Serous cysts have been confounded with dermoid, mucous or branchial cysts, although they do not, like those cysts, occupy a definite region corresponding to the branchial fissures. The neck is their seat of predilection, and they serve as a type of their description; when they are single or unique, they are almost always on the median line and on the left side; they occupy principally the antero-lateral surface of the neck; they are never as large on the median line, but may be of the size of an orange. Median cysts sometimes spread on both sides, but one side is noticeably larger; sometimes they descend on each side of the chin like a long beard, giving the little patient the strange appearance of an old man. These cysts may exist on both sides; when multilocular they have no special site; when multiple they resemble a bunch of grapes; sometimes their walls are so thin as to be actually absent. They differ from the pure dermoid cysts of the region by containing no hair and no sebaceous substance. Some are lined with ciliated epithelium; they are usually median cysts; they contain water or thick yellow matter. Dermoid or sebaceous cysts or atheromatous cysts are only truly such when the dermoid structure of the cyst walls can be well demonstrated. They may attain the size of a fist; when lateral, they occupy mostly the region of the sternomastoid; when median, they occupy mostly the supra- and infra-hyoid regions between the hyoid bone and the thyroid cartilage; the median cysts are sometimes a little to one side. They are often subcutaneous,

although Langenbeck says that in the neck dermoid cysts are more frequently deeply seated than in other regions and are often adherent to the muscles, ligaments, nerves, cartilages, and even to the vertebral column. They are uni- or pauci-ocular cysts; they sometimes contain hairs, seldom cartilage or osseous tissue; when they discharge they often leave fistulous openings. The sanguineous cysts at times are connected with the anterior jugular vein; they contain a reddish fluid which characterizes them upon exploration; occasionally they remain in connection with vessels. They are emptied by pressure, but they refill rapidly; they must not be taken for aneurysms when the vessels impart pulsations to them. Hemorrhagic sanguineous cysts are due to intracystic hemorrhages. Punctures and incisions are sometimes followed by intracystic hemorrhage, which may ultimately end fatally. The lateral serous cysts are the worst, because they become the largest and send more and deeper processes. Polycystic cysts, when extensive, are beyond treatment. Hydatid cysts are not so necessarily congenital as the serous. Bursal cysts call for the same remarks; they are usually over the hyoid bone, the thyroid and cricoid cartilages. Puerulent cysts or chronic abscesses of the neck may be due to lesions of the glands or of the surrounding bones and cartilages; although slower in their development they are subject to all the changes presented by the acute abscesses above described; they sometimes originate in the sheath of the sterno-mastoid.

The solid tumors of the neck are the following: Deep hematoma with clotted blood due to violent contusions, to punctures and ruptures of the deep blood vessels or to a cured but non-absorbed aneurysm, are occasionally met with. They can be diagnosed by their history, by the exploring needle; they are to be treated by incisions or by gradual dilatation on a guide if they occupy dangerous regions. Sebaceous cysts may so invade the deep tissues as not to be easily separated by the fingers from the deep parts; they are sometimes comparatively rather hard from high tension; the contents are almost fluid, yet the fluid is too thick to run through an ordinary exploring needle. Dermoid cysts present the following features: Branchial dermoid cysts of the neck are almost always of the simple type, *i. e.*, sebaceous matter and little hair, sometimes oil. The complex cysts containing osteo-cartilaginous masses are not really true cysts. Median branchial dermoid cysts of the suprahyoid region belong more properly to the floor of the mouth; these are often attached to the symphysis by a hollow or solid pedicle. Median branchial cysts are the most common mucoid cysts of the neck; their epithelium is cylindrical and sometimes ciliated. Dermoid cysts are frequent here; the cyst may be attached to the trachea. These cysts are not bursal cysts; the epithelial lining shows they are congenital; they are all congenital, but they may not become manifest except at a later period, especially at puberty. Lateral branchial cysts usually occupy the region of the sterno-mastoid. Median branchial suprasternal cysts sometimes penetrate into the mediastinum. Median thyro-hyoid cysts often take on a rapid growth at puberty or after a confinement; they are often opened by mistake, and this is followed by persistent fistula with mucous secretions. Lipomata are not uncommon; they usually send fibrous prolongations between the muscles and the vessels, extending sometimes to the bones, hence the difficulty and danger of their removal. Simple adenoma or

pure hypertrophy, is not rare. Strumous adenoma is not rare. Adenoma of Hodgkin's disease or multiple adenoma should not be extirpated except to relieve pressure symptoms. Syphilitic adenoma is of frequent occurrence and is found most commonly along the sterno-mastoid or in the posterior region. Syphilitic gumma is not rare. Encephaloid, colloid and melanotic are rarely primary; when primary, they are perhaps developed in the sheath of the vessels and not in the glands; they are almost always due to infection secondary to lesions on the face or the internal cavities. Pulsating encephaloid is extremely rare on the neck. Solidified hematoma resulting from contusions or punctures or ruptures of the deep vessels, or from solidified but non-absorbed aneurysms, are not very uncommon. Simple adenoma or lymphadenoma is the only incontestable primary tumor developed in the neck. Strumous adenoma and tuberculous adenoma are very common; usually they are secondary and the original lesion is found about the face, neck, mouth, nasal cavities or throat; they usually form a chain and sometimes a long solid tumor; they usually ulcerate the skin by a granulomatous infiltration; recurrences are frequent. Schüller recommends for them eight or ten drops of guaiacol after each meal in milk.

Primary syphilitic adenopathy of the neck is seen in cases of chancre of the lips and tonsils; it is usually submaxillary. It is peculiar in that it rapidly acquires a large volume, which is an important diagnostic point. Secondary syphilitic adenopathy is common, especially at the nucha; that is the place to feel the pulse of syphilis, says Ricord. They are usually in the groove between the trapezius, in the fossa of the nucha and in the mastoid region, and are usually due to a lesion of the scalp, but may develop under the influence of the poison in the blood. Tertiary adenopathies are rare; they assume the sclerotic or gummatous form. Syphilitic adenoma presents the same features also, especially in elderly people. Lipoma of the neck presents the following forms and varieties: superficial or deep, the deep have been observed near the large vessels, near the carotids, also in the peripharyngeal connective tissue; congenital lipoma, diffuse and adherent, or not, to the bones; lipoma with a broad base; lipoma with a narrow base, pediculated (one weighed twenty-nine pounds). Diffuse lipoma affects the nucha specially and may encircle the neck; congenital and symmetric lipomata have a neuropathic origin. Fibroma is rare; it rises from the fibrous layers, bones, sheath of vessels, sometimes is embryonic. Congenital branchial fibrochondroma of the neck is seen in all regions of the branchial arches. It occupies almost always the external orifice of a congenital fistula, a little above the sternoclavicular articulation. Myxomata and myomata are rare; one case of chondroma is on record, following chondroma of the scapula; those independent of parotid and lymphatic glands are very rare; some tumors are very large; they may adhere to the vessels and to the deep structures. Cutaneous plexiform neuroma is frequent in the neck. Osteoma is also frequent. Carcinoma, primary and independent of larynx, pharynx and glands, is rare; it may develop in the aberrant lobes of the thyroid. Some are deep, having developed from the branchial arches. Epithelioma is usually secondary to epithelioma of the face, larynx, tongue, pharynx, esophagus, tonsil, pleura, lung or breast. One or two enlarged ganglions, hard, without pain, appearing toward the age of 50, are likely to be an epithelioma.

Sarcoma of the lymphatic glands is very rare, because sarcoma is propagated through the veins. Scirrhus is rarely primary; it is oftenest secondary to other affected parts. *En résumé*, the infectious granulomata of the neck are tuberculous, syphilitic, leprous, glanderous, actinomycotic. Actinomycosis and glanders first show in the submaxillary and cervical glands.

(To be continued.)

SOCIETY PROCEEDINGS.

New York Academy of Medicine.

The New York Academy of Medicine held its semi-centennial celebration on Friday evening, January 29, at Carnegie Music Hall, under the Presidency of Dr. JOSEPH D. BRYANT. The following were the officers on the occasion referred to:

Committee on Arrangements.—Dr. William M. Polk, Chairman; Drs. Robert F. Weir, Charles McBurney, D. B. St. John Roosa, Wm. T. Lusk, A. Alex. Smith, Edward G. Janeway, Landon Carter Gray, Edward D. Fisher.

Committee on Invitation.—Dr. John H. Girdner, Chairman; Drs. Egbert H. Grandin, Clarence C. Rice, Charles Inslee Pardee, Prince A. Morrow.

Committee on Entertainment.—Dr. Daniel Lewis, Chairman; Drs. M. Allen Starr, Clement Cleveland, Nathan E. Brill, H. Holbrook Curtis, Arthur M. Jacobus, T. Mattack Cheesman.

The feature of the evening was an address by the President of the United States, the Honorable GROVER CLEVELAND, which we reproduce verbatim. The President, it would seem, has a very clear idea about the functions of a physician in general as well as of a citizen. It is worthy of reproduction here as a very wholesome tonic to those who hold that the moment a man enters the profession he should forego his citizenship and thenceforward be a political enunch.

PRESIDENT CLEVELAND'S SPEECH.

President Cleveland spoke as follows:

"I have anticipated the share assigned to me on this occasion with considerable trepidation for various reasons. I have been chiefly disturbed, I believe, because of my inability to discover satisfactory grounds for my right to join those who celebrate the semi-centennial of a medical association.

"If, in passing through that period in boyhood when the desirable choice of future activity seemed to rest between running away from home to be a sailor and staying at home to be a doctor, I inclined toward the more quiet and orderly of these pursuits, this surely furnishes no basis at this late day for a claim of relationship to the medical fraternity. Nor do I forget that less than seven years ago I was accorded the privilege of participating in the exercises when the corner-stone was laid of the building which is now the home of the organization which tonight celebrates its half century of useful and honorable existence. But this incident, which aroused an interest still undiminished in the welfare of the Academy of Medicine, hardly entitles me to a share in the felicitations of those who have since borne the heat and burdens of its work while I have enjoyed the ease and happiness surrounding public station.

REPRESENTS THE LAYMEN.

"In confessing, therefore, that I have no right to even standing-room within the inner circle of the profession, I have boldly and without the least authority determined to speak to you as a representative of the vast army of patients and laymen.

"At the outset, I desire to remind you that you owe us much. Though largely in the majority, and with plenty of members to spare, those who are well conducted among us do not vex you with hurtful competition. Instead of making life hard for you by an observance of the laws of health, we assist you by indulging in all sorts of irregularities. We are obedient and submissive to your commands—that is, when we are sick—and we sometimes pay your bills even after a recovery to health, which we are always certain would have resulted without your interference.

"In these circumstances, if when in perfect health we venture to assert ourselves and tell you what is in our minds, it is not fair to liken us to a certain personage who when sick a saint would be, though very differently inclined when well.

"We begin by conceding most heartily and without the least reservation the learning and skill of those now constituting the medical profession, and the wonderful advance that has been made through their untiring labors and investigations in the alleviation of human suffering and the saving of human life.

TRIBUTE TO THE VILLAGE DOCTOR.

"It may be this seems to you an acknowledgment so much your due as to be hardly worth making. You should, however, value it because it is sincerely made by those who were not born yesterday, but who hold in lasting and tender memory the ministrations of the village doctor of fifty years ago, and are now the living monuments of his faithful care. He, too, alleviated suffering and saved human life. We know that it was not given to him to see the bright lights that now mark the path of medicine and surgery, but you can not convince us that he groped entirely in the dark. We remember without abhorrence his ever-ready lancet and the scars of his blood-letting found in every household. We endure with complacency the recollection of his awful medicine case containing bottles, powders, and pills, which, whatever might be thought of them now, seemed then to be sufficient for all emergencies—to say nothing of the tooth-pulling tools and other shiver-breeding instruments sometimes exposed to view. If he was ignorant of many of the remedies and appliances now in use, he in a large measure supplied the deficiency by hard-headed judgment, well-observed experience and careful nursing. Besides, it was in his favor that he did not have to bother his head with many of the newly invented and refined diseases that afflict mankind today. He had no allotted hours for his patients, but was always on duty; and we knew the sound of his gig as it rattled past in the night.

"Your ways are better than his; but we desire you to regard this admission as all the more valuable because it is carved out of our loyalty to our old village doctor, who brought us through the diseases of childhood without relapse, who saved from death our parents and our brothers and our sisters in many hard combats with illness, and who when vanquished and forced to surrender was present in the last scene to close the eyes of his dying patient and sympathize with those who were present.

FAITHFUL IN ALL TIMES.

"I hasten to say that we do not for a moment suppose that advancement in the science of medicine and surgery has smothered the faithfulness and tender consideration which characterized the practitioner of former days. If we seek charitable service to the sick and suffering, a noble appreciation of obligation to humanity and self-abnegation in the discharge of professional duty, we must look for them among our physicians and surgeons of today.

"If we have now arrived at an understanding, you are, I hope, prepared for a suggestion quite in keeping with the extremely moderate and reasonable disposition that characterizes the patient and layman. You have invaded our benighted contentment and led us out into broad fields of scientific discovery. This has inspired us with a new-born spirit of wisdom and criticism which demands that new and larger fields be opened to our complacent gaze. You have penetrated the places where the germs of disease are hidden. We are quite certain that you should be required to destroy the origin of disease and ultimately usher in the day when the only escape from the world will be through a passageway marked: 'Old Age. Exit.' If this has the appearance of exacting too much, or if business considerations present obstacles to its accomplishment, I think we ought, perhaps, to reduce our claims, or at least give our doctors time to find other employment.

WORK FOR THE FUTURE.

"In the meantime, those of us who are conservative must be allowed to hope that further investigation will continue to point the way to the prevention of disease. For this investigation we must still rely upon the efforts of those who have already done so much in that direction, encouraged and stimulated by such effective organizations as the Academy of Medicine. We are sure that this work, having arrested the attention of the world's brotherhood of medical science, will not be neglected; nor need we fear that America's contribution to splendid results will be deficient.

"In some instances, however, investigation has performed its part and only effective action in other quarters is necessary to supply needed remedies. In such cases, of course, you are absolved from all responsibility in your professional character by exhibiting dangers and warning against them. Thus certain diseases which you deem contagious yet remain imperfectly isolated. You have demonstrated the peril to health of unwholesome water and noxious surroundings; and yet much remains to be done by way of protecting our people against these dan-

gers. You have established a code of ethics which condemns charlatanism in all its forms, and yet ignorant pretenders roam over the land offering to perform miracles, or are located in our towns and cities, preying upon the weakness of the sick and afflicted, while men and women are allowed to lie without medical attention, deluded with the hope that faith will save them in their last extremity. Within the limits of your professional power and influence you seek to restrain any approach to criminal malpractice; yet newspapers disgustingly though covertly advertise the way to such crimes and startle their readers with sensational tales of death and misery to which they are directly accessory.

PHYSICIAN AS CITIZEN.

"I need not suggest that such evils are allowed to exist by reason of the insufficiency of our laws or a laxity in their execution. I have intimated that for this condition you are not responsible in a professional sense, but are you sure you are doing all in your power as citizens to remedy the situation?"

"The village doctor was not only our physician, but he was a man of influence in all neighboring affairs. In every matter that concerned the good of the community he was at the front. He was president of the village or represented his town in the County Board of Supervisors, and if he was ever late in visiting a patient it was because he lingered at the postoffice to discuss the political situation. Thus he joined with the performance of professional duty a discharge of the obligations of citizenship.

"We can not but think that the discoveries and improvements in medical practice which we now enjoy are dearly bought if the members of the profession, in their onward march, have left behind them their sense of civic obligation and their interest in the general public welfare. We can not accuse you of utter neglect of your duty to your country; and yet we can not keep out of mind the suspicion that if your professional work in exposing evils were more thoroughly supplemented by labor in the field of citizenship those evils would be more speedily corrected.

UROED TO TAKE PART IN POLITICS.

"If laws are needed to abolish abuses which your professional investigations have unearthed, your fraternity should not be strangers to the agencies which make the laws. If enactments already in force are neglected or badly executed you should not forget that it is your privilege and duty to insist upon their vigorous and honest enforcement. Let me also remind you of the application to your case of the truth embodied in the homely injunction: 'If you want a job well done, do it yourself.'

"If members of your profession were oftener found in our National and State legislative assemblies, ready to advocate the reformatory measures you have demonstrated to be necessary and to defend your brotherhood against flippant and sneering charges of impracticability, the prospect of your bestowal upon your fellowmen of the ripened results of your professional labor would be brighter and nearer.

"While thus suggesting the need of your influence in legislative circles for the accomplishment of reforms related to your profession, you will, I hope, permit me, in conclusion, to enjoin upon you the duty of an active and general interest and participation in public affairs for the promotion of your country's good in all its phases. Our government was founded in the faith and anticipation that those who loved it most and were best able to hold it steady would be at its helm. Without this it will surely go astray. Never did patient need your medical treatment more than the body politic now needs the watchful care of your patriotic and disinterested citizenship.

"No object or personal ambition and no activity of professional life should be permitted to withhold from our government the tithe of devotion and service due from its thoughtful, intelligent and educated citizens. The reward of a willing recognition of our obligation to watch and protect our free institutions and preserve them from weakness and decay, will surely come when a just government supported by the patriotism of a loving people shall bestow with equal hand upon us and all our countrymen the blessing of national peace, contentment and happiness."

SELECTIONS.

The Tribulations of the Medical Profession in France.—We are all more or less dissatisfied with the state of things in the medical commonwealth in these realms; it is interesting, therefore, if not particularly comforting, to note that our brethren in some foreign countries are even as we are in this respect. There is

France, for instance, where it is sometimes said the profession occupies a more fortunate position. If we are to believe a distinguished journalist—M. Hugues Le Roux—we have no reason to envy our French *confrères*. M. Le Roux has recently discussed in the *Figaro* the question, Shall our sons be doctors? He answers it, implicitly, with an emphatic negative. In the first place it is not easy to become a doctor. M. Le Roux estimates that, reckoning in the expenses of preliminary education, it costs something like £1,600 to get the diploma. Then comes a weary period of waiting for patients, entailing further expense. If a practitioner starts in a country district he has to face the local "vet.," the *curé*, the bone-setter, and the blacksmith; and he is called in only hopeless cases, so that, with a confusion between cause and effect natural to the untutored mind, he comes to be looked upon with suspicion as a kind of Angel of Death. In towns there are the hospitals, which not only give indiscriminate relief to people of the working class, but take paying patients at charges varying from 2 to 12 francs a day; in these receipts the medical staff has no share. Then there are the clubs, which can always get doctors to serve them at 2½ d. a visit. There is also the competition of unqualified practitioners. In spite of the law—on paper—against the unlicensed practice of medicine, Paris swarms with herbalists and "curers" of all kinds, and the vilest quacks advertise their wares in the newspapers without let or hindrance. M. Le Roux states that there is in a certain town a priest who professes to have a secret remedy for incurable diseases. His door is thronged with patients from 5 A.M. to 8 P.M., and appointments have to be made two or three weeks beforehand. This clerical healer is said to hand over £4,000 each year to his archbishop for the purposes of the Church; what he keeps for himself is not stated. The pharmaceutical chemists, with their various "specialities" and plausibly written pamphlets vaunting their efficacy, are also formidable rivals to the legitimate practitioner. The attempts which have been made by medical associations of different kinds to remedy these evils have so far failed; and, indeed, it is not easy to see how there can be any real betterment in the state of the profession so long as it is overcrowded. If M. Le Roux's article deters any considerable number of parents from making doctors of their sons, it will have served a useful purpose. It might not be amiss if some popular journalist were to enlighten the mind of the British *paterfamilias* on the same subject.—*British Medical Journal*, December 5.

Treatment of Heart Troubles. Schott's *Gymnastics and the Nauhaim Baths*.—The *Therap. Woch.* of January 3 contains a comprehensive, practical and theoretical article on this subject by Sir T. Grainger Stewart, Professor of Clinical Medicine at Edinburgh, in which he describes the fine results he has seen accomplished at Nauhaim, with directions how to secure the same at home. He states that there is no group of diseases in which so much can be effected by the physician in relieving and restoring the organs to their normal condition, as in disturbances due to functional derangements of the heart, but that the secret of success is careful discrimination of the appropriate treatment for each individual case. The Nauhaim methods will not supplant the traditional treatment with rest, diet (especially the change to the dry diet recommended by Clark and Oertel) and medicines, in which digitalis takes the lead. But they supplement them with advantage, and used alone or in combination, are of great assistance in the task. Tobacco should be entirely avoided, or only used to a very slight extent after a meal. Alcohol taken regularly, in small amounts and with the meals, is beneficial in cases of heart weakness, especially those consecutive to diphtheria, etc., or caused by old age. The best form is whisky, from 6 to 60 grams once to three times a day, never exceeding 220 grams; the slightest excess is particularly injurious. If taken between meals it should be combined with milk, or better, with milk

and the beaten white of an egg. The importance of exercise is becoming more generally recognized, and benefit is derived from passive gymnastics (Swedish, massage, etc.), which he ascribes to the improvement in the circulation of the lymph in the tissues, as also to the mechanically increased flow of blood through the muscles. Patients are able to stand this form of exercise who would be injured by active gymnastics. But in almost every case the active gymnastics with limited resistance, devised by Dr. Schott of Nauhaim, prove wonderfully effective. They consist of a series of carefully regulated movements, performed slowly and moderately; no movement of any member or set of muscles is allowed to be performed more than once at a time and absolute rest follows each single or combined movement. The movements are not to be such as to accelerate the breathing, and the physician in charge is on the watch for the slightest distention of the nostrils or contraction of the corners of the mouth, change of color in the lips, yawning, perspiration or palpitation. If any of these symptoms appear, it is a signal for the immediate cessation of the movement in course of performance, and the member is at once supported, or otherwise brought into repose. The patient is instructed to breathe regularly and without interruption and in case this is difficult for him, or he holds his breath for any reason, he is reminded to continue breathing and during each movement to count in a whisper. The clothing must be loose so as not to interfere with the circulation. By observance of these rules there is no disturbance of the respiration or heart action, and auscultation and percussion before and afterward convinced Professor Stewart that in a large number of cases the heart sounds grew more distinct, while the area of dulness was perceptibly decreased; the rhythm of the pulse was much improved and the beat stronger. This immediate effect passes away after a while, but the heart seldom returns to its previous dilated condition and remains smaller than before the gymnastics. One case was a Russian official, who came to Nauhaim with debilitated heart action, anasarca, some ascites, slight hydrothorax and in all probability also hydropericardium. The left border was 7 inches from the median sternal line and the right more than $1\frac{3}{4}$. Dr. Schott did not hesitate an instant to order the active gymnastics for him, although the case seemed too advanced for this in the writer's opinion. He was present when it was carried out. The patient displayed considerable nervousness at first, and for moment a disposition to faint, but quickly recovered, and the gymnastics were continued. The seance lasted twenty minutes, and examination afterward showed that the apex beat and the left limit of the dulness had receded $\frac{3}{4}$ of an inch toward the center, the right $\frac{3}{8}$ and the upper border $\frac{7}{8}$. In one month from the commencement of the treatment the patient was completely restored and could climb quite high eminences. The apex beat was in the mamillary line. When seen a year later he was constantly improving, with no trace of hydrops, although he had taken no heart tonics nor medicine of any kind. Similar results were observed in so many cases that Professor Stewart has introduced the system into his own hospital and private practice, with much better results than from passive gymnastics. He ascribes the benefit derived from it to the chemical and physical changes it accomplishes. The circulation is mechanically accelerated and the exercises stop just short of the point at which any extra effort is required of the heart itself. The Oertel mountain climbing exercise is adapted to less severe cases, or to those which have graduated, as it were, from the passive and active gymnastics, but the writer has no personal experience of the method.

A very important factor in the Nauhaim cure are the baths. The waters are saline, 28 to 35 degrees C. in temperature and the patients find them very refreshing. They can be artificially prepared by adding $1\frac{3}{4}$ kg. of salt and 250 grams calcium chlorid to 250 liters water. This corresponds to the bath first given,

when the duration is eight minutes. Another is given in two days, after which they are given twice in three days, then three in four days, increasing the length to twenty minutes or half an hour and the strength of the bath by more salt, while the temperature is raised to 30 degrees C. After twenty or twenty-five of these baths a "sprudel" or effervescent bath is given, containing a quantity of free carbonic acid, or a "sprudel" bath in flowing water. This effect can be obtained artificially by adding to the bath described above one package of "Sandow" powders and tablets for a "sprudel" bath and two for a "sprudel" flowing bath. Examination of the patients before and after the baths demonstrated the same decrease in the area of dulness, increased energy of the pulse, etc., as after the gymnastics, while tests of baths in ordinary Edinburgh water produced no such effect, nor even in salt solutions at the same temperature, but as soon as the "Sandow" powders were added to the water and carbonic acid liberated the same results were secured as at Nauhaim, showing that it is the combination of these substances that produces the favorable results, probably owing to some action on the nerves. The Nauhaim cure commences with the baths, which require less exertion of the patient than the gymnastics. He is dried carefully with warm towels by the attendants and protected from taking cold, the feet being kept especially warm. He then takes slight refreshment and rests an hour or more.

Professor Stewart concludes by stating that he finds puncture of the pleura of surprising benefit in many cases of hydrothorax which diuretics have failed to relieve, with even the removal of only a small quantity of the fluid which has been causing dyspnea by its pressure on the heart. In many cases the fluid was found in much larger quantity than the dulness indicated. Ascites required puncture also, but is less satisfactory than the pleural operation. Successful drainage with the Southey canula will often prolong life, but he only resorts to it in extreme cases, on account of the low vitality of the punctured skin. Complications in the digestive apparatus are treated with suitable medication, massage of the abdomen, etc. Torpidity of the liver is often cured by purgatives and external stimulation, acid bandaging and the internal administration of mineral acids and taraxacum. The alteration in the blood requires appropriate iron or arsenic medication, and it is important in every case of cardiopathy to investigate the number of red corpuscles and the amount of hemoglobin, so as to meet any alteration with the proper remedies. The condition of the lungs must also be carefully watched, especially for indications of edema, which must be dispelled by more or less powerful external applications, if possible. Bronchitis also affects the heart action. The patient is sometimes waked up in the night with dyspnea, due either to the condition of the heart or lungs. The best remedies here are whisky in hot water, milk or soup, Hoffmann's drops (ether); in extreme cases subcutaneous injections of ether, strophanthus or strychnin. Counter-irritants in the lung or heart region and cupping are also often useful. In extreme dyspnea and cyanosis from inflammatory disease of the respiratory organs venesection is indicated and the resort to this in time often saves the patient's life. Cutaneous edema is treated as usual, supplemented by massage of the lower extremities and bandaging the limbs, beginning at the toes. Torpid action of the kidneys is treated with non-irritating diuretics, energetic heart treatment and counter-irritants over the kidneys. Sleeplessness is often cured by taking a few ounces of beef tea with a little whisky or brandy just before retiring. Opiates must be avoided that exert a depressing effect on the heart, but benefit is derived from chloral and large doses of potassium bromid, morphin, paraldehyde, sulfonal and trional, and even chlorodyn in some cases. One patient has been taking the latter every day for a year with good results and no inconveniences. Pains in the region of the heart are relieved best by nitrite, but also by opiates and local

applications. The same treatment is indicated no matter what the lesion may be to which the enfeebled condition of the heart is due, except when there is reason to suspect that an inflammatory valvular lesion is in an advanced stage with degeneration of the cardiac musculature, in consequence of lesions of the coronal arteries. In this condition extreme circumspection in the use of gymnastics and tonics is required, and the main dependence must be on absolute rest with the administration of arsenic and potassium, the latter, combined or not, with ammonium carbonate. He has never seen unfavorable results follow the administration of digitalis in lesions of the aorta.

PRACTICAL NOTES.

Surgical Treatment of Deafness.—When deafness is due wholly or principally to some disturbance in the transmitting apparatus, it can be cured by an operation, according to Garnault, consisting of the excision of the tympanum, ablation of the hammer and incus and mobilization or extraction of the stapes, performed through the mastoid. Rinna's test allows the cases that would be benefited by the operation to be distinguished from those that would not. Garnault states that every case of the kind in which the cranial perception of the diapason is superior to the aerial perception, should be operated.—*Bulletin de l'Acad. de Méd.*, December 29.

Acute Otitis of the Middle Ear, Complicated with Mastoiditis, Cured with Antistreptococcus Serum.—A girl of 8 was brought to Wodon for treatment, with a temperature of 39.5 to 41 degrees C., pulse 140, intense headaches, insomnia, tendon spasms and agitation, with numerous streptococci in the pus from the ear. Twenty cubic centimeters of antistreptococcus serum were injected in the inside of the thigh and an improvement was evident the next day. The temperature fell; the discharge from the ear gradually diminished and finally ceased; the mastoid region lost its inflamed appearance, and in ten days the child was entirely cured. The disfigurement from trephining was avoided, and as Wodon remarks: "Our conduct is henceforth traced for us."—*Presse Méd.*, from the *Presse Méd. Belge*, No. 44, 1896.

Morphino-Cocain Anesthesia.—Ceci has used a combination of morphin and cocain in 544 cases, and recommends it in high terms as invariably successful. He administers a maximum dose of 2 centigrams of morphin fifteen minutes before operating on adults, and half this amount for children, and cocain at 2 per cent., warmed. Contrary to Reclus' method, he makes deep injections. He considers this method of anesthesia indicated in all cases when the field of operation is not too extensive or vague. He does not use it for children or easily excited, intractable persons. But in operations on the bladder, urethra, foot, leg, etc., it renders especial services, and lasts from thirty to fifty minutes. There are no accidents from its use, merely a dryness of the throat and thirst after maximum doses, with slight psychic excitement.—Reported at the Italian Surgical Congress, *Presse Méd.*, December 19.

Serum Treatment in Chronic Rheumatism.—A curious fact, observed by Cassin, is quoted in the *Journal de Médecine*, August 10, which refers to a case of chronic rheumatism treated by injections of Cheron's serum. The patient was a man, aged 49, who had been suffering from chronic rheumatism since he was 37, all the joints being successively affected, and where no result was obtained by any therapeutic method, arsenic, salicin, etc., proving useless. Cheron's serum was then tried, 5 to 10 c.cm. being injected daily either into the deep muscles of the back or the tissues round the affected joint according to the part affected. The result was surprising, the patient being able to resume the movement of the joints. It would seem that the rheumatic condition continued, but its effects were kept in abeyance by the regular use of the injection.—*British Medical Journal*, December 5.

Etiology of Infective Diseases.—Numerous facts have demonstrated that contagious diseases can originate without contagion. We know that the germs can live normally in various ambient media, the cavities of the human organism included, until some unknown cause rouses them to virulent action. Kelsch states that it should be the task of science to determine the causal circumstances, cosmic, hygienic, telluric or whatever they may be, as much as to determine the germ themselves. All prophylactic measures should aim to improve the media until they become unfavorable for the development of the germs, the cavities of the human organism included, and local and individual hygiene should supplement the preventive isolation, etc., which now constitutes our prophylaxis of infective diseases. His study of the subject is an interesting contribution to epidemiology; it is published in full in the *Bulletin de l'Acad. de Méd.* of December 22.

The Bicycle and the Kidneys.—The *Gaz. degli Osp. e delle Clin.* of December 24, describes some recent investigations of the urine of healthy subjects before and after bicycle riding, which showed in half of the cases such an abundance of albumin and cylinders of various kinds that the diagnosis of acute or chronic parenchymatous nephritis would certainly have been made by anyone unacquainted with the circumstances. It is evident that the condition is what Leube designates as physiologic or functional albuminuria, with the difference that Leube and Senator state that there is no traces of cylinders in physiologic albuminuria, while in eight riders examined, members of a bicycle club, tube casts of all kinds were found in abundance in all but two, with more or less albumin in all. Four other riders gave out after an hour and a half or three hours ride, and in two of these the urine was normal; in the other two it was moderately albuminous, with no casts. Five healthy boys also showed albumin in the urine after riding. The writer concludes that the frequent repetition of such experiences can scarcely fail to terminate in chronic nephritis sooner or later.

When to Operate in Appendicitis?—The surgeons now claim this trouble exclusively and do not hesitate to assert that intervention is always necessary to prevent immediate or future dangers. Immediate operation is indicated in diffuse peritonitis from appendicitis as cases have been known to recover with it, and it offers the only chance. Aside from these acute cases, the moment for intervention is, in children as early as possible after the diagnosis has been made. In adults the third or fourth day, during which time medical treatment should be employed, ice, opium, caffeine, serum and calomel in fractional doses, with constant surveillance to operate promptly if alarming symptoms occur. If the pus does not issue with gentle manipulations, it is exposing the patient to grave dangers to prolong them. The pus will flow in two or three days if a loose mèche of iodoform gauze is inserted. The appendix is easily removed in children. In adults if it is not visible and can not be felt with the finger, it is not prudent to prolong the search, and the operator should not hesitate to leave the appendix imbedded in its false membranes.—L. Beurnier, *Journal de Méd. de Paris*, December 27.

Electricity in Obstetrics.—O. C. Sudlow announces that he has found faradization useful in promoting delivery, arresting hemorrhage and assisting in the expulsion of the placenta. Its principal effects are: 1, its sedative action, enabling it to take the place of chloroform and chloral; 2, its oxytocic action, hastening parturition by increasing the strength and the effectiveness of the natural uterine contractions; 3, it favors the expulsion of the placenta and arrests uterine hemorrhage. The sedative effect was obtained eight times in twelve and the oxytocic nine times. In twenty cases out of twenty-seven the expulsion of the placenta was materially assisted, and hemorrhage was promptly arrested in three cases out of four. The best abdominal electrode is the hand of the operator, but a flat.

sponge covered with a sheet of rubber can be substituted. The positive electrode is placed on the sacro-lumbar region and the negative on the abdomen, or they can be applied on each side of the uterus, with the precaution that the current does not pass through the child's head. The sedative effect is obtained with ten to fifteen minutes of the current, gradually increasing the force until it is felt without pain. When an oxytocic effect is desired, the current should be applied stronger and intermittently, stopping just short of actual pain. To favor the expulsion of the fetus a feeble current should be applied as soon as the child is delivered.—*Presse Méd.* from the *Revue Int. d. Electrothérapie*, August and September, 1896.

The Sound in Diagnosing Renal and Ureteral Calculi.—The symptoms of calculi in the urinary passages are often deceptive, presenting sometimes the picture of intestinal occlusion, etc. But if purgatives are used as indicated for the latter, fatal collapse may be the result. For this reason Kolischer advises using the sound, as the presence of a solid body is easily recognized by its resistance to the instrument. It can also push an imbedded stone along into the pelvis of the kidney as indicated in reflex total anuria. (Hohenegg's case.) It may also possibly reduce the size of the concrement (Casper). Kolischer has also succeeded in causing the descent of the concrement into the bladder three quarters of an hour after injecting 3 grams of vaselin oil through a hollow sound. Injections into the pelvis of the kidney are easily made, but it does not seem practicable to irrigate it. He concludes his review of the subject in the *Wien. klin. Rundschau*, of December 27, by recommending repeated cystoscopy in the lull after an attack to prevent growth of the concrement. Mainzer also has been recommending cystoscopy in the *Berl. klin. Woch.* of December 7, especially for the female. It renders an exact diagnosis of urinary fistulas possible, helping to decide the three questions: 1. Are the ureters intact? 2. Where is the hole in the bladder located? 3. Is there such an opening? Cystoscopy is also valuable in helping to diagnose troubles in neighboring organs, perforated dermoid cysts, extrauterine pregnancy, etc. Landau combines the use of Casper's and Brenner's cystoscopes, after filling the bladder with sterilized water, and dipping the instrument in glycerin.

The Cure and Prevention of Curvature of the Spine in Pott's Disease.—Thirty-seven hunchback children have been relieved of their deformity without danger or serious complications by Dr. Calot, who recommends his method as absolutely without injury to the general health of the child. In the gravest cases he removes the posterior bony wedge that prevents the straightening of the spine. In two cases he was obliged to resect a wedge-shaped piece of the rachis. In the other cases the correction was accomplished by external maneuvers alone, preceded in some cases by the removal of the projecting spinal apophyses. The child is placed on its belly, under chloroform, and the spine is restored to its normal position by means of traction exerted on the ends of the vertebral column, while strong pressure is exerted on the hump at the same time. Two assistants pull at each end of the trunk, while Dr. Calot presses without fear and with all his might on the hump. The two segments of the vertebral column are thrown out of gear and straightened; the hump no longer exists! To maintain the correction a very tight and large circular plaster cast is applied at once, still under chloroform, to the trunk, descending from the head, as far as the pelvis, both inclusive. He ascribes the success of the operation to the care with which this cast is made and applied. The first cast is left three to four months, the second the same length of time, and occasionally a third. At the end of five to ten months there is no trace of the deformity left in most cases, while the health of the child has not suffered in the least. Dr. Calot exhibited several of his cases at a recent meeting of the Paris Académie de Médecine.—From the farewell number of the *Union Médicale*.

