality and connected with faulty metabolic processes in the system. Time and space forbid me to develop the matter to its fullest extent. But this I do urge: That the patient should be studied in all aspects and treated more on the broad principles of general medicine than simply by the various local measures at the time in vogue, commonly with the addition of arsenic internally. It would surprise the profession could they but know how universally this remedy is given by the general practitioner when anything whatever is wrong on the skin, and it would be even a greater surprise to know to what a very slight extent arsenic enters into the treatment employed by those best acquainted with and most successful in the practice of dermatology.

Much could be written on the evils of narrowness of thought and practice in this branch of medicine, and many illustrations could be given of the harm resulting from not studying cases thoroughly and then treating the patient in the directions indicated thereby, instead of by local applications alone.

As well might the neurologist give temporary relief to headache or sleeplessness by sedatives or hypnotics without searching out and removing the cause; as well might the oculist seek to improve the eyesight by glasses alone when syphilis had altered the deeper structures; as well might the laryngologist only relieve a tuberculous laryngitis by topical applications without seeking to overcome the cause by hygiene and proper remedies; as well might the orthopedist only support a lateral curvature by braces and expect satisfactory results, without employing means to strengthen the weakened muscles on which the condition depended; as well might the gynecologist expect to get good results by local treatment in a leucorrhoea which was dependent upon debility and constipation without relieving the underlying causes.

The proper treatment of certain diseases of the skin often involves the most extended knowledge and practice of general medicine; and he but poorly serves his patient who prescribes only a local treatment without fully going into the case and rectifying, as far as may be, the systemic errors which often play a great part in its production and continuance.

It would lead us far beyond the proper limits of this paper to treat fully of all the possibilities which might be presented in connection with the subject under discussion. But I may be pardoned, even if I traverse ground well known to many, in pointing out some of the more common aspects of the subject, as they are presented to me in daily practice. I will, therefore, briefly indicate the lines on which investigation and therapy should be directed in connection with many of the patients presenting diseases of the skin.

How large a proportion of the ordinary run of cases may require general constitutional treatment can be judged from the fact that out of 10,000 miscellaneous skin cases in the writer's private practice, recently analyzed, over 6,000 or more than three-fifths of all belonged to five of the more common inflammatory diseases of the skin, all requiring more or less of general treatment; while there were even less than 1,000, or not 10 per cent. belonging to the three classes of new growths, hypertrophies and atrophies, and only about 10 per cent. of syphilis and parasitic diseases together.

To correctly understand and properly treat a large proportion of the general run of skin cases, therefore, there is need of the physician considering the patient, briefly though it may be, in reference to the action of his entire system. Some of the points to be regarded we will consider under the following heads:

1. Digestive system.
2. Renal system.
3. Cutaneous system.
4. Nervous system.
5. Circulatory system.
6. Respiratory system.
7. Sexual system.
8. Anemia, gout, rheumatism, syphilis, malaria.

1. *Digestive system.*—It is hardly necessary for me to dwell much on the importance of attending to the digestive system in skin patients, for all will immediately recall the intimate relations which every one must have observed between digestive derangements and the skin; and the subject of auto-intoxication from the products of mal-assimilation has received much attention lately at the hands of Bouchard and others, and merits the most serious consideration.

Urticaria and acne furnish, perhaps, the most striking examples of auto-toxic skin disorder, as they are constantly seen to follow promptly upon digestive disturbances. But the same may often be observed in eczema, while psoriasis will frequently be seen to be more active when these occur, and the itching of pruritus is always augmented thereby; falling of the hair may continually be observed to occur with each attack of dyspepsia and even syphilitic skin lesions will frequently appear aggravated when the digestive functions are disturbed. In many cases, however, the connection may not be very apparent at first sight, and it will sometimes require considerable persistence to establish the digestive derangement which is at the bottom of the difficulty.

Primary digestion, either atonic or fermentative, often due to errors in diet and hygiene, is not very infrequent in these patients, but secondary and intestinal indigestion is more common. It is almost needless to remark that the condition of the tongue often affords a most valuable guide in regard to these disorders, and should always be studied, even when the necessity of regarding this aspect of the patient's condition does not seem apparent at first sight.

Constipation in a varying degree is perhaps the most frequent derangement, and is often the source of incalculable mischief in skin cases. But even this may not be easily discernible, for many patients are ignorant of what should be the normal action of the bowels, or are too careless or unobservant to report correctly at first in regard to this function; the affirmative answer so often given to the routine question "Do the bowels act regularly?" will not infrequently be found to be a long way from the actual truth, medically; that is, if it is desired to determine thereby whether the bowels are performing their excretory function in a perfect manner. Far too little attention has commonly been paid to the character and quantity of this excretion, and it is well recognized that there may even be a daily discharge from the bowels while the most extreme state of constipation exists, with vast amounts of concretions past which fecal matter may find exit. Time and space forbid entering more fully into this portion of the subject, which, however, is of the utmost importance in connection with many cases of skin disease.

Liver disturbance plays an important part in many skin disorders, as it does in those of other portions of the system, and should always be considered and treated in this connection. The great value of small and repeated doses of calomel and of nitric acid in many conditions of the skin needs only to be seen to appreciate this point.

2. *Renal system.*—Next to the exhalation from the lungs, that of the kidneys is the most important of all the excretions, as far as relates to the life of the patient. Its total suspension for a day is fraught with great danger, for a much longer period it is death. Its derangement is both a cause and a sign of disease. At the present writing no account is taken of organic disease of the kidney, for practically this is not very often found among skin patients. But functional disorder of the urinary secretion is a most common occurrence among those presenting diseases of the skin, and will often prove to be a very important element in their treatment; careful investigation of this function should never be neglected in skin cases of any importance.

It is not possible to enter here largely into the consideration of all the changes which may be found, and their significance in different cases, for many pages would not suffice to cover the subject, and a few hints must suffice.

Not only may transient albuminuria and glycosuria be of importance, and the grosser appearance of the urates, uric acid and the oxalates and phosphates have their significance, but the bile salts and pigments and indican may point to disorders requiring correction, while the percentage of urea is always an item worthy of consideration. This latter constituent of the urine, urea, suggests what is perhaps the most important element to consider in this connection, namely, the total quantity of the kidney secretion in the twenty-four hours, not only as relates to the watery element, but mainly as to the total solids, or excrementitious products which are thus eliminated, for it has been shown that urea bears only a certain relation to the other solids and to the toxicity of the urine.¹

While the acidity and specific gravity of separate specimens of urine are often of some value in the guidance of the case, the true indications of the workings of the kidneys can only be obtained from a

¹ Transactions of the Medical Society of the State of New York, 1897.

knowledge of the total amount excreted in the entire day and the estimate thereupon of the solid excreta. When thus tested it will be found that many patients presenting obstinate affections of the skin suffer from an insufficient kidney excretion, either as to its watery or solid constituents, or both, the relief of which will prove of the utmost advantage in managing the eruption on the surface. The researches of Haig and others have shown also, I think, conclusively that the relations of uric acid to the system are of the greatest importance, and have much to do with the production of disease in the skin, as well as in other organs; although few will entirely agree with all that author has claimed in this direction.

3. *Cutaneous system.*—The importance of the skin as an emunctory organ and as a regulator of the heat of the body should never be forgotten, and its general condition should always be inquired into and appreciated in connection with skin cases. It is well known that many general diseases have their origin in a chilling of the surface, or check of perspiration, and the relations between the excretion from the skin and that of the kidneys is well recognized.

Therefore the general condition of the skin, its harshness or dryness, the tendency or not to active perspiration with heat or exercise, are all elements which have much to do with the general health, as well as with special eruptions on the skin. It is not at all uncommon for skin patients to present some of these departures from health in the general expanse of the skin.

With these may be mentioned the general appearance as to sallowness or vascular derangement of the skin. The condition of the subcutaneous and adipose tissues is also important, with which may be mentioned the weight of the patient, whether there has been loss or gain, etc. It may thus be remarked incidentally that the weight of the patient is an element to be taken into consideration in connection with the dosage of internal remedies, even as age is to be considered in the therapeutics of childhood.