Recent Surgery of the Stomach Abroad.—Angerer of Munich has performed twenty-nine operations on the stomach, among them pylorotomy six times (three for cicatricial and three for cancerous stenosis). All died in three weeks except one, who recovered but succumbed to a recurrence of the cancerous affection seventeen months afterward. His twenty-three gastroenterostomies were more successful with the Hacker than the Wolfler method (one recovery in six operations by the latter method and nine in seventeen by Hacker's). Five patients gastroenterostomized for cicatricial stenosis resulted in two recoveries. One died from hemorrhage from a large ulcer in the pylorus and two from shock. The necropsy of one of the latter showed that the stenosis had been produced by the head of the pancreas, which had forced itself into the stomach through a perforation in the posterior wall. The seventeen operated for cancerous stenosis all died (three in one day; four in two; one in five, and the rest in from nineteen days to seven and one-half months). All the patients received liquid food from the very day of the operation, beside rectal alimentation. (*Presse Méd.* from *Munch. med. Woch.*, Nos. 42 to 45, 1896.) We notice that Obalinsky reported at the recent Polish Surgical Congress that he had resected the pylorus and part of the colon on account of cancer, with complete recovery of the patient in ten days. Schnitzler recently performed an exploratory operation on a patient (female, 35) for a tumor of the stomach which could be distinctly palpated, and had been causing great pain and vomiting of blood. When the stomach was exposed it was found in absolutely normal condition, but as he was inspecting it a tumor suddenly formed under his eyes in the pylorus region, 6 to 7 cm. long by 4 to 5 cm. in width, hard and completely obstructing the lumen. It was evidently a hysteric phenomenon or some reflex spasm from an ulcer or erosion of the gastric mucosa. The tumor was opened with a straight incision, but no deviation from the normal was discoverable and the opening was closed with an oblique suture to prevent the recurrence of the muscular contractions. The desired effect was attained, as the patient has been free from her troubles since. A similar "phantom tumor" in the abdomen is described in *Il Morgagni*, No. 10, cured also by an exploratory laparotomy.—*Wien. klin. Rundschau*, December 27.

Hematoma of the Dura Mater.—A very interesting but somewhat mysterious case is published by Dr. Munro in a recent number of the *Glasgow Medical Journal*. The patient was a cooper about 50 years of age, who was admitted to the wards of the Victoria Infirmary in January, 1895. He had been in his ordinary health a few hours before when he suddenly fell down in general convulsions. The seizures followed each other very rapidly, but after a time it was noticed that the convulsion became almost restricted to the right side, although the left leg was still slightly involved. Consciousness was not regained, and on admission it was observed that the mouth drooped to the right. Each fit commenced with conjugate deviation of the eyes and head to the right side, and then tonic, followed by clonic, spasm affected both legs and the right arm. No cardiac lesion was detected and the urine was not examined. The temperature rose to 106.8 degrees F. before death ensued. The condition of the brain found at the necropsy is of much interest. No significant abnormality was found in any other organ. When the dura mater was removed it was found to be lined on the left side by an adventitious membrane about as thick as itself, firm and adherent, although it could be stripped off. It was reddish in color and was not adherent to the pia-arachnoid except in the region of the left olfactory bulb. There was no evidence of hemorrhage to the naked eye and the membrane appeared to be of recent development. It clothed the inner surface of the dura mater, above, below and laterally. It was, however, absent from the left side of the falx and from the superior surface of the tentorium. Microscopic sections showed it to be much less transparent than the

dura mater. It consisted of several layers and its deeper half contained more pigment than the half next the dura mater. The pigment was reddish-yellow and was distributed in round or oval clumps of considerable size within cells. The basis of the membrane was a vascular and cellular fibrous tissue. The dura mater was not abnormally adherent to the bone on the left side. No other intracranial abnormality was discovered. Dr. Munro, in discussing this case, directs especial attention to the occurrence of what was apparently a hematoma of the dura mater in a patient not an inmate of an asylum. It is undoubtedly rare, and that this false membrane was the result of repeated hemorrhages is probably indicated by the fact that it could be easily separated from the dura mater and by the presence of pigment almost certainly derived from the blood, in the membrane. Such a condition has been described in connection with general paralysis of the insane. It has also occurred in infantile scurvy, but we are not aware of any other condition with which it is associated, unless we include a similar if not identical condition in syphilis. There was apparently no recent change in the condition which would account for the status epilepticus leading to the fatal issue.

Benzosol in the Treatment of Intestinal Tuberculosis, Secondary to Pulmonary Phthisis.—Dr. Kofron of Cleveland, in the *American Therapist*, December, outlines the case of a musician, aged 21, whose tuberculous affection appeared to date back two years. For five months, diarrhea with pain in the abdomen, flatulence and tenesmus had progressed so that he had often found it necessary to cancel engagements on this account, and because of the feverishness that came on in the afternoon, lasting until 11 or 12 o'clock at night. In January, 1896, he had a severe hemorrhage from the lungs, losing at least a pint of blood; this recurred in about two weeks, when he lost about two pints of blood, and was obliged to stay in bed for three weeks. After leaving his bed he found that he had lost 30 pounds in weight; was very weak, and was unable to follow his occupation. The annoying diarrhea and severe cough also continued. The physician previously in attendance examined the sputum and stated that tubercle bacilli were numerous. He took a good many creosote capsules, which had but little effect on the diarrhea; each movement was still accompanied with the passage of flatus and some tenesmus. Benzosol was begun in April, in four grain doses every four hours, and continued with apparent results for one week. He reported on May 8th, and thought he was somewhat better, as he did not pass so much gas when his bowels moved, although loose passages still continued. He then ordered benzosol, five grains four times a day, for one week, and after that five times a day; he had to report in about three or four weeks, or if worse to return sooner. He reported June 19, and said that he was getting along well; it had not been necessary to come before. Now his bowels move once or twice a day, and almost a natural movement without pain and very little gas; his appetite was greatly improved and his cough had become less severe, and he expectorated very little; the powders of benzosol four times a day, were continued. In July he was able to resume his work at playing the violin, filling four engagements each week, and stood the work very well. In September, he complained that his bowels were again loose, and wanted to know if he could not take some other medicine instead of the benzosol powders. To satisfy him, and as a control-medication, this remedy was discontinued and an emulsion of cod liver oil was prescribed. He returned October 1, saying that the diarrhea was even worse, as the movements were frequent, and the pain, flatulence and tenesmus had returned. He reported one week later, that he was decidedly worse, his bowels being looser than ever. He was again put upon benzosol, four grains four times a day, Dover's powder, 5 grains at bed time and a strict diet. He reported in October and November that he was again improving, and as well as he was before, being able to fill his musical engagements, with either violin or trombone, every evening, in some weeks. The writer is persuaded that the treatment by benzosol has been the agent effecting the marked improvement in his patient's condition.

Phloridzin Diabetes.—Phloridzin is a crystallizable glucosid obtainable from the bark of the stem and root of the cherry and some other rosaceous trees. That the sugar excreted by the urine after its administration was not derived from the glucose of its molecule was, however, clearly established by two facts, either of which would be sufficient: 1, that the quantity of sugar passed in the urine is far greater than the total amount of phloridzin administered; and 2, the complementary part—phloretin—left after the sugar is removed from the glucosid produces glycosuria. Phloridzin, it was to be remarked, produces a very severe form of glycosuria, the quantity of sugar in the urine being 40 to 50, or 80, or even over 100 per 1,000, according to Dr. Pavy, before the November meeting of the Physiological Society of London, as reported in the *Lancet* for December 26. Phloridzin causes glycosuria whether administered by the mouth, or by subcutaneous or by intravenous injection. When given by the mouth the glycosuria lasts until the next or even until the third day. When administered by subcutaneous injection the effect is produced more quickly, but ceases sooner, the glycosuria frequently being found to have passed away by the next day. This more rapid disappearance of sugar from the urine after subcutaneous injection was a point of importance in interpreting the results of experiments. On the strength of certain experiments by Von Mering it had been asserted that phloridzin produces glycosuria without glycohemia—sugar in the urine without an increase of sugar in the blood. In three experiments made by Von Mering the estimate of the amount of sugar in the blood brought it within the normal range. It was pointed out that Von Mering made use of a mode of analysis attended with the employment of a large quantity (2 liters) of water. Coagulation was effected by heat, and after filtration the filtrate had to be evaporated down to a small bulk before the sugar was estimated by Fehling's solution. In another recent communication to the Physiological Society Dr. Pavy showed that a very large loss was liable to occur when a solution of sugar is subjected to prolonged ebullition. In one experiment in which 0.595 gram of sugar from honey was simply boiled in a flask with a liter of water for twelve hours, the loss amounted to 54 per cent. In another experiment with sugar from diabetic urine the loss was 57 per cent. Again, it was important in order to ensure that all the sugar shall be extracted, to get a coagulum which can be readily and effectively washed. Both requirements are fulfilled by the alcohol process. The experimenter must be alive to the fallacies which lurk in the analytic methods. If he be properly on his guard against these, very accurate results might be obtained. Thus, in a series of experiments brought to the notice of the Society, sugar was added to the blood in known quantities and afterward estimated. The error never exceeded 5.5 per cent. and was usually much less. In addition to the fallacies connected with the mode of analysis, there were others connected with the circumstances as regards the state of the animal at the time of collection and the manner in which the collection was made which must be guarded against. Both chloroform and ether led to the presence of an abnormally large amount of sugar in the blood. This, unless taken into account, would form a seriously vitiating factor. Speaking of some experiments of Levene on phloridzin glycosuria it was pointed out that he had neglected to give consideration to this source of fallacy, and that he had also delayed taking the blood supposed to be under the influence of the subcutaneous injection of phloridzin till the following day, when the opportunity was given for the effect of the drug to have passed away. Guarding against the various sources of fallacy enumerated, Dr. Pavy, experimenting on the cat, subcutaneously injected 0.5 gram of phloridzin and examined the blood and urine taken at times of killing from one to five hours afterward. The table of results placed before the Society showed that sugar was found to be present in abnormal amount in the blood, and that, therefore, it was not correct to say that there is no glycohemia in connection with phloridzin glycosuria. As in other cases where sugar is found in increased amount in the blood, the amylose carbohydrate obtainable from the blood coagulum presented itself in notably larger quantity than usual.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the ASSOCIATION living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, FEBRUARY 6, 1897.

SACREDNESS OF PROFESSIONAL CONFIDENCE.

The Playfair violation of professional confidence met with practically unanimous condemnation by the medical profession, which therein but reiterated ethics it had taught for more than twenty centuries. Nearly seven decades ago, the American medical profession viewed with equal severity a similar breach of confidence by DELPECH, although there were much greater extenuating circumstances and although he was assassinated therefor. The *Medical Magazine* (March, 1833, published at Boston) remarked anent the assassination of DELPECH:

"This tragical event while it cost the profession a most distinguished member, has also left an impressive admonition on a point which can not be too strongly addressed to the awakened attention of medical advisers. M. DELPECH was a victim to an atrocious act of professional infidelity and without attempting to justify the deed in the agent of it we are free to declare our opinion that, as a retribution on the offender it is most just and salutary.

It is essential to the value and the responsibility of the medical profession that the intercourse between the physician and his patient should be strictly confidential and no penalty can be too severe for a violation of it. The physicians first, and as we maintain, his paramount duty is to his patients. So deeply is the whole community interested in the inviolability of his professional fidelity that while on the one hand neither courtesy, friendship nor bribery should tempt him to communicate any matter which his patient may confide to him as a physician, society is bound on the other to protect him from any attempt to extort them under the forms of legal proceeding.

This point of honor and duty is well understood and, as we believe, rarely if ever violated of intentionally by the physician of our community; but there is an undignified and mischiev-

ous kind of tattle in which some gentlemen indulge generally for the purpose of magnifying their own business or skill, that is always liable to run into disclosures which are not intended by them at the outset nor even perceived at the time. Such talk is always an offence against good taste and indicates a mind not only destitute of materials for valuable conversation, but too regardless of the obligations incurred by confidence reposed.

The homicide had been a patient of DELPECH some time before. He was treated for varicocele. The case was attended with circumstances that rendered it imprudent for him to form a matrimonial engagement. DELPECH having been consulted by the family into which the patient wished to marry, gave them some intimation of his patient's condition. The patient met DELPECH at the theater the night before the fatal deed and demanded a retraction of what had been said to the family. This was refused. The assassin stationed himself in the balcony of a house and watched the approach of DELPECH's cab, when with one shot from a double-barreled gun he killed the servant and with the other DELPECH. He then retired into the house and blew out his brains with a pistol. DELPECH expired in a few minutes. He was in his 60th year. He was a chevalier of the Legion of Honor, professor of clinical surgery in the University of Montpellier and surgeon-in-chief to the principal hospital.

The mental status of the homicide was doubtful. Victims of varicocele are but too apt to have as a result suspicious mental states which are a fruitful source of baseless jealousy and ideas of marital infidelity. DELPECH however in revealing the patient's physical condition went beyond his duty as a physician and violated the French civil code. Censure by the *Medical Magazine* of the results of medical gossip is as valid now as it was seven decades ago.

THE LEGISLATIVE CONTROL OF VIVISECTION.

We again call attention to the question of vivisection, which has been given especial prominence during the past year by an organized attempt to limit by legislation, and thus virtually prevent, the useful pursuance of this valuable procedure in experimental physiology and therapeutics.

In order indirectly to gain national condemnation of vivisection, the District of Columbia was chosen as the ground for action, and a measure to this effect was introduced into the United States Senate, entitled "A bill for the further prevention of cruelty to animals in the District of Columbia." This attempt to enforce legislative control of vivisection was accompanied by documentary evidence so replete with misstatements, distorted statistics and unreliable opinions, that the casual lay-observer would at first sight believe that a great system of cruelty was in vogue in the scientific and educational institutions of this country.

Happily for the best interests of the nation, a vigorous resistance has been offered to the passage of

this bill. A joint committee from the various medical and other scientific societies and educational institutions of the District of Columbia was appointed to prepare a memorial to refute the allegations and show the erroneous statements made in advocacy of the bill, and in behalf of those truly interested in the relief of suffering humanity, to protest against the proposed legislation. The result of the work of the joint committee is published in Document No. 31, issued from the Senate during the second session of the 54th Congress; and no one can gainsay that they have dispassionately and effectually accomplished their mission.

The committee verify their statement that no amount of "patient research" or "experience," without experiments on living animals, could possibly have secured the same results as have been obtained by the application of the experimental method to biologic problems, by carefully enumerating the numerous discoveries directly due to methods analogous to vivisection. Starting with the investigations of DAVAINÉ in 1850 proving the anthrax bacillus to be the cause of the infectious disease known as anthrax, the progress is reviewed down to the most recent research in immunization and serum therapy. These facts are well known to the medical profession, as are also the hundred of physiologic truths, discovered by vivisection. They can not be denied.

Not only humanity, but also the lower animals have been benefited by the very methods which the "cruelty-to-animals" fanatics seek to suppress. Means have been developed to prevent infectious diseases in our beloved domestic animals. The ravages of sporadic pneumonia, tuberculosis, glanders, anthrax, hog cholera and many other animal-diseases are fast diminishing in civilized communities. As a result of Congressional legislation and appropriation for instituting methods believed to be suitable for the eradication of contagious pleuro-pneumonia, every trace of this disease was removed from the United States within a brief period of less than six years, and at a cost (\$1,509,100.72) that was trifling in comparison with losses likely to occur annually as soon as the disease had obtained a foothold among the cattle on the Western plains. There is promise of a similar result in infectious swine-diseases, from which, according to Dr. SALMON, the loss has been from \$10,000,000 to \$25,000,000 annually. In 1894 CHAMBERLAND reported that a total of 1,988,677 animals had been inoculated in France, and the loss from anthrax had diminished from 10 per cent. in sheep and 5 per cent. in cattle to less than 1 per cent. in sheep and one-fourth of 1 per cent. in cattle, a saving of over \$2,000,000.

Let the friends of the animal and the antivivisectionists ponder over these facts and carefully consider the whole question before they rush headlong in their ardor to prevent cruelty and suppress the very methods

that will render the condition of the domestic animal more comfortable. The humanitarian, the scientist, and the economist are working toward a common end, and narrow-minded bickering and selfish reasoning can never prevail. We do not say that there never have been abuses, but we believe that they have generally been in the hands of private experimenters. We feel sure that the laboratories of our scientific institutions will always permit unlimited inspection of their methods. Secrecy can only serve to increase the antipathy of the opponents of vivisection.

There is no doubt that the majority of persons capable of expressing an unbiased opinion are overwhelmingly opposed to the legislative restriction of vivisection. Sixty-eight medical and scientific associations from all over the country, and including the most liberal-minded and humane men of the day, have adopted resolutions to this effect.

With the joint committee we unhesitatingly affirm that,¹ "The voice of science and medicine, so far as it receives authoritative utterance, is overwhelmingly opposed to legislation of any kind which would take in any measure the direction of experimental medicine and physiology out of the hands of those who, on account of their special fitness, have been chosen by the authorities of our higher institutions of learning and of research to convey instruction and to conduct investigations in these departments. Unnecessary and offensive in the highest degree would it be by any system of official inspection, such as that proposed in this bill and which might readily be used as a system of outrageous espionage, or by legislation of any kind, to attempt to dictate or control how and by whom, and for what purposes, and under what conditions, and upon what animals in the laboratories and the institutions of the higher learning, experiments shall be made. The decision as to these matters should be left wholly to those in charge of these institutions, who are the ones most competent to judge of them."

"BUSINESS" METHODS OF QUACKS.

One perennial newspaper jeremiad bewails the alleged lack of "business" ability on the part of the regular profession as contrasted with the redundant "business skill" of the quack. These quack "business" men have shown of late tendencies to "business" of a type which is usually rewarded, in ordinary mortals, by a sojourn in a penitentiary. One Chicago institution, incorporated under a most alluring title, placed advertisements in all the Chicago dailies, for which it paid. It thereupon proceeded to insert in country newspapers similar advertisements on credit, for which it gave the Chicago dailies as reference. The newspapers, in country and city, fulsomely lauded the skill of the advertisers. The bills for country advertise-

¹ Quoted from the Memorial of the Association of American Physicians.

ments not having been paid, inquiry was made which resulted in the discovery that the concern first incorporated had sold out to its own members incorporated under another title. The United States postoffice authorities thereupon arrested the members of the last corporation for misuse of the mails. Such changes of title have long shielded the quack against malpractice and other suits. It is to be hoped that the United States authorities will succeed in putting a check on these procedures. The credulity of the press in the present instance is closely akin to that gullibility arising from blunted moral sense which makes countrymen such ready victims of the seller of counterfeit money. An Indianapolis instance of similar "business" skill seems to indicate the necessity for an examination by the United States comptroller of the currency, of an Indiana national bank. Among the old dodges of quacks is the "no cure no pay" guarantee concerning which CRABBE ("The Borough") years ago sang:

But now our quacks are gamesters, and they play
With craft and skill to ruin and betray;
With moustrous promise they delight the mind,
And thrive on all that tortures humankind,
Vold of all honor, avaricious, rash,
And twenty names of cobblers turned to squires
Aid the bold language of the blushless liars;
And then in many a paper through the year
Must cures and cases, oaths and proofs appear,
Men snatched from graves as they were dropping in.

From time immemorial "no cure no pay" guarantees have turned up as judgment notes. MENECRATES the charlatan (B. C. 300) had such guarantees for "sacred" (incurable) diseases. These were usually the so-called "nervous diseases" of the advertising quacks, and of course included an enormous number of cases of hypochondriasis. According to ATHE-NEUS ("Banquet of Savants") MENECRATES signed a written "no cure no pay" guarantee with these "incurables," who found they had engaged themselves to serve as slaves after being cured. MENECRATES sometimes renamed them with a cognomen of the Grecian gods and took them with him in a species of temple chariot. He called himself Jupiter (WITKOSKI: "Le Mal qu'on Dit des Medecins"), wore a purple robe, a crown of gold upon his head and a scepter in his hand, and paraded about with his conclave of spurious divinities. He once wrote to PHILIP, King of Macedon, as follows:

MENECRATES Jupiter to King PHILIP, greeting. Thou art King of Macedon and I am King of Medicine. Thou canst make men in health perish when thou desirest. I can save the sick, guarantee to cure all diseases up to the extremity of old age. Those who are well, if they follow my orders, live forever. If thou hast soldiers to guard thy person and life, I have for protectors those I have snatched from the jaws of death. For it is I, Jupiter, who giveth life.

King PHILIP responded in fitting terms:

PHILIP to MENECRATES, greeting and better sense. Go to Anticyra and drink hellebore for thy brain.

MENECRATES wrote in about the same terms to

ARCHIDAMUS, King of Sparta, and other rulers, always employing his self-given title, Jupiter.

PHILIP one day invited this quack to dinner together with his retinue of so-called "gods." The quack was placed upon a throne ornamented in the greatest magnificence and with all the mock ceremony possible. A table was placed before him on which were all the first fruits of the season and delicious cooked meats, but these were served only to the King's convivial companions who were in the joke; the servants merely allowed MENECRATES and his troupe of "gods" the odors from empty cups used in libations. Jupiter MENECRATES, finding himself the laughing-stock of the company, flew away from the repast with his "gods."

Despite this early exposure of the "no cure no pay" dodge, it still flourishes in full luxuriance. A most outrageous case of this kind lately occurred in Indianapolis. It throws light alike on the source whence many quacks obtain capital and on the lack of care with which certain banks give discount. Suits have just been filed against an Indianapolis medical institute and a local national bank to recover \$300,000 obtained from residents of the Mississippi Valley through the "no cure no pay" dodge. The "institute" claimed to be an Indiana corporation with a well organized hospital having a staff of consulting specialists. Agents of this institute gave guarantees all over the Valley that it would cure all chronic diseases. These guarantees were purchased and discounted as notes by the bank to the amount stated. As in many instances the diseases, for the cure of which a guarantee was given, were of a kind that the patient shrank from being exposed to public view; hundreds of dollars were paid on these notes. Aside from these \$300,000 was obtained on guarantees which would bear inspection, and for this amount suit has lately been brought. Against such "business" methods the medical profession has made that protest for thousands of years which first found formal expression in the Hippocratic oath and later in the Code of Ethics of the AMERICAN MEDICAL ASSOCIATION. It certainly will not abandon its ethical principles at this late day at the behest of sensation-mongers for antique confidence operations of the type described.

MINING FATALITIES.

During the year 1896 there were 497 men killed in the coal regions of Pennsylvania. This last annual contribution to the mortality record shows the awful regularity with which the destruction of life among miners proceeds. The total number of outright deaths for the past three years was 1,327. In addition 4,780 miners were maimed, many so seriously as to be incapacitated for future work. As a consequence of these sad happenings, 633 women were left widows and 1,752 children became orphans, and in nearly

every case were dependent on poor-boards and charity-organizations for their future sustenance. The compensation of coal miners is woefully small in view of their obnoxious and hazardous occupation. Few of them are able to save any money; and their only hope lies in mutual relief-organizations, and among the penurious aliens, even these are sometimes disregarded.

It is only when some terrible catastrophe like the tragic Twin Shaft disaster occurs, that the fearful accident-mortality among miners is brought to public view, and measures for relief advocated. Such events soon pass out of mind, and agitation for reform subsides; but the grim hand of Death goes on unmolested. Despite the laws for systematic inspection and improved means of ventilation, there seems to be no diminution in the death rate.

According to a writer in the *New York Herald*, Mr. WILLIAM CONNELL, a recently elected member of Congress from the Lackawanna district, and one of the largest individual operators in the region, expressed himself in favor of a tonnage tax to maintain a fund for the helpless and poverty-stricken families, whose fathers have yielded up their lives to the insatiable greed of the unscrupulous mine-owners.

This proposition seems to ameliorate the effect, but leaves untouched the cause. To the mine-owner it is simply an extra price paid for the human life sacrificed; and moreover the increased expenditure in mining will be compensated for in some other way. Either the miner or the consumer will indirectly pay the tax, and the mine-owner will sit in his office and still count the plentiful proceeds of his deadly operation.

If the money expended for miners' hospitals and relief funds could be paid outright for the preservation of the necessary life-preserving pillars that are now ruthlessly undermined, these calamities would soon cease, and the actual money saved, outside of the value of the lives preserved (for each life has a definite money value), would far overbalance the worth of the paltry tons of coal, the mining of which is the root of the evil.

The only sensible manner for a legislature to proceed in these cases is to destroy the cause, by passing laws requiring rigid mine-inspection, and appropriating a sufficient sum of money to render these laws fully operative. Make a life-tenure of office for the mine-inspectors, and fix the salaries sufficiently large to induce capable and conscientious men to accept the positions. The capitalists would howl and the lobbyists bribe; but a few years of persistent agitation would convince the legislators, and we would witness the triumph of humanity over political trickery and mercenary greed.

THE DOMESTIC ANIMALS AND CONTAGIOUS DISEASES.

The fact stated in the public press that the bubonic

plague now devastating Bombay and threatening Europe largely owes its extension to that household vermin, the rat, is significant enough to suggest some serious considerations.

Various animals, in their domestication, have been and are recognized as agents of contagion, though the extent of the danger has been, as usual, both underestimated and exaggerated, according to the special circumstances of the time. Ordinarily no one troubles himself as to the dangers of hydrophobia, but at certain seasons of the year there is almost an annual massacre of the innocents for the fear of this rather rare and, possibly in many cases, somewhat questionable disorder. Then the public returns to its old equanimity and the affectionate brutes slobber over their human friends and whilom foes with impunity. The danger of this practice seldom seems to suggest itself to zoophiles and yet it is a very possible and probable one when certain diseases are prevalent. Even if the animals themselves are immune to certain diseases the chance of their conveying the contagion in their hairy coats constitutes a danger to be considered, and renders caution advisable. Dogs have been said to carry scarlatinal infection, cats and fowls are claimed to be especially liable to diphtheritic disease which is directly communicable to man, and rather recently a particularly fatal infection has been traced to parrots so often kept as domestic pets, and its bacillus has been isolated by a French physician, M. NOCARD. It has been found to be pathogenic to many other domestic animals, and they, it is probable, can also transmit the disease. It appears to be not at all rare in parrots, in France at least, and is very readily transmissible to the human species, in whom it is very fatal. It is suggested that by this infection a number of hitherto unaccountable local epidemics can be explained.

The moral of all this is, not that we should encourage any unreasonable fears of the domestic animals, they are generally harmless enough, but that physicians should cultivate a habit of observation of their condition and health as involving that of their masters. In times of epidemics of diphtheria and scarlet fever a dog or cat with prominent social instincts should be at least under surveillance as a domestic pet, and it is desirable in any event to use precautions against such animals undergoing exposure to diseases which they can themselves transmit. A little attention to this particular line of observation may aid also in the detection of the origin of many isolated cases of disease that are otherwise not easily accounted for. In fact it is a not unworthy function of the physician and sanitarian to attend more than is perhaps done at the present to the health conditions in the lower animals, more especially those that have generally escaped this supervision, the dogs, cats, fowls, and even the semi-domesticated vermin, the rats and mice

in certain cases, with special reference to the welfare of his human clientele. This is not a particularly new recommendation, it has been made before, but it is one the repetition of which is occasionally timely.

THE PLAGUE TO BE INVESTIGATED.

We notice by a syndicate letter in the daily press (we have not seen it in any medical journal) that Dr. WALTER WYMAN, Supervising Surgeon-General of the Marine-Hospital Service of the United States, has put his powerful mind on a "special study of the bubonic plague," and that we will very shortly hear something in the way of some important discovery which will electrify the scientific world. We know that this must be so, for the female correspondent who filled two or three columns of the syndicate letter has solemnly assured us that this is a fact. If the veracious correspondent had informed us that Dr. KINYOUN of the laboratory was about to develop something it might have been credited in scientific circles, but if any human being ever heard of the much advertised WYMAN in any scientific capacity it would be a pleasant surprise to know of it. In the meantime, Germany has sent Prof. KOCH to Bombay to study the plague where it exists. Kitasato, when he discovered the microbe of the plague, discovered it in China, where the disease was prevailing; YERSIN, when he confirmed it, did so in the field of its ravages; but the American method of investigating diseases at long range is of recent invention and seems to be confined in its application to the head of the Marine-Hospital Service, who cleverly confronts an epidemic by gazing at the dispatches through the bottom of his glass at a "high tea," and giving the results of his highly original investigations to the admiring society reporter. Great are the results produced by the proper distribution of the products of the Washington florists; and tremendous the effects brought about by careful attention to the social functions of the Capital!

The code of morals which prevents country practitioners and obscure members of the profession in the city from advertising, does not seem to invade the sacred precincts, nor penetrate that luminous halo which surrounds the bureau officer at Washington, and in consequence we have syndicate letters galore, as a rule written a few weeks before the incoming of a new administration.

CORRESPONDENCE.

"Chloroform and Ether."

FREEMONT, ILL., Jan. 17, 1897.

To the Editor:—In the JOURNAL of January 2 Dr. Galloway publishes a communication with the above title, in which he criticises an article of mine that I read last September before the Mississippi Valley Medical Society and which was published in this JOURNAL a few weeks ago.

When I sent out my questions contained in that paper unfortunately many prominent surgeons of the eastern cities

were away on their vacations and their answers came too late to be embodied in that article. Later, however, I received many replies, some of them quite lengthy, including replies from such men as McBurney and Bangs of New York, and these men without an exception prefer ether to chloroform as a general anesthetic, because they consider the former immensely safer than the latter.

Nearly all of them give chloroform in exceptional cases, which they distinctly specify.

The words in italics which the Doctor quotes from my paper are the words used, not by me, but by the most eminent men on our continent, who were kind enough to answer my questions, knowing they would be put on record as holding the views they expressed. The Doctor concludes from the tenor of my paper that: "Any student, laborer, messenger boy or member of the patient's family may safely give ether, but chloroform requires a careful and experienced man, therefore he concludes chloroform should not be given."

I have only one answer to make to this quotation, that is, that there is nothing in my paper to warrant any such interpretation of its contents, and I will wager that of the thousands of readers who have read my paper, Dr. Galloway is probably the only man who so misinterprets its meaning. On the contrary I hold that all general anesthesia is accompanied by a certain amount of danger, and I prefer ether to chloroform because the latter is the far more dangerous agent of the two.

I believe with Dr. Penrose of Philadelphia, whom I quote, that the best man among those present to assist at any operation should be generally chosen to give the anesthetic.

Apropos of this subject, I had a little episode in my practice a few years ago that came near resulting in the death of a patient of mine, in whose case I intrusted the giving of the anesthetic to a lady friend who happened to be present. It was a case of secondary hemorrhage following a bone operation on the tibia. The patient had not lost a very large quantity of blood, and her condition was fairly good, but as she was extremely nervous I concluded to anesthetize her before attempting to arrest the bleeding. I had both ether and chloroform in my satchel, but I chose the latter, and why? Simply because it was so easy to give, and acts with such wonderful rapidity. I poured about a drachm of this liquid on a folded napkin, and in three minutes my patient was in a condition of complete insensibility. I now poured about another drachm on the cloth and showed my lady assistant how far from the patient's face she should hold it. I then rapidly opened up the wound and found three small arteries spurting; I put the forceps on the largest of these, ligated it, and when I looked for the others all bleeding had ceased. I turned to examine the patient and found her face was as pale as if dead. Her respiration had ceased and no pulse was perceptible at the wrist; the only sign of life still remaining being a feeble contraction of the heart at long intervals. I had no one present to assist me, save two women, and no time to lose in loading a hypodermic syringe with heart stimulants. I stood my patient on her head, used artificial respiration, dilated the sphincter ani, and in fact worked with the desperation of a drowning man for twenty minutes before my patient showed the least signs of returning animation. I shall remember the terrible agony of that half hour as long as I live, and would not repeat it again for a small fortune. Had that patient died I should have always blamed myself for not putting on a tourniquet as a temporary expedient and sending for a physician to assist me.

In this case, however, if I had been a little more thoughtful, a little less careless, a little less lazy and used the safer anesthetic I sincerely believe I should not have had the terrible experience I had in this case. However this may be, it taught me a valuable lesson which I shall heed for all future time, and that is not to trust the administration of an anesthetic of any kind, whether ether or chloroform, to "lady friends,

laborers or messenger boys," or any one else, except the best physician whose services I can get.

My only variation from this rule is in cases of child birth, where, by the way, I generally use chloroform, believing it to be safer in this class of cases than any other.

I take a napkin large enough to fill a common tumbler about half full, when well packed in. I drop chloroform on this napkin in about drachm quantities at a time, and the irregularities of the patient's face render it impossible for my lady assistants to shut out entirely atmospheric air, should she hold the glass down close over the patient's nose and mouth. If I am using forceps I only use traction on my instrument for a minute or a two at a time, and in the intervals I scrutinize carefully the action of my anesthetic upon my patient. If I am performing version, that is a procedure which is soon ended and I can anesthetize my patient before I begin, and insensibility will continue long enough to finish the operation.

I quite agree with Dr. Galloway on the great importance of having a proper man as an anesthetizer, and believe with him further, that many of the untoward events that follow the major surgical operations are the result of an improperly administered anesthetic.

The only place where I have seen anesthetics given by men who did nothing else is in the hospitals of London, and they generally begin the anesthesia with nitro-oxid gas, and follow it immediately with ether. My experience, however, which is considerable, has led me to believe that men who are so chary of human life as to go to the expense and trouble of employing no one but a professional anesthetizer never employ a man who gives chloroform. There may be exceptions to this rule but if they exist I have never seen them.

Besides I quite agree with the Doctor that he has been treated in a most penurious manner by those to whom he has administered an anesthetic, and if he would only adopt an anesthetic that is, if figures and statistics are worth anything, from five to twenty-five times as safe as the one he uses, he, if skilled in its use, would be able to give a new record to some of the great operators who are now so fond of giving us their statistics, for I believe, Dr. Galloway, your position is often one of greater responsibility and more onerous than that of the man who wields the scalpel. W. S. CALDWELL, M.D.

The Rubber Nipple on the Infant's Bottle.

BELOIT, WIS., Jan. 30, 1897.

To the Editor:—In your Editorial in today's JOURNAL on "Sanitary Trivialities" as a commendation of Dr. Ernest Wende of Buffalo for securing an ordinance prohibiting the use of rubber tubes on nursing bottles. At the last meeting of the Wisconsin State Medical Society I called attention to this crime (as it really is a crime), as follows: "The first thing a new father does when he finds the mother has no milk, is to go to the drug store for a nursing bottle. For some unknown reason the druggist is nearly always sure to give him one of these abominations, with a tube six inches long and a brush with which to wipe it out. I have often wished the druggists and manufacturers could take their food for life through such tubes. Somebody spoke about sterilizing bottles; but you can not sterilize these tubes, and the tubes are nearly always sold. If proper, I would like to make a motion that this society condemn most emphatically all these tubes, and that nothing but a pure nipple be used."

Dr. C. F. Dougherty of Muscoda, Wis., then said: "I am an advocate of common sense ounce bottle and nipple, but no rubber tube, because I think the milk can be more contaminated with germs through the long rubber tube than where they are not used, and I second the motion."

Several members spoke against this form of nursing bottle, but the discussion was ruled as out of order and the motion

was laid on the table, though Dr. Dougherty earnestly protested and said that "to lay this motion on the table would result in laying many babies on the table in a coffin."

For the past three years I have carefully watched my cases of cholera infantum and acute milk infections, etc., and every case has occurred in bottle-fed children, and in children using these long tubes.

In our later days of asepsis and cleanliness it seems criminal to permit the sale of long hose nursing bottles, for it literally causes a "slaughter of the innocents." All honor to Dr. Wende for his course! Yours truly,

ERNEST C. HELM, M.D.

Testimonials.

NASHVILLE, TENN., Dec. 18, 1896.

To the Editor:—As an editor you must be a very wise man, and as a wise man you must be possessed of all knowledge, therefore I write to you for information. I have just finished reading a neatly gotten up little pamphlet, a reprint from an article that lately appeared in one of the New York journals, sent me by the firm whose widely advertised tissue-former it advocates, and written by a "professor of anatomy and histology," with the title "F.S.S.C., London, etc.," and he hails from a place that would almost touch a line drawn between Chicago and here. "In Bright's disease," he says, "the administration of ——— will often temporarily increase the number of casts in the urine, but it must be remembered that Bright's disease is not in itself the disease, but the result of albuminous deposits in the kidney resulting in ulcerations. A moderate use of ———, however, has in most instances even controlled the ulceration."

Do you think, Mr. Editor, that he came over here from England because they would not allow him to stay in that country any longer, or is this the latest pathology from London, with Dr. "F.S.S.C." right up to date and I away behind?

Yours very truly, ERNEST B. SANGREE, M.D.

About Diploma Mills.

BENTON HARBOR, MICH., Jan. 22, 1897.

To the Editor:—I understand the charter of the Illinois Health University has been annulled, but you will see that the same J. Armstrong, Mary E. Sellers, Demuheller & Co. are in another "mill" of the same sort, and have supplied their graduates here with diplomas from the "Independent Medical College," which is run on exactly the same rules as their other "mill."

It seems that your State officers will allow this same company of confidence men to carry on their nefarious business regardless of anything or anybody; in fact it appears as though they were aids and abettors in their transactions. What can be done about it? Very respectfully,

W. RYNO, M.D.

Reviewers.

MINNEAPOLIS, Jan. 22, 1897.

To the Editor:—Permit me to thank you for your editorial on "The Reviewing of Medical Publications" in the Jan. 16, 1897, number of the JOURNAL. It is not long ago that I put upon the market a text-book (Outlines of Materia Medica and Pharmacology). It had its weak points and no one would recognize these facts sooner than the author. One reviewer dwelt upon a typographic error in the spelling of one word, that was, however, properly spelled in many places throughout the book. In this same review the book was severely criticized because of its weakness in therapeutics when the preface distinctly stated that it was *not* a work on therapeutics.

Another reviewer who signed himself "R. W. W." and who is the American editor of an English work on materia medica, made the most vicious criticisms. At the same time they dis-

played ignorance and injustice on their part. The book was open to criticism but not the kind of criticism it got. Very truly,
H. M. BRACKEN, M.D.

Advertising.

January 20, 1897.

To the Editor:—It has for some time appeared to me that a few otherwise reputable physicians in the community in which I reside, have been guilty of flagrant wrongs in the way of allowing their names to be placed about in an advertising manner. The matter of which I have complained has been mentioned to some members of the profession and a few of them take the position that I am not correct. An expression on these points from the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION would be appreciated. The matters to which I wish to direct your attention are, the placing of physicians' names and addresses on large placards to be hung up in hotel rotundas and other public places, page advertisements in city directories of private infirmaries for the treatment of diseases of a certain class, physicians' names on a piece of glass to fit on the telephone box, and the sending of notices of a physician's removal of his office to families on whom he has never practiced. As before stated, I have contended that these instances are palpable and gross violations of the spirit of the Code of Ethics. Please give your reply through the JOURNAL.

M. D.

ANSWER:—Your own ideas relative to such conduct, as quoted in your query, are correct. Such things are frequently done in thoughtlessness, but more commonly are the result of a desire to obtain notoriety. Upon nothing is the Code so explicit as this. "It is derogatory to the dignity of the profession to resort to handbills, private cards or public advertisements, inviting the attention of individuals affected with particular diseases, publicly offering advice, etc." The methods mentioned are certainly equivalent to public handbills, etc. Skilled and reputable physicians do not need these methods to obtain practice, and others are better without it when they are compelled to resort to such schemes; or rather the profession would be better without them. (See Code, page 9, section 4.) Recently such an advertisement was observed by a prominent layman, who estimated the author of it justly as "One not possessing the requisite skill to obtain the confidence of the community." The sending of one's card, or notice of removal, to families on whom they have never practiced is very improper, a true bidding for practice.

PUBLIC HEALTH.

Smallpox in Germany Chiefly Imported.—Smallpox in Germany destroyed 65,000 lives per year a century ago. Now the average number is 114 per annum, and most of these are immigrants from those countries "over the border," where less stringent laws regarding compulsory vaccination exist.

Experimental Tests of Preventive Inoculation of Cholera.—Some interesting experiments have been made in Berlin recently with the results that inoculation of seventeen healthy men, most of them physicians whose names are well known to science, a guarantee of the accuracy of the observations, confirmed in every respect the results obtained by Dr. Haffkine in India. The experiments were carefully studied with control tests, and are described in the *Deutsche med. Woch.* of January 1. They show that the effect of inoculation lasts a year, and therefore if a cholera epidemic should gain foothold in any country, it could be stamped out by this means. It also refutes the objections raised by some physicians in India to Dr. Haffkine's work, which was described in this JOURNAL, Dec. 5, 1896.

Length of Period of Contagion.—According to the circular recently sent to the principals of all the educational establishments in France, the period of isolation after smallpox, scarlet fever and diphtheria must be forty days after the first day of invasion, sixteen days after chickenpox, measles and mumps, while after whooping cough attendance at school should not be allowed until thirty days after the coughing spells have entirely disappeared. Tuberculosis is added to the list of contagious diseases, and the principals are instructed to inform the parents if a pupil's bronchitis, enteritis, etc., persists after a certain length of time, as hygienic measures are required in these cases, life in the open air, etc., impossible to secure in educational establishments, where the crowded rooms, etc., are distinctly injurious to the patient, while exposing others to contagion.

New Rules in Pennsylvania Regarding the Contagious Dead.—At a recent meeting of the State Board of Health of that State, Dr. Lee secured the adoption of the following new regulation: When a body, dead of a contagious disease, is to be disinterred, the following precautions shall be strictly observed: "1. No one shall be present at the disinterment except those necessary to perform the labor and one adult male relative of the deceased. 2. A hermetically sealed zinc-lined box, sufficiently large to contain the box, coffin or casket already in the grave, shall be in readiness to receive the latter. 3. When within six inches of the top of receptacle containing the body, the earth shall be saturated with one-fifth per cent. solution (1-500) of bichlorid of mercury. 4. The receptacle containing the remains shall on no account be opened, but shall be at once placed in the box provided as above and hermetically sealed, and said box shall not be opened on arriving at the place of destination." This was adopted.

Good Results from Antidiphtherial Serum in Vienna.—Professor Paltauf of Vienna reports upon a year's experience with the *heilserum*. In 1,100 cases of diphtheria in various parts of Austria treated by antitoxin, 970 recoveries took place, a mortality of 12.5 per cent. The report furnishes strong evidence as to the great value of the treatment in the diminished mortality, and also when it shows that the earlier the treatment is used the more effective is its action. In the cases where the injections were used as early as the second day of the disease, the mortality was 6.7 per cent., while in cases first treated on the third day it amounted to 19 per cent., and those treated on the fourth day to 24 per cent. On and after the sixth day it was upward of 33 per cent. When it is remembered that in previous years the mortality seldom was under 40 per cent. it is clear that we have in the antitoxin a measure exceeding all others in usefulness.

Anti-expectoration Regulations at Brooklyn and Boston.—In the spring of last year the presidents of all the surface and elevated railways of Brooklyn were notified by the Commissioner of Health to conspicuously post in all passenger cars a notice reading as follows: "Spitting on the floors of public conveyances is a public nuisance and a source of danger to the public health. It is hereby prohibited. So ordered by the Commissioner of Health." The employes of each company were required to enforce that order. As certain of the roads had not fully carried out that regulation, on Jan. 25, 1897, a peremptory notification to their officials was issued. The following notice has, by order of the Boston Board of Health, been posted in all the cars of the West End Street Railway Company, Boston: "The Board of Health adjudges that the deposit of sputum in the streetcars is a public nuisance, source of filth and cause of sickness, and hereby orders that spitting on the floors of streetcars be, and hereby is, forbidden." Above this order is posted a copy of the statute stating that the fine for infringement of an order of the Board of Health is \$100. The Chicago Health Department has issued a similar notice.

The Quarantine Board of Pennsylvania.—The third annual report shows an increase of work and efficiency on the part of this commission. The constitution of the Board is now as follows: Richard A. Cleeman, M.D., president, appointed by the College of Physicians of Philadelphia; Benjamin Lee, M.D., secretary, ex-officio member, as secretary of the State Board of Health; Henry C. Boening, M.D., quarantine physician, appointed by the Governor; Thomas Winsmore, appointed by the president of the Philadelphia Maritime Exchange; Theodore B. Stulb, ex-officio member, as health officer of Philadelphia; Henry M. Dubois, appointed by the Mayor of Philadelphia, and Ernest Laplace, M.D., appointed by the Governor—four out of the seven being physicians. The executive officer of the station is the quarantine physician, Dr. Henry C. Boening. The deputy physicians residing at the station are Dr. Alfred R. Seymour and Dr. J. B. M. Ward. The Board's function for the present is one of observation or "inspection" only, there being no provision for detention or disinfection. If sickness of a communicable nature is discovered on a vessel, or if circumstances lead to the suspicion that the vessel is herself infected, she is simply remanded to the Federal quarantine down the Bay. The Chief Executive of the State, however, may at any time, if in his judgment the public welfare requires such action, reestablish a fully equipped quarantine station with modern appliances for disinfection, hospitals and barracks. The new station, twenty miles below Philadelphia, is upon leased property in the old borough of Marcus Hook. The leased steam-tug by means of which the boarding of vessels is done is unsuitable; a new boat should be built expressly fitted for the service. There are three comfortable residences on the property. The grounds are tastefully laid out and shaded by fine old trees. The central building, opposite the head of the pier, is set apart as the administration building, and also contains accommodations for the captain of the boat. The residences on either side are occupied by the deputy quarantine physicians. There are also three good barns and stables on the place. By the courtesy of the Maritime Exchange, telegraphic communication with the city office in Philadelphia is maintained during the day through the exchange station immediately adjoining. During the night the general office is at Linwood. In removing the new station, and resigning its function as a quarantine of detention, many of the old rules and regulations for the government of the Board and of the station became obsolete. The Board has, therefore, deemed it wise to revise them and harmonize them with the present conditions.

BOOK NOTICES.

Leprosy and the Charity of the Church. By Rev. L. W. MULHANE. 12mo, cloth, pp. 155. New York and Chicago: D. H. McBride & Co. 1897.

This little book is a compilation of facts, showing the heroic work of charity accomplished by the sons and daughters of the Holy Church who are engaged in the care of lepers in various parts of the world, from Canada to the islands of the Pacific, and from Iceland to the regions of India.

The reverend author mentions the cases reported by Dr. McDougal in this JOURNAL, Feb. 3, 1895, and quotes the opinion of Dr. A. W. Hitt of Louisville that the cases were genuine leprosy. He sounds a note of warning about the increase of leprosy in this country, and makes some practical suggestions regarding the exclusion of persons affected with this disease.

The editor of this JOURNAL, Dr. Hamilton, when supervising Surgeon-General, issued a circular which was approved by the President of the United States, which forbade the entry of any vessel into any port of the United States until the master of the vessel filed a declaration that there was no leper on board the vessel. This declaration was a part of the ship's papers.

A suggestion was also made by Dr. Hamilton in his report looking to the segregation of all lepers in the United States, but the weakness or incompetence of his successor has prevented the fulfillment of the suggestion. The State authorities and the church must do the work unless the Government takes hold of it.

The Sequels of Disease. BEING THE LUMLEIAN LECTURES DELIVERED IN THE ROYAL COLLEGE OF PHYSICIANS, 1896, TOGETHER WITH OBSERVATIONS ON PROGNOSIS IN DISEASE. By Sir DYCE DUCKWORTH, M.D., LL.D. 8vo, cl., pp. 227. London, New York and Bombay: Longmans, Green & Co. 1896.

These lectures will be of substantial aid to those engaged in the study of prognostics and the sequels of disease. Their pleasant style and keen insight make them interesting, and their instructive character constitutes them contributions of real value to medical literature, useful alike to the practitioner and the examiner for life insurance. The work is not an exhaustive one, its size prevents that, but in typhoid fever and syphilis the sequelæ are fully mentioned. We regret that our limitations of space will not permit us to quote from the work *in extenso*, but we venture the assertion that few medical men, having once commenced its reading, will stop until they shall have finished.

Diseases of the Stomach. By MAX EINHORN, M.D. New York: William Wood & Company. 1896.

This work by Dr. Einhorn forms a valuable addition to the "Medical Practitioner's Library." Written by one who is thoroughly acquainted with the subject, it gives all the information regarding methods of examination, diagnosis and treatment, that can be gathered from the scattered literature of gastrology. The author does not appear to be an enthusiast, but is gifted with a goodly amount of common sense, enabling him to guide the beginner through the shoals of laboratory experimentation and fanciful therapeutics to the solid ground of practical utility. This book is a valuable handbook for reference regarding everything that is needed in the treatment of gastric diseases, presenting in a convenient form all the fruits of recent investigation in this important field of medical research.

The Diseases of Infancy and Childhood, FOR THE USE OF STUDENTS AND PRACTITIONERS OF MEDICINE. By L. EMMETT HOLT, A.M., M.D. With 204 illustrations, including seven colored plates. 8vo, cl., pp. 1117. New York: D. Appleton & Co. 1897.

In the last year we have had some notable works on diseases of children. The volume under consideration compares favorably with other recent works and in some respects it is in advance. The work is well illustrated and is very comprehensive from a medical standpoint, the strictly surgical topics in connection with pediatrics being omitted. The discussion of nutrition and foods is very complete.

The old-fashioned dosage by "apothecaries" weight, long since abandoned in the Pharmacopeia, mars an otherwise valuable work.

Swedish Movements or Medical Gymnastics. By Dr. T. J. HARTELIUS. Translated by A. B. OLSEN, M.D., with Introduction and Notes by J. H. Kellogg, M.D. 8vo, cl., pp. 162. Battle Creek, Mich.: Modern Medicine Publishing Co. 1896.

Dr. Hartelius is recognized as the leading authority on Swedish movements, and we have his certificate conspicuously printed to the effect that the translation correctly interprets his treatise, which was founded upon the principles of Ling's system.

The comments of the editor, Dr. Kellogg, are wise and judicious. The illustrations are clear and concise.

Artificial Anesthesia, A MANUAL OF ANESTHETIC AGENTS AND THEIR EMPLOYMENT IN THE TREATMENT OF DISEASE. By LAURENCE TURNBULL, M.D., Ph.G. Fourth edition, revised and enlarged. With Illustrations. 8vo, cl. Philadelphia: P. Blakiston, Son & Co. 1896. Price \$2.50.

The three previous editions of this book were published in

1878, 1879 and 1889 respectively, and it will be seen that the work has steadily increased in bulk and amount of information.

The author is a firm and consistent advocate of ether as the safest systemic anesthetic. The book has been brought up to date and is one of the most valuable on the subject.

A Guide to the Clinical Examination of the Blood for Diagnostic Purposes. By RICHARD C. CABOT, M.D., with colored plates and engravings. 8vo, cl., pp. 405. New York: William Wood & Company. 1897.

This work, the first of its kind in America, shows the swing of the pendulum in the direction of the humoral pathology as modified by modern bacteriology. As a laboratory guide it will be of immense value, and to the painstaking clinician it will be a labor-saver. We predict a wide field of usefulness for the book, which is of interest to all practitioners. The illustrations are fine, although we must be permitted to doubt the necessity of going to Leipzig to have them made.

The Retrospect of Medicine, A Half Yearly Journal containing a retrospective view of every discovery and practical improvement in the medical sciences. Edited by James Braithwaite, M.D., Lond., assisted by E. F. Trevelyan, M.D., Lond., B.Sc., M.R.C.P. Volume cxiv, July to December, 1896. (Issued January, 1897.) London: Simpkin, Marshall, Hamilton, Kent & Co., Ltd. 12mo, cl., pp. 440.

This volume is fully up to the high standard of its predecessors and should find a place in libraries of those who desire a brief synopsis of current medical literature.

Transactions of the American Surgical Association, Volume XIV. Edited by De Forest Willard, A.M., M.D., Ph.D., Recorder of the Association. Printed for the Association. 8vo, cl., pp. 742. Philadelphia: William J. Dornan. 1896.

If the American Surgical Association had no other claim for existence than the publication of this volume, it would be a sufficient justification. We undertake to say that no previous volume surpasses it, nor do the published transactions of foreign surgical societies show any better work. It is true that the topics are different and that as a rule the light travels westward, and we are found discussing the topics which interested Europe a few years ago. We were wonderfully belated on the subject of tuberculosis (so were the English), but we have made up for it by the practical way in which the subject is now taken up. In a year or two we suppose we will see the wounds, injuries and diseases of the liver occupying the attention of the Association as it is now in France. However, we still adhere to our faith in American surgery, that it is the most practical and life-saving of any. The interesting address of Dr. Tiffany on Gasserian operations for trigeminal neuralgia gave rise to an interesting discussion. The mortality was 21 per cent. and the exact location of the lesion doubtful. Notwithstanding this fact, the opinion was marked in favor of operation after exhaustion of all proper therapeutic measures.

It is with some surpris that we read the discussion on trauma of the kidneys, and the unchallenged opinion that all cases of injury to the kidney followed by hematuria should be subjected to operation. In two cases under our personal observation recovery took place without unpleasant incident under rest and abdominal support with internal administration of opium and gallic acid. Neither case would have done better by operation. In penetrating wounds of the kidney the conditions are different, and there can be no question of the propriety of early operation. We have nothing but praise for the volume, which is in all respects creditable to American surgery.

Transactions of the American Orthopedic Association, Tenth Session held at Buffalo, N. Y., May 19, 20 and 21, 1896. Volume IX. 8vo, cl., pp. 276. Philadelphia: Published by the Association. 1896.

This book is one of the most attractive volumes published by the Society. Beside the papers and proceedings, it contains several excellent Roentgen ray plates exhibited by Dr. De Forest Willard. An interesting paper by Dr. Harry Sherman of

San Francisco, on iodoformization of bones and joints in tuberculosis, led to an interesting discussion, the burden of which was to the effect that iodoform emulsion was negative in its results in these cases. One of the speakers with charming naïveté asserted that the standards of general surgeons were different from those of the orthopedic surgeons! As the dead and the absent are always wrong, the "orthopedic" surgeons had the best of it.

Transactions of the Medical Society of New Jersey, 1896. 8vo, cl., pp. 448. Newark, N. J.: L. J. Hardham. 1896.

This volume contains the papers read at the annual meeting of the Society, and also obituaries of the following: George Taylor Robinson, Emma W. Edwards, Charles F. J. Lehlbach, Luther F. Halsey, C. H. Dunham, W. W. I. Phillips, Alexander Betts, Levi D. W. Miller, Job Symes Crane, David H. Miller, J. J. Daly and Thomas L. Hough. The New Jersey brethren show by their admirable papers that they are *au courant* with the best medical thought of the time.

NECROLOGY.

H. R. KELLY, M.D., of Galion, Ohio, died Jan. 4, 1897, after an illness of only six days. He was 62 years of age. Dr. Kelly was born Feb. 7, 1835, in Shamokin Township, Northumberland County, Pa. He received his early education in the common schools until reaching the age of 13, serving then as a clerk in a store for two years. At the expiration of that time he began teaching school and continued until 1853, when he removed to Ohio. Upon arriving he settled in Perry Township, Morrow County, teaching school one year. In 1854 he became a student of the Ohio Wesleyan University at Delaware, pursuing his studies until 1856, when he went to Cincinnati, where he attended a course of medical lectures, after which he came to West Point, Morrow County, and engaged in the practice of medicine until 1865, when he went to Columbus and attended another course of lectures at Starling Medical College and graduated. He practiced medicine at West Point until 1870, when he removed to Galion. The deceased was married in 1858 to Miss Matilda Emma Keech of Chester County, Pa. One son survives, Webb J. Kelly, the well-known Secretary of the American Academy of Railway Surgeons. In addition to attending to a large practice Dr. Kelly has been foremost in many local affairs and has held a number of positions of honor and trust. He was a member of the Ohio State Medical Society and in 1878 was appointed a trustee of the Girls' Industrial Home at Delaware. For twelve years he was a member of the board of education. He was connected with the medical and surgical department of the Erie Railway for twenty-seven years and was the oldest surgeon on the road. He was a member of the Knights of Pythias, and its first representative to the grand lodge. With one exception he was the oldest Odd Fellow in Galion and was a Mason thirty-five years. He enjoyed a large practice and as a citizen he was most highly esteemed.

THOMAS T. JANEWAY, M.D., of New York city, a relative of Professor Edward Janeway, M.D., and son of Colonel John H. Janeway, the well-known army surgeon who was retired about four years ago, died January 15. He was born in Princeton, N. J., in 1860 and educated at Andover, Mass., until the time of taking up the study of medicine. His preceptor was the late Dr. Willard Parker, under whose guidance he graduated from the New York College of Physicians and Surgeons in 1883. He became associated with Dr. Daniel M. Stinson, the associate and son-in-law of Dr. Parker, and so continued until last year. He was a physician of wide reputation and was highly respected by members of the profession. His death took place in Bermuda, whither he had gone for a respite from overwork. Close application to work brought on a condition of ill health, and it was hoped a trip to Bermuda would set him on his feet again. He was accompanied by a friend and was expected back early in February. It is supposed heart disease caused his death. He leaves a widow.

GEORGE CONNER, M.D., of Cincinnati, aged 53 years, died at his old home, New Richmond, Ohio, January 12, after a brief illness. Dr. Conner had practiced medicine in Cincinnati

several years, having graduated at the Miami Medical College in 1872. He married Miss Elizabeth Archard, the well-known New York journalist.

SAMUEL H. CHARLTON, M.D., of Seymour, Ind., died January 12 in his 70th year. The Doctor held many prominent professional positions and was a member of the ninth international medical congress.

B. B. ADAMS, M.D., Washington, D. C., died suddenly January 25. He was a practitioner in the District for upward of twenty years.

ASSOCIATION NEWS.

Section on Ophthalmology.—Members of the AMERICAN MEDICAL ASSOCIATION interested in ophthalmic medicine or surgery, and desiring to read papers before the Ophthalmic Section at its next meeting in Philadelphia, June, 1897, are earnestly requested to forward not later than March 1, 1897, the titles of such papers either to Dr. G. E. de Schweinitz, Chairman, 1401 Locust St., Philadelphia, or to Dr. Horace M. Starkey, Secretary, 70 State St., Chicago. There is every indication that the meeting will attract a large attendance of American ophthalmologists, and those desiring to contribute to the scientific business of the meeting, and who have not yet indicated either to the President or to the Secretary the subject which they will present, are particularly invited to comply with the request contained in the above notice, as it will not be possible to keep open the list longer than March 1, 1897.

SOCIETY NEWS.

New York County Medical Association.—The annual election took place on the 18th ult., when Dr. J. E. Janvrin was elected president for a second term; Dr. J. B. White, vice-president and Drs. M. C. O'Brien and N. G. Bozeman as secretaries; Dr. J. H. Hinton, treasurer; Dr. N. J. Hepburn, executive committee for four years. This, the largest local society of the country, has 977 active members on its list. In the year previous the total was higher yet, 1068.

New York State Medical Association.—The thirteenth annual meeting of the Fifth District Branch of the New York State Medical Association will be held in Brooklyn on Tuesday, May 25, 1897. All Fellows desiring to read papers will please notify E. H. Squibb, Secretary, P. O. Box 760, Brooklyn.

MISCELLANY.

Gift to the Institut Pasteur.—The Baroness de Hirsch has announced her intention of bestowing two million francs upon this institution, as a memorial to her late husband.

Vicarious Renown.—The Health Commissioner of Chicago, Mr. Wm. R. Kerr, is now engaged in booming himself for Mayor of the city, on the strength of the excellent sanitary work performed by that well-trained sanitarian, Dr. Frank W. Reilly, the Assistant Commissioner of Health.

Chloroformed Bromoform.—The alcohol solution of bromoform mixes readily with water if chloroform is added to it as follows: bromoform, 1.20; chloroform, 0.80; rum, q.s. to make 120 c.c. One teaspoonful contains 0.05 bromoform and 0.33 chloroform.—*Jour. de Méd. de Paris*, January 3.

Dr. Edward Kershner.—Dr. Edward Kershner, late of the Navy, has received the important appointment of Chief Physician at the Randall's Island Hospitals, New York, going on duty there on January 4. This item of news will be gratifying to many who watched the fight put up by Dr. Kershner on behalf of what he believed to be a sanitary principle against his sanitarily ignorant superiors of the "line." His friends will

congratulate him that now he has nothing more malignant than the ward-heeler to fight against for the maintenance of his position.

Stepdaughter Entitled to Compensation as Nurse.—The stepdaughter is not bound, by the ties of consanguinity, to render her stepfather gratuitous services as a nurse and attendant during illness and decrepitude; but for such services, the supreme court of Louisiana holds, *Succession of Stuart*, Nov. 16, 1896, she is entitled to compensation.

Values a Laborer's Leg at \$15,000.—The appellate division of the supreme court of New York holds, in *Tully v. New York and Texas Steamship Company*, Dec. 1, 1896, that \$25,000 is too much to allow for the loss of a leg to a person 28 years of age, presumably in good health and strong, but who had no established business, and earned about \$12 a week at such employment as he could obtain; yet it holds that \$15,000 would not be out of the way.

International Honors.—The Emperor of Germany has conferred the decoration of the Kronen Orden of the second class upon Professor Roux of the Paris Institut Pasteur, and the French Republic has inscribed the names of Behring and Löffler upon the roll of the Legion of Honor. The Royal Society of London has also bestowed medals on Roentgen and Gegenbaur the anatomist (Heidelberg), and the Humphrey Davy gold medal upon Moissan of Paris, distinguished for his chemist researches.

Kinetographic Photography of the Heart.—Lechner's kinetograph allows twenty-five, thirty or more photographs to be taken in the course of a second, and is of great assistance in studying the activity of the heart. Braun has been using it to photograph the movements of the heart of a dog that was still continuing its beating. They were reproduced with absolute fidelity, and when enlarged showed certain details in the cardiac transformations that have always escaped the eye on account of the rapidity of the movements.—*Bulletin Méd.*, December 20.

Bellevue Hospital Medical College.—On January 20 this institution suffered a considerable loss by fire, which is believed to have originated from a defective electric lighting wire. The upper floor, containing the dissecting room, was entirely burned out and the lower floors were badly damaged by water. The laboratories were not seriously injured and the college records were for the most part spared. No serious interruption in the lecture courses has resulted from the conflagration, the rooms of the Carnegie laboratory and the Bellevue amphitheater having been put to use by the lecturing faculty.

The Obstetric Staff of the Health Department of Chicago met at the Auditorium Nov. 21, 1896. This staff, with Dr. Charles S. Bacon as president, is composed of physicians residing in the various quarters of the city and represents practitioners from the regular, homeopathic and eclectic schools. The object of this staff is to aid regularly licensed midwives in cases of difficult labor, to compel the registration of all midwives and to assist in the prosecution of those occupied in illegal practices. The staff holds meetings on the second Saturday of alternate months for the purpose of discussing the progress of the work and the reported cases. The registrar will record and tabulate all cases reported to him.

The Lee-Metford Bullet.—It is pretty well known that the troops in the Chitral campaign were not altogether satisfied with the "stopping power" of the Lee-Metford bullet. This has led to a number of experiments and a new bullet has now been devised in India for the Lee-Metford rifle which is stated to be admirably adapted to its purpose. Experimental trials have been made with it on an extensive scale at Meerut and elsewhere in the presence of a large number of officers, troops and medical officers, with most satisfactory results. The new bullet, while requiring no increase of caliber in the rifle or alteration in the charge of powder, retains the present range

and makes excellent shooting and inflicts the desired "stopping wound." It is the invention of Capt. Bertie-Clay, R. A., superintendent of the DumDum ammunition factory. Colonel Hill, in the course of a lecture to the troops at Meerut, said as the result of his personal experience that the Lee-Metford rifle with the new bullet was the most perfect weapon in existence.—*London Lancet*, December 26.

Nitrogen Monoxid in Obstetric Anesthesia.—The expense of the apparatus required to generate nitrogen monoxid has prevented its general adoption. But A. N. Rakhmanov recommends it in high terms in consequence of his experience with it in thirteen cases. The pains were absolutely abolished; the contractions of the uterus were normal and much more regular than before its administration, while there were no accidents for either mother or child. He urges the installation of the necessary apparatus in every large maternity institution, as nitrogen monoxid is the most anodyne and the easiest to manage of all our anesthetics.—*Bulletin Médical*, January 6.

Ranvier's Theory of Cicatrization.—Some recent experiments on rabbits have confirmed Professor Ranvier's assertion a while ago, that the union of wounds is not due necessarily to a multiplication, a proliferation of the epithelial cells, but to the fact that they become hypertrophied and slide down into the V-shaped space left by the incision, and in this way the union of the two edges of the wound is effected. Incisions in the cornea of rabbits show the process in the most interesting manner, and owing to its simple structure the various steps in the process can be watched and closely followed. As he remarks, the deeper cells of the corneal epithelium are like soft elastic balls compressed in a sack. If the wall of the sack is cut open at any point the balls will escape. When an incision is made into the epithelium of the cornea the cells are at first pushed back by the entering knife and then slip back again into their places, seeking the lower level until the wound is entirely closed by them, while the adjacent tissue is correspondingly depleted. They frequently show a number of nuclei in the course of twenty-four hours. The *Bulletin Méd.* of January 6 contains a detailed description of these interesting experiments.

Study of the Renal Circulation with the Roentgen Ray.—By injecting preparations with metallic substances the circulation can be studied with cathode photography to an extent and with a precision never before attained. If the photographs are then mounted to examine through the stereoscope, wonderful exactness can be secured. Poncet and Destots of Lyons announce the following results of their study of the renal circulation in this way: 1. The arterial circulation of the kidney is lobar and terminal. It divides the kidney into an independent anterior and posterior kidney. The one exception is the artery of the superior lobe which sometimes divides into two branches, so that in injecting it the whole of the upper end of the kidney is injected. 2. The intra-pyramidal artery divides by false dichotomy at the level of the cortical substance, but it does not anastomose with the collateral; there are no true arterial arcades. 3. A multitude of capillaries issue directly from the arteries and proceed to the glomeruli without passing through the multiple intermediaries. In incomplete injections the capillaries are seen emerging directly from the arteries, like needles on a pine bough or hoar frost on a branch. 4. The pyramidal arteries proceed from the glomeruli. 5. The veins anastomose readily so that the entire kidney can be injected through one single small vessel.—*Bulletin de l'Acad. de Méd.*, December 29.

The Mussulman Member of Parliament in France.—It seems that the new member from Franche Comté is not only a devoted Mussulman, but a popular and skilful physician, Dr. Grenier. Interviewed for the press he declares that he is charged with a prophetic mission, and hopes to see converts to his faith. The

Journal de Méd. de Paris asks: Why not? The two principal features in which Mohammedanism differs from other religions are polygamy and the daily ablutions. It remarks that these would not be bad innovations in France. Polygamy would increase the birthrate, while rendering many people happy and reducing the number of old maids, and if every Frenchman were obliged to wash his face and feet morning and night, there would be a transformation, a regenerescence of the race, and Dr. Grenier would have accomplished more for hygiene than all the rest of the scientists.

Non-expert Can Testify as to Existence of Hymen.—The objection was made, in a prosecution for an attempt to commit rape, that a female witness who was asked as to whether, when she made an examination of the child on the Friday after the offense was alleged to have been committed, there was any hymen there, was not competent to testify in relation to a matter of this kind; that it was a matter connected with the anatomy of a human being and that, to be competent, a witness should possess the same intelligence and knowledge that a physician or professor of anatomy does. The witness testified that she thought she knew what the hymen was and that, if it was what she thought it to be, it was not there. The overruling of the objection, the supreme court of California holds, in *People v. Barney*, Oct. 20, 1896, was not error. Certainly, it says, it can not be necessary that a witness should be a physician or a skilled physiologist in order to be competent to testify as to the existence or non-existence of any part of the human body, when the matter can be determined by ocular inspection.

Cincinnati.

DR. CHARLES A. L. REED has opened an office at No. 32 Garfield Place.

DR. GILES S. MITCHELL has been appointed gynecologist to St. Mary's Hospital, to succeed Dr. George E. Jones.

THE SUIT for \$25,000 against Dr. George H. Goode for malpractice has been decided in favor of Dr. Goode in the United States Court of Appeals.

A MAN appeared at the City Hospital last week with the following conditions: A silver plate 4 x 6 inches in the occipital bone, phlegmasia alba dolens, knee cap dislocated to posterior surface of leg, five ribs resected, his heart on the right side and a bullet in his pectoral muscle. These were all chronic conditions of several years' standing.

DR. G. I. CULLEN has been appointed on the surgical staff of the M. & C. Railway.

Philadelphia.

A STRONG SENTIMENT is abroad in the community in favor of increased accommodations for the insane and especially for the treatment of the criminal insane. By order of the court all of the insane convicts in the Eastern Penitentiary have recently been removed to the State Hospital at Norristown, where, by the way, one of them has since died under circumstances pointing to brutal treatment by the attendants, the case being now under investigation by the trustees. It is mentioned because it affords apparent support to the claim made by the prison authorities that the insane convicts could be treated as well in the prison as in the hospital. Judge James Gay Gordon, who has especially interested himself in this matter, appointed a commission consisting of Drs. S. Weir Mitchell, Thomas G. Morton, Charles K. Mills, F. B. Janney, and Assistant District Attorney Thomas W. Barlow to examine the insane prisoners at the penitentiary and the commission unanimously favored their removal to the hospital. On January 23 Judge Gordon and a party of invited guests paid a visit to the institution for the criminal insane at Matteawan, N. Y., under the charge of Dr. Alison. Their impressions were very favorable. It is thought that a strong appeal will be made to the legislature to make an appropriation for an institution of this character in Pennsylvania, as, indeed, has been recommended by Governor Hastings in his annual message.

THE SUPERIOR COURT has decided that the drug store act of 1887 as amended by act of 1891 is unconstitutional and reversed the judgment of quarter sessions court of Philadelphia in a case where a man was convicted of carrying on the business of an apothecary without being registered or having a certificate from the State Pharmaceutical Examining Board. The defendant owned several drug stores in Philadelphia, employ-

ing qualified assistants to carry them on. Personally he neither filled prescriptions nor sold drugs. Judge Reeder of the superior court gave his opinion that the law referred to came under the head of "objectionable class legislation" and declared it unconstitutional on this account. The act of 1891, amending the first section of the act of 1887, prohibits unqualified persons from engaging in the business of retailing drugs, etc., and provides a penalty for its violation which the section amended did not provide, and the amending act also excepted the "widow or legal representative of a deceased person who was a manager or registered pharmacist" from the provisions of the act, and declared it to be lawful for such person to carry on the business of such deceased persons, provided that the actual retailing, etc., "be done only by an assistant, qualified and registered" as required by the act. The reversal of the lower court is based on the ground that this is unconstitutional class legislation.

IT IS HOPED that a pay hospital for contagious diseases will soon be opened in this city. The Women's Health Protection Association in conjunction with the County Medical Society recently gave an entertainment in aid of this object, consisting of a concert, progressive euchre and dance at the Academy of Fine Arts, January 7, and realized a handsome sum. Twenty-three hundred dollars were subscribed previously, as a nucleus of the fund, by the Woman's Edition of the Press.

AN ANNEX to the diphtheria pavilion and an administration building for the Municipal Hospital have just been completed. The new pavilion contains two wards, each 40 feet long and 25 feet wide, and four private rooms, two of which are 13 by 13 feet, located at the west end and separated from the wards by a vestibule which opens upon a large porch, 25 feet long, enclosed in glass, which may be removed in the summer season. On the east end of the new pavilion is a porch and corridor 9 feet wide and 38½ feet long connecting the pavilion with the administration building, which separates the large and small pavilions. The space between each pavilion and the administration building is twelve feet in length and nine feet in width—all enclosed in glass, which may be removed during the summer season. The new pavilion is supplied with fresh air drawn from a stack some fifty feet from the building and conveyed under the ground through a tunnel to a chamber, where it is heated by steam coils and then propelled by a fan into the wards and private rooms. The foul air is driven out of the apartments by a fan drawn by an electric motor.

Washington.

TO SELL MEDICINES TO SOLDIERS.—The Vice-President has laid before the Senate a communication from the Secretary of War transmitting a letter from General Miles, president of the Board of Commissioners of the Soldiers' Home in the District of Columbia, recommending that Congress authorize the medical department of the United States army to sell medicines and hospital supplies at cost price to the Soldiers' Home in the District of Columbia. General Miles says that as the medical department of the army does not pay any internal revenue tax on whisky and alcohol, it can furnish these articles to the Soldiers' Home at a much less price than for which they can be purchased of private parties. The law does not permit the medical department to sell these articles to the Soldiers' Home, and Congress is asked to enact legislation necessary to permit it to do so.

HOSPITAL INCORPORATED.—Articles incorporating the Episcopal Eye, Ear and Throat Hospital were filed January 26, by Bishop Satterly, Thomas H. Looker, Redford W. Walker, Gilbert M. Husted, A. D. Van der Veer and Susan Ladd Johnston. The free treatment of all diseases of the eye, ear and throat is the purpose of the institution. The consulting physicians are Drs. W. W. Johnston, J. Taber Johnson, J. W. Bayne, J. Ford Thompson, S. C. Busey, and N. S. Lincoln. The attending physicians were named as follows: Drs. T. M. Murray, J. H. Bryan, E. O. Belt, Frank Hyatt, W. H. Wilmer and W. H. Fox.

A MEDICAL APPOINTMENT.—Dr. B. F. McGrath, formerly resident physician at the Central Dispensary and Emergency Hospital, has resigned from the resident staff of the Home for Incurables and been appointed by the directors a member of the House Staff of Columbia Hospital for Women.

THREE IMPORTANT MEDICAL BILLS PASS THE HOUSE.—Three bills effecting the sanitary condition of the District passed the House on January 25: A bill for the regulation of cemeteries and the disposal of dead bodies; a bill to regulate privies, and a bill to prevent the spread of contagious diseases in the District of Columbia.

A HOSPITAL FOR CONTAGIOUS DISEASES NECESSARY.—There is the greatest necessity for Congress to act promptly and pro-

vide a hospital for the care of contagious diseases prevailing in the District. Hardly a day or week passes that some unfortunate person suffering with diphtheria or scarlet fever is not going the rounds, to the different hospitals, seeking admission and being invariably turned away because of its absence of proper facilities for their care. The recent legislation regulating contagious diseases will help reduce the number of such cases, but Washington will never be a modern city until Congress appreciates the serious situation and protects themselves and our citizens by providing a suitable hospital for the care and isolation of contagious diseases.

TWO SCIENTIFIC POSITIONS VACANT.—The Civil Service Commission will hold examinations in this and other large cities where there are applicants, on February 20, for the purpose of securing eligibles for the positions of preparator of specimens and assistant biologist, Department of Agriculture.

THE PUBLIC SERVICE.

Army Changes. Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from Jan. 23 to 29, 1897.

Major Phillip F. Harvey, Surgeon U. S. A., is granted leave of absence for two months, to take effect on or about Jan. 18, 1897. By direction of the Secretary of War.

Capt. William O. Owen, Asst. Surgeon (Ft. Bayard, N. Mex.), is granted leave of absence for one month, to take effect about the 1st proximo. Major Clarence Ewen, Surgeon, having served over thirty years in the Army, is on his own application, by direction of the President, retired from active service this date, Jan. 26, 1897.