4. *Nervous system.*—Many observations of most careful clinicians have demonstrated beyond question the intimate connection between many affections of the skin and the nervous system, and even in many eruptions which are not distinctly recognized as "neurotic" great benefit may result from a proper attention to this feature of the case.

Sleep is one of the most important elements to consider in connection with many diseases of the skin, for without proper and refreshing sleep it will often be impossible to effect much permanent benefit. As the writer has recently discussed this subject at length² it will not be necessary to enter upon it very fully on the present occasion. Suffice to say, that while in certain instances the disturbance of sleep, as by itching or pain, will be a marked feature calling for relief; in a far larger number of instances the faulty character of the sleep will only be learned after some patient investigation. Very often it will be found to be dependent upon errors of assimilation and occasionally upon circulatory disturbance; sometimes it is purely psychic, and it may be that even external causes can be found, which, by preventing full and refreshing sleep, have contributed largely to the continuance of the eruption. A case has recently occurred to me where the prolonged illness of a child so disturbed the father's sleep that this formed an

important element in the continuance of a neurotic eczema on the backs of the hands.

Headaches are a very common symptom in those coming for the treatment of skin affections, being often closely related to the disease itself, and should always receive solicitous attention from the physician.

Neurasthenia, or a general nervous debility, is also very frequently met with in these subjects, and must be overcome, as far as possible, in order to obtain satisfactory results in many cases. There are many points in this connection which could be easily and profitably enlarged upon, but time and space forbid. In approaching a rebellious skin affection, however, due consideration should always be given to the condition of the nervous system.

5. *Circulatory system.*—While this may seem of less importance than some of the other portions of the subject, its bearing in certain cases is often very marked. Digitalis and aconite, as representing the therapeutics of two very opposite conditions of the circulatory system, may often, with other kindred drugs, play a very important part in the treatment of some skin affections. Palpitation and flushing of the head and extremities, as well as cold and clammy hands and feet, are constantly met with in connection with many diseases of the skin, and must receive attention, either as indications of other disorders or on their own account. Purpura is an affection where blood vessel disease is strikingly exhibited.

The indications afforded by the pulse are most important in many patients affected with disease of the skin, and the time-honored practice of judging of the patient's general condition by the character of the pulse should never be neglected in this class of cases.

6. *Respiratory system.*—While relatively little is known as to the variations in the performance of the work done by the lungs, or their effect on the general system or special diseases, there are often features relating to the respiratory system which may be of much importance in connection with some skin cases. The most notable illustration is the occurrence of tuberculosis, in the patient or family, in connection with which we find lupus, tuberculosis cutis, and forms of scrofulous eczema, etc.

But certain other conditions of the respiratory tract are also not infrequently found to be associated with or even related to diseases of the skin; such are asthma, hay fever, bronchitis, catarrh, etc., and in certain instances their existence and continuance may have a very important bearing on the case. The occasional alternations of asthma or bronchitis with attacks of eczema and psoriasis is sometimes very striking.

Chronic catarrhal conditions of the upper air passages may be observed in a very considerable share of patients with eczema and acne, and the continuance of this causing (as well as indicating) disturbance of the digestive tract will aid in making the case rebellious. In this connection may be mentioned the breath, which by its varied and often offensive odor may indicate various deranged conditions both of the upper respiratory passages and of the alimentary canal.

7. *Sexual system.*—The common observation of the development of acne at the period of puberty in both sexes, as well as the increase of the eruption at each menstrual epoch in females, especially in those exhibiting any disorders of this function, call attention to the fact of the relation between the skin and

² The Medical Record, New York, Nov. 20, 1895.

the sexual system. Instances are also multiplying in literature where other eruptions have been found to be distinctly dependent upon such relationship, and the present writer is constantly meeting these in practice. Perhaps the most striking example of all is found in what is known as "herpes gestationis," where, with each recurring pregnancy an acute, intensely irritating papulo-vesicular eruption appears, vanishing abruptly after the uterus is emptied of its contents.

The condition of the menstruation is, therefore, a very important one to consider in connection with many diseases of the skin, and the various disorders of it will often be found to improve greatly with the carrying out of wholly proper treatment for the latter.

Not only should the character of the menses be known and appreciated, but often physical or other changes in the female generative organs may have their influences in diseases of the skin, and should be rectified. Leucorrhœa is also always of great importance, both as a sign and cause of weakness, and its existence should always be known and the trouble remedied. Also in certain females there may be an amount of pruritus vulvæ, perhaps dependent upon the leucorrhœa, which may so depress the patient and prevent sleep to such an extent, as to prove a hindrance to the cure of the skin affection.

The occurrence of acne at puberty in the male, as already mentioned, shows that the sexual organs in this sex also have some, though less, influence on the skin. But the connection between stricture of the urethra and herpes genitalis and pruritus ani is also well recognized; and undoubtedly masturbation can cause rebellious acne. Sexual excess can likewise influence unfavorably many eruptions.

8. There remain yet several more general matters requiring consideration in patients with diseases of the skin. These are: 1, *anemia*; 2, *gout and rheumatism*; 3, *sypphilis*, and 4, *malaria*.

1. *Anemia* is a fertile cause of many skin complaints, as it is constantly observed that many eruptions return whenever this state recurs; it should, therefore, always be recognized and treated when present. It is, of course, not infrequently associated with, or dependent upon derangements of some of the systems of the body which have been already considered, but very often it is due largely to erroneous diet and hygiene; the latter should always be very closely looked into and cared for in patients with diseases of the skin.

2. *Gout and rheumatism*.—These, as well as certain diseases of the skin, are often only the expression or result of some of the systemic disturbances which have been already considered; but as they may be such definite and commonly well-marked conditions, and represent such a well-recognized train of systemic changes, it is well always to know whether they have been present in the patient or his ancestors. Much has been written in regard to the part played by uric acid in many diseases, and it is certain that the recognition of the lithemic state, or *uricacidemia*, is of very great importance in connection with certain diseases of the skin. Whether we are to look upon the uric acid itself as the real cause of any of these troubles is still somewhat of an open question; certain it is, however, that it forms one link in the chain, or one easily demonstrable sign of the faulty metabolic process which may result in gout and rheu-

matism. Hence these diseases are important to recognize and treat in connection with many diseases of the skin. The beneficial results from the internal administration of salicylate of soda in some of them points strongly to a connection of this nature.

3. *Sypphilis*.—This great poison has reached out until it has influenced countless lives, and today is represented by nearly 10 per cent. of all cases which come to public skin clinics, or appear in private dermatologic practice. It should, therefore, always be considered in all its possible bearings on this class of cases; although, fortunately by practice its features can generally be recognized without much mental effort and without much interrogation of the patient. But, on the other hand, caution is necessary not to suspect this cause too strongly in skin cases, for, as remarked, less than one-tenth of all cases are of this nature. When present, and properly treated, the results in this class of patients is most satisfactory, whereas, if unrecognized, but little benefit can result from local or wrong internal treatment.

4. *Malaria* is regarded by some as productive of many skin diseases, and certain cases of urticaria are unquestionably of this nature, and cured only by quinin in efficient doses. It is certain also that by its depressing effect and by the liver and other disturbances which it may cause, it can act prejudicially in many diseases of the skin. It should always be looked for and treated when present.

There is very much more which could be said with advantage, both in connection with the points already considered and with many other items pertaining to the general medical relations of diseases of the skin. But already this paper has probably far exceeded what many would have expected from the subject. Enough has been said, however, to show that dermatology is an important study, not only because of the great interest which the varied conditions of the skin may present, but also on account of the very many vital relations which they may bear to other disorders of the economy.