Major James C. Merrill, Surgeon U. S. A., is granted leave of absence for one month.

Capt. Robert B. Benham, Asst. Surgeon U. S. A., retired from active service by reason of disability.

Capt. Eugene I. Swift, Asst. Surgeon U. S. A., has been granted further extension of sick leave of absence of two months.

Change of Address.

Boyer, E. N., from 308 Jersey St. to Franklin House, Quincy, Ill.
Binkley, J. T., from Columbus Memorial Bldg. to 492 49th St., Chicago, Ill.

Barrett, E. J., from 12 Harrison St. to Palmer House, Chicago, Ill.
Beebe, Brooks F., 117 E. 4th St. Cincinnati.
Chapel, V. P., from Irvona to Newberry, Pa.; Cross, G. D., from Philadelphia to 618 Edgemont Av., Chester, Pa.

Jones, George E., from Cincinnati, Ohio, to Conneraville, Ind.
Johnson, C. W., from St. Louis, Mo., to Litchfield, Ill.
McBride J. H., from Wauwatosa, Wis., to 1761 Q St., N. W., Washington, D. C.; Murdock, E. P., from 571 W. Adams St. to 601 Washington Boul., Chicago.

Ramsay, R. T., from London to Danville, Ky.; Rigdon, R. L., from Market and 3rd Sts. to 1615 Brodrick St., San Francisco, Cal.
Silver, H. M., from 39 7th St. to 5 E. 43rd St., New York, N. Y.
Wood, E. S., from Fairmount to 524 Michigan Av., Leavenworth, Kan.

THE CLIMATE OF THE EAST COAST OF FLORIDA.

GENERAL HEALTHFULNESS, FREEDOM FROM FOGS, MUD AND DUST; ATTRACTIONS FOR THE INVALID AND TOURIST; NATURE'S SANITARIUM FOR THE CONSUMPTIVE.

S. G. WORLEY, M.D.

ST. AUGUSTINE, FLA.

W. L. HUGHLETT, M.D.

COCOA, FLA.

If it be true that the Rocky Mountain region "is a land lifted up by nature into the pure serene for the invigoration of the race," it is equally true that the peninsula of Florida, jutting out into the southern seas, offers to the aged and invalid a most inviting climate for the comfort of advanced years and the prolongation of life. Much has been written and said of Florida. Some who have come to the State and fortunately regained health and otherwise prospered have painted a picture in glowing colors of Florida and her wonderful climate; others, less fortunate, have given the dark side. It is our purpose as medical men and residents of the section, to give the world reliable information regarding this, the American Riviera.

By the east coast of Florida we mean that section of the main land between the St. John's River on the west and the Atlantic Ocean on the east; St. Augustine on the north and Key West on the south, the entire length of which is traversed by the Florida East Coast Railway and Key West and Miami Steamship Company. This territory includes the Counties of St. Johns, Volusia, Brevard, Dade and Monroe. Along this section and within a distance of a few hundred yards to a mile of the ocean, there is a system of waterways making an inland route almost the entire distance of the State. These waterways are lagoons, arms of the sea; they have been given the names of rivers, lakes and bays, and thus we have along the coast, the Halifax and Indian Rivers, Lake Worth and Biscayne Bay. These waters are all a clear blue, are salt and abound with fish, oysters and water fowl in winter. The land, for the most part, is high and dry, the native forest is of oak, hickory, pine and palmetto, but this has given way in many places to orange groves and pineapple fields or to vegetable gardens. The soil is a rich, heavy sand; we have neither dust nor mud; no frozen ground or slush. The prevailing winds are from the east, and the resident population, living for the most part within a few miles of the ocean and directly on these inland waterways, enjoy excellent health. We believe this to be the most healthful section of Florida and the climate is certainly as near perfect as is to be found. Before this section of the State was opened up people got their ideas of Florida

from visiting at Jacksonville, St. Augustine and other places in the northern part of the State, and many of them not seeing in those places the tropical growth they expected to find, have been sometimes disappointed. While the climate of these places is very desirable and their hotel accommodations are excellent, yet they do not present the "land of flowers" appearance that the visitor wishes to see. Let them remember that these places are in the northern part of the State, that one can travel south from Jacksonville 400 miles, a distance greater than from New York city to Richmond, Va., and yet be on the main land of Florida. By reference to a map it will be seen that Florida extends through six degrees of latitude, or from about 29 degrees north to 24½ degrees going south, a distance of over four hundred miles on a due north and south line. Certainly traveling this distance in a semi-tropical country must bring one to a mild and balmy climate, and such is the climate of the lower east coast of Florida. We shall not take up space by giving comparative statistics with other favored sections, but will present a few tables showing the temperature at several Florida points where the United States government has kept observers.

Seven months of the year on the east coast of Florida is our summer, with a temperature ranging from 70 to 95 degrees. At Jupiter, a government station a little more than half way down the coast, the highest temperature of the summer months for eight years past was 95 degrees F. and the lowest 64 degrees F. So far, then, as the summer temperature is concerned this statement will suffice. The spring and autumn in Florida is simply delightful, temperate weather. What is generally understood as the Florida season or winter are the first four months of the year.

Our temperature table below will include three important points about equal distance apart. Jupiter is a little below a line equally dividing the mainland of the State north and south, but is about half way between Jacksonville and Key West, the latter cities being the northern and southern extremes. The figures are taken from tables furnished by the Weather Bureau of the United States Department of Agriculture:

TEMPERATURE TABLE—FAHRENHEIT.

	JANUARY.			FEBRUARY.			MARCH.			APRIL.		
	Maximum.	Minimum.	Mean.	Maximum.	Minimum.	Mean.	Maximum.	Minimum.	Mean.	Maximum.	Minimum.	Mean.
Jacksonville	81	15	55	84	*14	57	88	27	62	92	34	69
Jupiter	83	34	65	87	*27	67	87	33	68	93	55	76
Key West	79	55	67	80	52	66	82	54	68	83	66	75

*These low temperatures are the record of the great freeze of 1896, the lowest temperature recorded in sixty years in the State. The lowest in eight years previous to this was 26 degrees in Jacksonville, 33 degrees in Jupiter.

From the foregoing table and also from another

submitted below, it can be shown that no other section of country in temperate latitude presents so equable a climate as the peninsular or southern portion of Florida. A perfect climate is only ideal; it is not a reality. In point of temperature a perfect climate would never fall below 70 degrees or rise above 75 degrees, as such a temperature would be more conducive to human comfort than any other. In no part of the world can such a climate be found. But if we extend this range ten degrees each way and say 60 to 85 degrees, we then have a climate that is obtainable for a considerable portion of the year. We say 60 to 85, because when it falls below 60 it is too cold for comfort, or above 85 it is too warm for comfort. From this it will be seen that the place that has, during the year, the largest number of days the temperature of which falls wholly within these limits, comes the nearest to a perfect climate.

The following table is compiled from the reports of the Signal Service of the United States Army. The headings of the lines and columns sufficiently explain their contents, bearing in mind that the figures indicate the number of days in that place for that month, no part of which the temperature was below 60 degrees nor above 85 degrees:

*Near Rock Ledge on the Indian River, table by Rev. J. H. White, observer Weather Bureau.

While the highest average maximum temperature for the months noted varies very little along the entire east coast, it being 86 degrees at Jacksonville, 87 at Jupiter and 81 at Key West, it appears there is a decided difference in the average minimum temperature, it being 25 degrees at Jacksonville, 37 at Jupiter and 57 at Key West (these minimum figures being for the coldest winter on record). Thus, while the summer is very uniform the winter temperature varies about 30 degrees, or from 25 degrees in Jacksonville to 57 degrees at Key West, a distance of about five hundred miles. Going south then from Jacksonville one may expect for every 100 miles traveled an increase of temperature from 4 to 6 degrees, there being a difference of 12 degrees between Jacksonville and Jupiter and 20 degrees between Jupiter and Key West. Key West being entirely surrounded by water, makes the winter climate relatively warmer and summer cooler than on the main land.

For twenty-five years the mean or average temperature for Jacksonville is as follows: November 62 degrees, December 56, January 55, February 57, March 62, April 69.

For eight years past the mean or average temperature for Jupiter is as follows: November 72 degrees, December 67, January 65, February 67, March 68, April 72. These figures showing a general average difference of 10 degrees between Jacksonville and Jupiter, approximately bear out the previous estimate. We, therefore, have in the Jupiter station a good basing point for calculating the temperature along the coast, and it will work very satisfactorily. For instance, one wishes to know about the average temperature for the month of January at Rock Ledge and Miami. We find the average at Jupiter is 65 degrees for January, Rock Ledge is about 100 miles north of Jupiter and would have an average temperature of 61 degrees; Miami is about 100 miles south of Jupiter and would have an average temperature of 69 degrees. For the present we have to figure this way, as many of the resort places are new and have no regular reliable weather reports.

From other data at hand we observe further, that along the east coast of Florida the temperature is from 4 to 6 degrees warmer for every 100 miles going south than other portions of the State. This is accounted for in several ways. The waters of the gulf are shallow near the land, whereas on the east side the ocean is deep in near the shore; there, too, the cold waves or winds which come to South Florida come across the gulf from Texas—Texas “northers” as they are called—and although they are tempered in coming across the gulf by the warmed waters, yet they are our cold winds. In fact, these winds from the northwest bring what damaging cold we have on the east side. A greater factor, however, in moderating the cold of these northwest winds and in regulating the climate of the east coast of Florida is that wonderful ocean river, the gulf stream. It sweeps in between the west end of Cuba and Key West and flows close in shore along the southeast coast of Florida, and as its waters are considerably warmer than the ocean proper and our prevailing winds being east, the warmed air thus brought over materially modifies our climate, making the winters warm and the summers cool by winds fresh from the ocean.

The regular “norther” which we have occasionally on the east side is a water wind and never brings frost. A glance at the map will show that Jupiter is nearly one hundred miles east of Fernandina, so that all of the due north winds that strike the coast east of Fernandina are water winds, always warmer in winter than those from the land; our cold, icy winds always come across the land and from the great northwest. Such then is a general review of the temperature of the east coast and its modifying influences. There are other things of great importance beside the range of temperature which should shape our judgment as to any climate; chief among these are humidity, fogs and dust.

The average humidity in Jacksonville for twenty-five years is 74, and for the last two years at Jupiter was 80; this is a fair average for the east coast. Now, as to fogs. One of the writers of this paper has lived twelve years on the Indian River, during which time he has not seen twelve foggy days, and here it rarely rains or is cloudy all day. From the weather bureau report from Jupiter station we make the following quotation: “Total number of foggy days, dense fog for over one hour, two in 1894, three in 1895.” This is, indeed, the land of sunshine. We have little or no dust, the soil along the east coast of Florida is a

rich heavy sand; it does not grind up into dust, consequently we do not have dust storms, prevalent in some sections; beside there is little open country and the wind has no chance even if it were dusty. There is but little clay in the soil; it is porous and furnishes an excellent filter for the rain that falls, so we have no mud. One hour after a heavy rain persons can walk in their shoes without getting their feet wet or shoes muddy. Think, then, of a country averaging three-fourths of the days of the year with clear skies, moonlight nights only rivaled in the tropics, no dust, no mud, no frozen ground or slush, no fogs to speak of, no unbearable heat or humidity, and an average winter temperature of from 65 to 85 degrees. These are the climatic conditions of the east coast of Florida.

Now as to the general healthfulness of this section. The Commissioner of Agriculture for the State of Florida has furnished us the following statistic data for the counties of the east coast of Florida, population and death rate according to the census of 1895. Population: St. John's County, 7,708; Volusia, 11,480; Brevard, 4,558; Dade, 3,322; total population, 27,068. Deaths: St. John's, 63; Volusia, 23; Brevard, 9; Dade, 7; total deaths, 102. Death rate less than 4 per 1,000. If there is any error about this statement, as some will no doubt suppose, the State officials are responsible for it. We present this table as an offset to many slanderous reports concerning the general healthfulness of this State and section, also for the purpose of directing attention to what is, so far as we can ascertain, the lowest death rate of any section of the United States. In the so-called sickly sections of the country and in nearly all of our cities throughout the States the death rate is four or five times as great as here.

From an interesting article on the climate of New Mexico, appearing recently in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, we make the following sweeping quotation: "Statistics have proved that the West Indian Islands and the *Gulf States* are unfavorable for most lung diseases and rheumatic fevers, as well as abdominal disorders generally, being hotbeds of malaria." There are undoubtedly sections of the Southern or Gulf States, notably along the Valley of the Mississippi River, that are extremely malarious, but such a wholesale statement as the foregoing must be corrected. Grant that these sections do have malarial troubles, they are not, as a rule, fatal, and it can be shown by statistics that the death rate of the Southern States as a whole is less than any other grand division of the country and the climatic conditions are here more favorable for the prolongation of life.

In defense of Florida we quote as follows from a report by Surgeon-General Lawson, published just the last war: "The climate of Florida is remarkably agreeable, being subject to fewer atmospheric variations and its thermometer ranges much less than in any other part of the United States, except a part of the coast of California. (This report made before the east coast of Florida was settled up.) As respects health, the climate of Florida stands *preëminent*. That the peninsula of Florida is much more salubrious than that of any other State in the Union is clearly established by the medical statistics of the army. Indeed, the statistics in this bureau demonstrate the fact that diseases that result from malaria are of a much milder type in the Peninsula of Florida than in any other State of the Union. These

records show that the ratio of deaths to the cases of remitting fever has been much less than among the troops serving in any other portion of the United States. In the middle division of the United States the proportion is 1 death to 36 cases of remitting fever, in the northern division 1 death to 52 cases, in the southern division 1 to 54, in Texas 1 to 78, in California 1 to 122, in *New Mexico* 1 to 148, while in Florida (a Gulf State) it is but 1 to 287." It would be idle talk to say there was no malaria in Florida, people appreciate truth. Wherever there is heat, moisture and decaying vegetable matter there must be some malaria, but what of it, when it causes no deaths. Beside this, people, and physicians as well, are too often in the South disposed to call every trifling ailment, even biliousness and disorders of digestion, malaria. It frightens outsiders, it means nothing to us.

The east coast of Florida is fortunate in having little or no malarial troubles. For the most part the land is high and dry, the soil is sandy and water does not stand upon it. The people for the most part live along the banks of the rivers within a few miles of the ocean. There is almost a constant prevailing east wind fresh from the ocean, and the miasmatic vapors that form about the low lands and marshes west of us are blown away, so that our air is very pure.

A prominent physician of the Indian River country states "that in twelve years he has not seen a case of scarlet fever, diphtheria or true croup, has had only three cases of pneumonia, all sequelæ of la grippe and all recovered; has never had a death from simple malarial fever; that rheumatism is rare amongst those who are properly fed, and that most asthmatics do well and nearly all consumptives are benefited in this section."

Another prominent physician, in an article on the health of Brevard County (this county being 100 miles long, making one-fourth of the east coast), makes this statement: "For the last four years I have not used over four ounces of quinin or its kindred compounds in my practice annually. There is but little tendency for the remitting and continued fevers to pass into that state known as typhoid."

From the same writer (Dr. Geo. W. Holmes) I quote further: "The Indian River furnishes an unsurpassed asylum for the invalid from the chilly blasts of old winter. It is equaled by few sections of the world in its freedom from damp and foggy mornings. Its sandy soil swallows up whatever rainfall the passing showers may bring, leaving the surface free from redundant water, so that there is absolutely no mud for the pedestrian to chill his feet with.

"The invalid seeking recuperation from the ravages of that invincible destroyer of our race in northern latitudes, pulmonary disease, will meet in many of the resident population practical demonstration of its beneficent influence. The writer of this article came to this section in January, 1875, from central Ohio, suffering from pulmonary consumption. Improvement was definite the first winter, and a continued residence has resulted in confirmed good health, continuing to the present year, 1896."

Statements could be multiplied at great length setting forth the advantages of this favored section, but we think enough has been said to warrant physicians throughout the country in advising their patients who have incipient phthisis or are otherwise in feeble health to come to this section of Florida. Not only

may they be safely advised to come here for the winter months, but to make for themselves permanent homes.

The east coast is comparatively speaking a new section of the State. In other years, when a trip to Florida was the popular thing, the east coast was quite inaccessible. A journey from Jacksonville or St. Augustine to Rock Ledge or Lake Worth required many days and great inconvenience; this now is all changed. About five years ago Mr. Henry M. Flagler, a New York millionaire (and member of the Standard Oil Company) undertook what was and is a stupendous project—that of building and operating a railroad from St. Augustine south to the Keys, the present terminus being at Miami, 366 miles south of Jacksonville. Mr. Flagler has also constructed along this line of railroad at different points the most expensive and elegant hotels in the South, perhaps in the world. It is then no longer a question of expedition or comfort in travel or entertainment after reaching this section. There is much in this section to attract the tourist and invalid. There is no rough mountain scenery, the land in no place rising more than 100 feet above the sea level; but for broad expanse of water view, for evergreen tropical vegetation, for fine fishing and hunting, for balmy air in which the invalid can remain out of doors nearly all the time, we have a country unequaled. A few years ago the forest of palms and hard woods stood in its primeval glory. Now it is broken in many places, and here and there thrifty little towns dot the coast, where once stood the Seminole tent. The attractions of these little towns are varied, all now offering the comforts of life.

Going south from Jacksonville is St. Augustine, the first east coast town, noted for its antiquity and its magnificent hotels. It is said that the Ponce de Leon Hotel in St. Augustine is the finest structure of its kind on earth; and its service is unsurpassed. Going yet further south the next places of importance are Ormond, Daytona and New Smyrna, on the Halifax River and ocean front; these places are noted for their fine sea beaches, admirable for bathing, which, with beautiful shelled streets, make it very attractive for the bicyclists and for driving outfits.

Still further south, down on "the Indian River," we come to Rock Ledge, "the beautiful." No place in Florida presents more natural beauty than Rock Ledge. The shelled drive along the rocky front bordering the Indian River, overhung with moss-draped oaks and the evergreen palmetto, is something enchanting. Here too is the home of the famous Indian River orange. Rock Ledge has three excellent hotels and a number of boarding places suited to all classes of people. One hundred miles below Rock Ledge and we come to Lake Worth, in the midst of semi-tropical scenes and pineapple plantations. On the peninsula between Lake Worth and the ocean Mr. Flagler has erected the Royal Poniciama Hotel at Palm Beach, with accommodations (including "the Inn") for 1,000 people. Everything has been done here to make glad the heart of the visitor.

Yet further south nearly a hundred miles, down on Biscayne Bay, we come to Miami, and for the present "here we rest."

Miami presents a strictly tropical appearance. Its cocoanut trees, with profusion of vines and beautiful flowers, make a scene that can not perhaps be observed anywhere else in the United States. At this place Mr. Flagler is having erected another beautiful hotel,

the Royal Palm, which will be ready for guests the coming season. So much, then, for the country and its advantages.

In closing, we wish to present some views for the benefit of the consumptive. In the present state of our knowledge there is no specific cure for pulmonary tuberculosis; neither is there any climate or section where all can be cured. Patients have been sent in all directions. They have been advised to climb into "the blue serene" of the mountains where the air is light and pure, and where respiration could be carried on with less difficulty than at the sea shore; they have been sent to the wide plains to breathe the dry air (and likewise the dust); they have been sent to the far north where the air is so cold that the bacilli might be frozen out; they have been sent to the tropics where no pneumonia would aggravate. Alas! no place suits every case; some are doomed to disappointment. Now, we offer you the east coast of Florida as nature's sanitarium. In a paper read before the last meeting of the Florida State Medical Association, Dr. George Troup Maxwell stated that forty years ago pulmonary consumption was almost unknown in Florida, the disease now existing having been brought into the State by outsiders. To this statement we can add the testimony of many physicians now in the peninsula of Florida that, except in cases of heredity or clear infection, consumption is almost unknown among the resident population. This should give great encouragement for sending patients with pulmonary and catarrhal affections to this section. (Our health officials might profit also by this lesson, for in extending our hospitality we are inviting a foe.) Physicians in advising a change of climate must consider more than range, or variations of temperature. Sick people are sensitive, especially so are consumptives; although as a rule they are the most hopeful class of invalids, they are much affected by scene and environment.

Little benefit could be derived in a uniform temperature of 80 degrees, if there was nothing in sight to delight the eye or gratify the palate.

What the consumptive requires is a climate so mild that the tuberculous process is not aggravated by respiring chilled air. Congested conditions of the lungs and bronchial tubes deprive him of a certain amount of oxygen absolutely necessary for life and comfort.

They should be out of doors amongst the trees and flowers, breathing in nature's remedies. They should have the sunshine, which here they can have three-fourths of all the days of the year.

They should have fresh fruit, fish and vegetables, which here abound, the orange, pineapple, grape fruit and saw-palmetto berry growing here in their greatest perfection. They should have good beef, eggs, bread and milk, which can now be had anywhere along the east coast. Neither air, sunshine or drugs alone will cure a consumptive; they must be fed until we shall have discovered a remedy that will destroy and rid the system of tubercle bacilli without destroying life.

A country showing such a low death rate as ours must be healthful, and a healthful country is better suited to invalids than those sections where much sickness prevails. It will be difficult to find a climate better suited to the invalid class than that of the east coast of Florida. Here in midwinter he may bask in the sunshine or hie himself (or herself) to the shade of the beautiful evergreen trees. At night he is

soothed to slumber by the murmuring of the mighty deep. From his window he may look out upon a broad expanse of blue water, salt and pure; upon waving palms and beautiful fragrant flowers. At the table he may have the most nourishing food, the most luscious and healthful fruits.

Here there is no dust, no frozen ground, mud or slush; but few damp mornings, and the invalid's life is full of variety, and a pleasant existence rather than a weary fight for life.

Being ourselves thoroughly convinced that no section of our great country offers so mild and equable a climate, so low a death rate or so many advantages and conditions favorable for the prolongation of human life, we take pleasure in presenting these facts, and will gladly give further information if desired.

INFANT MORTALITY DURING LABOR, AND ITS PREVENTION.

BY Z. LINCOLN WHITMIRE, M.L., M.D.

URBANA, ILL.

The time was when women brought forth her offspring with pain and suffering, without the presence of midwife or physician; but from the beginning the process has been accompanied by dangers to the mothers and more or less mortality among the children. Although we lack full statistics it can safely be asserted that among the uncivilized peoples (those wholly uninfluenced by civilization) the rate of infant mortality is far less, during labor, than it is at the same time among the civilized peoples. This may seem at first a broad statement, but by comparing the two classes of peoples we can easily find sufficient causes to warrant the assertion.

Man, in the first stages of his existence, was semi, or wholly, barbarous. From that state of being he has gradually grown through the successive stages of civilization to the highest type of human possibility at the present time, a refined and civilized being. He left his footprints all along the way and today they may be found scattered throughout the world in the various civilized, half civilized and savage peoples that mark the different stages of his progress.

In order to get a better understanding of the existing circumstances let us examine the two extreme stages of his existence in respect to his life and characteristics in each stage, and judge of their influence on the mortality of the children of each class. Take, for instance, the wholly uncivilized races, those completely isolated from the influences of the civilized world; with them, like with the lower animals, it is a pure case of the survival of the fittest. Stout, robust, healthy people, living a life of activity and open air exercise, every muscle in their bodies is well developed; every organ is in a perfect state of healthy activity. Where anything is definitely known about them, history and science teach us that they are a perfectly healthy and happy people where civilization has not cast its baleful shadow upon them. Every man, woman and child is in a direct line of healthy ancestors. Each and every one is of good blood, is well developed and has an enduring constitution. They all dress in accordance to the demands of the climate in which they live. In warm climates, where most of them live, they are not encumbered with clothing to any great extent. In cold climates, where warm clothing is necessary, they wear thick fur clothing, but wear it loose; for experience has taught them

that thick clothing, loosely worn, will keep them much warmer than the same clothing worn with a tight fit. Hence, no matter in what latitude they may live, we find them wearing no restraining bands or no tight laced corsets; nothing, in fact, to retard their normal growth or to check the natural development of any part or organ of the body.

With pregnant women this is an important factor; but there is another, and perhaps greater, difference between these women and their civilized sisters. Child-bearing with them is a pleasure as well as a duty, for they have nothing to fear from the dangers of it, as compared to the civilized woman. Although the uncivilized sister is a hard-working woman and does all the work of the place, even up to the time of her confinement, she seldom has a miscarriage. Her good health and free and unrestrained development are guards against it. She neither fears the dangers of childbirth nor dreads the ordeal of pain. Her fine physique and her healthy ancestry reduce these to a minimum. Her children live and thrive and in time reproduce their kind, and people their country with types of robust, strong and healthy people, who multiply upon the face of the earth as God commanded.

Between the uncivilized and the ultra-civilized there is a class that have felt the influence of civilization without themselves being civilized thereby and are, in every such instance, losers by the contact. The American Indian is a good example of this class. Over them has civilization cast its shadow and upon them left its blight. Among them came the civilized Christian with the Bible in one hand, a flask of brandy in the other, the germs of tuberculosis in his system and a Hunterian chancre under his prepuce. He left behind him a degenerating race of miserable débauchés, suffering from the ravages of consumption and rotting with syphilis, whose path through the world is best marked by their graves.

Let us now consider a people upon whom the effect of civilization has been to improve them intellectually, to enfeeble them physically and, in far too many instances, to render them morally depraved, namely, ourselves.

Ease, luxury, indolence, licentiousness and intemperance, the creations of that corrupt offspring of civilization, fashion, are the sins for which our healths and the healths of our children have to suffer. For nearly, if not quite, fourteen centuries we have been inheriting and transmitting the vitiating effects of these vices, so that what wonder is it that today we are degenerated physically from what our earliest ancestors were, and what wonder is it that some of us are morally depraved? What wonder is it that we are a race of tuberculous syphilitics?

Our women are in a worse condition, if possible, than the men. How little are they prepared to bear children. Like their husbands, they are the offspring of a physically enfeebled race. Civilization has raised them mentally above the plane of their barbarian ancestors; but, being naturally of a frailer constitution than the men, the physical retrogradation that they have undergone, side by side with the male portion of the race, leaves them today but a faint outline as compared with the sturdy robust persons of their female progenitors.

They marry, like their mothers before them, for purely social and financial reasons; and seeing about them the fatal effects of reproduction, they shun that duty accordingly. Themselves the progeny of a

symphilitic degenerated ancestry, they dread the responsibility of reproducing their kind. The married life of one is almost the counterpart of that of each of the rest. Her physical development being probably imperfect, she may not have the normal sexual desires associated with a married life. But whether she complies with the wish of her husband through desire or through a sense of duty, she takes the precaution to avoid pregnancy. This precaution is often unnecessary because of some abnormal (and congenital) condition of her generative organs, but more often because of the pathologic condition of the generative organs of her husband (attributable to youthful indiscretions); but it is taken nevertheless, and the mode that is usually employed is one that of itself will soon render the woman sterile, to say nothing of its being apt to make her an invalid for the rest of her life. I refer to the practice of using a cold water douche (with some strong astringent dissolved in it) just after coition, and while the uterus and its appendages are hot and congested with blood. But society has too many demands upon their time to allow such a small matter as her health or her life to interfere and cause her to be laid up at home for a year or more with a baby to attend to; and business has too many demands for money to spend it in raising and educating a child. Nor can the woman have her beauty sapped out by a nursing child. If she becomes pregnant it is an accident; but even then she is not without hope. There is still another hope, abortion. And, though I blush to acknowledge it, she finds no trouble in securing a physician who can ease what few conscientious scruples she may have left by finding some excuse for producing premature labor. This again removes a stone from the foundation of her already frail constitution; and so they multiply. What wonder that the rate of infant mortality during labor is greater among the civilized races than among the uncivilized? It is only too true.

These are only the remote causes, and not those with which the physician has to deal in treating a complicated labor case. By carefully studying the immediate causes (of which there is a classified list below) it will be seen that a great part of them are the effects of the remote causes just mentioned. Their origin may be found in the inherited diseases, in the congenital or acquired physical defects, or defects in the physiologic functions of some organ of the body (caused by inherited or acquired disease); and last, but not least, they may be caused by a too faithful subservience to the demands of fashion, whose slave the woman is, as was her mother before her. The immediate complications of labor cases, from the effects of which the physician is called upon to protect the child's life, are as follows:

I.—Those located in the maternal tissues.

1. Deformed pelvis.
2. Tumors obstructing the passage.
3. Unyielding perineum.
4. Uterine inertia.
5. Ante-partum hour-glass contraction.
6. Displacement of the uterus.
7. Rupture of the membrane.

II.—In the cord and placenta.

1. Short cord.
2. Cord around some part of child.
3. Knots in the cord.
4. Prolapse of cord.
5. Placenta previa.

III.—In the child

1. Head presentation.
 - a. Head abnormally large.
 - b. Body abnormally large.
 - c. Face presentation.
2. Breech presentation.
 - a. Head pressing on the cord.
 - b. Arm thrust past the side of the head.
3. Twin labor.
 - a. Children wedged.
 - b. Head-lock.

There is no other case in which the physician's services are required, where he is so universally placed at a disadvantage, as in a labor case. He is not usually called to attend the woman till she has been in pain for some time, and then he is obliged to hasten to the scene of action lest, if the case be a normal one, the child be born before he arrives; and should it prove to be a badly complicated case, he finds himself there almost empty-handed, or at least without the very instruments and medicines that he needs; for, in his haste, he has left them at home. Such trivial circumstances make no difference to the people whose relative or friend he is to attend. No matter what may be the nature of the complication that exists, he is expected to meet it with skill and promptness.

I heard the late Professor J. S. Knox of Rush Medical College say that he never undertook the care of a labor case unless it was placed in his charge before the eighth month of gestation. If all physicians would make that a rule it would be better for the mothers and children, and of infinite benefit to our reputations as successful obstetricians. By doing that we would place ourselves in the most favorable position to meet the complications and would thus be more apt to secure a living child, and to prevent, in many instances, the death of the mother. For we would not be taken by surprise, but being forewarned would be forearmed, and that is no insignificant item in handling complications that may cause the death of a child.

Let us take a hypothetical case to which we are supposed to be called thirty to sixty days before labor is expected. We first inquire into the history of the case and its progress since conception, so as to be able to determine the probable date of its completion. Her family history and her personal history must be investigated, not omitting to question her as to the number of births, stillbirths and miscarriages she may have had. Should she report any we must use our best efforts to determine the probable cause of each. For this we will find her personal history of value, and a digital examination of her vagina (and of the uterus and its appendages) will be indispensable. If, during this examination, which should be thorough, any obstructions are found that are sufficiently large to endanger the life of the child in passing, they should be examined to ascertain whether their character is such that they can be reduced in size or removed. They should then be treated at once in the manner best adapted to their nature and to existing circumstances. Before departing word should be left for a sample of the patient's urine to be sent to your chemist for examination each morning for eight or ten days. This should be repeated at intervals till the patient is confined, and if albumin is found to be present each time and in large and increasing quantities, one may be certain that the patient is going to have

uremic convulsions if nothing is done to prevent it. It was for this examination more than any other one reason that Professor Knox insisted on having charge of his cases before the eighth month. Furthermore, this early examination makes one complete master of the situation, so far as surprises are concerned (in the way of complications that may be found or anticipated at this early time).

This brings us to the classified list of complications. Of the class located in the maternal tissues, the first is:

Deformed pelvis.—By this is meant a pelvis in which one or more of its diameters is so small that a normal-sized child can not pass through without endangering its life. It is true there are degrees of deformity, but to be classified with the complications that endanger the life of the child during labor, it must be as above stated. This narrowing of the pelvis may be due to various causes and it may be deformed in various ways: 1, it may be deformed by being misshapen or twisted; 2, it may be from a bony growth, caused by disease or by bone tissue being thrown out to heal some injury to the bones of the pelvis; 3, it may be deformed by being too small in every diameter, though perfectly regular in shape. This is usually called a contracted pelvis. The first two of these may be congenital in origin or may be the result of injury or disease. The last (when found in a large or medium sized woman) is due to a thickening of all the bones of the pelvis, or from an insufficient development of the whole pelvis; but it is most commonly found in small women, where the pelvic cavity is in just proportion to the other parts of the body but too small for the passage of a normal-sized child by a natural delivery.

A deformed pelvis is one of the complications that can be discovered at any time by an examination. In examining a pregnant woman, either before or at the time of confinement, the size of the pelvis and of the conjugate diameter in particular, should be noticed, and if it appears small it should be measured at once. In measuring, bear in mind that a conjugate diameter of three inches will allow a living child to be extracted, with or without forceps; three to two and a half inches, may be delivered by forceps or version; while two and a half or less, may be delivered by craniotomy. If, before the time of confinement, the patient's pelvis is found to be too small to allow the child to pass, we have to weigh the desire for a living child against the dangers of Cæsarean section or symphyseotomy at full term, and in accordance with our decision await for full term or induce premature labor. Unfortunately, we are not usually in a position to discover the deformed pelvis till we are at the bedside of the woman to attend her in confinement. Premature labor is then out of the question, and we have left four modes of procedure to choose from. We can secure a dead child by craniotomy or embryotomy, and a living one by Cæsarean section or symphyseotomy. In making our decision we must take into consideration the state of the patient's health and the probability of her being able to withstand the operation that we decide to perform. As to the severity of the operations themselves, statistics show us that symphyseotomy is not only far less dangerous than craniotomy, but it has the advantage of securing a living child. This is an important feature, for, where a woman is conscious of having a living child, she will recover much more rapidly (other things being equal) than where she knows the child to be dead. It may also be

stated that embryotomy is almost out of the question, for it seldom occurs that craniotomy will not do all that is necessary. As to the choice between symphyseotomy and Cæsarean section, statistics and observation will soon settle that. The child has a much better chance of living when symphyseotomy is performed, for the delivery is in every way natural, while it is a matter of record that the mother has a far better chance of recovery. This will seem perfectly clear when one stops to think of the greater amount of mutilating necessary to perform Cæsarean section; whereas in symphyseotomy there is very little blood drawn, the incision may be made subcutaneously and the abdominal cavity is not opened at all. Hence, under ordinary circumstances, symphyseotomy should be chosen to secure a living child in all cases where the choice lies between it and Cæsarean section, craniotomy or embryotomy.

Tumors obstructing the passage.—The word "tumor" is here used in the sense of the word from which it is derived, *tumere*, meaning to swell. That is, any swelling of the tissues of the mother from the uterus to the vulva, inclusive. These tumors may be the result of inflammation; they may be distinct pathologic growths of benign or malignant nature, or they may be caused by bony growths beneath pushing out the flesh, in which case they come under the class of deformities of the pelvis and are discussed there. Whenever tumors are found and are of sufficient size to be a serious impediment to labor, their exact nature must be determined at once. If they are the result of inflammation they may usually be reduced in a short time, a few hours, by the application of a hot water douche or more rapidly by lancing, according to the demands of the case and of surrounding circumstances. If they are distinct pathologic growths, the only means of freeing the passage is by extirpating them. This, of course, must depend upon the time you may have and upon the condition of the patient. When it is found to be impossible to reduce the size of the tumor, and at the same time the circumstances and conditions are such that it should not be extirpated, the physician is placed in the same position in which he would be if the case were one of deformed pelvis. That is, if the tumor is so large that it will prevent instrumental delivery, the physician would have to choose between symphyseotomy and Cæsarean section if he wishes to secure a living child, or he would have to perform craniotomy if he decides on a dead one; and the same circumstances must be taken into consideration that were mentioned under the treatment of deformed pelvis. Hence, where not especially contraindicated, symphyseotomy should be performed.

Unyielding perineum is the third in this class and is not a very common case. By that it is meant that it is very uncommon to see a perineum so non-elastic as to endanger the child's life. When the perineum is not elastic enough to allow the child to pass and at the same time is too tough to rupture, the pressure of the uterus is sure to destroy the life of the child. That is the kind of perineum that comes within the scope of this paper, though it is of uncommon occurrence, it is by no means impossible. When such a case occurs the physician is sometimes able to deliver with forceps and he should make an effort to do so, but he will not always succeed. It is not always possible to determine whether or not the perineum is going to rupture till it actually tears; and since the less yielding the perineum is the greater is the damage

when it tears, it is not always best to wait till it actually declares itself, but to wait only till it looks as though it will probably tear and then cut notches in the edge at each side of the median line, so that it will not tear down the center and involve the sphincter ani as well as the perineum, but will tear in the line of the notches and a short distance only, thus saving a very troublesome wound and allowing the child to pass by, with or without forceps.

As to the immediate closing of the perineum, nothing better could be mentioned than the teachings of both James H. Etheridge, M.D., Professor of Gynecology and Obstetrics, and the late Charles T. Parkes, M.D., Professor of Surgery, both of Rush Medical College, and in the words of the former: "I have taught for years that the perineum that has been pommelled for two hours or more by a delayed second stage of labor, where the head descends upon the perineum, stretching it a little and then receding till the perineum is almost black and blue from mechanical violence, should not be closed by immediate operation, but that the operation should be delayed for twelve weeks. In cases of labor where the violence to the perineum is not done, the immediate operation is highly proper. This was also the teaching of our old friend, Dr. Charles T. Parkes."

(To be continued.)

APPENDICITIS WITH PURULENT PERITONITIS.

Read before the Kentucky State Medical Society at Lebanon, Ky.,
June 11, 1896.

BY J. G. CARPENTER, M.D.
STANFORD, KY.

In presenting this subject the writer wishes to deal with its pathology and surgical treatment; and report successful clinics that have occurred in private country practice with the giants of the profession, viz., the general practitioners. There is no theme of more surgical importance than appendicitis, with or without perforation and gangrene. Whether we be physicians, general or abdominal surgeons, sooner or later we must confront suppurative appendicitis with purulent peritonitis.

As a rule the general practitioner is the first to see these cases. Upon his knowledge of pathology, early diagnosis, complications and surgical treatment, hangs the life and destiny of the patient; and it is incumbent upon him to give the danger signal, operate, or call a surgeon who will, and save life. Not an ideal, but life-saving, conservative surgery. It is not so much how many operations are performed, as how many lives can be saved? For a physician to let a patient die for want of clean skillful surgery, is nothing less than murder.

The time has come when one can no longer dilly-dally—batten the patient with opium, waste time with poultices and wait for tomorrow. No doubt many, many physicians today as they see and learn more of the pathology of appendicular lesions, illumined by the light of surgical science, lament over the "past and the might have been" and think of lost opportunities and patients sacrificed to timidity or want of skill.

Our knowledge of appendicular and peritoneal inflammation and successful surgical treatment, has not come from college professors; but from earnest, honest, skillful and wise general practitioners, who

have grown to be successful and ideal abdominal surgeons. Early diagnosis, early preparations, short anesthesia, quick skillful surgery, means the saving of a life, removal of dangers that daily menace health and happiness; a minimum of shock, and one or two per cent., mortality.

Today we will open the abdomen, give our attention to the appendix and cecum, and study their morbid anatomy and that of adjacent organs as it concerns our subject. Recurrent appendicitis is a constant indication for section and appendicectomy, suppurative or ulcerative appendicitis with or without perforation into the abdominal cavity or the appendix, enclosed in thick lymph walls and adhesions, is a most cogent reason for operation. Imprudence in eating, exercise, or a blow, or fall, carrying a heavy weight, straining at stool, a sneeze, colic, paroxysm of laughter, cough or emesis, is liable at any time to strain, stretch or rupture the abscess wall, or the latter from septic pus laden with microorganisms may become macerated, disintegrated, perforated, leak, rekindle the peritonitis, produce bands of lymph or an adherent appendix; and constrict the lumen of the bowel and cause intestinal obstruction or purulent peritonitis, and death—for death in a few hours or days will come unless early diagnosis, section, irrigation and drainage are done as life-saving measures.

Inflammation may extend from the cecum to within the lumen of appendix, or the appendix may be primarily the "*fons et origo*" of irritation, inflammation and perforation with abscess or gangrene and the cecum remain normal, or the latter in turn become violently inflamed, lacerated, or gangrenous and perforated, as was so beautifully shown in a case operated upon and patient saved by the writer.

The appendix may be adherent to the liver or gall bladder, broad ligament, ovary, tube, bladder, uterus or sigmoid; it may become twisted around the small intestine, finally causing obstruction, or become a part of an inguinal, umbilical or scrotal hernia. From repeated attacks of appendicitis lymph exudation is thrown about the appendix and upon and around neighboring structures. If upon the intestines, bowel paralysis may result or bands of lymph may cause destruction of tissue. Lymph may form in sufficient amount in all directions on the peritoneal surface and form a barrier more or less complete, sufficient to protect the peritoneal cavity from septic infection when abscess forms in the pericecal regions; in other cases there forms a distinct abscess wall completely encysting the appendix, and constitutes the tumor so often observed in these cases. It is usually well defined, immovable, more or less dense and painful to pressure; although it may contain pus as a result of the perforation of the appendix there is no fluctuation until the tumor increases in size; as it approaches the surface, super-imposed tissue becomes edematous. Such an abscess may open through the abdominal wall and so establish a fistula between the bowel, the abscess cavity and external abdominal wall, over a point where the abscess should tend, with sufficient lymph wall to protect the peritoneum; ulceration and perforation may suddenly cause the gravest symptoms of shock and collapse, and death eventuate in twelve or twenty-four hours therefrom, unless section be done by a competent surgeon. A patient may have only one attack of appendicitis, recover completely and never have a recurrence, because the foreign body, appendolith, has escaped into the cecum, also sub-

sidence of inflammation and escape of appendicular secretion; the appendix may now undergo atrophy and be converted into a cord-like body, no longer a source of trouble or danger, "appendicitis obliterans."

The appendicular abscess may empty into the peritoneal cavity or into the super-imposed tissues and reach the surface, or in both cases by attachments and perforations. discharge into intestine, colon, sigmoid, uterus, bladder, vagina, become adherent to liver with abscess, and also cause abscess of omentum, tube or ovary. In perforated appendicitis with pericecal abscess and purulent general peritonitis, temperature 103 or 105, respirations 40 to 60, pulse 150 after section, with irrigation, drainage and rest, they have become normal within twenty-four hours, and patients made afterward prompt recovery.

It is most frequently impossible to differentiate between disease of the appendix and cecum, owing to their close relation. Both organs are covered by peritoneum through a portion of their extent and are liable to irritation, inflammation, ulceration and perforation. Perforation of the appendix is quite common, of the cecum rare and can only be settled positively by section. The diagnosis must be made between appendicular or cecal inflammation and acute intestinal obstruction, volvulus, intussusception, fecal impaction (obstruction may be simulated by the attending peritonitis, owing to the paralyzing effect on the bowels), also from spinal or perinephritic abscess.

Abscess of ovary and tube, abnormal pouch, or diverticulum of the ileum, is sometimes found in the right iliac region, also non-malignant and malignant tumors. Strangulation of the bowels, intussusception, volvulus, as a rule come suddenly; impaction of feces, psoas or iliac abscesses or tumors come on gradually; their physical characters and clinical history are usually sufficient to form a diagnosis. Abscess of tube and ovary and impaction may be diagnosed by the history, digital and conjoined manipulation. The final diagnosis must be made when the section is done.

Appendicitis may be complicated with an enlarged, elongated gall bladder, gangrene of the appendix vermiformis, with necrosis of mesentery and ileum, or pericecal abscess and fecal fistula. If the peritoneal cavity has been invaded by abscess, the intestine can be easily reached and cleansed through the lateral or median incision. The length of incision is from three to six inches, parallel with the colon and extending an inch or more above the middle of Poupart's ligament, upward and outward over the appendicular region to the outer side of the right linea semi-lunaris and continue downward until the peritoneum, cecum, appendix or pus-cavity is reached.

The appendix may be adherent and have to be separated, or have a mesentery of its own, its entire length; this must be tied in sections and cut away, the appendix ligated close to the cecum with silk or cat-gut, and cut off, and the peritoneum stitched over the stump with Lembert suture as a protective barrier to further infiltration of leakage; some operators invaginate the stump and stitch the peritoneal surfaces. The appendix has been found floating in the abscess, detached from the cecum; pericecal abscess may exist and the appendix seem normal; removal of the latter would be conservative and prophylactic against future mischief. An appendix with its cecal end closed, containing a foreign body or secretion, or enlarged, ulcerated, sloughing and perforated or adherent, should

always be excised, and the stump before being covered by peritoneum should be iodoformized. The abscess cavity and the peritoneal cavity should the latter be involved, must be irrigated with hot distilled water, 98 to 105 degrees.

A long glass drainage tube should be placed to the bottom of the pelvis in the hollow of the sacrum, the abscess cavity drained with a large rubber tube, the wound coaptated with the necessary sutures, supported by rubber adhesive strips and dressed aseptically, pro re nata. Dr. Nicholas Senn's conclusions are these, viz:

1. All cases of catarrhal and ulcerative appendicitis should be treated by laparotomy and excision of the appendix as soon as the lesion can be recognized.

2. Excision of the appendix in cases of simple, uncomplicated appendicitis is one of the easiest and safest of all intra-abdominal operations.

3. Excision of the appendix in cases of appendicitis before perforations have occurred, is both a curative and prophylactic measure.

4. The most constant and reliable symptoms, indicating the existence of appendicitis, are recurring pains and circumscribed tenderness in the region of the appendix.

5. All operations should be done through a straight incision, parallel to and directly over the cecum.

6. The stump after excision of the appendix should be carefully disinfected, iodoformized and covered with peritoneum by suturing the serous surfaces of the cecum on each side over it with a number of Lembert stitches.

7. The abdominal incision should be closed by two rows of sutures, the first embracing the peritoneum, and the second the remaining structures of the margins of the wound.

8. Drainage in such cases is necessary and should not be dispensed with.

We must know how to deal with adhesions, lacerations, necrotic spots, perforations and fistulae of the bowel and adhesion of appendix to other organs such as the liver, gall bladder, uterus, Fallopian tube, ovary, omentum and sigmoid; removal of pus tube; ovarian abscesses, omental and mesenteric abscess, ovarian cyst with twisted pedicle, and suppurating ovarian cyst. We may meet with one or more of the complications of ruptured extra-uterine pregnancy, psoas abscess, or foreign body, such as extra-uterine bone. Often in suppurative appendicitis with perforations and purulent peritonitis the indication will be to incise into the peritoneal cavity and abscess, evacuate the pus, wash out the cavity, drain and wait until a future time to remove the offending cause, or deal surgically with other complications. More surgery than this, will often mean death of the patient, and the aim of every true surgeon should be to save life; and then when the patient's life has been saved by the primary operation and he has recovered sufficiently the ideal or secondary operation can be done to remove the offending cause. Should the appendix have sloughed away nature may have hermetically sealed the stump and prevented fecal extravasation; should it be intact, then amputation with invagination of the peritoneal surface, continuous or Lembert suturing is the model way. First, however, antisepticise the stump with carbolic acid, mercuric bichlorid and iodoform applied locally before suturing.

If necrotic spots of cecum exist, they must be excised with scissors. If small or large rents of cecum

exist, the peritoneal coats must be turned in and sutured with Lembert suture. In addition to this the stump or traumatism of the cecum may be reinforced and strengthened by omental graft, or the meso-appendix or two inches of parietal peritoneum may be excised, the lips of the peritoneum sutured and the patch applied to stump of appendix or cecum. These measures will prevent frequent formation of adhesions, and should be done when necessary and possible, since denuded surfaces of peritoneum are liable to become permanently adherent to adjacent abdominal viscera.

Case 1.—Patient, male, age 12 years. Received a blow over head of cecum, worked several days after injury, no discoloration of skin or swelling. In two weeks pain returned, locomotion impaired, leg flexed on thigh, later on abdomen. Patient in this condition three weeks, with fever, one physician an irregular, "said he had hip-joint disease." Another "typhoid fever." When seen by the writer, the pulse was 130, and he was having two chills a day with copious perspiration; temperature 103.5 F., tumor over appendix; section, irrigation and drainage saved boy's life. Removed a quart of foul pus. Temperature and pulse normal in twenty-four hours. Boy's father and uncle—woodmen, acted as assistants.

Case 2.—Patient, male, age 12 years old. Was hurt over the right side of abdomen. Ten days after began to complain of pain over McBurney's point, impaired motion and locomotion, leg and thigh flexed, pulse and temperature elevated, tumor size of a large orange outlined over appendix. Operation was advised and accepted. Drs. Joseph Pettus and Steele Bailey consultants. An incision one and a half inches long with evacuation of a quart of pus; irrigation and drainage, rest and asepsis saved patient's life. Remaining part of peritoneum cavity was fortified by plastic lymph and not disturbed. Appendix not found, temperature and pulse normal next day.

Case 3.—Male, age 25 years, former health good, engaged in farm work, mowing a few days after returning from college. From to and fro motion of right arm, with elbow over cecal region, pain with tenderness developed without redness of skin or swelling; temperature elevated in evening with recessions in the morning, simulating typhoid fever, gurgling also present about the eighth day; pain and tenderness became more intense, and swelling began to appear. Appendicitis was diagnosed by Dr. J. H. Parker, of Corbin, and confirmed by Dr. R. T. Ramsey, of London, both of whom advised surgical treatment and called the writer to operate. On examination a tumor the size of a cocoon could be mapped out over McBurney's point; section, irrigation and drainage, asepsis with rest saved patient. Almost or about one gallon of pus was removed from right half of peritoneal cavity, which was an enormous abscess extending from the liver to Poupart's ligament and medial line of abdomen to right lateral wall. The appendix could not be found, the adhesions were not disturbed, the abdomen was drained for two weeks, irrigated and dressed twice a day for this time; patient third week after operation dismissed. Had we hunted for appendix by breaking up adhesions and infected the other half of the peritoneal cavity we doubtless would have lost our patient. To do life-saving surgery we must know when to stop.

Case 4.—At Knoxville, Tenn., I was called in consultation with Dr. Jones to see a former Kentucky boy, for recurrent appendicitis and advised abdominal section and the family declined operation at that time, "said if our prediction was proven correct in the future, and another attack occurred they would submit to operation;" he did have a recurrence and was operated upon by Drs. Jones and James M. Black, both former Kentucky general practitioners, with section, drainage and irrigation. On account of the extensive suppuration and subsequent perforation of cecum, the abdomen had to be opened a second time, and resection of bowel done for perforation, and still the patient made a beautiful recovery.

Case 5.—In April, 1895, Dr. Eugene J. Brown, of Mt. Vernon, Kentucky, sent the writer a telegram to come and do laparotomy. As I was from home on another operation that day with Drs. Wesley of Middleburg, Kentucky, Dr. J. F. Peyton, responded to the call, and found a case of perforated appendicitis with purulent peritonitis. Abscess wall bursted and pus in possession of abdominal cavity. Drs. Brown and Peyton operated by section, irrigation and drainage, and saved patient. The appendix had sloughed and disappeared, the stump was sealed off from the peritoneal cavity by adhesive inflammation and finally by definitive healing. In two weeks patient was in

town on horse-back, hair parted in the middle, and pistol round his waist and drunk as the devil could wish for.

Case 6.—Mr. G., age 20 years; has had one or more attacks of pain over caput coli, indisposition for a few days; was unloading cross-ties and said he strained himself in lifting, by placing elbow against his right side; that night his former pain returned and increased in severity and was worse than ever before, incapacitated him for labor, and prostrated him in bed. Dr. Samuel Perkins, of Bee Lick was called, and found patient in great pain over McBurney's point with nausea and acceleration of pulse, increased temperature and respiration, legs and thighs flexed, abdomen tender to touch; and pain only slightly relieved by hypodermics of morphia; free purgation and hot applications. He diagnosed appendicitis; advised operation which was accepted, and sent for the writer to come and operate, and bring Dr. W. B. O'Bannon to assist; patient was beautifully prepared and on section there was found an omentum adherent to abdominal wall and a circumscribed abscess occupying the right lower fourth of abdomen with purulent peritonitis of this locality. The abscess was perforated, emptied and irrigated and a suppurative and gangrenous appendix found with large perforation at its junction with cecum, and containing an appendolith one by three-fourths inch in size. The latter was removed, the appendix enucleated, the meso-appendix carefully separated from it and a gangrenous portion of cecum excised with scissors; the lips of wound were approximated, serosa to serosa, and Lembert suture used; the length of wound was 2½ inches long after suturing was finished; the meso-appendix was turned over cecal wound to patch it and kept in apposition by a continuous suture; the peritoneum, was scarified to secure adhesive union, and hastened definitive healing. In two weeks the abdominal wound had healed without an unfavorable symptom. Recovery has been complete.

Case 7.—Miss —, age 8 years; former health good; ate freely of frozen apples; on last Sunday of January 1896, at night, was taken ill with purging, vomiting and pain in bowels which was taken to be colic by parents; and home remedies used for a day or two. When the writer was called he found patient in the throes of appendicitis with circumscribed peritonitis; for three days patient had high pulse, temperature and quick respiration; legs and thighs flexed; and suffering intensely. On the fifth day, the symptoms all greatly improved and the patient was better for two days, when former symptoms returned in severity—case much aggravated; operation advised, accepted and performed on the eighth day, a large globular mass was found over caput coli. Drs. Steele Bailey and J. F. Peyton present in consultation and assisted in operation. On opening peritoneal cavity with one and half inch incision, pus welled up into wound, the right lower fourth of peritoneal cavity was involved in one huge appendiceal abscess. The rest of the peritoneal cavity was protected by a lymph wall. The appendix could not be found and adhesions were not broken; section, irrigation, drainage, rest and aseptic after-treatment cured patient in three weeks.

Two cases of non-operative treatment of recurrent appendicitis at last accompanied with purulent peritonitis and death. Two patients who had had former attacks of recurrent appendicitis were treated for colic with opium, poultices and dirt by ignorant incompetent physicians and promptly died. Post-mortem showed clearly that both could have been saved by timely life-saving surgery in skillful hands.

The successful issue in these cases is due no doubt to hot water and soap bath before operation and also in most cases to free purgation, section, thorough evacuation, irrigation and drainage of pus cavity and abdomen, removal of the diseased organs, if not previously sloughed away, also of the pyogenic debris. The most complete irrigation with hot distilled water, dealing surgically and quickly with laceration, fistula and necrotic spots of bowel, complications of appendix and cecum *per se* and other organs. To these, with subsequent asepsis and rest, assiduous watchfulness and attention of nurses, general practitioners to assist in operations and give the after-treatment, we owe our success.

The conspicuous absence of meddlesome neglectful nurses and young internes, with holding of chemic antiseptic from the abdominal cavity, the avoidance of dirty antiseptics and dirty asepsis, so often seen in the general hospitals, and to total prohibition of opiates,

and the inestimable advantages of pure country air laden with ozone and sun-light also had their parts. With all nature in harmony the country gives the surgeon many, many advantages over our city confreres and enables these general practitioners to make diagnosis, assist in operation and give after-treatment.

We must constantly remember that our aim is to do life-saving and not ideal surgery; for ideal surgery is only done in the *deadhouse*. The tyro in abdominal surgery, the "pseudo-specialist" will get turned down oftener, do more incomplete neglected work in the abdominal and pelvic cavities than any where else in surgery. Stanley's "March through the Jungles and Exploration of Africa," "Travels up and down the Congo" are child's play when compared to the successful work of the skillful abdominal surgeon. Today the harvest is ripe and still first class abdominal surgeons are few, because too many of our present crop are "younglings"—graduates from second or third class medical schools and attend three or six weeks at some polyclinic, or go to Europe, live a kind of nomadic life for a month or six weeks, return, and call themselves special surgeons, before they have even vaccinated a baby, lanced gums of teething children, or had any experience in cholera infantum. Dr. J. Marion Sims and all other great and illustrious special surgeons, served a long apprenticeship in diseases of children and general practice before they began major surgery; and in the future, so must all successful surgeons do likewise—the greatest, noblest, most useful, purest, best and most skillful doctors beneath the canopy of heaven today are the general practitioners. They are the back-bone and sinew of our illustrious profession; they are our giants and the custodians and must be the final judges of our work and skill.

Professor Senn states in substance in his book on intestinal surgery that every county-seat or town of one thousand or more population should have a surgeon prepared and equipped to do the operations of abdominal surgery. Again he has stated you must be careful or you will have every cross-roads doctor doing an operation for appendicitis. The warning has been timely but not heeded.

Dr. Senn certainly could not mean the active wide-awake, equipped, thoroughly prepared country physicians, of large towns, who have served an apprenticeship in abdominal surgery under the great surgical lights of our profession, like himself, the Prices, Wyeth, McBurney, Ashton and others too numerous to mention. Abdominal surgeons have proven idiopathic peritonitis is a *myth* and that peritonitis is the surgical disease and should be treated surgically. Recurrent and suppurative appendicitis with or without purulent peritonitis is a surgical disease like gun-shot and stab wound of abdomen, and should be treated early with good first-class surgery. The surgeon knows what he can do by treatment—knows he has a cause and effect, and the physician when in doubt procrastinates; it should be, when in doubt send for a surgeon,—cure effect, by removing the cause. As a rule the average physician, or as Professor Senn terms them the "cross-roads doctor," would rather take their chances of escaping from the lion's den than try to do a laparotomy for appendicitis.

The writer most respectfully acknowledges the valuable information received at the operations and from literature of Drs. Joseph and Mordecai Price, William Easterly Ashton, and Professor Senn and Morton, Sr.

DISCUSSION.

Dr. J. N. BAUGHMAN, Flat Lick—I regret that I arrived a little too late to hear Dr. Carpenter's paper on this subject, but I want to speak in behalf of "scrub" doctors. I have noticed that in nearly all of the papers read before this and other societies that physicians tell us just how to do the operation in appendicitis, whereas the after-treatment is entirely left out. In cases of appendicitis, just as soon as we cut down we find there are inflammatory adhesions. We break these up, and if they were let alone in a great many cases the wound would unite. One of the nicest preparations to prevent readhesions is aristol or iodoform. Aristol has no poisonous effects, and when applied to inflamed tissue it forms with the lymph a thin film which acts as an impenetrable barrier between the white leucocytes on the healthy side, so that the few wandering bacteria by aseptic preparations are left on the other side in almost hopeless condition. They have no chance to get through. Aristol is perfectly innocent in its action. It will remain for an unlimited time and prevent readhesions. This is one thing that we should consider. We should aim to do work that will reflect credit upon ourselves, as well as save the patient.

Drainage is an important thing. I remember having a case to look after some time since in which I used a drainage-tube, but I do not think I shall do so again, for I think that pure aseptic gauze makes the best drainage we can have. Within twenty-four hours after the operation we can dispense with the drainage-tube, provided we have an ample supply of aseptic gauze on the outside to absorb all the products from this drainage-tube.

Another point struck me forcibly, and I do not know but that it is a new idea. In Halstead's operation for hernia a number of mattress wire sutures are introduced. Sometimes after operating upon a case of appendicitis we get hernia as a result in spite of all the precautions we take. Would it not be a good idea in some cases, where we have fear of getting hernia, to put in a lot of aseptic wire so that the abdominal contents could not possibly get through. I do not know whether this would work. I think it would. It does in hernia operations, and why would it not in cases where we perform laparotomy?

Dr. A. M. CARTLEDGE, Louisville—There are one or two lessons to be taught from the report of the cases to which we have just listened. We have had reported a case in which a patient had subsequent pyemia, metastatic abscess of the liver and rupture into the ileum an inch and a half above the ileocecal valve. The next lesson we have to learn is that 90 per cent. of the cases of suppuration rupture into the intestine. A patient who has had an abscess rupture into the intestine is not well, and such patients creep about for years and years. Many cases of supposed recurrent attacks of appendicitis are simply recurrent abscesses filling up and periodically discharging into the intestine. It is an extra-appendicular abscess. I think that it is the main lesson the papers teach, and it is a very important one.

Dr. H. H. GRANT, Louisville—The profession perhaps do not think enough about the pathologic condition which exists in appendicitis. There is a foreign body in all cases of diseased appendix, and not only that, it has become now foreign material, inflamed, suppurating, and oftentimes gangrenous. This condition exists in a large proportion of cases of appendicitis which are severe enough to be attacked surgically. In a large proportion of cases the appendix is found either perforated or gangrenous. If it were possible for the X rays to show us the condition present in these cases of appendicitis which are supposed to get along well, in 95 per cent. we would see a condition which would encourage us to operate even if the patient is doing well. If we bear in mind that nearly all of the cases terminate fatally, while a few recover in spite of neglect, it would encourage us to demand early operative interference. The important point for us to remember is that the appendix

is a diseased, infectious foreign body accomplishing no possible good, and that its removal can be safely and easily effected under favorable conditions, and for this reason early operation should be instituted where the indications are sufficient to warrant us to believe it to be a surgical condition. Little harm can come if an operation is done too early, or if it is done even where it was not necessary. In a large proportion of cases fatal results follow the neglect of the golden opportunity. This has been impressed upon me by the observation of a recent case. If we bear in mind the fact that we have in these cases infectious material to deal with, and if we could picture in our minds the condition underneath the skin, we would be encouraged to operate in many instances where we perhaps postpone it from day to day until the time for satisfactory operative interference has passed.

Dr. ARCH. DIXON, Henderson—It is the duty of the surgeon or physician, as soon as he makes a diagnosis of appendicitis, to call in a surgeon and operate. I recall three fatal cases simply because the attending physician temporized about the matter, thinking perhaps the cases would get better. If they had been operated on promptly when the diagnosis was made they would have gotten well. I have been surprised to read some recent remarks by Dr. Hunter McGuire, of Richmond, in which he advised waiting to see what the patient is going to do. My experience teaches me that the very moment that a diagnosis of appendicitis is made we should operate. I believe it is the proper thing to do.

Dr. J. G. CARPENTER, Stanford—Pus in the abdomen or peritoneal cavity demands prompt surgery. That many patients recover from appendicitis without operation is a fact. I have had seven patients in my practice to recover without operation, and seven cases with suppurative appendicitis recover with operation. Two of my cases died from want of operation, as was proven by postmortem examination. They could have been saved by prompt surgery. Four other cases were complicated with pus tubes, ovarian cystoma, ovarian abscess and fibroids, and they recovered. I saw these last cases in the practice of Dr. Price of Philadelphia. Prompt surgery was resorted to, pus tubes and appendix were removed, and all made prompt recoveries. But where complications exist, where the patient is dangerously sick, I believe it is better to do conservative surgery. Open the abdomen, irrigate and drain, for if we go hunting around for the appendix and breaking up adhesions we will infect the remaining portion of the peritoneal cavity and lose the life of the patient. So it is a grand thing to know when to stop, and I believe most of our fatality occurs in these suppurative cases where meddlesome surgery has been done, the surgeon not knowing when to stop. There is no reason why the general practitioner should not operate himself. There is no reason why he should not be posted in the pathology after he has served an apprenticeship in abdominal and pelvic surgery. It is safer for him to operate for appendicitis than to send a hundred miles for a surgeon, for in doing this the patient may die before the surgeon gets there. It seems to me all folly for the general practitioner not to be able to operate on these cases. He should operate, and if he does not do so he is derelict in his duty.

As to the after-treatment, the general practitioner who is up to date is a safe man. No better man or physician can be found to administer the after-treatment. If he is the physician that he ought to be, the patient will fare as well at his hands as in those of the surgeon. We will find cases where it is best to use a drainage-tube, and in other instances we may use gauze.

Dr. R. D. PRATT, Shelbyville—I must differ with my friend Dr. Carpenter. I do not think that there are many general practitioners scattered throughout the country who are expert as abdominal surgeons. I think there are few abdominal surgeons among general practitioners, and it seems to me that when we get these cases that require operation they should be

relegated to the specialist. We have a number of eminent abdominal surgeons who can do this work well, and therefore I would take the opposite view, that it is almost criminal for a general practitioner, when it is easy to get an abdominal surgeon, to go into the abdominal cavity.

I do not agree with Dr. Dixon that all cases of appendicitis are surgical. In the twelve cases that recovered and that were reported by me, I will acknowledge that two of them were probably surgical, but they got well in spite of medical treatment. One of them, a young woman, who had abscess which ruptured into the bowel, had perfect drainage take place, and as far as I can learn she has had no recurrence. This was three or four years ago. I think at least one-half of the cases of milder type will recover without operative interference, provided that there is not too much medicine given. This leads to the one point that I particularly desire to emphasize, and that it is the use of opium. I do not believe opium should be given except for the excruciating pain that some of these patients have, and then only in sufficient doses to make the pain bearable.

LARYNGO-PULMONARY PHTHISIS.

Read Before the North Chicago Medical Society, Dec. 28, 1896.

BY C. J. WHALEN, M.D.

INSTRUCTOR IN RUSH MEDICAL COLLEGE AND IN CHICAGO POLICLINIC.

In speaking of phthisis it is a fact that a large number of cases are complicated by a disease in the larynx, which we know is tuberculosis. It seems strange that, as tubercular diseases in the larynx so often accompanies a similar process in the lungs, it should not more frequently be encountered as a primary disease.

It has been questioned by many careful observers, whose names carry much weight of authority, whether laryngeal tuberculosis ever occurs primarily; they insist that the primary lesion was in the lungs, and that when the laryngeal disease developed, the lung disease was marked by it or that the tubercular process while present in the lungs was not recognizable by physical signs.

Most authors writing after improved methods of diagnosis and the use of the laryngoscope, seem to agree, that while it may occur primarily, clinical facts present a strong weight of evidence against such an occurrence. I have never seen tuberculosis of the larynx when I was not able to detect signs of similar condition in the lungs.

Personally I believe that the disease does occur primarily in the larynx, although it rarely if ever gets into the hands of the physician before lung symptoms are evident. In the light of our present knowledge of tuberculosis, it would seem inconsistent to state that the larynx, of all organs of the body, is exempt from primary deposit of tubercle. When it does develop in the larynx, it is as a new center, and not extending by continuity of tissue. The influence of primary laryngeal tuberculosis on the lungs is sooner or later to develop pulmonary phthisis.

The diagnosis of the disease in the larynx of the living subject is comparatively easy after extensive lesions in the lungs have taken place. Few of us have reached or ever will reach that degree of perfection in the auscultatory art that will enable us to recognize positively the incipient lesions of pulmonary phthisis.

A person would need to be extremely skilled to say assuredly in a case of laryngeal phthisis that there are no pulmonary lesions; although a physical examination of the chest may be negative, it ought not by itself to

be taken as absolute, when we remember how unsatisfactory often the signs and symptoms of incipient phthisis are.

Statistics show that laryngeal tuberculosis occurs in about 30 per cent. of cases of consumption. It is more frequently met with in the male, and like phthisis pulmonalis it is seen more between the ages of 20 and 30 years.

Etiology.—The discovery by Koch of the bacillus of tubercle in 1882 placed beyond doubt the specificity of the throat manifestations in tubercular patients. The tubercle bacillus, although being the essential cause of tuberculosis, is after all from a prophylactic standpoint a minor element in its many etiologic factors; every one of us at some time in life would take so many tubercle bacilli into our system that, were the other etiologic factors favorable, we would all die of tuberculosis.

The autopsy table shows that in a large percentage of cases examined where death was due to other causes, there is evidence discoverable of the conquered onslaughts of the bacillus. Decreased power of resistance and unhygienic influences are also to be mentioned as causes of phthisis, and in proof of this claim we have only to point to the high rate of mortality from tuberculosis in those confined to prisons and workshops.

It is a well established fact that a large percentage of all dairy cows, and especially those of the Alderney breed, die tubercular. It is the children of the rich and well to do that are brought up on this milk, and it is this class that contains the greatest proportion of tubercular children.

All other factors entering into the etiology of phthisis are grouped under the head of predisposition.

Symptoms.—Two forms of tubercular laryngitis are found clinically, acute and chronic. The early manifestations of the acute form are indicated by marked congestion of the mucous membrane. The chronic and much more frequent form is early manifested by marked pallor of the mucous membrane. Aponia, dysphonia, dysphagia, stridulous breathing, dyspnea and cough and anemia of the larynx, are the symptoms usually met with. Infiltration of ary-epiglottic folds, is an early symptom, as is infiltration of the inter-arytenoid folds later on.

The dysphagia of laryngeal phthisis is terrible; indeed, there is no disease known to the practitioner of medicine in which the patient suffers more than in the later stage of laryngeal phthisis. These patients have the appearance of one suffering from pulmonary tuberculosis. The skin is sallow, hot and dry, or bathed with profuse sweat. Hoarseness is present in nearly all the cases. More or less dyspnea is early noticed, especially upon exertion. Symptoms of laryngeal obstruction occur late in the disease. In a large percentage of cases the act of swallowing is attended by so much discomfort that the patient prefers to suffer from hunger and thirst rather than swallow.

The disease in the larynx progresses in proportion to the disease in the lungs, but sometimes the laryngeal disease stops at a non-ulcerative stage and the swelling of the epiglottis and arytenoids with paresis and thickening of the vocal cords alone remain for months.

When there is ulceration over the arytenoids, parts that are never at rest, but move with every breath, at every effort in swallowing or speaking, they are con-

stantly irritated until they become the cause of indescribable torture.

Prognosis.—In 1880 Morrell Mackenzie in his classical work expressed the concensus of opinion of the laryngologists up to that time. He claimed "that the prognosis in laryngeal phthisis is always unfavorable, and is not certain that any case can ever recover."

The prognosis of sixteen years ago has been considerably modified by the results which have attended the efforts of laryngologists for the last few years. Indeed, cases of spontaneous healing of tubercular ulceration of the larynx have been reported by Heryng, Bauveret, Virchow and Jarvis.

J. Solis Cohen (*JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, 1883, page 261) "mentions a case as being alive and doing well eight years after the establishment of complete health."

Lennox Browne (*Jour. Laryng., Rhinol. and Otol.* London, 1894, page 185) says "he can only point out one case in his practice in which a cure was effected." In this case the larynx, pharynx and one lung were involved, tubercle bacilli being demonstrated in the scrapings from the granulations and in the sputa. Seven and one-half years after her first visit to him her lung remained healthy, she had gained in weight, and no bacilli could be found in the sputa.

In a large proportion of reported cases of cures of laryngeal phthisis, the time elapsing between their first visit and the report is too short to make them of great value as statistics, but it is satisfactory in this connection to note that healing of tubercular ulceration of the larynx does occur.

I find in looking over a large number of statistics that the proportion of recoveries are exceedingly small; perhaps not more than one-fourth per cent. if all cases of this disease were reported, but the fact of an occasional recovery under treatment affords sufficient satisfaction to indulge in the hope that with our constantly improving methods of diagnosis, the general practitioner who sees the patient first will recognize the laryngeal lesions early and will apply appropriate treatment, or refer him to a specialist, in place of devoting all his skill and knowledge to arresting the lung symptoms, forgetting that the secondary trouble in the larynx may be causing his patient more discomfort and weakening him more rapidly than the disease in the lungs.

In making a prognosis as to time it is well to remember that the very acute cases terminate fatally in from six to twenty-four weeks. Those showing a more chronic tendency run their course in from six months to three years. These patients do not die from the effects of the tubercular disease of the lungs, but from exhaustion caused by pain and starvation, dependent upon an ulcerated larynx, and where the ulceration was over the arytenoids, these patients have been known to suffer the pangs of starvation and die rather than endure the indescribable torture caused by attempts at swallowing. These cases are very rapidly fatal; they die of inanition generally before the lungs are very extensively involved.

In making a diagnosis of laryngeal phthisis it is well to remember that one of the first symptoms in point of time will be laryngitis. It will have all the symptoms of chronic catarrhal laryngitis including the exhausting cough. There is no disease of the larynx which is so easy of diagnosis when met with in its typical form as tuberculosis. "The clubbing"

of the arytenoids is generally looked upon as pathognomonic of tuberculosis. In the vast majority of cases the lung lesions begin at the apex and it is almost invariably so in laryngeal phthisis.

Treatment.—The chief modes of treatment are medical, surgical and climatic.

The medical treatment should be the same as in uncomplicated pulmonary consumption; namely, cod liver oil, oil of cloves, calcium chlorid, iron, hypophosphites, creosote, or better still, guaiacol, which possesses all the antiseptic properties of creosote and is free from many of the objections to that drug. It is essential that the guaiacol be perfectly pure, as otherwise it may cause dyspepsia, a symptom that is present in a large number of cases of phthisis. The guaiacol should be given at meal time and on no account whatever when the stomach is empty. It should be dropped into a capsule just before being taken, beginning with three minims and slowly increased until the patient is taking ten, fifteen or even thirty minims. I can recall two cases in which this mode of medication was pursued, in which I was able to administer forty minims three times a day without the slightest gastric disturbance.

Oil of caryophyllum is less irritating to the stomach than guaiacol and should be given under the same instructions, except that it can be taken oftener, and when administered between meals the patient should take a glass of milk with it if possible. Like guaiacol it should never be taken on an empty stomach lest it cause irritation.

It may be necessary to precede the meal by inducing anesthesia of the parts by means of local anesthetics. It has been found that these patients suffering from painful deglutition can swallow more comfortably by assuming the prone position as suggested by Morris Wolfenden (*Lancet*, London, July 2, 1887). The patient is to lie flat on his abdomen with his feet and body higher than his head, and by means of a tube sucks the fluid up and swallows it. By this method he is able to take plenty of nourishment, while in the erect position he could not take a swallow without suffering excruciating pain.

For producing local anesthesia, I find that a solution of guaiacol in olive oil in strength from 15 to 40 per cent. sprayed into the larynx fifteen minutes before eating will produce an anesthesia which lasts for many hours. In cases where this is disagreeable, a spray consisting of morph. sulph. grs. iv, acid carboic and acid tannic, one-half dram of each, glycerin and aqua dest. q.s. ad one oz., sprayed into the throat will temporarily relieve the dysphagia. This should be applied one-half hour before eating. This solution was recommended by Dr. Ingals as long ago as 1885 and the fact that such an experienced and painstaking operator as Dr. Ingals is using this solution in his practice at the present time speaks volumes in its favor.

The use of cocain as a local anesthetic is not to be advised except in very advanced cases, and toward the end even this will have to be given up, and codein and morphin will be our only means of preventing unnecessary suffering.

Under prophylactic treatment the early lesions of laryngeal phthisis yield promptly, but unfortunately for the patient, they seldom come into the hands of the laryngologist until extensive ulceration or destruction of the lungs renders the prognosis hopeless.

It is unfortunate that the laryngeal symptoms in

these patients should be treated by practitioners of medicine, without an inspection being made of the larynx, but is this so much to be wondered at when we think of the small number of physicians skilled in physical diagnosis who have any technical knowledge of the use of the laryngoscope?

The treatment of the larynx demands above all on the part of the patient complete silence, I admit that it is not always very easy to obtain this, but it should be observed as far as it is possible to do so.