It is quite probable that much that has been said is entirely familiar to many present, but, unless I am much mistaken, these principles are not universally put in practice in connection with the ordinary treatment of diseases of the skin. As remarked at the opening, local therapeutics has been so much advocated and arsenic is so universally believed to be "good for diseases of the skin," that the former are too often pushed to an unreasonable extent and the latter is too wholly relied on. In many, many instances, as my notes of cases abundantly show, Fowler's solution has been the only internal remedy which had been previously prescribed, even when proper investigation showed the most palpable departures from health, which were of the greatest causative importance to the eruption.

To be a good specialist in dermatology, or in any other specialty, one must be a good general practitioner. The specialist who confines his study and thought only and exclusively to his own branch, and can not or does not embrace the entire field of general medicine, can never succeed in the highest degree, and certainly can not serve his patients in the best manner possible.

I beg to assure my hearers that all this has not been written in any captious spirit, nor from any theoretical standpoint. All that has been said comes from the practical experience of over a quarter of a century

contact with just such conditions as have been mentioned, and all is written from a profound feeling and belief that only by proper attention to the matters here indicated can the most good be done to those coming under our care with many of the diseases of the skin.

4 East Thirty-seventh Street.

DIABETIC COMA AND THE TREATMENT OF DIABETES MELLITUS.

BY EDWARD L. MUNSON, A.M., M.D.

ASSISTANT SURGEON U. S. ARMY.
FORT ASSINIBOINE, MONT.

The disease diabetes mellitus has long furnished the science of medicine with some of its most difficult and obscure problems, one of the most interesting of which is that symptom-complex called diabetic coma, which in many instances brings this affection to a fatal termination. It was at first believed that this condition was induced by an effusion of serum into the arachnoid but later investigations failed to confirm this theory. The idea was then advanced that the phenomena of diabetic coma were due to the action of some toxic body on the organism and a large number of substances have from time to time been considered as the essential factors in the production of this condition. Urea was long believed to play an important part in this as in other affections characterized by marked nervous and cerebral symptoms. Repeated experiments have shown, however, that if free diuresis is maintained, as is the case in diabetes, it is almost impossible to produce any untoward symptoms by the injection or ingestion of this body. It has been repeatedly shown that urea, under such conditions, is no more toxic than common salt. Frerichs then advanced the theory, on observing the presence of large quantities of ammonia in the urine previous to or during the occurrence of coma, that coma was produced by a so-called ammonemia, the ammonia being produced from the uræa by an abnormal ferment by which it is broken up in the production of ammonium carbonate. Experiments on animals, however, showed that enormous quantities of alkalies could be tolerated by the system without the production of any severe symptoms, although it was possible to produce convulsions by the continued injection of large amounts of alkalies. About the same time Petters (*Prager Vierteljahrsschrift*, 1857, III, S. 81) noticed the occurrence of acetone in the urine of certain cases of diabetes and believed that this body was the cause of the peculiar odor of the breath and urine in certain cases of this affection. Acetone, however, is by no means present in a large proportion of cases of diabetic coma and is symptomatic rather of the early stages of diabetes. It was soon shown by Kussmaul that doses of from 4 to 6 grams continuously administered had no harmful effects whatever. Experiments by the writer showed that single doses reaching as high as 36 gm. had but slightly stimulant and intoxicant effect upon the system.

Gerhardt (*Wiener Medicin. Presse*, 1868, No. 28) then discovered a reaction which he believed to be due to the presence of ethyl aceto-acetate, a body which was soon shown to possess no toxic properties whatever. It was then advanced that ethyl aceto-acetate was toxic from the free acetone which it yielded in its decomposition, but the harmlessness of the latter body in the system was soon after demonstrated,

while later proof that ethyl aceto-acetate did not exist in diabetic urine showed the entire falsity of this theory. Diacetic acid, the body which gives the well known reaction with ferric chlorid in the urine of these cases, was soon after discovered by Tollens and more completely investigated by Jaksch ("Ueber Acetonurie und Diaceturie," Berlin, 1885), who in almost every case of diabetic coma was able to demonstrate its presence in the urine. He believed that it was formed in the intestine by the union of acetone and formic acid and attributed to it the production of diabetic coma, in what way he was unable to state. Experiments on animals and men, however, made by Frerichs and Kussmaul (*Deutsch. Arch. für klin. Med.*, 1874, S. 11) have shown that 10 to 20 gm. of this acid could be given in health without the production of any grave toxic symptoms and that it therefore possesses no poisonous properties in itself. It is interesting to note that after the administration of such large doses of this acid none whatever appeared in the urine although considerable amounts of acetone were present, thus showing that in the healthy organism a higher oxidation of this acid takes place.

"About this time investigations made by Coranda and Halleworden proved that the ammonia in the system fulfills two functions: 1, to contribute to the formation of urea, and 2, to neutralize all acids introduced into the system or produced there in the metabolism of the organism. It was also demonstrated by them that the ammonia excretion furnished an exact estimation of the acid out-put. On extending these researches to various morbid processes it was found that in certain fevers, etc., there was a great increase in the ammonia excretion, the patients becoming carnivorous by feeding upon the albumins of their own systems. In diabetes especially very large ammonia excretions were noticed, showing that in such cases there was a great excess of acid produced in the system which was neutralized by the available ammonia of the organism. At this point Stadelman, Minkowski and Külz discovered in the urine of diabetics with a large ammonia excretion an acid heretofore unknown, which was found to be identical with beta-oxybutyric acid. It was noticed that patients with a large ammonia excretion were especially liable to die of coma and this suggested to Stadelman his theory that diabetic coma is an auto-intoxication, produced by an excess of acids within the body. So he at once began a series of experiments upon the introduction of acids into the circulation, using only those which could be potent through their affinity to alkalies and which in themselves possessed no toxic properties. The moment such an acid enters the circulation it attacks the first alkali available. In the case of man and the carnivora this will be the ammonia, in combination with which it becomes inert and is thus carried out of the system. Herbivorous animals, however, have no such ammonia production and the acid must at once attack the sodium and potassium of the blood and tissues. By such injections it has been found that symptoms identically resembling those of diabetic coma can thus be produced in those animals and that a prompt neutralization of this acid by a further injection of alkalies will at once restore consciousness. It has been therefore believed that after the production of the acid bodies in diabetes for a certain time they are neutralized by the available ammonia. At last, however, there comes a time when the production of ammonia can not keep pace with

the acid production, the fixed alkalies are attacked and diabetic coma due to acid toxemia is the result" (Graves, in *Proc. of Conn. Med. Soc.*, 1889).

This theory of the origin of diabetic coma is undoubtedly in the main correct, but diacetic acid as well as oxybutyric acid is to be regarded as a co-agent in the production of coma. In a specimen of diabetic urine examined by the writer 76 gm. of diacetic acid was found by the method given in a previous paper. This amount of acid was excreted during a period of only six hours and it is readily seen that the twenty-four hours excretion might easily reach 125-150 gm. When it is remembered that this quantity of acid is equal in acidity to about 70 gm. of concentrated sulphuric acid it is understood what an enormous amount of ammonia would be necessary to render it inert. As was stated in a former paper, over 16 gm. of ammonia was present in the six hour sample of urine which showed this remarkable acidity and it is evident that the production of such extraordinary quantities of ammonia could not be long maintained. The patient passing this sample of urine died from pneumonia about 48 hours afterward. In regard to cerebral symptoms, it was often noticed in the case mentioned that they varied directly with the intensity of the ferric chlorid reaction; that they appeared synchronously with the appearance of this reaction and almost disappeared upon the ferric chlorid test becoming greatly diminished while under a mixed diet. The cessation of the intense cerebral symptoms, on allowing carbohydrates in moderation and accompanying the decrease in the excretion of diabetic acid, was most marked. From a condition bordering on coma the patient within a few hours regained the use of faculties entirely, while his headache, vertigo, neuralgia, etc., either disappeared or greatly improved.