For my own part I am convinced that of the different methods of topical applications for the larynx, all remedies are best administered in the form of spray under high pressure. The intra-laryngeal insufflation of powders has not proven satisfactory with me.

Dr. Lennox Browne claims to get the best results in the preulcerative stage from a spray of menthol, or menthol and iodol. I have used it faithfully in a limited number of cases and I must confess that I derived little if any benefit from its use.

Lactic acid seems to have stood the test of time admirably well, although it has been unfavorably reported on by so good authorities as Schnitzler, Massei and others. The concensus of opinion seems to be that as symptomatic treatment, it excels every other known. It has certainly retained the confidence of those who have had the largest experience. The patients gain in weight, the appetite improves, the night sweats diminish and the expectoration becomes less purulent.

The strength of the solution used should vary from 20 to 60 per cent., according to the toleration of the larynx and the necessities of the case. It should be applied with a probe wrapped with cotton, considerable friction being used.

A spray of tri-chlorid of iodine, varying in strength from $\frac{1}{4}$ to 1 per cent., seems to give satisfaction in the simple catarrhal form before ulceration has taken place.

In a case that had resisted the modes of treatment just mentioned above, I was able to promote healing of the ulceration by a solution of guaiacol in strength from 15 to 50 per cent. in olive oil, varying it according to the toleration of the patient; in one of my cases a solution of 50 per cent. gave little if any discomfort, cicatrization took place within six weeks, considerable infiltration however remaining for eight months.

Guaiacol is a local sedative and lessens the pain accompanying the ulceration, not being escharotic, it continues to be absorbed and its effects are much more lasting than other local anesthetics.

The surgical treatment includes extrinsic and intrinsic operations. Under extrinsic operations are to be considered extirpation of the larynx, which I believe has never been done for tuberculosis.

Tracheotomy, while it might seem suggested in some cases, should be done only for relief of dyspnea. In a few cases it distinctly reduced the swelling within a few weeks and death ultimately ensued from pulmonary disease.

Intrinsic operations on the soft parts consist of curetting the larynx, and it is only resorted to where the pulmonary conditions are favorable and the laryngeal infiltration is located at an accessible point in the larynx. A more satisfactory method is that advised by Professor Krause, who uses a set of double sharp spoon instruments made for the special object of cutting away portions of diseased tissues, applying after

the operation, lactic acid to the denuded part; this operation is claimed to be very painful even under cocain, and there will probably be considerable discomfort for a few days afterward; this method should not be thought of if there is much involvement in the lungs.

I do not think that these patients should be deprived of the one great chance to prolong their lives by change of climate. Patients who can afford the luxury of a residence in the South should be sent there, where no doubt spontaneous recovery is greatly favored. The choice of climate becomes a matter of importance in many instances. A location should be selected in which there is an absence of damp soil. A dry aseptic atmosphere seems to be most desirable to these patients. Fortunately for those afflicted with phthisis, a desirable climate can be reached in a few hours' ride. Mexico, New Mexico, Florida, portions of Alabama and Southern Georgia are desirable winter residences. During the summer months a suitable climate may be found in the Adirondacks in New York, Montana, South Dakota and portions of Colorado. It is especially desirable to have our patients in the more southern climates during the months of February, March and April.

In conclusion, allow me to outline briefly a few histories recording some good results from the local use of guaiacol in laryngeal phthisis.

J. H. B., lawyer, age 30, called on me in October, 1891, complaining of a hacking cough, which had begun to annoy him about eight or ten months previously. He attributed all his troubles to a catarrhal condition of his throat and nasal passages. I found upon inspection of these parts, the inferior turbinated bodies in both nares were greatly swollen, three-quarter filling the cavities. The uvula was greatly elongated, which together with a chronic pharyngitis was responsible for the continual effort at clearing the throat.

An examination of the chest revealed moderate dulness over the right apex as low as the second rib, harshness of respiration over the same side as low as the sixth rib, together with numerous subcrepitant râles heard over the same locality only as low as the third interspace.

After amputation of a portion of the uvula and a thorough cauterization of the nares, he was placed on large doses of maltine with hypophosphites, together with creosote in from 5 to 10 minim doses after meals. Under this treatment he improved rapidly and at the end of ten months all active manifestations of the trouble in the lungs had disappeared.

Patient remained well for one year, when on a damp, chilly day while sight seeing at the World's Fair, he contracted a severe cold which was accompanied by slight hoarseness that gradually increased in severity.

Six weeks later he came to consult me as regarding his hoarseness and the return of his lung symptoms. I found upon inspection of the larynx, the usual condition met with in chronic laryngitis. Physical examination of the lungs revealed practically the same signs as before, with an increase of subcrepitant râles. I advised a return to his former medicine, but substituting guaiacol in place of the creosote, as I found it to be less irritating to the stomach. He was advised to begin with 5 drops and gradually increase it to 20 drops, in capsules, after meals. At the same time I began a spray of acid tartaric, grs. 1, acid carbolio, zinc sulph. ãñ grs. 2, aqua dest. 1 oz. This I found could be substituted by a much stronger one, consisting of acid tartaric grs. 2, zinc sulph. grs. 15, and aqua dest. 1 oz.

In spite of these vigorous applications, at the end of two months his hoarseness was more pronounced. Examination revealed beginning tumefaction of the arytenoids and aryepiglottic folds, with infiltration of the ventricular bands.

Being now convinced that I had to deal with a case of laryngopulmonary phthisis, I began the daily use of a spray to the larynx of a $\frac{1}{4}$ per cent. of the trichlorid of iodine, which I soon found could be increased to $\frac{3}{4}$ per cent., later to 1 per cent. without any discomfort whatever to the patient. This treatment was continued for two months, when ulceration of the left vocal cord warned me that more heroic treatment should be resorted to. I substituted lactic acid in varying strength according to the tolerance of the throat, but after three weeks the general condition of the throat seemed to be growing worse.

I resolved to try local applications of guaiacol (being the first time it was ever used in such cases), beginning with a 20 per cent. solution in oil of sweet almonds. A spray was made daily to the larynx, the strength being increased to 25, 30, 40 and ever 50 per cent. with very little discomfort. These applications were followed in a few weeks by a gradual but sure improvement, the ulceration healing completely in less than two months, some swelling remaining for about ten months. The general improvement of the patient, with arrest of lung symptoms went hand in hand with improvement of the larynx.

Examination of the lungs, March, 1896, four and a half years after his first visit to me, showed no extension of his lung trouble, although numerous tubercle bacilli were found in the sputa by Dr. Frank Jay and myself.

Status præsens: The larynx is apparently normal, except where the left vocal cord was partially destroyed, the remaining portion of the cord being much redder in color than its fellow. Some hoarseness still remains, but this has improved wonderfully during the last year. This is all the more remarkable, because he has been obliged to talk many hours a day, being employed as an attorney in the claim department of a large corporation, and he has not been absent from his duties on account of sickness during the whole time he has been under my care, except when taking his yearly vacation, when he has gone South during the month of March.

A microscopic examination, July, 1896, revealed only a very few bacilli on a number of slides examined, and at my last examination, three years after the beginning of his laryngeal symptoms, I was unable to find any bacilli after a very careful examination.

W. J. O., American, age 20, referred to me by Dr. J. B. Murphy. I found to be in the last stages of laryngo-pulmonary phthisis. Death from inanition seemed close at hand. Deglutition being so very painful, I resolved to try the guaiacol, in 25 per cent. solution as before, applying it by means of a Davidson's No. 59 atomizer, the applications being made three times a day, one-half hour before taking nourishment. This seemed to relieve the dysphagia in a marked degree, although he died two weeks after my first visit. I am certain that this short time preceding dissolution was rendered much more comfortable than such cases usually are by other methods of treatment.

F. O. R., machinist, age 22, called to see me in June, 1896, complaining of a cough, which had lasted for six months. He had lost gradually in weight and strength, had frequent night sweats, loss of appetite and gradually increasing hoarseness for four weeks, with slight dysphagia for one week. Temperature 103, with a full regular pulse beating 100 per minute.

A physical examination of the chest revealed decided dulness over the left apex as low as the third interspace, with harshness of respiration over the same region, together with very numerous subcrepitant râles. Inspection of the larynx revealed a clubbing of the arytenoids, much more marked on the right side than on the left. A small superficial ulcer could be plainly seen on the left ventricular band, and a microscopic examination of the sputa revealed numerous tubercle bacilli.

I made daily applications to his larynx of a 30 per cent. solution of guaiacol, which he claimed made his throat feel very comfortable and with marked improvement in his hoarseness. He discontinued his treatment at the end of three weeks, because of some intercurrent indisposition, and I subsequently learned that he died of acute nephritis ten days later.

To summarize, 1. We are still in need of a panacea in laryngeal phthisis. 2. Trichlorid of iodine, guaiacol and lactic acid are the best local remedies. 3. Good results have been reported from cutting away portions of the diseased tissues and applying lactic acid. 4. Guaiacol, or a solution of morphin, tannic and carbolio acid in glycerin and aqua dest., are most satisfactory to relieve pain. 5. Cocain should only be resorted to in extreme cases. 6. Surgical treatment should not be recommended in advanced phthisis. 7. Tracheotomy should be performed only for the promotion of euthanasia in cases of severe stenosis of the larynx.

I am indebted to Dr. B. M. Linnell of this city for the histories of the following three cases, which were treated by him in his private practice, and were read before the North Chicago Medical Society the same night as the preceding cases reported by me.

Case 1.—Mr. B., age 25 years, street car conductor, married. Family history good. Patient had pneumonia four years ago,

was ill for one month, but afterward felt well for two years. Two years ago he spit up a mouthful of blood. Has had two hemorrhages since, the last one three months ago. He has been coughing more or less ever since the first hemorrhage. In the morning he raises some thick yellow sputa and coughs up during the day about half an ounce. About three months ago he began to get hoarse, can not speak above a whisper at the present time. His strength is fair, appetite good, but has lost ten pounds of flesh. He did not expect to have his lungs benefited by treatment, but desired his voice back again so that he might be able to "call the streets" as a conductor.

On examination of larynx, I found the arytenoids swollen and congested. The cords were dull and did not meet at phonation.

The examination of the chest revealed extensive consolidation under the scapula of the right side posteriorly; some rales.

Treatment.—Began spraying the throat with a 25 per cent. solution of guaiacol in oil of almonds; made an application three times each week. The patient was taking creosote, so I had him continue that. In two weeks the swelling went down and the patient began to use his voice, but was still very hoarse. About December 1 taught him to use a Davidson's No. 59 atomizer with a spray of zinc sulph. 2 grs., boric acid 8 grs., menthol $\frac{1}{4}$ gr. to the ounce of distilled water. This he used twice each day and by December 15 was able to talk as well as ever. Now he uses his spray once a day and the swelling is almost gone. The cords meet perfectly at phonation.

Case 2.—Miss W., age 19. Family history negative. In September, 1895, had an attack of pleurisy. Has been coughing ever since. Began to get hoarse three weeks after. Was under treatment until Jan. 10, 1896, when the hoarseness was about gone.

In May, 1896, patient became very hoarse. On examination of larynx, July 11, 1896, the vocal cords were found thickened and remained 1-16 of an inch apart on phonation; congested. The arytenoids and the ary-epiglottic folds were swollen and congested. The patient was put on a spray of 50 per cent. guaiacol solution in almond oil and improved some. The swelling went down rapidly.

In September, 1896, after neglecting treatment for one month, an ulcer appeared on the posterior larynx, which has reappeared several times whenever patient was neglected, but always disappeared again with the application of a 50 per cent. guaiacol spray. At present the swelling is gone and vocal cords are clear, but the cords do not yet quite meet on phonation. Consequently she is still hoarse. Unfortunately, there are pulmonary complications, which are progressing rapidly and will probably be fatal.

Case 3.—Mr. S., farmer, age 26, unmarried. Family history negative. Had pleurisy nine years ago, left side. Has been hoarse more or less for two years. No cough, general health excellent, appetite good, weight 150 pounds, remains about the same, temperature 100 F., pulse 100. Had been hoarse since last February, constantly. Could hardly speak above a whisper at the examination. The arytenoids were badly swollen and with the swelling of the false cords the true cords were hidden entirely from sight. The larynx was swollen and tender externally, especially on the left side.

Patient's larynx was sprayed three times a week with 25 per cent. guaiacol solution in oil of almonds. Constitutional treatment consisted of carbonate of guaiacol, 10 to 20 minims, three times daily, with tonics. In six weeks the external tenderness had disappeared and the swelling reduced some. Internally the swelling had gone down one-half and one vocal cord appeared, the right. The patient was then sent home and given a spray of one-quarter of 1 per cent. trichlorid of iodine, to use twice daily. In December the swelling was still more reduced and the left vocal cord came into view for about one-half its length. The patient was then given a spray of zinc sulph. solution, about 15 grs. to the ounce of water. In this case the effect of the guaiacol was very marked, reducing the swelling very rapidly. So far I have not been able to find any pulmonary lesion, though the history of the case might lead one to suspect its presence.

All of these cases I believe to have been helped greatly by the use of the spray of guaiacol varying in strength from 25 to 50 per cent. I believe a constitutional treatment always helps and besides the forms of guaiacol and creosote, give a general tonic like nux vomica or cod liver oil.

36 Washington Street.

THE EXAMINATION OF THE RECTUM AND THE FEMALE GENITAL ORGANS WITH REFLECTED LIGHT.

BY W. F. MITCHELL, M.D.

LANCASTER, MO.

In the examination of the rectum or the female genital organs, it is the usual custom of the physician to introduce the speculum and cast the eye in proper range to view the parts exposed. In so doing, he proposes to have all the light in his favor by placing his patient on the chair with the light from the window to enter the cavity exposed. In making the examination, he must of necessity throw his head in such position to obscure to a degree the entrance of the full volume of light and beside his position is such he can take only a partial survey of the parts at one time. It occurred to me from the use of the laryngoscope a person could with ease and much more fully obtain an entire view of the rectal or vaginal passages by using the same plan as in the examination of the throat, which can be done with more ease and satisfaction than any other way. A person can use a window in his office, raise the curtain and allow the sun's rays in and turn the operating chair or bed in position with the patient's head toward the window and take a position in front of the patient, introduce the speculum, and having the mirror properly adjusted you throw the sun's rays into the rectum or vagina, giving you a full and clear view of the parts. The light from a window even on a cloudy day will give you a pretty fair view. Then when one has the advantage of the electric light, there can be no question as to the utility of the plan in the examination. Or you can use the ordinary student's lamp with pretty good satisfaction, giving the advantage you do not occupy a strained position in getting a proper view. In making an examination of the rectum, I introduce the speculum, having adjusted the head mirror and looking through the aperture in the center of the mirror, I am able to take in view all exposed surface, viewing the condition of the mucous membrane, whether there is undue discoloration, or whether there is any lumps or piles within the rectum, etc. Then withdraw the speculum and reintroduce it to give a view of each side of the bowel, which completes the examination. In the examination of the female, place her in the attitude usually occupied by such patients, in the chair in the same position to the light as in the case of a rectal examination. Let the sun's rays reflect into the vagina. You at once can see the condition of the os uteri, the condition of the walls of the vagina, and making treatments have the free use of your hands in the manipulation of instruments, having at the same time a full light upon the parts to be treated. The only thing required in this method of examination is the familiarity in the use of the reflecting instrument, always adjusting it to the forehead so that you see through the aperture in the mirror, and unless you use it in this manner, it will not be satisfactory. It has served my purpose for an examination in this class of cases much better than any other mode I ever tried. I don't remember of ever reading in any text book or journal of this method. It may be that others would prefer to examine by the direct light, but as for myself I prefer the reflected light, for it seems to give me so much clearer view than I am ever able to obtain by any other means. I use the bivalve speculum.

Let us have a Department of Public Health!

CLINIC.

BY E. FLETCHER INGALS, M.D.

PROFESSOR LARYNGOLOGY AND DISEASES OF THE CHEST, RUSH MEDICAL COLLEGE, CHICAGO.

Case 1.—Hypertrophy of the tonsils with frequently recurring tonsillitis.—Gentlemen: The first case I present to you is a girl 11 years of age who has been brought to me from a neighboring State on account of frequently recurring tonsillitis with which she has been troubled for several years. Her physician tells me that almost every time she takes cold she suffers from quinsy so that at least three or four times during the year she has this painful disease. He attempted to remove the tonsils, but was unable to do so. Upon examining the fauces I find that the tonsils are slightly enlarged. Neither of them is more than three-fourths of an inch long by half an inch broad and three-eighths of an inch in thickness. Both of them are covered by the anterior pillars of the fauces so that it would be impossible to engage the gland in a tonsillitome; this explains why the doctor failed in the attempted operation. Ordinarily, with tonsils no larger than these I should not recommend an operation, but in this case the glands become inflamed so frequently that something is necessary in order to reduce their size or to remove them entirely. Several times I have under similar circumstances caught the enlarged gland with a vulsellum forceps which had previously been passed through the fenestra of the tonsillitome; the tonsillitome was then slipped over the gland and the latter was speedily removed, but in the majority of such cases profuse bleeding has followed, which has sometimes lasted for many hours; therefore, I can not recommend this operation. Usually with tonsils as small as these, when it becomes necessary to do something to prevent frequent inflammation, I am in favor of cauterizing two or three points at each sitting with the galvano-cautery and repeating these sittings once in from four to six days until the glands have been sufficiently reduced to prevent further inflammation; but in this case the child lives at a distance and it would not be convenient for the doctor to use a galvano-cautery at home; therefore, he requests me to adopt some adequate measures for relief. It will be impossible to get these tonsils with the tonsillitome without first having separated the anterior pillar of the fauces from the gland and this would require considerable time and unnecessarily give the child very severe pain if she were not under an anesthetic. We will therefore give her chloroform and I will remove the tonsils with the tonsil forceps and enare as is my custom in young children.

The child having been anesthetized, I place a gag in the mouth to keep the teeth apart, and depressing the tongue pass a blunt hook between the anterior pillar of the fauces and the tonsil; with the forefinger of my left hand and the hook I have now separated the anterior pillar from the tonsil and have nearly enucleated the gland. The tonsil is now seized with tonsil forceps and a wire loop of the ordinary polypus forceps is passed over the forceps and down over the base of the gland, which is easily removed by tightening the milled wheel. I find that I have completely removed the gland and we need have no fear of hemorrhage after this operation. Turning the child with its face to the other side of the table I now remove the tonsil from the left side in the same manner. This is accomplished without difficulty. Having removed both of the tonsils I pass the forefinger into the naso-pharynx, which I am somewhat surprised to find filled with adenoid growth. Perhaps I should not be surprised because in the majority of cases where the faucial tonsils are hypertrophied the pharyngeal tonsil is also enlarged, but this child did not present the usual symptoms of naso-pharyngeal obstruction. The case illustrates very well how likely the surgeon is to fail who contents himself with removing the faucial tonsils without examining the naso-pharynx, as I would have been tempted to do in this case, had the glands been large enough to catch in the tonsillitome. I will now remove the adenoid growths with the bent forceps, of which I have spoken in a previous lecture. Having cleared out the greater portion, I find also considerable thickening back of the orifice of the Eustachian tube, which must be carefully removed in order not to injure the normal tissue. I will pass a nasal bone forceps through the nose to be sure that the posterior nares are free, and to remove some small masses that still remain at the upper part of the opening of the nasal cavities into the naso-pharynx.

The operation has been thoroughly performed without pain to the child and we may be confident that she will not again

suffer from tonsillitis. We will recommend that the throat be gargled once an hour for the next three or four days with a solution of a dram and a half of carbolic acid to a pint of water. We will recommend also that a mild antiseptic spray containing one-third of a grain of thymol and three minims of the oil of cloves to the ounce of liquid albolene be used through the nares several times daily.

Case 2.—Fracture of the nose with bending and thickening of the septum.—This young man has been sent here by one of our old alumni on account of deformity of the nose which resulted from a fracture that he sustained thirteen years ago. The patient is now 18 years of age and it is altogether probable that the deformity has increased considerably within the last few years. We find the lower end of the nasal bones bent about one-fourth of an inch to the left of their normal position, but the tip of the nose is again bent back to the right nearly the same distance beyond the median line. There is no depression of the nose, so that no building up will be needed in case an operation is performed. The patient is a good deal annoyed by obstruction of the nares; indeed he is unable to get any air through the left side, though he can breathe fairly well through the right much of the time. His principal anxiety is to have the nose straightened so that it may make a better appearance. Upon examination of the nares with a good reflected light I find that the septum has been bent so far to the left that the concavity of the right side reaches beyond the normal plane of the left side of the septum, but the partition has been thickened to nearly three times its ordinary size, and at the lower anterior part the edge of the septum has been crowded off to the right, causing the deformity of the tip of the nose in that direction. In this instance it will be impossible to get free breathing space without cutting away the redundant portion of the septum and then bending it back to its normal position; but this can not be done under a general anesthetic and straightening of the nasal bone could not well be done without it. We will, therefore, have to make two operations. The first will be done upon the septum under the influence of cocaine, and after this heals we will attempt to restore the nasal bones to their normal position. When the part has been well cocaineized we will cut away the redundant tissue with trephine knives or scissors as described in a former lecture, saving as much of the mucous membrane as possible, and taking care to cut through the upper portion of the septum sufficiently to destroy its resiliency. With nasal forceps we will then replace the septum in its normal plane and pack the left side with antiseptic surgeon's lint, which we will leave in position for five or six days. Subsequently we will have the patient wear a gutta percha tube to hold the septum in the normal plane. This will have to be worn four or five weeks, by which time the second operation should be made.

To correct the external deformity we will place the patient under the influence of ether and refracture the nasal bones so that they may be pushed over into their natural position. It is not practicable to fracture the nasal bones with the septum forceps, therefore, when the patient is anesthetized we will fold up a bit of cloth making a pad about a quarter of an inch thick. This will be placed against the nasal bone, the end of a spool placed against it, and the spool will be given several sharp raps with a hammer. The bone will thus be loosened until it can be easily pushed over. The septum forceps will then be introduced into the nostrils and the septum and nasal bones will be crowded over at least one-eighth of an inch beyond the normal position, where they will be held by packing the left naris with antiseptic surgeon's lint. If necessary we will at the same time place an external splint upon the nose. This may be made from a piece of gutta percha such as dentists use, shaped by the aid of a pattern first made of paper. This when dipped in hot water will become very pliable and can then be crowded down over the nose upon the cheek and held until it becomes cool and firm. A pad will then be placed upon each side of the splint thus formed and the whole will then be held in position by adhesive straps. This dressing should be worn about two weeks. It is necessary to crowd the nasal bones at least one-eighth of an inch beyond normal, otherwise when healing takes place they will be drawn back too far to the left.

Case 3.—Syphilitic sore throat.—This woman is 32 years of age. She complains of sore throat which she says has been troubling her for the last seven months. Her general health is good and she gives no history of similar previous disease. She has not been able to eat with comfort for the last seven weeks, therefore has eaten very little and as a result she has lost thirty pounds in weight; nevertheless her complexion is good, her skin cool and moist and the pulse only 84 per minute.

Upon examination of the fauces, I find a large ulcer fully the area of a silver dollar involving principally the left tonsil, the

pillar of the fauces, the left side of the palate and the left side of the pharynx, though it extends also over a small distance to the right side. This is a deep ulcer with sharp-cut indurated edges and an areola of congested mucous membrane extending for nearly half an inch outward from its borders. There are several chronic diseases of the throat that may give rise to soreness, such as rheumatic sore throat and neuralgia of the pharynx, but there are only three that are likely to cause ulceration, viz., cancer, tuberculosis and syphilis. The principal points in the diagnosis of this case are the general good health, the nearly natural condition of the pulse and temperature, and the deep ulcer with indurated borders surrounded by a zone of congested tissue. In the early stage of cancer of the fauces we are likely to have a good deal of irregular induration and finally when ulceration takes place the granulations are of a fungus character and roll out over the borders; or if the base of the ulcer is free from granulation, the borders are apt to be thicker and more irregular than in this case and they are not surrounded by the distinct areola of congestion which is presented here. In cancer of the throat there is usually a great deal of sharp lancinating pain which occurs even before the advent of ulceration. Although the signs and symptoms are not typical we may safely exclude malignant disease in the case before us.

In tuberculosis of the throat we commonly have widespread but superficial irregular ulceration involving little more if any than the mucous membrane and attended by pain more severe than in this case, though in rare instances we do get the deep ulcer. In practically all such cases there is excessive pallor of the mucous membrane of the palate, the patient presents a cachectic appearance and there is a pulse of from 110 to 120 or 130 with a temperature two or three degrees above normal. In nearly all, we will be able also to detect the signs of pulmonary tuberculosis.

With this patient we have no history of cough or expectoration and there is nothing else in the personal history to suggest tuberculosis. On the contrary from the history we have every reason to believe that she has been exposed to the contagium of syphilis. The exclusion of other diseases, the history, and the peculiar appearance of the ulceration, leave no doubt as to the specific nature of this disease.

We will apply to the ulcer a strong tincture of iodine and each treatment will consist of carefully touching the spot five or six times with a small swab saturated in the iodine, the parts being allowed to dry before the mouth is closed. In this way we will color the whole surface of the ulcer of a deep brown and it will appear glazed and dry when the treatment is finished. This treatment should be repeated daily for about ten days, and once in two days for five or six days longer and once in three days for two weeks longer, by which time the ulcer will probably be healed. We are not likely to see any evidence of healing for four or five days, but after that the new tissue will be seen extending out from the borders and soon after the ulcer will rapidly close. If at any time when the patient returns the ulcer seems larger instead of smaller we will conclude that the last application was too severe, we will then make a lighter one, or if, as sometimes happens, the case should not progress favorably we will substitute the iodine by a 20 grain solution of sulphate of copper, which latter may be applied with the atomizer. At the same time the patient will be given the iodide of potassium in doses of from 5 to 30 grains after each meal. We will begin with 5 grains and have the dose made 5 grains larger each day until 30 grains are reached. Care will be taken that the medicine is always freely diluted. I usually tell the patient to put the medicine in enough water to make one swallow, to take several swallows of water before the medicine and to drink at least a glass full afterward. In this way irritation of the stomach can be avoided. If I find that the ulcer is healing properly I will not carry the dosage to the highest limit here recommended, but may be contented with 15 or 20 grains at a dose. The treatment will in all probability relieve the pain within forty-eight or at most sixty hours, and if then the patient has not a good appetite we will give the tincture of nuxvomica, 7½ minims at a dose, and if the iodine eruption should appear we will add to the medicine about 4 minims of Fowler's solution at each dose. Under such treatment as this, an ulcer as large as a quarter will nearly always heal within from two to three weeks and I have no doubt that even this large ulcer will be cured within four or five weeks. I have not recommended mercurials in this instance because in the tertiary stage the iodides appear to me preferable. I do not now recollect any similar case in which this method of treatment has not been followed by speedy recovery.

Case 4.—Chronic tuberculosis.—This boy is 17 years of age and tells us that he has been sick for the last four years, during which time seven abscesses have developed on the chest

and left arm and have finally been opened or discharged spontaneously. The patient complains today of soreness at the inner end of the second costal cartilage of the right side, where he thinks another abscess is forming, though he says that the area of soreness is not so large now as it was a few days since. He tells us that he is somewhat short of breath and that he expectorates about 4 ounces of yellowish sputum daily. He is 17 years old but is smaller than boys of this age generally. He weighs 101 pounds, which I think a fair weight for his height. It is probable therefore that he is not much emaciated. He gives no distinct symptoms of pulmonary disease in his past history, but says there has been some trouble with the right lung. Notwithstanding the expectoration he makes no special complaint of cough, his tongue is clean, the appetite and digestion fair and on the whole his general condition is very good, but I find the skin hot and dry and the pulse 127 per minute. Upon inspection I find three large scars each nearly three inches in length at the lower part of the right side. I find two smaller scars just above the left nipple near the left edge of the sternum and a scar four inches long at the upper part of the left humerus. There is also a scar in the region of the appendix which appears as though he had been operated on for appendicitis. He tells us that the trouble first appeared in the lower part of the right side as a distinct tumor, which was finally opened and which gave vent to a large amount of pus. I find decided dullness on percussion over the lower third of the right lung, in front, latterly and behind, but the upper part of the lung yields normal resonance as compared with the left side. Over the upper two-thirds of this lung the respiratory sounds are about half as intense as upon the left side, and over the lower third of the lung the sounds are very feeble and I suspect those that are heard are transmitted from the air cells above or from the left lung. The heart is in its normal position, its pulsations are rapid, regular and of good force and there are no abnormal sounds. As the boy is unable to give us an intelligent history we can not make a positive diagnosis, but from the history of an abscess developing early at the lower part of the right side and from the consolidation and retraction of the lower portion of that lung that still remains we have reason to believe that he suffered first from a circumscribed empyema confined to the lower part of the pleura, and it is probable that the cavity opened through the lungs and a bronchus and never completely healed, so that the secretions he now expectorates (to the amount of four ounces daily) come in the main from the pleural cavity. The respiratory sounds over the left lung are normal excepting a few indistinct subcrepitant rales.

There can be little doubt that this case is tubercular although the diagnosis has not been confirmed by microscopic examination. Even if it were not tubercular in the beginning, tuberculosis would probably have ensued by this time in the lower portion of the right lung, and the subcrepitant rales in the apex of the left lung indicate that the disease has now made its appearance in that organ. The treatment must be tonic and supporting. I will recommend for him 3 grain doses of the citrate of iron and quinine three times daily to be taken before meals, and from 10 to 20 grain doses of chlorid of calcium to be taken after meals in from 1 to 4 drams of maltine with the hypophosphites. We will begin with the smaller doses and gradually increase the amount. Cod liver oil might be given in this case in place of the maltine, provided it agreed with his digestive organs. It is impossible at this time to discover any physical signs of a cavity in the lower part of the right pleura, therefore, no operative measures can be recommended, though possibly subsequent examinations may show us that the suspicion I have already expressed, that the sputum now being raised comes from a circumscribed cavity in the pleura is correct. If that should be proven then an opening should be made and free drainage established. We can not safely make a prognosis in this case until the sputum has been examined. If it should show the presence of numerous tubercle bacilli, as we suspect that it will, then the duration of the case would hardly exceed eighteen months. If on the other hand it should be proven that there were no tubercle bacilli present, we would not be surprised if the boy should make a fair recovery in the course of from twelve to twenty-four months and live thereafter for many years.

Case 5.—Hypertrophy and dilatation of the heart with fibroid phthisis.—The consulting staff have to present a patient 21 years of age, of whom they make the following report: The patient complains of pain in the region of the heart which has troubled him for the last two years; there is also a good deal of palpitation and considerable dyspnea, with cough and profuse expectoration. Notwithstanding these he says he is able to do a little work, but he has not been employed for the last nine months. They find no hereditary predisposition to tuberculosis, or indeed to other diseases that might account for his

present condition. The appetite and digestion are good and the weight normal. The pulse is 110 and his temperature 100. Upon examination of the chest the area over which the heart's impulse can be seen is found to be enlarged, being at least four inches in diameter; but the strongest impulse, indicating the position of the apex of the heart, is nearly in its normal position, though the extreme line of cardiac dulness as marked out by the consulting staff extends one and a half inches to the left and about as far below the normal position. Upon palpation I find the greatest force of the impulse half an inch to the left of the maxillary line. Upon auscultation I heard a distinct systolic murmur in the second intercostal space of the right side close to the sternum, and an impurity of the first sound of the heart is heard over a greater portion of the aortic area. This is due to some obstruction in the aorta or at the aortic valves, which condition is probably the main factor in the enlargement of the heart. Further examination shows that the left side of the chest is three-fourths of an inch smaller than the right, but the expansion is the same upon both sides. Dulness is found over the upper part of the left lung, extending down to about the fourth rib in front and to the fifth rib behind. In this region the expiratory murmur can scarcely be heard, but there are no râles. The vocal fremitus appears to be a little exaggerated over the whole of the left side. Over the lower third of the left lung there is also some dulness with a very feeble respiratory murmur, but over the middle portion of this lung the respiratory sounds are much more distinct. The sounds at the lower part of the left lung are about one-third as intense as upon the right side. Over the upper portion of the right lung the respiratory murmur is diminished in intensity, but the quality is normal. Over other parts of this lung the sounds are natural or slightly intensified. It has been suggested that the cardiac symptoms and signs in this case are due to simple hypertrophy, but with an uncomplicated hypertrophy we ought not to find a pulse of 116 and the patient ought not to be annoyed by palpitation; beside, the impulse would be considerably stronger than we find it in this case. The heart is evidently both hypertrophied and dilated and, as already stated, this condition is doubtless largely due to the obstruction in the aorta, but it is probable that the obstructed pulmonary circulation is partly responsible.

While there is no doubt about the condition of this man's heart and about the consolidation of his lung, there is still much reason for speculation as to the cause of his trouble. The patient tells us that the disease came on at first with a sharp pain in the side, and says that this pain lasted for a few days and then became less and less severe, but that it has continued to some extent ever since. It would appear probable that he suffered first from an acute pleurisy, but that it became chronic and that the effusion was not absorbed for several weeks or possibly months. During this time the inflammation of the pleura gradually extended to the lung itself, the intervesicular tissues being involved, and finally the new connective tissue contracted and obliterated most of the air cells in the apex and a considerable number of those in the base of the left lung. This is not an uncommon condition after pleurisy. The temperature in this case may be due either to the condition of the lung, or to endocarditis or myocarditis. The continuous pain from which the patient suffers in the region of the heart would suggest that inflammation may be still going on in that organ. The cough and expectoration, however, would suggest that the rapid pulse and increased temperature are the result of changes in the lung.

The sputum has not been examined, therefore we can not tell whether tuberculosis has set in, though as I have already told you, it is almost sure to occur sooner or later when chronic inflammation of the lung follows pleurisy. In the absence of a positive diagnosis we will prescribe for this patient 5 minims of the tincture of digitalis to strengthen the heart action, 30 minims of the tincture of hyoscyamus to lessen the cough, and 5 grains of the iodid of ammonium not only to lessen the cough but to diminish the cardiac pain. These will be given in syrup of glycyrrhiza three or four times a day. If a microscopic examination should reveal to us the presence of tubercle bacilli, the proper treatment for tuberculosis would be given in addition to that for the heart. It is so unusual for pulmonary tuberculosis to occur in connection with chronic cardiac disease that it is sometimes assumed that the two are antagonistic. If this man were 45 years of age, we might well inquire whether the pain and rough sounds over the aorta were not due to slight dilatation or to an aneurysm of that vessel, but as he is only 21, I think it more reasonable to attribute them to changes in the heart itself. The prognosis as to recovery is necessarily unfavorable, but unless some accident occurs, we believe that this patient may hope to live at least three or four years.

REPORT OF A CASE OF GUNSHOT WOUND OF THE CHEST.

BY J. F. JENKINS, M.D.

TECUMSEH, MICH.

In the evening between the hours of 8 and 9 o'clock of April 26, 1896, a messenger came to my office from Dr. O. N. Rice of Tipton, some six miles distant, requesting me to come to his assistance; that there were two persons in that hamlet who had recently received gunshot wounds.

Eugene C., age 50 years, weight about 200 pounds, was shot in the chest while his assailant stood some fifteen feet from him; after shooting C., the young man fired a bullet through his own head, dying within an hour afterward.

The revolver was a 32-caliber, and the bullet struck C., as the reader will observe from the photograph about two inches to the left of the right nipple passing through the lung, and although the missile has not been extracted, the present indications are that it is buried in the tissues on the anterior surface of the right scapula near its inferior angle. An hour after receiving the wound, the patient was breathing rapidly and was suffering from shock. A careful search was then made for the bullet by pinching up the skin and tissues beneath, but with negative results. The wound of entrance was neither probed nor examined by the finger, and notwithstanding considerable hemorrhage occurred from the wounding of the intercostal artery, yet the bleeding subsided spontaneously. The cutaneous surface about the wound was shaved and thoroughly cleansed, the wound dressed antiseptically, and the

patient placed in a semi-recumbent position; hypodermics of morphin were given occasionally, sufficient to relieve pain. A moderate hemoptysis took place which continued more or less until the fourth day. On the following day upon an examination of the chest, there was found a circumscribed pleuritis and traumatic inflammation of the lung extending downward from the second intercostal space on the right side.

Twenty-four hours after receiving the wound, the temperature of the patient was 100 degrees, respiration 40 per minute, and pulse 102. Absolute quiet and an expectant course of treatment was adopted; antiseptic dressing was applied to the wound, which healed without suppuration. On the eighth day the temperature was 99.4, pulse 84, and respiration 24 per minute.

In the following night the patient complained of severe pain along the posterior portion of the right leg below the knee, and when examined was found swollen, the skin was pale and cool; there was tenderness along the course of the external saphenous vein, which felt like a whip cord. The phlebitis of the external saphenous was doubtless caused by a septic embolism. During the succeeding ten days the temperature varied from 99 to 102 degrees, respiration from 20 to 26, pulse from 84 to 110 per minute. The limb was elevated, and warm applications were made to the extremity; frequently the limb was immersed in hot water from ten to fifteen minutes at a time. A supporting course of treatment was followed, and sufficient anodynes to control pain.

Four weeks after the shooting, the respiratory murmur could be distinctly heard over the greater part of the lung, excepting along the course of the bullet, the phlebitis had subsided, and the patient discharged by Dr. O. N. Rice, who skillfully conducted the case, and who has kindly given me his history after my second visit.