While it is believed by the writer that the theory that diabetic coma is due to an acid intoxication is correct, there are various bodies and processes which must also receive consideration. The great tissue oxidation in diabetes is closely allied to, and resembles, the katabolic changes in certain high and exhausting fevers. In fact, from their close resemblance in this respect, diabetes is essentially a fever without temperature. The urines of such affections, besides containing acetone and diacetic acid in quantities which in general are not sufficiently great to induce coma, contain various alkaloids which have been shown to possess exceedingly toxic properties. In diabetes, the leucomain creatinin has been found to be greatly increased in amount and it is believed that an excessive production of toxic alkaloidal bodies may contribute to the production of diabetic coma. The shock to an already depressed nervous system, caused by an excessive metabolism and the presence in the blood of large amounts of effete material must also be taken into account. Coma diabeticum, therefore, should be regarded as directly caused by a toxemia resulting from an abnormally excessive decomposition of albumin, both systemic and ingested, and its occurrence should therefore be retarded or prevented by limiting such albumin decomposition as far as possible.

In the treatment of simple glycosuria all exciting and predisposing causes should be discovered and removed. All nervous excitement should be carefully avoided and a tonic treatment combined with plenty of sleep, moderate exercise and hygienic living, should be instituted. There need be no exclusion of carbohydrates from the diet under any circumstances.

The treatment of diabetes mellitus, it can not be too strongly insisted, should not be directed toward the elimination of the sugar present in the urine, but rather toward the abnormal metabolic changes by which this sugar is produced. As should be most evident, the mere presence of glucose in the urine does not constitute the disease but rather the morbid conditions under which the excessive production and consequent presence in the blood of this abnormal quantity of sugar is rendered possible. What the writer believes these conditions to be has been detailed in a previous article. The severity of a diabetes is not therefore to be estimated according to the quantity of glucose excreted but rather by the rapidity of metabolism, digestive disorders, abnormal and toxic constituents of the urine and finally, of the greatest clinical importance, the cerebral and nervous symptoms. It must be remembered that the sugar excreted is only a symptom of the tissue katabolism going on within the organism, provided the patient is ingesting considerable quantities of carbohydrates. If on a proteid diet, he may still be diabetic and yet for a time excrete no sugar, it being produced from albumin within the capacity of the system to completely oxidize it. If ingesting carbohydrates and excreting no sugar the patient can not be diabetic. It has been shown in a former paper that the asthenic and toxemic condition of the diabetic is due to an excessive metabolism, partly induced in the natural course of the disease and furthered by artificial conditions of diet. Such being the case the treatment of diabetes will have one great indication—to retard and prevent as far as possible any excessive oxidation of albumins, either ingested or systemic.

In regard to diet, as has been shown, a strictly proteid diet, instead of removing, may even increase the dyscrasia of a true diabetes, nor, in advanced cases, will it be efficacious in its only object, the disappearance of sugar from the urine. As the effects of a rigid proteid diet have been detailed in a previous paper, it will only be necessary in this connection to state that a purely proteid diet should under no circumstances be employed. Foods of all varieties, provided they be nutritious and wholesome, should be allowed, although of course no excesses in eating should be permitted. Moderate amounts of carbohydrates in the form of bread, oatmeal, or rice should be by all means encouraged. Alcohol in moderation should be given, both on account of its stimulant and supporting properties as well as its well known power of retarding tissue metabolism. Moderate exercise should be directed and cheerful society insisted on to prevent the patient, as far as possible, from falling into that condition of melancholia and nervous depression which so frequently accompanies this affection. Sleep should be induced, if necessary, by hypnotics. The bowels should be kept open by laxatives or enemata, and any treatment having the slightest tendency toward depressing the system should be most carefully avoided. As for medication, since diabetes is essentially an affection due to an exhausted and depressed nervous system, tonic doses of phosphorus would be indicated. Strychnin from its well-known action of promoting metabolism, should be avoided. All drugs which have been shown to retard metabolism are indicated. Among these are antipyrin, codeia and arsenic. An advanced case of diabetes, however, should in our present knowledge be looked on as an incurable affection and the attention given to conserving the strength

and resources of the patient, delaying tissue waste and as far as possible lessening the liability to coma.

With regard to diabetic coma the writer does not hesitate to state his belief that an exclusive meat diet is in many cases entirely responsible for the occurrence of coma and that in a large majority of cases a fatal ending by coma is hastened by artificial and abnormal dietetic conditions. The treatment of coma, therefore, should be prophylactic and identical with that directed toward a retardation of albumin decomposition, since it only occurs through the action of the toxic by-products resulting from an excessive metabolism. Should, however, the coma be threatening or actually induced it has been recommended by Stadelman and Kirstein (*Wochenschrift für prak. Med.*, 1889) to employ at once large intravenous injections of alkaline solution, say 30 gm. of sodium carbonate in one liter of distilled water. This treatment has two objects, first, to neutralize any free acid which may be present and, secondly, to keep the blood in a normal condition of fluidity and dilute, so to speak, any toxic agents present. This injection should be slowly continued as long as the pulse of the patient shows toleration or until the urine excreted becomes alkaline. If necessary it should be repeated. This treatment should be employed as early in the coma as possible, since the chances of success decrease progressively with the length of time during which the coma has existed and consequently the length of time in which the oxy-acids and other toxic bodies have acted. This treatment of coma has been tried in a number of cases with only a small proportion of permanent recoveries but with general improvement and returning consciousness in nearly all these cases, the consciousness in many instances continuing for as much as 48 hours. These patients, after regaining the entire control of their faculties, again relapsed into coma and so died. This was explained by Minkowski (*Deutsch. med. Woch.*, Nov. 1889) on the ground that an almost irreparable damage had been done to the nervous centers upon the induction of coma. He advocates this treatment in all cases in which there are severe cerebral symptoms.

Intercurrent affections should be considered without reference, in most cases, to the existing diabetes and should be treated according to the complications and indications which may arise. Diabetes brings in its wake no secondary affections except such as may be induced in any exhausted and non-resistant organism.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

VII.—THE RISE OF GERMAN SURGERY UNDER AUGUST
GOTTLIEB RICHTER.

(Continued from page 1025.)

Göttingen at this time was full of animation. Heine was summoned from Saxony to follow out Winkelmann's ideas regarding ancient literature. By studying the same he wished to cultivate the heart and the mind and awaken a taste for all that is beautiful and good. As one of the first men, Germany owed him a renewal of the literary studies and a coterie at Göttingen, who upon German education exercised an immense influence. Moreover, there were

the bright sparks of humor scattered by the highly talented Lichtenberg, who, of Richter's age, was a professor since 1770. There was also the Göttingen alliance formed about this time (1772), who lay a certain amount of claim to the resurrection of the national literature. That Richter showed an interest in the poetical effusions of Voss, the two Stollbergs, Bürger and others, and that he was a friend of the poets, like his colleague, Kästner, the mathematician, nothing is said. Nor that he was also a friend of the king's sons and of the Dukes of Cumberland, Cambridge and Sussex, who studied in Göttingen from 1786 to 1791. Soon a great literary activity was displayed among the entire medical faculty of Göttingen. Besides Vogel and Richter, Murray, Baldinger and Blumenbach began the publication of their journals for specialists.

Gradually Richter's lectures covered more ground, also that of medicine, and during the years of 1770-1790, when he had obtained his prime of life, his courses were on the following topics: 1. Special therapeutics every day for half a year, that is, during the winter term on acute, during the summer term on chronic diseases, at first making use of Gaubius' theories. 2. Surgery, on which he lectured daily for half a year at the hospital; in winter on medical and in summer operative surgery, "so that he practically demonstrated the same." 3. Ophthalmology daily, sometimes privately, sometimes publicly. 4. Diseases of the bones, during the winter session twice every week, open to the public. 5. General therapeutics. 6. Semiology. 7. Dietetics, publicly. 8. On directions given daily in the hospital for clinical, practical exercises. Now and then, during the first few years of his courses he lectured on several chapters of physiology and guided examinations in surgery. When more advanced in age Richter continued principally his medical lectures and discontinued those on surgery, held for six months at a time, and only occasionally gave a lecture on ophthalmology; hence Arneemann delivered lectures on parts of surgery, of instruction in operations and instruments, of syphilis and of diseases of women and children; and Wardenburg lectured on instruction in bandaging and surgical medicines, pharmacology and on legal medicine. Himly taught special pathology, ophthalmology, also medical surgery. C. M. Langenbeck, anatomy, instruction in operating and bandaging, ophthalmology, on diseases of the bones and directed courses in operating on cadavers. This subdivision of the lecture courses, as well as the establishment of various clinics, lessened the professorial duties of Richter as he grew older. His success as general practitioner grew day by day; those who were given up by others came to him as a last resort. Patients from distant lands, and even princes sought his advice. He was especially noted for his gentleness of touch in operations.