A CASE OF FLAT RACHITIC PELVIS; PROLAPSE OF THE CORD WITH THE HEAD; VERSION AND EXTRACTION.

Read at the Meeting of the Obstetric Staff of the Chicago Health Department, Nov. 21, 1896.

BY JOS. B. DE LEE, M.D.

Lecturer on Obstetrics, Northwestern University Medical School, Obstetrician to Mercy Hospital, to the Chicago Lying-in Hospital, etc.
CHICAGO.

Mrs. H., iv-para; two forceps deliveries; one craniotomy; one spontaneous delivery, child living.

Present labor at term, began Nov. 9, 1896, at 9 P.M. Dr. A. E. Coy was called before midnight and found the cervix admitting two fingers, cephalic presentation and a large loop of pulsating cord in the vagina. Pains were strong and soon dilated the cervix.

At 2 A.M. Dr. Coy kindly invited me to see the case.

Patient is a large, strong, apparently well-built Irish woman. Spines, 28½; crests, 31; trochanters, 34½; Baudelocque, 19; conj. diag., 11; conj. vera, estimated at 9 to 9¼ cm.

Position, O. L. A.; heart tones, 140 per minute, strong and regular; head freely movable above the inlet.

Internally—perineum torn deeply at some previous labor, cervix thick, os admits the hand easily, old scars in the vagina, head movable above the inlet, sagittal suture transverse, small fontanelle at left, large to right and lower than the other. Pelvis roomy below and at the sides, contracted in the conjugate diameter.

There were two methods of treatment open to us, first, reposition of the cord and bringing it over one leg; second, version and following this, extraction.

Usually it lies with the choice of the operator or

his individual skill, which one of these procedures he adopts, but in this case the presence of a contracted pelvis, as evidenced the pelvic measurements and the history of the case, decided in favor of the version.

The patient was put on the table, anesthetized and the parts sterilized. The anterior foot was now brought down, but the version could not be completed as the head could not be dislodged from the inlet. A maneuver known as that of Justine Sigmundine was now tried. A stout sling was put on the foot and while pulling on this with one hand the head was pushed up from below with the other. Version completed, after which the heart tones were rapid but otherwise good. We waited fifteen minutes and undertook the extraction, for which the patient was allowed to awaken from the chloroform. It required considerable traction aided by pressure from above to deliver the trunk, and the arms were thrown up alongside the head so that great difficulty was met in delivering them.

The head was arrested at the inlet, Smellie-Veit maneuver and strong pressure from above brought it down to the vulva, where it was found that the cervix had contracted tightly around the head. Chloroform was again given and the cervix slowly worked upward by the fingers. By separating the walls of the vagina and vulva and wiping the passage clear, air was allowed to the child's mouth.

After delivery the trachea was cleared with the tracheal catheter and the slightly asphyxiated child revived by the usual methods. It was a female, weight 7½ pounds, length 50 cm. The puerperium was entirely normal.

Among the many interesting points this case presents, a few may be touched on. The maneuver invented by Justine Sigmundine, "Royal Midwife to the Brandenburg Court," is of signal use in cases of difficult version. Where the head is held tightly against the inlet or in the lower uterine segment, enough traction may be put on the leg as to break it without dislodging the head, even when the traction is aided by upward pressure against the head from the outside. One may also bring down the other leg and try the turning on the two. The little maneuver just mentioned is simpler and the following extraction is rendered easier if the other limb be allowed to remain in place with the breech and thus dilate the cervix more (that is, if the extraction be made on one leg). In the hardest cases it may be necessary to put slings on the two legs and push up the head with the hand in order to complete the version.

Where, in the interest of the child, an extraction by the breech is undertaken before the cervix is completely dilated, it may happen that the cervix, irritated by the passage of the child through it or by many and hasty manipulations with the hands, closes down on the head of the child, button-holing or imprisoning it in the uterus. Under these circumstances the child is lost, if it is not given air, in a very few minutes. At the risk of tearing the cervix and of grave post-partum hemorrhage one may forcibly pull the head out. In these cases, traction brings the head to the vulvar outlet and the cervix may be seen. Under chloroform the fingers may slowly work the constricting edge over the face, and the mouth now being free, it is cleansed and air allowed to it by separating the labia and vagina with the fingers. In this way the child may breathe while the cervix is given time to relax and slip back off the head. Carl

Schroeder in this way saved a child whose head was arrested for twenty minutes.

In primiparæ where one is desirous of saving the perineum by slow delivery of the after-coming head, it is possible, where the mouth is in the vulvar outlet, to give the body to an assistant to hold and allow the child to breathe in this position. A longer time may now be taken for the delivery of the occiput.

PECULIARITIES OF THE SURGICAL DISEASES AND INJURIES OF THE NECK.

BY EDMOND SOUCHON, M.D.

PROFESSOR OF ANATOMY AND CLINICAL SURGERY, TULANE UNIVERSITY,
NEW ORLEANS, LA.

(Continued from page 269.)

Special tumors of the neck.—The neck sometimes presents hernial tumors, already described. Also salivary calculi developed especially in the submaxillary gland.

Diagnosis and treatment of the tumors of the neck.—Percussion discloses the nature of gaseous tumors; besides, pressure reduces them, violent respiratory efforts reproduce them; pneumatocele follows the respiratory movements. Exploring the swelling with needle and syringe will reveal the fluid or the solid nature of a tumor. The following are the liquid tumors which should not be extirpated: Liquid hematoma, and chronic abscess. Liquid hematoma follows blows or contusions, or punctured wounds or incised wounds, when the lips have lost their parallelism; they may be due to a cured aneurysm; they should be left alone unless they cause pressure symptoms or unless they are too long in dispersing; then they should be aspirated; they should be incised early, if they reproduce; they need disinfecting and a drainage tube with or without a supplemental opening at the most dependent point. Chronic abscesses may be treated first with injection of iodoform (etheral or mucilage), or by incision, disinfection, and proper drainage; when they resist this treatment, the mucous membrane of the interior should be curetted; when possible the membrane should be extirpated. Recent aneurysms should not be extirpated before trying milder means.

The following are the solid tumors which should not be extirpated: Comedones, clotted hematoma, recent strumous adenoma, Hodgkin's adenoma without pressure symptoms, recent tuberculous adenoma, recent syphilitic adenoma, recent gumma, solidified hematoma in dangerous regions, salivary tumor and calculus, hernial tumor, pulsating encephaloid.

Comedones characterized by small elevation of the skin with a black depressed center should be treated by squeezing or expression. Clotted hematoma is recognized by the same history as liquid hematoma, by the fact that very little liquid pours through the syringe and the tumor does not diminish in bulk; it should be incised away from the line of the important structures (vessels and nerves), properly injected, packed or drained. Recent strumous adenoma is recognized by its presence in strumous children without any symptoms of tuberculosis anywhere. It should be treated here as everywhere else. Hodgkin's adenoma is usually multiple; there exists also enlarged glands in the axillæ and groin; the spleen is enlarged, also sometimes the liver; the white blood corpuscles

are not increased. It should be treated internally by arsenic, ergot, iodid potassium in high doses. Recent tuberculous adenoma is suspected from the general condition of the patient or from the presence of the bacillus in a central gland removed for that purpose; tuberculin might assist; it is treated on the same principles as incipient tuberculosis of the lungs. Recent syphilitic adenoma is revealed by the presence of syphilitic lesions in the neighborhood, which may account for the enlargement, or at a distance, or by a syphilitic history; the specific treatment is the best diagnostic means. Recent gumma presents the same remarks. Solidified hematoma, resulting from the same cause as the liquid or clotted hematoma, when in a dangerous region, should be incised away from the line of the larger vessels and nerves and the fibrinous clots removed; then properly packed and drained. Salivary calculi are diagnosed by the needle of the syringe returning a sound as though striking a metallic body; they should be removed by incision, preferably from inside the mouth when possible. Hernial tumors have already been described. Pulsating encephaloid is characterized by pulsation with expansion and attachment to the bones; when the needle is not thrust too deeply into the cavity it may become filled with serum.

The following are the liquid tumors that should be extirpated: Angioma, varix, lymphangioma, persistent aneurysm, serous cysts, hydatid cysts, bursal cysts (hygroma), tendinous cysts, persistent circumscribed abscesses or tuberculous abscesses. The following are the solid tumors that should be extirpated: Warts, papilloma, xanthoma, mycosis fungoides, sebaceous cysts, dermoid cysts, solidified hematoma in non-dangerous regions, lymphadenoma (simple hypertrophy), Hodgkin's adenoma when causing pressure symptoms, persistent strumous adenoma, persistent tuberculous adenoma, persistent syphilitic adenoma, persistent gumma, lipoma, fibroma, myxoma, myoma, neuroma, chondroma, osteoma, encephaloid, melanotic, colloid, epithelioma, carcinoma, and scirrhous sarcoma.

In the case of the tumors which must be extirpated to be cured, the nature of the tumor can not be determined positively and safely until after their extirpation, when by a microscopic examination the prognosis is established.

The point of prime importance is to decide if these tumors can be removed and with what difficulties, risks and dangers.

Superficial or super-aponeurotic tumors are diagnosed by the possibility of isolating the tumor from the deep parts, by grasping it with both hands and trying to make the fingers join beneath it; when the tumor is too large to be grasped by the hand or the two hands, the radial border of one hand is placed under one side of the base and the other along the other side, the hands are moved toward one another and thus appreciate the thickness of tissue between the two. When very thick it is likely that the tumor has also grown toward the deep parts and must be studied as a deep tumor. There is absence of pressure symptoms in superficial tumors. Deep or super-aponeurotic tumors are more interesting because of the greater danger of their complete removal. They are recognized by the fact of their incorporation with the deep structures; when large they become superficial and may come close to the skin or become attached to it. The condition of the skin is important to deter-

mine; when distended by large tumor a portion of it must be dissected along with the tumor to prevent redundancy of the flaps; when the skin is adherent, it should also be removed. The margins must be next delineated; when circumscribed or limited, it is a favorable sign, because the tumor will be easier to remove along a well determined line of dissection with safety and in its entirety, that far at least; when the margin is diffused, it is a most unfavorable feature, because of the uncertainty of the line of dissection and the absence of all assurance of removing all the diseased parts. By freezing sections of tumors on the spot and examining them there also under the microscope, is the only positive assurance. The non-adhesion or the adhesion of the tumor to the bones is important to determine; when the tumor is movable, it must be determined whether it is clear of the important structures, *i. e.*, of the vessels, nerves and special organs. When it is clear of the important structures, the extirpation will be easier and safer. When it is over or near these structures it is often impossible to determine the degree and nature of the adhesions until the operation has reached that stage. When the adhesions are loose and are easily torn all is well. When the adhesions are resistant then there is constant danger of cutting or tearing away some of the structures with all the possible risks and dangers. When those adhesions are also extensive the case may be hopeless. Double ligatures and double hemostatic forceps must be freely used, never cutting except between the two. It is prudent also in those cases to endeavor to locate the large vessels and to pass a provisional ligature under them before dissecting too close to the dangerous points. This provisional ligature is removed after all the bleeding has been controlled or it may be decided to convert it into a permanent one. When the tumor is adherent to the bone, if it is clear of important structures, again all is well, as it may be gouged out with little risk. When it is over or near important structures the risk is greater. When the attachment is extensive the risk is also much greater and complete extirpation may be beyond all our means.

It is always of the utmost importance to explore the regions of the lymphatic glands which receive the vessels from the affected regions. When the glands are only inflamed sympathetically they should be left alone. When the glands are enlarged in malignant diseases they should be removed; to leave them behind is a grave surgical mistake, since the disease will be reproduced and another operation will have to be performed, whereas it should have been done with the first.

Surgical operations of the neck in general.—The surgical operations for the relief of the affections of the neck in general has been described with the various diseases calling for them. However, the following remarks may be added. In operations on tumors in dangerous regions, split the capsule and enucleate contents first, if possible; then remove capsule, but this should only be done as a last resort. In some cases the pressure symptoms of tumors should be anticipated by tracheotomy, because they may be so sudden, that there is no time to perform the tracheotomy; there is less risk and less danger to life than to wait and risk a sudden death.

(To be continued.)

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

TABLE OF CONTENTS.

I.—DOCTOR AND BARBER.

Social relations in the first half of this century; Prejudice; Physician's dress; Family physicians; How soon can one become a great and renowned physician? Education of physicians; Dissensions in consultations; Title; Drinking, physician's income; Beard and barber; Lepers and bathers; Education of the barber-surgeon (*des Wundarztes*); His social position; Country barber-surgeons; Consultations between physicians and surgeons; Various classifications; Surgical fees; Separation of surgery from medicine; Extinction of barber-trust.

II.—THE QUACK.

Family quackery, old women, shepherds and others; The charlatan at the annual fair; Secret remedies; Hernia curers, castrators; Cataract-couchers, Hilmer, Knight Taylor; Stone cutters; Frère Jacques, Rau; Hangmen, Tortur, Guillotine; Quacks in foreign lands; Remedy against quackery; Our time.

III.—AT THE UNIVERSITY.

Academical training; The German student; Rough student's life; Göttingen bushwhacker's band (*Hainbund*); The student in war; Number of those who study medicine; Lectures, Latin language, dictation; Gatherings, libraries; Professors, their rank and income; Misdemeanor of the doctor-graduation, dissertation factories, our time; State examinations; Ceremonies, religious confusion at the graduation; Women doctors; Study of anatomy, public prejudice; Anatomical theater, scarcity of cadavers; Pathologic and surgical anatomy.

IV.—NOTICE ON HOSPITALS.

Charité in Berlin; The Allgemeine Krankenhaus in Vienna; Small German hospitals; Hospitals in England, St. Bartholomew Hospital in London, and others; Hospitals in France, Hôtel Dieu and Charité in Paris, and others; Hospitals in Sweden, Denmark and Russia; Diet; Mortality, small number of operations; Ventilation, J. Pringle; Proposition to improve hospitals; Experiments in putrefaction; In-lying hospitals.

V.—SURGICAL INSTRUCTION AND LITERATURE.

Schools of surgery in Germany and Russia; Practical instruction at universities, polyclinic, clinic; Surgical instruction in Paris: Desault, Ecole de Santé, Pensions, visits to Pelletan, French students, Boyer; Surgical instruction in London; John Hunter, Edinburgh; Book-making of German surgeons, servilism, Latin or German; Mutilation of the German language by the French; Translation craze, esteem for foreign countries; Surgical periodicals, reviews; Text-books, prices of books.

VI.—LORENZ HEISTER AND CONTEMPORARIES.

Heister; Z. Platner; Günz; Ludwig; Mauchard; Kaltschmidt; Bass; Haller; Schulze; Eschenbach; Vater; Detlef; Holzendorff; Eller; Senff; S. and A. Schaarschmidt; Muzell; S. Pallas; Z. Vogel; J. E. and O. J. Wreden; Schwarz; Walther.

VII.—THE RISE OF GERMAN SURGERY UNDER AUGUST GOTTLIEB RICHTER.

Frederick II; German poets and musicians; Kant; Social relations in the second half of this century; Surgery and clinical institutions at Göttingen; The life of Aug. Gottl. Richter; Richter as a surgeon, as a writer, as a teacher, as a physician.

VIII.—PROFESSORS OF SURGERY AND PRACTICAL BARBER-SURGEONS (*WUNDAERZTE*).

Van Swieten's reform; Joseph II and Maria Theresa; The Medico-Surgical Josephsakademie at Vienna; Masters of Art and Doctors of Surgery; Institute for surgical operations; Austrian surgeons: Brambilla, Leber, Plenk, Steidele, Hunczovsky, Mohrenheim, Wrabetz and others; C. C. von Siebold; J. B. von Siebold; Brünninghausen, Hesselbach; Henckel, A. F. Pallas, Zenker; Loder, Köhler; Arnemann, Wardenburg, Michaelis; Rougemont, Iseflamm, Weidmann, Metzger, Sommer, Löber, Sprengel, E. Platner; The practitioners Thilenius, Brückner, Ehrlich, Eckoldt, A. F. Vogel, Schneider, Jäger, Fielitz, Böttcher, Bernstein and others; The oculists Barth, Schmidt, Beer, Lobstein, Hellman and others.

IX.—THE ACADEMIE ROYALE DE CHIRURGIE AT PARIS.
PIERRE JOSEPH DESAULT.

Surgeons at the time of Louis XIV; Wrangle between the medical faculty and barber-surgeons (Wundärzte); Foundation of the Académie de Chirurgie; Memoirs, prize subjects, members thereof; Its influence; Education of French surgeons; Reforms of the French Revolution; J. L. Petit, le Dran, Morand, Garengot, Quesnay, Arnaud de Ronsil, de la Faye, le Cat, le Vacher, Verdier; Louis, A. Petit, Sue, Hevin, le Blanc, Pouteau, David, Goulard, Frère Côme, Levret; Desault; Sabatier, Chopart, Lassus, Deschamps, Pelletan; French medicine; Bichat, Pinel, Corvisart.

X.—ENGLISH SURGERY. JOHN HUNTER.

Bacon von Verulam; Maxims of English Surgery; The English: Cheselden, Sharp, Bromfield, White, Gooch, Alanson, Warner, Willmer, Hill; Pott; 4 Scotch families: Alex. Munro with his sons Donald and Alexander; Benjamin, John and Charles Bell; Allan and John Burns; William and John Hunter. Adherents; Surgeons in the remaining foreign countries.

XI.—WAR SURGERY UNDER FREDERICK THE GREAT.

The beginning of German military surgery; Interest of Frederick the Great; In the seven years' war; Portable and stationary field hospitals; Transport, diet, medicines; The siege hospital at Schweidnitz; Fresh air, neutrality, mortality; The surgical Pepinière at Berlin; The Prussian hospital steward; Bilguer; Schmucker; Theden; Voitius, Mursinna, Görcke; Jasser, Ollenroth and other regimental surgeons; The military sanitary regulations under Joseph II; Of minor states.

XII.—FRENCH AND ENGLISH WAR SURGERY.

The beginning of the French war surgery; The first flying and stationary hospitals; Improvements under Louis XIV and XV; Organization of war hospitals and military physicians under Louis XVI and the Republic; Means of transportation; Ravaton, Colombier; Trecourt, Lombard, Percy, Moreau, Boy; English regulations; the lash; J. Hunter, Jackson; J. Pringle, fresh air, recreation of the sick; Brocklesby, barracks; Count Stair, treaty for the protection of the wounded; French and German voices concerning barracks and protection treaty.

XIII.—GERMAN MEDICINE.

Leibnitz; University of Halle; Thomasius, Wolff, Franke; System of Medicine by Hoffmann and Stahl; Boerhaave; Haller; Gaub; Vienna School: van Swieten, de Haën, Störck, Stoll; Neurologic pathology, Unzer; Humor pathologists Ch. L. Hofmann and Kämpf; Classification of diseases; Study of the ancients; System of J. Brown; Realization of Chemistry and physicians; Special pathology; Remedies; Medical practitioners.

XIV.—INFLAMMATION AND WOUNDS.

German theories on inflammation; J. Hunter's teachings on the finer precedence of curing inflammation and wounds; Treatment; Lumbar abscesses; Misuse of the sound and plugging of the wounds; Lint, breiumschlag, cold water, lead preparations, etc.; Bloody suture; Fresh air, baths in fever; Cold showers in typhoid; Arresting hemorrhage, thrombosis; Ligature of the arteries; Compression, agaric; Early attempts at subcutaneous surgery.

XV.—DISEASES OF THE BONES, JOINTS AND MUSCLES.

Fractures, Caries, Malum Pottii; Necrosis; Osteomyelitis abscess of the bones, exostosis; Luxations; Coxitis; Tumor albus; Hydrarthrosis; Loose bodies in joints; Joint neuralgia; Sprains of the muscles; Rupture of the tendon of Achilles; Caput obstipum; Orthopedia; Venel; Club-foot.

XVI.—DISEASES OF THE BLOOD VESSELS, NERVES AND SKIN.
NEOPLASMS.

Aneurysms; Phlebitis, wounds of the veins; Lymphangitis; Anesthetics; Tetanus, compression of the carotid, facial pains; Ulcers; Furuncle, carbuncles, erysipelas; Burns, chilblains, Whitlow; Warts, Corns; Neoplasms, scirrhus and cancers; Breast, lip and chimney-sweep's cancer; Encysted tumors; Ganglion, teleangiectasis.

XVII.—DISEASES OF THE HEAD AND FACE.

Skull fractures, trephining; Face wounds, artificial nose; Nasal polypus; Hare-lip; Cleft palate; Diseases of the teeth; Opening of the Antrum of Highmore and frontal cavity; Diseases of the tongue; (Ranula); Tonsils; Parotid gland; Operations on the ear.

XVIII.—DISEASES OF THE THROAT, CHEST AND ABDOMEN.

Tracheotomy; Throat wounds; Foreign bodies in the esophagus; Esophagotomy; Gastrotomy; Goitre; Chest wounds; Paracentesis of the thoracic cavity; Mechanical treatment of phthisis pulmonaris; Opening of the pericardium; Paracentesis of the Abdomen; Abdominal wounds; Abscess of the liver;

Openings of the gall-bladder; Extirpation of the spleen; Hernia.

XIX.—DISEASES OF THE URINARY AND GENITAL ORGANS
AND OF THE RECTUM.

Lithotomy; Catheterism; Ischuria (strictures, swelling of the prostate); Cystotomy; Hematuria; Nephro-lithotomy, extirpation of the kidney; Hydrocele; Sarcocoele; Castration; Varicocele, testicles in the groin; Phimosis; Amputation of the penis; Symphysectomy; Vesico-vaginal fistula; Atresia of the vagina; Dropsy of the Ovaries; Fistula ani; Hemorrhoids; Atresia and strictures of the rectum.

XX.—GUNSHOT WOUNDS, AMPUTATION, EXARTICULATION,
RESECTION.

Gunshot wounds in general; Gunshot fractures; Conservative surgery; Gunshot wounds of the joints; Injuries by cannon balls; Primary or secondary amputation; Method of amputation; Exarticulation; Resections.

TRANSLATOR'S PREFACE.

It affords me great pride and pleasure to have been intrusted with the translation of one of the greatest historical works of the last quarter of this century. I only regret that the English language is inadequate to reproduce on the reader the same sentiment as the author has manifested in his own language; yet the English reader can but appreciate the wonderful and elaborate researches regarding the development of the history of surgery as promulgated for a period of one hundred years. The reader will be compelled to acknowledge in the work of Dr. Fischer the "genesis" of surgery. It is, I believe, just as essential for the surgeon to know the origin of his profession as it is for the theologian to know the origin of his creed. It is this that prompted the editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION to cause its translation and publication for the pleasure and instruction of the readers of the JOURNAL.

THE TRANSLATOR.

INTRODUCTION.

"That the historical information of matter diminishes with each generation of students is one of the worst phases of our present period of development in medicine. As a rule, it may be assumed that even the self-active younger worker's knowledge at the best covers from three to five years. Publications of five years past do not exist for them."—*Virchow, 1870.*

The farther the milestones of the natural medical philosophy are moved asunder the more justifiable is the question: Is it possible for the practicing physician to keep pace with the progress of science? After the young doctor has left the university and entered upon the starving years of his practice with the firm purpose of continuing his studies, he will soon unconsciously find himself at a turning point, when an irrevocable resolution must be made. Character, not talent, decides the course to pursue; the choice is a very serious one, usually for life. Either he bids farewell to science and steers directly into the laboratory of the medical workman, sometimes by means of the narrow and crooked path, plucking the forbidden fruit by the wayside, or he works on in order to obtain and merit the name of a learned practitioner.

However, a short rest after the strain of the closing examinations would be very beneficial, inasmuch as the university instructions would suffice for a few years. The great danger, however, lies in being idle too long; one year being extended to two, and if five years should pass, the young physician is incapable of making a scientific examination independently. After five subsequent years of indolence he will be shocked to note that even the professional works, which depend more upon the judgment of colleagues than upon the approbation met with by the practitioner, have become unintelligible to him. These impressions are not only caused by the writings of the specialists, but medicine and surgery have become strangers to the young doctor. Full of anxiety he seeks help from his older co-workers. The routinist has no scruples, he contents himself with his experiences. That is, the number of visits he makes and his practical tact, with which he creates great mischief. For of what little benefit to science are the experiences of so many variously occupied practitioners and hospital physicians who lack the talent to put the same to account! No more than light aids a blind man. On the other hand, the honest colleague often looks vexed; he complains of the imperfections of knowledge and frowns at the increase of literature in the journals, which he can not master. But if there is no apparent cause for his sorrows the displeasure is more frequently the result of his inability to advance, as, of all things, the preliminary sciences are not controlled.

If the practical physician desires to preserve his enthusiasm for science the best diploma that a university can bestow and an untiring strife toward perfection until old age, and not to remain a blunderer in all the branches of the vast number of

various professions, then he must not study medicine in detail today, tomorrow surgery, and obstetrics the next day, for he will fail. He will only feel satisfied when he has mastered one branch, which he can accomplish alone, as the study of a single science is continuous. This is not, however, to further the nuisance of the body of specialists, who give their sole attention to one science, ignoring all the others. Although most practitioners, particularly the country physicians, are no specialists in the modern sense of the word, each one of them has chosen some favorite study since his departure from the university. In this he may carry on his researches in detail, while in all the other branches he accepts the complete whole, paying no attention to the laborious examinations necessary, to the stories of the sick, the temperature charts and official reports of the sections heaped up in the ponderous journal of medical science, nor to the minute discussions of professors. Only under such circumstances should a practical physician become a specialist, but never to seclude himself with his hobby. The temptation to do so is very great. Yet the several professions must not be torn asunder if the mutual understanding is to continue; what the one imparts the other must receive, the connection must ever be an animated one.

At the present time there is a decided tendency toward the study of specialties, which is not only manifested by the new branches of the medical profession arising every year, by the establishment of special journals for each new division and by the steady increase of sectional meetings of the naturalists, but also by the deeper penetration into each branch. The one seeks his knowledge principally by the pathologic-anatomic course, another by consulting the statistics, others by experimenting with animals, and various other methods by which they try to improve. The many different ways in which each profession may be begun has immensely increased the amount of work done. But it must ever be remembered that the progress made does not depend upon the number of writers nor upon the haste with which the work is despatched. But on account of the division of labor and the special studies of so many men, a vast amount of material has been added to each profession, which is being collected by more than a hundred medical journals in Europe alone. The best men of former times always bowed their heads before the princely extent of the several sciences. A hundred years ago A. G. Richter declared that it was barely possible for one man to master surgery in all its details, knowing each branch equally well. In our time A. von Graefe felt very uneasy that he was no longer capable of fully controlling the territory of ophthalmology, although then in the prime of his industrial days, and B. von Langenbeck stated that there were only a few surgeons who could boast of the ability of surveying the entire dominion of surgery. These confessions force upon us the question whether it is right to demand a certain amount of time for the study of the history of surgery. In nearly all the periods historic studies played a secondary part, seldom remaining on top for a long time; at the utmost they were tolerated, offering no interest in their behalf.

About the middle of the last century a few German professors arose, who, on account of their superstitious and servile reverence for antiquity, desired to bring about a revolution in the study of history by revising the medicine of the ancients. The smallest details of the writings of Hippocrates were commented upon and blindly admired, a deep hidden thought being sifted out of the most insignificant parts; the truths of nature were perverted so as to make them conform to his and Galen's opinion. Thus was produced a great quantity of ancient literature, which hampered the progress of science. The manner of introducing the Hippocratic spirit of the simple observations of nature into the study of medicine was not understood; therefore the real advantage was lost.

An epoch of comparatively valuable historical works extended from 1830 to 1840. The mania for systems in the past century had so confused and distracted the minds of men that all interest in the achievements of foreign countries was lost, and only a few enlightened ones desired a thorough reformation. In 1840, Stieglitz, then 73 years old, wrote: The German profession has so deteriorated and relaxed, that every effort to arouse it, even if fraught with errors and absurdities, would be wholesome. During this crisis many took to studying the history of medicine, it being thought absolutely essential that the young people should undergo an examination in it and especial teachers appointed. On its foundation was to be erected a temple of science of a thousand years' standing, while before its study scientific regeneration would have ended! But the project failed. The mere recollection of such names as Johannes Müller, Rokitansky and Virchow, of the medical science journals that were first issued in 1840 for rational medicine and for pathologic anatomy, proved that the

researches in detail undertaken in the various branches of medicine had caused a revolution, and not history, which consequently failed, having received unmerited importance as a special line of study!

Now very little interest is taken in the history of surgery. Works appertaining thereto are so rare that in the archives of clinical surgery, only two columns were published within fifteen years. Notices of lectures on surgical history are seen only in isolated parts of the German universities (Berne, Breslau, Göttingen, Gratz); but it is a question whether they are always held, unless instituted by some of the more modern, prominent and practical surgeons. Baum, who knows everything, warmly advocates them and probably incited Professor Billroth's interest in them, as shown by the latter from the beginning and even now. After his treatise on gunshot wounds, Billroth wrote a brief abstract on historical surgery for the introduction of his work on general surgery, and with Pitha published a similar one in their manual. At the Vienna Exposition he exhibited a set of surgical instruments in connection with his work on the Extraction of Arrows and Bullets, which were in use years ago and are still used. Recently he published a large volume on historical culture, the methods of teaching and learning the medical sciences. From this we quote the following: "Regarding the lectures on historical medicine, it is very deplorable that they are continually growing less at the German universities, due alike to the scarcity of tutors and pupils.

I consider it an honor on the part of the higher medical faculties that they provide for lectures on the historical study of the medical sciences as shown in their catalogue, but I deem it not essential to insist on the students' attendance at these readings, the substance of which would not be heeded by a student having no desire for the historical studies. Where there exists a wish for genies investigation, a historical interest will also be manifested; inseparable thoughts, as it seems to me. All lectures ought to be permeated by historical genius, then not only the interest for a general contemplation of history would be awakened, but also special researches would be pushed on. I do not doubt that these lectures can be made very charming by associating more spirit and humor with the general history of nations. Such a discourse I would enjoy even today."

Mitteldorf, in company with his honorable colleague, Haeser, the great historical researcher, introduced one of the oldest German surgeons, Heinrich von Pflsprundt, who was famous for the unusual amount of historical knowledge that he possessed. Zeis wrote a treatise on Plastic Surgery and not long since Gürdt published an extensive work on the International Care of the Sick. The works of the ingenious Malgaigne are well known. Verneuil, one of the best modern practitioners of Paris, published a few of the unprinted documents of the old Académie de Chirurgie and arranged a course of lectures for the students, in order to awaken an interest in them for similar discoveries of history. Among those who assisted Verneuil, were the surgeons Beclard, Lefort, Follin, Broca and Trélat and seven other professors. Not long ago J. Rochard wrote a book on French Surgery of the Nineteenth Century. [Still more recently the works of Guy de Chauliac (A.D. 1360) and Henri de Mondeville (A.D. 1320) have been brought out by Nicaise. The latter was published from the MS. in the Bibliothèque Nationale.—Ed.]

Von Hasner contends that for years only a few of the younger ophthalmologists get beyond the boundaries of the archives of ophthalmology and in 1869 an animated discussion ensued about the oldest writings on the operation of cataract and was carried on by Haeser and Hirsch and the practitioners A. von Graefe and von Hasner. These titles, although incomplete, belong to practical men, whose works are of greater importance to us than the book-learned, be they ever so excellent (Littre's colossal work on Hippocrates, René Brian on Paulus Aegineta, Daremberg on Oribasius). I am of opinion that every German professor of surgery will approve of the value of the study of history, even if he allows an opportunity of expressing his views to pass by.

The main objection to historical studies is that they are too learned, afford no use at the bedside of the sick and do not at all promote surgery, therefore are of no real advantage. At best they are suitable for an old gentleman who has withdrawn into his quiet little sanctum from the tumultuous noise of the crowds and thence propounds a work from all the old timers; but this will not do for the young surgeon, he must keep pace with the times, and where the chances of immortality are greater for him than wrecking his reputation as a practical physician by his historical studies.

There is surely a great charm in taking part in questions up-to-date. But aside from this, that they fluctuate, are never stable and subject to fashion and by secondary circumstances

are for a time kept afloat, the one-sided preference given to a certain set of questions on one of the dominating auxiliary professions will ever leave loop holes in the other branches of surgery. It is not possible to organize an orchestra, when every musician wishes to play the first violin. Problems in surgery were greatly neglected by the cultivation of conservative surgery and the resection of the limbs was no longer a problem, until lately when doubts have arisen as to the capability of the amputated member to perform its functions properly after healing, and this operation again belongs to the most burning questions of surgery. But aside from the fact, that the difference between "learned" and "scientific" do not relate to the object, but to the cultivation of the same—for history can be treated so scientifically, on the other hand every practical question so learnedly—that the modern times consider everything with a touch of learnedness as old style. This idiosyncrasy was brought forth by the rightly repudiated book-learning, scraped together from the narrow confines of the study-room, heaping one citation on to the other, adding a piece or extract here and there until finally a literary work in mosaic results, which comprises everything; however, produces no life. It fills the mind with so much learned rubbish and instead of sharpening his faculties, stunts his reasoning powers and then produces a "learned professor" who can be outdone by the crudest practitioner. Such crippled personages rummage through the works of our greatest men, seeking a claim to priority, without having any interest in the true progress of science. At all times they have created much havoc, for the practitioner blinded by wisdom becomes confused in his studies; but when he has discovered that the gilded shell has no kernel, he sees that the learned man is of no use to his profession and condemns every kind of literary work. When the University of Göttingen was established in the year 1734, G. G. Richter was offered the chair of First Professor of Medicine. Richter, a scholar and strict follower of Boerhaave, read a collegium encyclopædicum dieteticum pathologicum on materia medica and practice. His wonderful scholarship, his linguistic accomplishments, and his very extensive knowledge of ancient literature were astonishing. He was master of the ancient and the modern languages; when only a boy, he delivered an oration in the Syrian language and composed a poem in Chaldaic. Later on he wrote lyric poems in Latin on the war at that time. Over eighty treatises were published by him; among them were the following: The advantages of a sound sleep; The disadvantages of night study; The best position while sleeping; The power of habit; Working by light at night; and The horrible aspect of a dead body. He also strove to explain theological subjects and asked theologians to return the good deeds on behalf of the medical profession. Similar tasks he demanded of his pupils, one of which was a dissertation on the naked body which did not consider Adam's nudeness offensive on account of the few innocent ones that surrounded him. His learning was greatly appreciated at that time and greatly aided in spreading the fame of the young university. But he accomplished absolutely nothing in furthering the progress of medicine.