In the summer of 1786 he undertook a trip to Switzerland and France. While in Paris he attended the meetings of the surgeons. He arrived in Vienna in the month of September, 1802, and was present at the sessions of the Joseph's Academy.

When Richter became a regular professor he married the very beautiful daughter of a ship-captain, Hoop, and lived very happily in the corner house on Jüden- and Kupfergasse, with his dear Jettie, who was very fond of wearing a string of real pearls in her hair above her forehead. She was unedu-

cated, fighting a continual battle with foreign words; furthermore, she was penurious, although she entertained much and put on great style. She died in Göttingen in the summer of 1833. Three children were born to them: Augusta Louise in 1772, Christiana in 1775 and George August in 1778. The latter became professor of medicine in Berlin and Königsberg, where he died in 1832.¹

The daughter, Augusta Louise, married, on Christmas, 1792, the Crown Prince of Saxony-Weimar's privy counselor, body physician and medical science professor of Jena, Justus Christian Loder.²

Of Richter's personality we know but little. His portrait,³ which was taken in his 54th year, and which was presented to him by his pupils, shows a powerful face with marked features, having a pleasant, good-natured expression. His friendly countenance, as well as his agreeable and polished way of speaking greatly captivated his patients. Goethe, who met him in Pymont in 1801 in the company of Prince Sanguszko, who was suffering with sore eyes, described him as, "Always being in the most amiable mood, full of dry humor, teasing and bantering, now ironical and paradoxical in his remarks, then again deep and sincere." The sunny side of his more advanced years is also shown in the following humorous letter:

GÖTTINGEN, Aug. 25, 1807.

My Dear Mr. Counselor Runde:—With pleasure I accept your invitation to assist in the coming operation of the "driving out" of his Satanic Majesty and the "driving in" of the Holy Ghost into your recently born daughter, and I will not be found wanting, in case his majesty should show a disposition to defend himself. For this operation you could not have chosen a better assistant, for you are aware of my religious spirit and know that I am somewhat experienced in operating. But I do not as yet know whether we will chase Satan, for he must have an abode somewhere, as we are not capable of depriving him of his existence. To send him, in the usual way, to the herd of swine, we do not dare, because they might become rabid and plunge into the water where they would drown and we would have to pay for them—unfortunately the times are too hard just now for such extravagance.

Yet you have a good sturdy baptizer. For in the end he must be excellent when called upon to bear the brunt. To say that I felt good about the matter I would have to lie about it. The girl is to be named Lenore, and I do not know how it is, but the name Lenore always makes me shudder a little. The Devil seems to especially approve of the Lenores.

For the rest I heartily congratulate you on the increase of your family and am delighted to hear that Hanchen is so well.

Here, we do not know ourselves how we are. Today Martens and Blumenbach go to Paris as representatives of the Academy to make their obeisance to the King of Westphalia. My wife sends her best regards. Your obedient servant,

A. G. RICHTER.

¹ George August was educated under his father's strict supervision for the medical profession and in the year 1800 received from him his doctor's degree. He was then sent on a journey for five years, his father's fame procuring the warmest welcome for him everywhere. Much of his time he spent in Vienna with P. Frank and in Paris with Dupuytren, who was then beginning his brilliant career. Returning home, he complied with his father's wishes and went to Prussia, passed the state examination in Berlin, where he settled as practical physician in 1805. A few years later when the university was established he received the appointment to deliver lectures on general and special therapeutics, etc. In 1813 he enlisted as military physician in the war against France, directed the hospitals at Torgan during the following year, and after the close of the war became regular professor in Berlin. Then he accepted a similar situation in Königsberg. In 1821, where he established a medical polyclinic, which he conducted for eight years at his own expense, until he obtained a subsidy. He died of apoplexy. His quiet but persevering activity, his uninterrupted diligence, enabling him to publish a work of several volumes in a short time, deserve special mention. His daughter, Fran von Hannecken, lives in Berlin at the present time.

² It is said that this union with the widower was an unhappy one, for when Loder, who was rather extravagant, went to Russia, Augusta Louise's parents forbade her from going with him and protected her property by a deed of feoffment. Mrs. Loder never saw her husband again, and afterward lived with her mother in Göttingen. Her daughter Bertha married a Herr von Lützow in Schwerin; her son August died in 1818.

³ Drawn by Schulz and engraved in copper by Lips. Other portraits of him are found on the frontispiece of his fifty-second volume of the "Allgemeine Deutsche Bibliothek" and of his "Manual for Physicians," which appeared in 1783, and one was done by Schwenterley in 1792.

Richter was a trifle egotistical and was wont to estimate everything according to the advantage to be derived therefrom; being naturally rather self-conscious, he was gratified with his own art. Yet he never mentioned his achievements for German surgery, nor spoke of his brilliant cures, a very common practice among lesser lights. If the reader is not fond of anecdotes, he may pass over the following trivial occurrences: When Professor Hegewisch of Kiel, afterward counselor of the University there, attended Richter's lectures and told the same where he was from, his teacher answered that in passing through that region on his way to Sleswick (to attend to a cataract operation at the court of the Landgrave of Karl von Hessen) he found it to be a dreary and barren tract of country. Hegewisch replied that the rear of the Duke's estates was, indeed, only prairie, but along the coast the land was very fertile and the scenery of various portions grand. Thereupon Richter replied: "Like an old coat with laces." About the year 1780 the well-known physician, Olbers of Bremen, received a letter from him, "written in the usual rude style, concerning nothing but an intended cataract operation." There are eight specimen letters of but little importance in the Göttingen library; the following written by Richter when a young professor, was a complaint made to the rector of the University against Surgeon Tolle for his bungling cure and improper conduct, of which he himself had been accused:

GÖTTINGEN, Feb. 29, 1768.

Magnifice Academicæ Prorector:—Your excellency will kindly permit me to communicate a case which seems to demand your attention. Three weeks ago I was summoned by a woman whose name is Kayserin and who had the previous day fallen heavily on her left arm. She had immediately called in Surgeon Tolle, who, after having looked at the arm, told the patient that it was broken in three places, whereupon she was terribly frightened. Then he put a thick compress lengthwise on the inner side of the arm and a similar one on the outside, and around these tightly wound a bandage at least eight yards long. Soon after this dressing the pains increased, the arm stiffened and, especially the hand swelled so that it turned blue, and Mrs. Kayserin was compelled to send again for Surgeon Tolle the same evening to change the bandage and relieve her pains. But he did not come until she had sent for him two or three times, and then did nothing more than loosen the same a little. The following day the patient summoned me; found the arm in the condition mentioned above and the hand still very much swollen. After a careful examination I told her that the dressing was wrong and harmful, that the bone had not been fractured. This statement gave her courage and confidence and she requested me to undertake the cure, which I promised to do. Mr. Tolle did not visit her, but sent word that he ought to know best when the arm needed bandaging. On the third or fourth day the patient notified Surgeon Tolle that his services were no longer required. On hearing this Tolle hastened to her home and entered her room so boisterously, keeping up such a tirade and stamping with his feet for an hour that the poor woman, who is consumptive, trembled from head to foot with fright. Among other things he said she treated him like a boy. When she told him I had assured her that her arm was not broken he said: "If it were broken, could I not cure it as well as Professor Richter?" He had to be a professor, too, some day. A few of the bandages which I had loosened and thrown onto the table he snatched up and hurled them out of the window on the street. Yes; even those which the patient had around her arm, he wanted to tear off and throw them out. Seeing a prescription which I had written for her on the table he asked who wrote it. The patient replied, "Professor Richter." He took the recipe, put it into his pocket and said she should get his compound. To say nothing of his improper language; that he behaved unmanly to the patient and other people in the house will bear witness to. The honorable body physician, Vogel, and his students, to who I presented my patient a few days ago, can testify that the arm was neither broken nor sprained. I believe that this case should have your excellency's attention, for not only did Surgeon Tolle frighten and deceive his patient with his incorrect statement of an existing fracture, but also

increased the harm done to her arm by his unskilful bandaging. Furthermore, through his boisterous actions he caused the patient's condition to become very critical a few days afterward, when she suffered with fever, sleeplessness, sweats and other afflictions; so that I had considerable trouble to bring her about again. Besides, I believe I have good reasons to demand satisfaction from Surgeon Tolle on account of his disgraceful language and behavior toward me, and all the more, inasmuch as this is not the first time that I have caught Tolle with such improper conduct. I leave him to your judgment, your excellency, and remain your excellency's obedient servant,
AUGUST GOTTLIEB RICHTER.

Until he grew quite old Richter enjoyed sound health, with the exception of a few attacks of gout. During his activity at the hospital he became very sick with spotted fever by infection and attributed his recovery to purgatives alone. Podagra he declares to have had at least fifteen times *in optima forma* contracted by cold or fright, usually in the joint of his big toe; yet he did not consider himself gouty. Ever a poor pedestrian, his feet pained him after short tours. After a serious inflammation of the joint of the middle finger, the same always remained thick and stiff. The attacks of gout were often so painful that, when he traveled to Cassel to attend a patient, he had to be lifted out of the vehicle, but taking a few glassfuls of strong, old wine, he was able to walk with ease to his patient's home an hour and a half later.

His fame spreading more and more, his honors grew apace. Several times he was elected prorector; in 1770 he became an associate and in 1776 an active member of the Royal Society of Sciences. In 1780 he was appointed body physician and two years later from the Palace of St. James he received a patent from George III. as follows: "We certify and acknowledge that We, in behalf of the learnedness and other good qualities Our body physician and professor medicinæ of Our University Göttingen, August Gottlieb Richter, commended to Us, have shown him the grace of bestowing upon him the designation of Our Privy Councillor." He had the title of consulting physician of the king of Westphalia, which honor he shared with unimportant men and hence was no honor. Several of the learned men dictated their works to him; for instance, Privy Councillor Nicolai, the first volume of his "Theoretical and Practical Treatises"; Wardenburg dedicated a portion of his translation of the Desault bequests, published by Bichat, and in no friendlier and more sincere way could he have expressed his gratitude to his dearest teacher. Abroad, Richter was the best known German surgeon. Perusing the first pages of Samuel Cooper's "Dictionary" we can see how often his name appears in connection with various articles. This frequency was also caused by the translation of several of his works. From the years 1775, 1777 and 1792 on we find him recorded as a member of the Royal Swedish Academy and the medical societies in Copenhagen and Edinburgh. To show his gratitude he dedicated the first volume of his "Medical and Surgical Remarks." In 1806 he became a member of the Society of Medicine in Paris.

His prominent position brought him in contact with the best contemporaries. At Göttingen the most friendly relations existed between him and Blumenbach, living together almost forty years. The dedications of his works disclose to us with what men he was on intimate terms. They were: A. V. Haller, Acrel, Theden, C. C. Von Siebold, Voitus, Leber, Starke, Rougemont, Bilguer, Weidmann, Morenheim, Hartenkeil, Goerike, Brünninghausen, Plenk and

Stoll. Although his life in general was very peaceful and flowed along without any great and shocking events to disturb it, he, too, had to learn that dogs bark at him who rides fast. But what man of talent has no enemies? We smile at him who follows in the path of science only at a distance; he who walks apace is looked at repugnantly and he who outstrips the others is despised. During the first years of his professorship Richter could not get along with Baldinger, who became regular professor of medicine in Göttingen in 1773 and was Richter's colleague for nine years. Also as a critic, he was not spared the petty literary attacks. These began with the first volume of the *Surgical Quarterly* by Professor Henckel of Berlin, whom Richter took to task, saying that the first part of his treatise on "Surgical Operations" had been carelessly written and with too little consideration, regardless of arrangement and connection. The second part he found executed in the same manner as the first; then passed a similar judgment on the third, and of the fourth he simply said: "It is the same old story." These disparaging criticisms from the pen of a young surgeon, which were severe yet always genteel, the old gentleman, Henckel, did not wish to stand and defended himself with a sledge hammer:

"The learned Professor Richter, the only one who censured me! Gently, gently, Professor! I honor you as a learned man! also as a surgeon; but *quantum est quod nescimus*. How can a learned man write so ungentlemanly! You live at one of the most famous universities and are daily surrounded by the most learned and most famous men! What will these gentlemen think of your great babble? Were you not a member of the same and did I not deem it a disgrace to myself, I would pay you back in your own coin. My dear Professor, I honor you on account of your numerous achievements. Do away with such baseness and vengeance! They do not improve the sciences. Drop all nonsense of that kind. Had I insulted you in my writings, you might have quoted those parts and published my superficiality in science whereby you would have obtained the greatest satisfaction from the learned profession; but you should do it in a wise way, that is for irrefutable reasons in honor of the profession and for the good of science. *Hic Rhodus, hic salta*. But I was amazed to find that you dared write such remarks about me. Do you know who I am? (Pardon this question.) Do you know what once happened to that newspaper editor? But I will here leave the matter and assure you that you will not have cause to fear anything further from me regarding the above. (Treatise on Surgical Operations—Part 4, 1772.) "Your friend."

It is a noble trait of Richter's character, that a few years later, after Henckel's demise he wrote the following magnanimous laudation: "This is the last writing of a very active, skilful and learned practical surgeon, of an experienced man, well read and full of enthusiasm for his profession, who, regardless of the lack of a few literary talents, achieved much for German surgery and whose memory I cherish and recommend to my readers, unmindful of the few literary disagreements Henckel and I had."

Another opponent who would not endure Richter's criticism was Professor Alix of Erfurt, who insulted him in the most vulgar fashion. But the young Göttingen professor did not allow himself to be disturbed thereby. Later he once more became involved in a violent quarrel, which his enraged opponent carried on with intense coarseness. In 1793, when the fourteen year old Prince von Wied had dysentery and was treated by the court physician, Hartung, with opium, he nevertheless grew so much worse that the court physicians Brüning and Wendelstädt of Wetzlar, were consulted. Both greatly opposed to opium, could not agree with the family physician, and believed that the sleep which had set in was due to the 100 grains of opium administered by Hartung and calumniated him as a poisoner throughout the city. Hartung appealed to Richter, who had recommended the use of opium

in cases of dysentery in his "Medico-Surgical Remarks," only a little while before this occurrence. Hartung acquainted him with the facts and begged his advice. Richter approved of Hartung's course, whereupon the latter very indiscreetly published his letter without his knowledge or consulting his wishes. This so enraged Wendelstädt that he wrote Richter a series of six letters, so immoral and so indecent that they were left unanswered. In 1794 Brüning published this filth in his work on the injuriousness of poppy juice in dysentery. He deserves that his name be blotted out entirely and it is sufficient for us to know that Richter came out victorious, having, as always, conducted the strife with great moderation. Unfortunately, this incident resulted in Richter, whose works had always been received with great enthusiasm, ceasing all publications henceforth. That he allowed himself to be discouraged and that he wrote no more, was weakness on his part, in spite of the great wrong done him; for he was only 51 years old.

His son admits that the bitter controversy, which his recommendation of opium, in cases of dysentery, had occasioned was the cause that the second volume of his "Medico-Surgical Remarks" did not follow the first directly. During the latter years of his life, the old gentleman loved peace; this is probably the reason that we have not heard of his interference in the frequent strifes among the students which took place at Göttingen during the period of 1790 to 1808. He disliked nothing more than literary strifes that afterward became personal onslaughts. Repeatedly his son begged him for the manuscript of the second volume until 1811, when his father finally yielded and sent him the same to Berlin accompanied by the following lines: "These matters were really intended for the second part of my 'Medico-Surgical Remarks;' however, I no longer have a desire to publish books and look upon my literary course as closed. Now-a-days if one wishes to please as an author, he must write in high-flown language; clearness and distinctness are no longer liked; but I can not do so and care not to learn it in my old age; thereby most physicians wear the spectacles of their theory on their noses, do not believe what they can not explain in their studies, but believe absolutely everything that belongs to their system; they are deaf to all carefully considered experiences. I therefore present you with this manuscript and permit you, in compliance with your wish to have the shorter treatises published in the 'Journal' of your friend, Professor Wolfart." When a year after the death of his father, the son faithfully published this part without any additions whatever, the book was universally considered invaluable throughout Germany. Richter became prematurely old. Had Richter been able to follow out the great ideas which threatened to overthrow all the old ones in England, then he would not have permitted his activity to be stayed by the younger, but unimportant surgeons, like Arnemann and Wardenburg, nor by the rising Langenbeck. Thus it was that in his more advanced age, he was more physician than surgeon.

Although over 70 years of age he was still very active and almost over anxious about the care of his health. Having suddenly taken ill with a severe attack of hepatitis, expodagra retropulsa, he died within a few days, on the morning of July 23, 1812. For forty-six years he had been a professor at Göttingen. With the words "festively buried," found in the church registry of July 26, ended the story of his

earthly career. Where his grave is, is uncertain. Just so much recollection remains of it as Hamlet's grave-digger had of Yorick, the king's jester, whose skull he recognized after twenty-three years, and the two grave-diggers at Göttingen would at least know whether the monument with the inscription, "Privy Councillor Richter," placed in the Albini Cemetery a few years ago, marked the true resting place, or whether the burial in the family vault in the St. Johannis Cemetery was really that of Richter's body. On August 22, for the departed one, Professor Mitscherlich, in the name of the Akademie, held memorial services, which he accompanied with Latin verses composed by himself (Pis manibus A. G. Richteri pia Acad. Georgia Augusta). A meeting was called for October 24 by the Society of Sciences expressly in memory of the deceased members, Heine and Richter; the latter's friend, Blumenbach delivered the memorial address.

Surgery in Germany owes its elevation and progress to Richter. Yet those who are anxious to see great discoveries by which the territory of science has been extended or guided into a new channel, seek in vain, for Richter's researches did but little to promote surgery. His achievements lie scattered throughout various fields and are, therefore, less sharply brought to light.

Richter was the first German to assimilate the ideas of French and English surgery and bring German surgery abreast with the times. In that respect he was an exception to the field surgeons' methods, which then still clung to the German surgeon and from which even C. C. von Siebold, Theden, Schmucker, Langenbeck and Brüninghausen could not be exempted. He rose far above these and became a model for Germany. He comprehended all that had been accomplished by the Parisian Académie de Chirurgie, but also much that had been suppressed in the bud. Richter knew of the great rise England owed to the founding of the Royal Society, to Wren, Newton and Stephen Hales; he was familiar with the best everywhere, with one exception. He did not appreciate John Hunter. This was a weakness of his. After Haller's astonishing works, he ought to have achieved more; outside of a scissors, he did not invent or discover much, but he combined and completed what others invented and discovered and transplanted it on German soil. This was his great work, of value only to Germany, but which earned for him a most honorable position. His sound and pointed judgment, his thorough but modest critique, combined with the spirit of truth and the freedom of science, were the means by which Richter exerted such vast influence over the scientific world of Germany. But before the shapeless, yet giant hand of a John Hunter, and even before the reforming spirit of a Desault, whom Richter himself acknowledged as the greatest of the then living surgeons, he had to withdraw.

Richter simplified operations.—While Heister had recommended a chaos of ill-shaped and useless instruments, Richter considered this outfit mere display, and thought it greater skill to perform the various operations with the scalpel alone. But he was ever ready to accept a new good instrument, and bade his colleagues and scholars to purchase for him anything truly useful which they might come across in their travels. He added nothing new of any consequence, for his were only modifications of other instruments. To these belong his angular bandage scissors, a pair

of nippers for polyps, an improved tracheotome, an amputating knife, a cystitome, a herniotome, an artery hook and others. How well German surgery was equipped with instruments, is shown by Tilly's "Catalogue," published in 1764 in Berlin, which contained 523 illustrations. Richter believed that at least 400 of them were useless and dispensable. Although the English instruments were considered the best, there were also a few German manufactures, for instance those of the mechanician Lütz of Würzburg, which were very fine. Most of the younger surgeons interested themselves almost exclusively for operative surgery, and thus greatly neglected the cure of many diseases by medicine. To be able to name all sorts of instruments, especially the most modern discovered by some one in France but scarcely known in Germany, to know every operative method, was all that was required for a young skilful surgeon of the times. Richter greatly opposed this tendency. When he informed Morand that the latter's rupture knife was pictured in various German text-books, he was astonished to find that this youthful invention of his was valued in Germany. Richter demanded a thorough knowledge of the origin, nature and course of a disease, matters about which few concerned themselves, without in the least underrating the operative ability of the surgeon. But he deemed it important, yes, even more so, to avoid operations and cure injuries without them if possible. How little knowledge was necessary for some operations, he said was proven by the wandering oculists, rupture surgeons and lithotomists, who seldom possessed more than their mechanical skill, knowing little of the anatomy of the case in hand, but nevertheless successfully performed some of the most serious operations. Every blockhead, he thought, could trepan and amputate, but to diagnose head injuries, heal complicated fractures of the leg without an amputation, or to discover the causes of or relieve an ugly ulcer, could only be accomplished by the profound, deep-thinking surgeon. The proper application of surgical medicines requires by far more ingenuity and knowledge than the art of operating. Inasmuch as surgical pathology was being neglected in the largest hospitals, he feared a decline of true surgery, if this rushing blindly into an operation continued among the surgeons.

As an author Richter was unsurpassed; he wrote in a very choice literary style. This was a great thing at a time when all the physicians were discussing the point whether the Latin or their mother tongue be the most appropriate for scientific works. Did he study Lessing's works, the "Literary Letters," "Laokoön" and "Dramaturgie," which appeared shortly before the beginning of his literary career, read them and make this classic prose his prototype? No other German physician's style compares with Richter's.

(To be continued.)

SOCIETY PROCEEDINGS.

Illinois State Medical Society.

Abstract of the Proceedings of the Forty-seventh annual meeting, held at East St. Louis, May 18, 19 and 20, 1897.

FIRST DAY—MORNING SESSION.

The society met in the Music Hall, and was called to order at 10 o'clock by the President, Dr. A. C. CORR, of Carlinville. Prayer was offered by the Rev. J. J. READER, of East St. Louis.

An Address of Welcome was delivered by the Hon. M. M.

STEPHENS, Mayor of East St. Louis, which was responded to by President CORR.

After the reports of the Executive Committee, Committee of Arrangements, and Committee on Registration had been presented, the reading of papers were taken up.

SECTION ONE—FIRST SESSION.

Chairman, Dr. JAMES B. HERRICK, Chicago.

Secretary, Dr. J. O. DE COURCY, St. Libory.

Dr. R. B. PREBLE, of Chicago, read a paper entitled

ARTERIO-SCLEROSIS AS IT AFFECTS THE HEART,

and exhibited specimens. The vascular cardinal changes may be conveniently classified in three groups; 1, those in which the coronaries are diseased; 2, those in which the valves of the heart are affected by the process; 3, those in which the heart is hypertrophied, but otherwise unchanged. In the first group we find the areas of anemic infarction of the myocardium due to thrombosis of the fine twigs of the coronaries. Death may result, but more often the infarcts are replaced by scar tissue giving rise to the chronic fibrous myocarditis. The scars may yield and an aneurysm of the heart result. These and other effects were illustrated by specimens furnished by Dr. Hektoen from the Rush Medical College Museum.

Clinically the cases of atheroma of the coronary arteries may be arranged in groups according to the systems most prominent in the course. In one group the angina pectoris with its radiating pains is the marked feature. It is necessary to distinguish the true angina from the pseudo angina seen in nervous cases, in intoxication especially with tobacco, and reflexly from diseases of the stomach, liver and other organs.

A second group are characterized by attacks of acute pulmonary congestion with dyspnea. A third group by suddenly or slowly developed signs of cardiac insufficiency. In still another group, rapid or slow or irregular heart's action, either constant or paroxysmal, is the marked feature.

There is no sharp line of separation between these various groups, for they merge into each other, and usually almost every case will show something of each group of symptoms.

Brief reference was then made to some points of difference between the valvular lesions due to arterio sclerosis of the valves and those due to endocarditis.

Dr. FRANK P. NORBURY of Jacksonville, followed with a paper on

ARTERIO-SCLEROSIS AS IT AFFECTS THE DRAIN AND SPINAL CORD.

The author said that arterio-sclerosis was by no means a rare disease, but it had only been within recent years that it had received the clinical attention it deserved. Thayer of the Johns Hopkins Hospital had informed us that it was seldom that an individual over 40 or 45 years of age was free from some evidence of the existence of this disease; also, that in the negro race it was a more common disorder than in the white.

The etiology of arterio sclerosis was not always clear, but we know that it may originate from the natural widespread fibrosis and degeneration or old age, from alcoholism, syphilis, tuberculosis, gout, rheumatism and diabetes, and further that inherited arterial degeneration may be a factor. Also purely local conditions may cause it, such as undue strain upon the vessels or from constant mental worry and anxiety, and even neurasthenic states may engender it.

Little reports two cases of cerebral degeneration with calcareous formations, following anxiety and mental effort. The author believes that arterio-sclerosis is usually a fundamental condition in such cases.

He next dwelt upon the pathology of the disease and considered it at some length.

A characteristic case was reported as follows: Patient, a male, aged 60, was for a number of years an inebriate. No syphilis. About two years ago he first complained of headaches, later dizziness, and then his friends noticed lapses of memory. Important business engagements were forgotten and papers misplaced. Later ataxic aphasia (transitory) appeared; also a slight glossoplegia; next slight facial monoplegia, which still exists; then profound vertiginous attacks followed by syncope. Then mental confusion, then delusions of suspicion, and finally some violence. He was then admitted to an insane hospital where he believed he was imprisoned for an imagined crime that he had committed. He became very emotional, slept poorly and was very restless. The motorial agitation together with other psychical symptoms leads Dr. Norbury to believe that the lesion especially embraces the motor and frontal regions. So-called senile dementia is really chronic cerebral atrophy.

Dr. E. J. BROWN of Decatur read a paper on

ARTERIO-SCLEROSIS AS IT AFFECTS THE KIDNEY,

in which he said that most observers now agree that the kid-

ney changes accompanying a general arterio-sclerosis are secondary to the latter disease. Some, however, still hold to the theory that all sclerotic changes in the blood vessels are secondary to a primary fibrous change in the kidneys; that the latter organs share with the heart, the brain and the liver most serious pathologic changes in most cases of general arterio-sclerosis. Bright himself noticed that chronic renal disease is often associated with hypertrophy of the left ventricle, and all subsequent investigators have confirmed his observations. Grainger Stewart found cardiac hypertrophy in 46 per cent. of the cases of granular contracted kidney, Loomis in 60 per cent., Dickinson in 74 per cent. and Gallabin in 80 per cent. Strümpell is inclined to regard the effect of a general arterio-sclerosis upon the kidneys as much less important than the effect of that disease upon the heart and brain, and he mentions only the "granulated senile kidney" as being due largely to atheroma of the renal arteries. In fact, in speaking of the etiology of arterio-sclerosis he ranks chronic nephritis with alcohol, syphilis, rheumatism, gout and lead poisoning as causes of that disease. Whether the kidney lesion is primary or secondary, there is no doubt but that renal symptoms occur sooner or later in the majority of cases of general arterio-sclerosis. In nearly all of the cases coming to autopsy, according to Osler, there is seen a sclerosis, patchy or diffuse, a condition practically that of contracted kidney. It is seen in a typical manner in the senile form, and not infrequently develops early in life as a direct sequence of the diffuse variety. He further states that it is difficult to decide clinically whether the arterial or the renal disease has been primary. We may be suspicious of a renal disease in every case where we have the four signs of a general arterio-sclerosis which are regarded as pathognomonic, namely, increased arterial tension, palpable thickening of the arteries, hypertrophy of left ventricle and accentuated aortic sound.

With reference to the prognosis, it depends upon the age of the patient, the etiologic factors in the disease, and especially upon the stage of the process affecting the renal tissues.

He then reported two cases illustrating two forms of general arterio-sclerosis, in one of which there was a predominance of renal symptoms, and the other with prominent renal symptoms, but with a fatal termination due to circulatory changes.

Dr. HENRY B. FAVILL of Chicago contributed a paper on

TREATMENT OF ARTERIO-SCLEROSIS,

which was read by Dr. Preble in the absence of the author. All treatment must find its reason in the consideration of three general factors: 1, the cell and its natural endowment. 2, the character of the supply from which the tissue derives its support; 3, the controlling influence which determines its nutrition and functional activity.

The common factor in the various types appears to be defective food metabolism. The active agency inducing this defect varies. We find it in the over-fed and in the under-fed, in the inactive and in the over-active, in the young, middle-aged and old. In its earlier stages it is usually associated with good digestion, rarely with dyspepsia. It is a post-digestive development. The most constant factor in a series of cases is evidence of incomplete disposal of nitrogenized material. Chemically we determine this by the short excretion of urea. This means short manufacture of urea, or defective separation of urea, or both. Clinically we detect the condition in symptoms of nitrogenic intoxication, the so-called uric acid manifestations. It is by these that our attention is primarily attracted, and in the analysis of these that we are enabled to demonstrate early arterial change. That the true toxin is uric acid is doubtful; that the toxic agents generated in this way are several is highly probable. These facts are not asserted as ultimate. Unless lightly held as provisional data, they are likely to mislead. They do, however, furnish the clinical characteristics, more or less demonstrable, which serve as a basis for the conclusion that the essential agent in this process is toxic, and for the most part auto-toxic.

The treatment of this stage of the disease is essentially hygienic. The initial proposition is, how to adapt the individual to his environment. In general the elements of food and physical expenditure are at fault. The food should be adequately introduced and thoroughly eliminated when no longer useful. Decided failure in either direction is destructive. For any given individual, "is his food adapted to his work?" should be asked. To meet this query, what do you demand? That his eliminating organs yield the proper representation of his ingesta. Clinically we have well recognized evidences of toxemia by which to measure the condition. Believing that the toxic agents are nitrogenous, we have approximate means in the estimation of urea and total nitrogens excreted in the urine. Marked departure of these from the standard average of health

demands explanation and correction. Given a good digestion, a mixed diet may be right or wrong according to its amount. Clinically we encounter, as a rule, the necessity to diminish the nitrogenous food, or to change the form of its use. That the struggle against this gradual toxemia is better accomplished by attention to this line of procedure, the speaker had not the least doubt. Practically it amounts to the gradual adoption of a mixed milk and vegetable diet, and experience fully warrants the advocacy thereof.

THE INDIRECT TREATMENT OF DISEASED HEARTS.