Another form of learning is the knowledge of literature, gathered from treasured volumes, yellow with age, and forgotten through the rapid flight of time, which, after revision, becomes most useful and forms a part of modern scientific education. For this learning literature is no graveyard, as it possesses the power to kindle the hidden spark needed to bring forth the treasures of literature, which the book-learned carry about with them, a dead, useless and splendid ballast. It proves that much which is being sought has already been discovered, and often saves some one, who is about to proclaim a newly found method, from the disgrace of having presented some old fact. Literature has somewhat been neglected in connection with our surgery, consequently there are many literary errors. Virchow considers the above neglect one of the worst phases of the present period of development. Those who renounce the direct use of history at the sick-bed, forget that they also reproach anatomy, the history of development and other auxiliary sciences, whose importance has been established beyond a doubt. Many think of abstract knowledge as Falstaff thought of "honor." "Can a leg be set with honor? No. Or an arm? No. Or can it quiet the pains of a wound? No. What is this honor? Air. I do not like it." One ought not to engage in the study of history until fully convinced of the real value of the same, but you must, first of all, be willing to be convinced. However, it is often very difficult to give up preconceived opinions, from which no one is exempt to depart from one's original principles and to confess one's error. And why? Because his egotism causes him to stubbornly cling to his false methods; his mistake he dislikes to expose before others, when an unsympathetic colleague censures him. No one sees what he does not wish to see, is incap-

able of standing a contradiction, suppresses the observation, which kills his own principle and which upholds the opinion of his opponent. Thus the lives of hundreds may be sacrificed for the want of magnanimity of one talented man. No progress is possible without the most rigid veracity. A man of character will acknowledge his mistakes, and nothing impresses a student more forcibly than his master's: "I do not know." Do not by means of mere words try to bridge over the loop-holes of science, nor assume things to be true, and do not give yourself the appearance of being omniscient, what in reality is not known at all. If the extent of a discovery is exaggerated and claimed before it has attained a certain degree of completion—it often happens that it is discredited and forgotten for a long time. By means of historical studies we learn to know the course of development of our sciences and their imperfections. They are the harbinger of great surgical discoveries, of which not one has dropped unprepared from the skies and often remind us of the saying: All these things have existed heretofore. They compel us to be modest and considerate, when we see that the great professionals were unable to enlighten us, and facts sworn to by every one today would be rejected ten years hence. The severity, which so deeply offends contemporaries, disappears by means of the scientific discussions, so that they rather view the inconsiderate writer, even if he be a genius, from afar—regardez mais ne touchez pas—and this is only noticeable in old age. Above all things they sharpen your judgment and guard against one-sidedness which are of inestimable value to our sciences, especially when the incentives for everything more modern are so powerful. The hunt for new methods and means has not yet ceased in our speedy times; we accept them with much enthusiasm when authorized by some great light, declare them infallible, and soon forget them again. The new always pleases only because it is new, and we would like to credit everything that we desire to be true. With these inclinations, in connection with which the tasks of yesterday were deemed old today, so that even the stationer prints the following year's date on the works of the last months of the old year, we learn by the way not to be deluded by deceiving appearances, nor to allow severe censure of the mistakes made. Our wits become more and more sharpened and we are soon able to readily select the cream of the literature contained in journals and exclude the chaff. The horizon of an eagle is not like that of a sparrow in the dusty air below. A knowledge of history will greatly aid in bringing about a more rapid progress in the science of surgery for our general benefit. The results obtained can be more correctly estimated by the education of the middle classes, to which most of the practitioners belong, than by the famous works of a few great men (geniuses). Of what avail is genius during an epoch when not within the comprehension of the practising physician? Not the least valuable part of history consists in encouraging the dejected practitioner and awaken new life, by the examples and great labors of prominent men. To know the history of his profession is a part of his general education and easily keeps pace with the study of the branches, so many grand and renowned men ever being ready to respond to our wants during our lives. An officer in the army can not rise above the routine of the daily tactics, if he does not become familiar with the strategy of Frederick the Great and Napoleon I; the musician may become a good performer, or a fine musical director, but he is no true artist without a knowledge of Sebastian Bach. The value of history must not, however, be overrated, and given the preference, for there is enough for us to learn in our own times and surgical studies would come to a standstill, if history were to redress the auxiliary sciences. Who will dare to prophesy which one is of the greatest importance to the future studies in surgery, experimental pathology, statistics or other things. Besides, this question is as indifferent to us, as the contest for priority of one or the other surgeon is absurd. Most appropriate is Goethe's answer: People should not discuss the point who was the greater, Schiller or he, but to be happy in the possession of two such men. It is very harmful to pit one branch against another in order to ascertain which one would be of the greatest value to the progress of science; whether a piece of work originates at the table of the microscopist, in the laboratory or at the bedside of some patient is all the same when something new is gained in a rational way. All pleasure in the study of natural philosophy ceases, when we pause to consider the question: Of what use at the bedside is the exact difference between a sarcoma and a carcinoma? We do not study the history of surgery for its sake alone, but for the results obtained by the remedies employed, and if I am exerting myself to awaken an interest in this auxiliary branch among practitioners—do I hear some one laughing? I would not for worlds exchange my calling as a practical physician with a professional philosopher. That a historical work, when considered an imposition, would

not be in great demand, I knew; but who thinks of the consequences when working out an idea. I wrote with the conviction that the younger generation of German surgeons know but little of the history of surgery, and as much as nothing of the German historical studies of surgery. The lack of interest is rooted in our egotism which permits us to concern ourselves only in what occupies our minds momentarily—and no one has time to trouble himself with his neighbor's thoughts while he is at work himself. A national feeling for our own past not existing, it had to be roughly awakened from its slumbers. It is to be hoped that more sympathy will now be extended to the history of our sciences as the study of self-culture is growing steadily among the Germans. This was the main difference between German and French surgery: The French honor and remember their great men, the Germans scarcely know the names of their predecessors; the French surgeon looks upon foreigners with contempt, not so the German. Often the rank which a nation holds among the races, corresponds to the notice taken of its scientific works. The past century when France controlled the laws, the whole of Europe studied French surgery and not until after the wars of 1813-1815 did the German profession rid itself of the French influence. Everything from France and England was blindly accepted and revered by the Germans, neglecting their home talent. Of course it was very advantageous for the German student to profit by the good of any of the foreign countries, but thus it was that the development of our surgery remained behind the times, being too weak to stand its own ground. This is not at all surprising. On account of a certain amount of characteristic sluggishness of the German nature, they seldom take the initiative, but when roused to action possess great power of penetration. This is not the case with the French surgeons, who reigned supreme in the past century and have since been outclassed by the German, because they were incapable of following the progress made, having so completely neglected the foreign profession. Enlightened minds have often told them the truth. In 1814 Madame de Staël said that they did not do justice to German literature because so few of them understood the language. In the December session of the Académie de Médecine, in 1860, Verneuil severely criticized the views of his colleagues, who still adhered to French provincialism, in the following extract:

"A l'époque où nous vivons, nul homme, si habile, si érudit, si actif qu'il puisse être, ne saurait prétendre représenter à lui seul, par son enseignement ou sa pratique, l'art et la science en chirurgie; cette vérité incontestable, je crois, pour les individus, ne l'est pas moins pour les nations, car nulle d'entre elles ne peut se flatter aujourd'hui de tenir exclusivement entre ses mains le sceptre chirurgical. . . . les foyers scientifiques, ne se concentrent plus dans une terre privilégiée; ils sont multipliés et disséminés partout sur la vaste étendue du monde. . . . On cherche dans la littérature étrangère le complément de la science nationale. . . . les résultats qu'on atteint en suivant cette voie sont immenses; mais par malheur, en France, on en parait moins convaincu que partout ailleurs. Soit indolence, soit confiance extrême dans leurs propres ressources, nos praticiens pour la plupart, restent indifférents au mouvement scientifique extérieur passé ou contemporain."

Perhaps as in former years, the great inventions and discoveries of the present age will be followed by an epoch of new developments in the medical sciences. The downfall of the French glory by means of German weapons was followed by a most promising institution in the month of November, 1872, erected at Nancy after the loss of the one at Strasburg. The medical faculty of the same subscribed for all the German medical journals, bought the German books, and even the dissertations, if at all valuable. The faculty had to arrange a specific German bibliography and make translations of prominent works, in short, aid the French physicians to become familiar with the German sciences. "Jusqu'ici nous avons trop vécu et trop pensé entre nous," said the president in his address to the new faculty. He said in a public meeting of the Institut de France, that her people had fallen so because they had lost all thought of truth by their selfish vanity and pride, they wanted to be deceived and imposed upon. This was the unanimous opinion of all her great men. France was crushed by the falsehoods with which her education of the young, her books and periodicals teemed. The French still read the works of their oldest surgeons and after fifty years or more, publish new editions, while the Germans ignore their famous predecessors and their achievements. No one remembers that Heister's Surgery was the most brilliant work of its time. A. G. Richter, who was Germany's greatest surgeon a hundred years ago, has now become a mythical character, even to our best educated physicians; his burial place in Göttingen can no longer be found, while Sir Astley Cooper, buried in the chapel of Guy's Hospital, has been honored by a memorial in Westminster Abbey. It will not be long before Dieffenbach's life is shrouded in obscurity. Every German student knows that Arnaud made a few suggestions on the crooked bone, that Dupuytren invented the enterotomy, although these are only

minor discoveries when compared to the great services rendered surgery by both men; but it is very doubtful if every student knows of Smucker's introduction of cold applications in treating injuries of the head, which course would be instinctively pursued by every peasant. In order to give a new impetus to the study of history, great works on that subject are essential; jeremiads are of no avail. At the present time it is more important to awaken an interest in the young student for the study of history in the universities, than to establish special professorships. The clinic instructor will most easily succeed in doing so. The practical physician clings to what he learned at the sick bed, but soon forgets things passed by on the part of his clinical teacher. Lectures should oftener be fraught with remarks on history, and even if his valuable time must not be spent in the pursuit of historical studies, a desire may be instilled and retained later on in his practical life. Although we can not wipe out the stain on history and literature, caused by our dearth of interest, let no one forget the enormous advantages to be derived from modern surgery in Germany, born about forty years ago during the great revolution in medicine. Only since that period has a national German surgery existed, having for its basis doctrines founded by Germany alone. It advanced so rapidly knowing just how to employ the auxiliary sciences and make the best possible use of all the results obtained in the natural sciences. With the increase in methods corresponded the growth of the number of students and each one, if master of any one method, could take part in the medical researches. Thus there was such an immense quantity of scientific matter produced more than during any other epoch of history. There was no end to the work, and the competition was exorbitant! The result was a feeling of analogous rights and independence of spirit among the workers, and to these the German surgery owes its scientific rise. Authority was overthrown regardless of the prestige of its social position, which no longer satisfies a student of today. So the doors were opened to progress, which passed unmercifully over all who opposed the spirit of the times or who were too weak to follow. It is no wonder that this self-consciousness at times attained an extraordinary degree and often causes a morbid condition, for many, talented or untalented, capable of a little work consider themselves as contemporaries in the progress of the sciences.

Buckle, the historian of culture, says of these: "We must remember that the deep thinkers are the world's benefactors, and not the great experimenters, nor the great observers, and not the well read nor the very learned, and those who point out the way to make discoveries are deserving of the highest praise, not those who make them. When the true course of research has been indicated, the rest is comparatively easy. A regular course of routine is always used, and it is not hard to find those who follow the old path, but to find people who will open a new route. Every period of time produces many men of ingenuity and considerable diligence, who are fully capable to add a part to science, but who are unable to extend its limits. A new method is required for such an extension.

In closing allow me to say a few words on the work itself. I chose the subject, Surgery One Hundred Years Ago, because the scientific practice had its origin in Germany at that time. German national feeling began to develop then and produced its deepest philosophers, greatest musicians and best poets. When some one remarks to me that the German surgeons of that time do not interest him because a few French and English contemporaries have far surpassed our countrymen in the sciences, I reply to him that the history of the German nation did not begin on that world-renowned day when the Emperor was crowned at Versailles. If the history of our surgery is to originate when surgical geniuses are born, then it can peacefully rest for a few hundred years, for nature is very miserly in the production of great men and they are to be found only at long intervals. The truly great surgeons are as scarce as the geniuses. This work embraces the eighteenth century, the latter half being the more important. The first part treats of the surgical classes, the last of the surgical sciences. The surgery of our Fatherland ought to be honored by the erection of a national memorial for which I would like to carry a few building stones. German surgery should not forget its youth and faithfully remember the dreams and battles of its childhood years. To present it with its proper coloring, German medicine and foreign surgery had to cast their shadows on it. The history of surgery is international; here French and English surgery have obtained full rights. It was not my intention to write a complete history of the eighteenth century. A picture of the skull is much more interesting to us than the top of the wild cherry tree. From this point of view I ask you to pardon the shortcomings. I write for the practitioners, not for the book learned. If history is to become an

animated practical study, it must be made as entertaining as life itself, but not with a cold heart, nor like a skeleton, pursue its course. History must be contented to wear a simple and becoming dress, instead of one adorned with learned ornaments. The savant has a right to demand information on the sources of knowledge; he must admit, however, that no reading matter or thesis is more fatiguing than that of which the text is decorated with figures referring to certain citations, and almost covered by the extended remarks. It would have been an easy matter to name the various sources, sentence after sentence, but I avoided the great mass of citations in order to obtain the good will of the practical physician. No surgeon will be able to incite a desire among practitioners to take up a neglected study with its dry literature. Such works are dead when issued and from the bookbinder they are ready for the library. *Le style c'est l'homme*. In order to produce as elegant a form of language as possible a hundred years ago France employed the so-called *hommes de lettres*, to whom the best physicians and surgeons, as Sabatier and Baudelocque, contributed their writings. No *hommes de lettres* exist to polish our works, therefore let us proceed!

(To be continued.)

Fourteenth Biennial Report of the Board of State Commissioners of Public Charities for the Years 1895 and 1896.

ARTHUR R. REYNOLDS, M.D., PRESIDENT.

For the last biennial period Illinois appropriated for State charities the sum of \$2,962,550. This is a large amount, yet it is only one factor in the incalculable sum which the State by private and public contribution devotes to the care of the dependent classes. Scientific investigation has demonstrated its economic value in discovering sources of disease and disability and in suggesting methods of prevention. We submit that the State can not afford to conduct its charitable institutions merely for the immediate and direct alleviation of suffering and the protection of the inmates, primary and vital as this purpose is. The State has in these institutions great resources for research and study. Their proper use in furthering medical education, in promoting scientific investigation is due to the future of society and to the taxpayers of Illinois. Such use means no lack of consideration for the sick and helpless charges of the State. On the contrary, it means for them, now and at once, more faithful humane care; while it means an effort to benefit future generations by prevention rather than by cure. Work has already been done in a few of our institutions in accord with above. We make further suggestions below, and in regard to others we make no specific suggestion at this time, although the principle is applicable to all.

The following classes of institutions are by law subject to the examination of the State Board of Charities in Illinois, namely: 1, State charitable institutions which have been enumerated before; 2, the county jails and almshouses; 3, industrial schools; 4, private insane asylums. To those various institutions in the period since the last biennial report nearly four hundred visits have been made by various members of this board. These visits have been made at irregular intervals and in most cases unannounced. The board does not undertake in what follows to discuss all these institutions in detail, but merely to make suggestions upon those subjects of most immediate importance or urgency.

BLIND.

The Eye and Ear Infirmary at Chicago, the School for the Blind at Jacksonville and the Industrial Home at Chicago constitute the State provision for the blind. We believe this provision is ample in scope, and, when the equipment of the Industrial Home is completed and the hospital at the infirmary enlarged, it will be adequate to the reasonable needs of the blind and a credit to the State. As we have indicated elsewhere, the infirmary at Chicago should be enlarged and the Industrial Home must be completed and equipped.

HOME FOR JUVENILE FEMALE OFFENDERS.

Since the last biennial report of the Board of Charities this institution has left its temporary quarters in the city and has moved to its permanent location near Geneva, in Kane County. It has a fine piece of land, about fifty acres, overlooking the Fox River and giving opportunities for dairying, gardening, poultry-raising and such outdoor occupations as girls may be taught. The building is of brick, two stories and attic, divided into sections or flats absolutely distinct, each having its own dining-room and kitchen, superintended by a matron, thus permitting classification of inmates. The girls are now taught the work of a house and sewing—other occupations will be added as rapidly as practicable. All the girls are now in school

half of each day. Girls are placed out in carefully selected homes, where their past history shall prejudice them as little as possible and where they may have the most favorable opportunity for a fresh start in life. Girls are placed in homes in accordance with Section 27 of the act creating this institution. The Home for Juvenile Female Offenders is administered upon the theory that if the girls are to be reformed they must be given new and better tastes and must be taught a way to gratify these tastes in the course of earning an honest livelihood. The trustees and superintendent are laboring with unusual earnestness and are entitled to great credit in the organization of this new institution. The Home is now caring for about seventy-nine girls. It is already crowded and such good work should not be limited by lack of equipment or space. We have elsewhere advised the erection of another simple cottage.

The provision for the deaf and dumb we believe is also generous and creditable to the State. Of course, the schools for the deaf and dumb and for the blind, like all educational institutions, need constantly some renewal or increase of equipment.

FEEBLE-MINDED.

The School for the Feeble-minded at Lincoln, which now contains 639 children, is crowded far beyond its capacity. Upon its books are 361 urgent applications; of these 162 are for epileptics.

Feeble-minded children and epileptics are found in many almshouses, and even in some insane asylums. The application list at Lincoln, however, shows that there are more children in private families who need State care than in institutions, parents only sending their children to an almshouse as a last resort.

A notice was sent out through the auxiliary county boards, which was published in the summer of 1896 in a portion of the county newspapers, requesting information as to epileptics. As a result of this a number of most pitiful cases were reported, indicating that of which the board is well satisfied from its general information and observation, namely, that the number of feeble-minded and epileptic in need of State care is much larger than is apparent at first, and above all that their presence in the community uncared for and unprotected is dangerous to them and to the public.

The presence of a feeble-minded child in the home of people of scanty means is usually a great hardship, often making the family incapable of self-support. As a matter of economy it is much wiser for the State to provide fully for the care of feeble-minded children than to leave them in homes which they practically reduce to pauperism by their presence. Even if this is not the case, the child can receive no proper training except by a degree of attention impossible in an ordinary family, and grows up into a positive menace to the community in too many cases; whereas, under proper guidance and protection such a child may be made, in some cases, almost self-supporting, and at least not dangerous to the community at large. We are of the opinion that the wisest economy as well as the soundest humanity requires that the State provide institutional care for all feeble-minded children whose parents can not give them proper care and protection at home. As the feeble-minded person never advances beyond childhood, we believe that the State is justified in assuming the permanent custody of all those who enter the institution for the feeble-minded and who can not be safely protected by their natural or legal guardians.

The State must especially learn the necessity of protecting feeble-minded women and girls. The moral imbecile is too often held to a stern responsibility which she can not even understand, but is now given the protection and segregation which her feebleness demands. Some of the facts as to parentage given in the list of children in the Cook County Almshouse, shown in the appendix to this report, as well as similar instances in many a county almshouse, point out the moral that the State should assume custodial care of this class.

It was plainly the original intention that the school at Lincoln should be a school for improvable feeble-minded children, not epileptics. But the pressure for admission has been so great that there are now at least 125 epileptic children at Lincoln. In our opinion the institution at Lincoln should be somewhat enlarged, and we have approved the request for the erection of a girl's cottage for sixty, and a house for boys on the farm to contain about fifty inmates.

EPILEPTICS.

We recommend that the State provide a separate institution for epileptics, for the following reasons:

I. As the proportion of epileptics is about 1 to 600 of the population, making in Illinois an epileptic population of about 8,000, from which the ranks of the dependent epileptics are

constantly recruited, and as the disease is one which at present almost baffles medical skill, we believe that the State should promote the study of this disease with a view to curative or preventive measures. This is only possible in an institution where such cases can be under constant observation.

2. The medical treatment and diet of epileptics should be different from that of feeble-minded children not epileptic.

3. As the institution at Lincoln was not intended for epileptics, this class has therefore been discriminated against necessarily in admitting children. As was stated above, 162 of the 361 applications now on file are for epileptics, so that a separate institution for epileptics would not only relieve Lincoln of about 25 per cent. of its population, but would provide for about 45 per cent. of those on the application list.

4. There are also throughout the State a large number of adult epileptics, found occasionally in almshouses, who are able to work a portion of the time, but whose seizures prevent their employment in the ordinary affairs of business life. An institution modeled somewhat after the Bielefeld Colony, in Germany, or the Craig Colony, in New York, seems to us the wisest expedient for the feeble-minded and epileptics of the State, who are now neglected, and whose neglect is not only causing great suffering, but is entailing an expense which can not be estimated, but which is certain to be very great upon this and future generations. The presence of adults able to work in a place particularly adapted to their infirmity would prove an economy and great assistance in the care of the helpless. Doubtless a considerable portion could be practically self-supporting under conditions which made it possible for them to work when able. We especially urge that this institution should be upon what is called the colony plan, and advise the purchase of at least one thousand acres of land for this institution. A considerable number of small buildings of simple construction will be needed to care for the various classes of inmates. Not only farming but various other industries should be provided, so that the colony shall be as nearly self-supporting as possible.

5. There are in our insane asylums a considerable number of epileptics, probably 7 per cent., or nearly 400, who are sane between their seizures, or who could be allowed more liberty than is considered prudent in the hospital for the insane. For instance, in the Central Hospital there are 100 epileptics, of whom the superintendent, Dr. Watson, says: "Ninety per cent. have lucid intervals and are all able to work more or less. They would be much better off in the country on a farm where they could be regularly employed at outdoor work." Good authorities recommend that a certain proportion of the epileptic insane be transferred to an epileptic colony. If for no other purpose we believe that the medical study of the disease makes it desirable that this class of patients should also be included in the population of an epileptic colony. There is no reason why they can not be cared for there as well as in any other institution, if separate means are needed. Thus there are now:

In the school for feeble-minded	125
In the insane hospitals (estimate)	400
Applicants for admission to Lincoln	162
In the almshouse (estimate)	100
Total	787

All of these could be cared for better in a separate institution besides an uncertain number known to exist who should be in the care of the State.

In conclusion, we urge an epileptic colony, first, to afford protection, together with the greatest degree of freedom consistent with the safety of the inmates and society, for a class of our population now suffering, neglected and too often a public menace. Second, to provide education, training and industrial pursuits for all who can be taught or who can work. Third, to apply the best medical care and investigation to the study of epilepsy so as to insure such alleviation as possible for the inmates, so as to obtain and diffuse knowledge as to the nature and prevention of this disease, and so that by a careful study of the influence of heredity the people may be fully informed of the responsibility of parentage, with the hope that the future burden of the State and society may be lightened.

STATE CARE FOR THE INSANE.

The following figures show the population of the various State institutions for the insane yearly since 1890:

June 30.	Northern.	Eastern.	Central.	Southern.	Criminal Insane.	Total.
1890	522	1,687	912	627	—	3,748
1892	1,010	1,710	1,180	840	118	4,858
1894	1,107	2,096	1,231	825	116	5,375
1896	1,178	2,158	1,207	829	123	5,495

The insane in the county almshouse are 2,265 in 1896.

The erection of the Western Hospital for the Insane near Rock Island, planned for 1,000, immediate capacity 480, and the Asylum for the Chronic Insane at Peoria, immediate capacity 200, will give much needed relief to our crowded State hospitals and will permit State care of a portion of the most urgent county-almshouse cases.

It is the conviction of the Board that the State should provide, without further delay, some complete and systematic plan of caring for all the insane of the State or for supervising authoritatively their care if any are left in the county almshouses. It is true that this Board has the duty of visitation, but an annual visit to an almshouse with no power to enforce any improvement in the care of the insane who may be confined there, becomes no better than a painful travesty when there is need of improvements which cost money and attention.

In many of the counties the following hindrances to reasonable care of the insane appear: 1. Political influence in the appointment of the almshouse superintendent. 2. The lack of popular knowledge as to what constitutes proper care of the insane. 3. Unwillingness of boards of supervisors to make necessary expenditure. 4. The practical impossibility of providing humane and adequate accommodation for a few insane, unless the cases are of the mildest type. Even if these difficulties are not all found in all counties, they exist in most, so that many insane do and must suffer (as all the reports of this Board for years past have shown) under our present arrangement. Common fairness seems to us to demand an equality of care which can only be secured by State maintenance.

In the opinion of the Board, any permanent plan should be elastic enough to permit the inauguration of experiments in "boarding out" quiet chronic cases, as we are strongly of the opinion that ultimately a certain proportion of our insane must be cared for in this way. The Board deprecates the suggestion of one large asylum for incurables, but would rather urge the extension of our present system of smaller mixed hospitals. The medical testimony gathered by the Board in 1895 shows that such European authorities as Dr. J. Morel of Ghent and Dr. Hartniz of Alt Scherbitz, and such American authorities as Dr. Wise, formerly superintendent of the St. Lawrence Hospital, N. Y., and the Ohio State Board of Charities, favor mixed hospitals as against special institutions for the incurable insane. The mixed hospital gives a working force, which is an important consideration, and reduces the cost of caring properly for acute cases. The stamp of hopelessness is set upon the hospital for incurables, and it is hard to enlist such medical interest or skill in its behalf as is necessary to maintain it above the level of an almshouse.

We wish to emphasize the need of a better popular understanding of the fact that insanity is a disease, no more discreditable to the victim or shameful to his relatives than rheumatism.

If the superstitious dread of an insane person could be overcome in the popular mind, many of the mild cases now immured for life in the institutions could be cared for at home, at a considerable saving of money to the State. If a proof of this were needed it could be too easily found in some of the chronic insane in almshouses. In repeated instances quiet cases returned from State institutions live with the other inmates without any difference in care, never running away, behaving peaceably and usually working far more faithfully than the sane inmate of equal strength. Again, numbers of old persons in various stages of senile dementia are received at the hospitals, not dangerous or unsafe to be at home, nor requiring care and attention impossible at home, but needing a little indulgence for their vagaries.

In regard to old people, we quote from Dr. Loewy, Superintendent of the Northern Hospital, who was asked to report upon this matter. He states as follows:

"Case 1. An old lady between 60 and 70 years old, in poor physical health, mental aberration very slight, as shown by simple mental enfeeblement. This patient has some means, and her conservator and myself have made repeated efforts to have her cared for by her sisters, but without result; and only within the past week have we been able to make arrangements with a neighbor of hers, where she used to live, to care for her. Her means are sufficient to care for her to the end of her days.

"Case 2. A patient about 60 years old, who is slightly exalted mentally, who occasions no trouble, and to my mind could be easily cared for at home were her relatives willing to put forth the effort.

"Case 3. A patient about 70, usually very quiet, no trouble to any one, but as her friends express it, she tires them out.

"Case 4. Very quiet patient, very slight mental aberration and has been here for several months. I have tried to get her children to take care of her, but they all evade any direct statement by me in regard to taking her home, by stating that they have not time to visit her.

"Cases 5 and 6. Patients each about 60, who have some

delusions of persecution, but I believe could be cared for at home.

"Case 7. Patient is very quiet and the mental aberration is extremely slight, and could be easily cared for were her friends willing to make a few sacrifices.

"Case 8. A very quiet patient, slight mental aberration and could be easily cared for.

"Cases 9 and 10. Two old men who are mentally enfeebled, one bedridden, but both could be easily cared for at home were it possible to make this a compulsory matter.

"I could cite many more cases, and think that on both male and female sides there must be between thirty and forty patients of this kind who could be cared for at home at least part of the year; but the friends of the patients evade any responsibility in the matter by stating that they do not want to take the patients home until full recovery takes place. I have just received a copy of the last report of the Southern California Hospital, and the Superintendent makes reference to cases which he thinks could be cared for at home but for what he calls a lack of filial affection."

Dr. William Watson, Superintendent of the Central Hospital, says:

"I have 134 cases of senile insanity; 94 males and 40 females. These people are all over 60 years old and might be cared for by their friends, if they were willing to take the trouble and cared to look after them."

Judge Orrin N. Carter, County Judge of Cook County, recently remarked upon the number of cases of senile dementia brought before him, and states that they are seldom dangerous or excited, and that their condition, sent away from the familiar surroundings of their lives to end their days in a great institution, renders them the most pitiable of all the insane brought before him.

MEDICAL EDUCATION.

If the increase of insanity is to be stemmed by the medical profession, we are satisfied that the general practitioner must be depended upon rather than the alienist. The general practitioner sees the patient when insanity might be arrested. The alienist usually sees him only when symptoms are unmistakable. The family physician knows the patient in the usual surroundings of his life and can discern the external causes which may provoke an outbreak. If he were acquainted with the symptoms of the disease he could often perform a preventive function impossible to the specialist.

We regret to see that several of the recognized medical schools of the State do not include mental diseases in their announcement of courses, and that the others allot this subject of such profound importance but meager attention; the school requiring most in this regard allowing the subject of mental diseases a credit of 1 out of the total 55 required for graduation. We earnestly bespeak the interest of our medical schools in behalf of more extended courses and better clinical advantages for this subject, and would heartily favor any reasonable arrangement with the State hospitals which should secure to students additional opportunities.

INTERNES.

It is largely in view of the importance of a knowledge of insanity to the general practitioner that we have urged the appointment of internes to our State hospitals for the insane. The Board wishes to acknowledge the approval of the Governor and the cooperation of the superintendents in the inauguration of the system of the appointment of internes by annual competitive examinations. The last examination was held in Chicago in May, 1896, and resulted in the appointment of nine internes, eight men and one woman, as follows: three to Eastern Hospital, two to each of the three other hospitals now in operation. It is believed that their usefulness to the hospitals and to themselves, and to the public, can be further greatly increased by arranging a course of work and investigation for them which shall be uniform in all the institutions.

(To be continued.)

SELECTIONS.

A Strange Experiment in Insurance in Switzerland.—The December issue of the *Consular Reports*, contains an article on a Swiss scheme for insurance against loss of work by the canton-governments of Berne and St. Gall. The following extracts will suffice to give to medical readers who are interested in insurance a glimpse of this singular experiment ostensibly begun in the interest of so-called "laboring classes." It may be stated

that St. Gall has already abandoned the plan, chiefly for the reason that the really industrious workingmen found themselves unbenefited, and the system resulted in the promotion of laziness and idleness. The article says: Statesocialism, it is claimed, has its strongest hold in the mountain republic. In almost every need the people look to legislation for relief. Notwithstanding numerous failures, the masses of Berne and Basle, Geneva, Zurich, and Lausanne look to the Government for aid unknown and unheard of in other countries. In 1893, a petition was sent to the Federal Government demanding laws against enforced idleness. The petition urged that each citizen had a right to remunerative employment, and asked that the law be invoked to aid him in getting it. To do this, it was demonstrated that in certain industries those then employed would have to work fewer hours in order to leave something for those who otherwise would be forced or kept out of employment. To carry out this scheme, the State was either to employ the idle in State factories, making the same goods, or to compel existing institutions to take them. The proposition was voted down by 308,289 votes against 75,880 in the popular assemblies. The vote by cantons was "No," and unanimous. However, to show good will in the matter, the Federal Assembly urged the federal council to appoint a commission to inquire into the matter. It might cost money, but it would be money well spent. The object was to find out whether it would be wise or worth while to open bureaus to aid the unemployed to get work and societies to insure against loss of labor. The commission has not reported. This has not deterred two cantons—Berne and St. Gall—from going ahead. Basle, Zurich and Lausanne are very much interested; what action they will take is not known. The Berne plan differs very essentially from that of St. Gall. In the former canton, it is left to the free will of the laborer to insure or not, as he or she pleases; in St. Gall, each must insure. The basis of the Berne system is as follows: The working people, laborers and professional men, are all united under one head. Each person insured pays 8 cents a month. Each city in the canton contributes 7,000 francs (\$1,351), formerly 5,000 francs (\$965). Members must have been enrolled six months, paid dues regularly, and be out of work fourteen days at least before being entitled to a pension. The aid given is 1 franc daily for unmarried men and 1.50 francs for married men. Only men are pensioned. The money is paid only during December, January and February. A workman who refuses to take any work offered him, or loses his work through his own fault, or joins in a strike loses all rights to the pension. On December 31, 1895, the organization numbered 605 members and had paid pensions to 169 persons during the year. In 1894, there were 390 members, and the parties to whom pensions were paid numbered 226. In this case, it was more a State help than a workingman's insurance club; for in 1894, unaided by the cantonal subscription, payment would have been impossible. Most of the men supported or aided belonged to the building occupations. These are more or less idle year in and year out. Hence it is hard to say what worth such an effort is to have in solving the huge social and comic problem, *i.e.*, the effort made in Berne.

Much misery, it is true, might in this way be wiped out, but men whose labor has always been steady and is likely to continue so complain bitterly about being compelled to support others in idleness whose labor, though at times uncertain, is for that very reason better paid when there is work. It is not in the nature of things for such a system to succeed even among so loyal, loving, and gentle a folk as are the Swiss. The effort is not in vain if it will teach the thoughtless how hard it is to make laws or to institute any system that is to take the place of thrift and economy during the days when work is plentiful. The decision of the commission will record the popular will, and that, as far as can be judged from facts at hand, will be adverse.

Treatment of Morbus Basedowii and Epilepsy with Total and Bilateral Resection of the Cervical Sympathetic.—T. Jonnesco of Bucharest has performed this operation nine times, stimulated by the success obtained by Alexander and Jaboulay in their partial operations. (See the *JOURNAL*, pages 546 and 1248, vol. 27.) In his three cases of genuine epilepsy there have been no attacks since, and only a slight transient vertigo in one case at times. In the two cases of morbus Basedowii the exophthalmus disappeared, the goitre diminished in size and the tachycardia ceased in one case, but still persists in the other. The other operations were for chorea with hystero-epilepsy, cerebral tumor with epileptic attacks, hysteria and progressive paralysis. No benefit was derived in these cases. The fact has been established by physiologic research and also by an attack of epilepsy occurring while Doyen was performing a hemicraniotomy, that a disturbance in the cerebral circulation occurs simultaneously with the attack. The troubles in morbus Basedowii evidently proceed from the sympathetic cervical, and resection of this nerve is therefore clearly indicated in this disease, even if it is necessary to tie the vertebral artery to complete it. He recommends the operation to others, stating that it is absolutely free from serious after-disturbances. He describes his technique in the *Cbl. f. Chir.* of January 16, which can be summarized as follows: 1. The incision in the skin begins at the posterior border of the mastoid process and is carried below the clavicle along the posterior border of the sterno-cleido-mastoid. The incision is made through the skin, the platysma myoides, the external jugular vein after ligating it in two places, and the branches of the superficial cervical plexus. 2. The posterior border of the sterno-cleido-mastoid is exposed, and 3, the nerve cord is found. Sometimes it is in the posterior wall of the cervical vascular sheath. Tearing open this sheath with the sound, the gangliated cord is easily distinguished by its relations with the internal jugular vein and its location outside of the pneumogastric. It can be seen through the prevertebral fascia and is easily distinguished from the phrenic nerve just outside of it. 4. It is drawn out and stripped of the connective tissue with a hollow sound, as far as the base of the skull. The fusiform superior cervical ganglion is then exposed front and back, and detached, preferably with the finger. When the upper end is reached and detached it is cut with a special pair of blunt curved scissors, first the branches and then the cord above, from front to back, from within forward, and from above downward, to avoid injury to the surrounding organs. The field of operation must be cleaned by separating some of the occipital attachments of the sterno-mastoid and drawing up the vaso-motor funiculus and the sterno-mastoid with a hook 4 cm. wide and 3 cm. long, inserted in the upper angle of the wound. 5. Resection of the middle and inferior cervical ganglia. The middle cervical ganglion is often absent, but two sympathetic branches are always found in the corresponding spot, surrounding the thyroid artery. In some cases the thyroid artery was so rigid that it had to be cut between two ligatures to expose the middle ganglion or the plexus that replaced it. The resection of the inferior ganglion is the most difficult part of the operation, as it lies in the deep groove between the scalenus posticus and the spine, covered by the vertebral artery and vein, in direct contact with it and of such size that they entirely fill the groove. Another difficulty is that this ganglion forms one single mass with the first and even the second thoracic ganglion, which extends along the spine in the thorax. The pleural cavity is also in more or less intimate relation with the inferior ganglion and the neighboring organs, so that it may be opened during the operation. If we consider also the enormous current of blood in the retro-clavicular veins and the arch of the subclavian artery, the difficulty of operating in this extremely vascular region becomes evident. But nevertheless the extirpation of the inferior cervical ganglion is possible and Jonnesco

has performed it twelve times. He inserts again the hook mentioned above and detaches some of the attachments of the sterno-mastoid to the clavicle. Then the gangliated cord is separated from the vertebral artery and vein, which are both pulled forward. The ganglion thus exposed is freed from the bone and by pulling it a little all the branches are brought into sight. These are cut in turn, including the vertebral and cardiac branches, and the ganglion is thus extirpated. If the pleura has been opened the wound is seized quickly with the forceps and ligated. The operation is completed with a deep suture, uniting the posterior border of the sterno-cleido-mastoid to the subcutaneous tissue. The skin is closed without drainage, which is useless. All the wounds healed rapidly *per primum*. The length of time required for the operation ranged from one-quarter to three-quarters of an hour. The only inconvenience observed was a transient redness of the face, lachrymal and nasal secretion and a transient contraction of the pupils. He considers his success sufficient to encourage others to work along the same lines, as a certain and safe method of treating diseases which have hitherto baffled us.

Health Points for Eastern People Wintering in Arizona.—The two principal towns in the southern portion, chiefly sought for their climatic advantages, are Phoenix and Tucson. Each of them has 10,000 inhabitants or more. They have the electric light, telephones, trolley cars, plenty of hotels, banks, book stores, good schools, churches, an occasional theatrical performance, sometimes a lecture or a circus, often a horse race, and, in the spring a thoroughly curious and interesting "fiesta." For the rest, people must take their amusements with them. Good horses are abundant and cheap, and there are plenty of cowboys—the genuine article—to show what horses can do. The driving for fifteen or twenty miles in almost any direction from Phoenix is nearly always easy. The roads are apt to be dusty; but there is one well sprinkled drive of six or eight miles, and since the winds are quite regular in their direction it is rarely difficult to choose a route on which the dust will be largely carried away from you. The unbroken desert itself is often as easy to drive over as an Eastern highway, and the whole valley is a paradise for bicycles or equestrians. If a mountain region, considerable altitude and a comparatively low temperature are desired, Prescott is in a picturesque region, near a great mining district, and has the social advantage of an army post, Whipple Barracks. Flagstaff is still higher, is in a region of dense pine forests and is within a hard day's journey of one of the wonders of the world, the Colorado Canyon. Oracle is a pretty mountain nook, embowered in splendid live oaks, like those of California, and is also near an important mining district. If lower altitude and a distinctly semi-tropic climate is desired, the three places most likely to be considered are Yuma, Tucson and Phoenix. The first is near the sea level, is the warmest and probably the driest of the three, has the least population and the smallest provision for visitors. Tucson is the oldest town in the Territory and, after Santa Fé, perhaps the oldest in the Southwest. Its adobe houses give it a Mexican look and are thoroughly comfortable. Its newer houses are of a handsome building stone found in the vicinity. The Territorial University is here, and it was formerly the capital. The elevation being more than double that of Phoenix, it is somewhat cooler, and as there is next to no irrigation near it the air is a little drier. Phoenix is in the center of the greatest irrigation in the Territory. The country for miles around smiles with green fields, covered with almost countless herds of cattle, and it is everywhere shut in by low mountains. It is the Territorial capital, has the Government Indian School, the Territorial Lunatic Asylum and other institutions, and is the general focus for the Territory. Like Tucson, it has its occasional wind and storms, perhaps not quite so often. At either place visitors who know how to

adapt themselves to circumstances can be entirely comfortable and in each they will find an intelligent, orderly, enterprising and most hospitable community. They will find a country full of mines, full of rich agricultural lands, abounding in cattle and horses, in vineyards and orchards, and the beginnings of very successful orange groves—a country in fact, as full of promise for hardy and adventurous men now as California was in the fifties. Above all, if it has been their lot to search for health in far countries, they will revel in the luxury of being in their own land, among their own countrymen, within easy reach of their friends by telegraph or rail, and in a climate as good of its kind as any in the world.—*New York Tribune*.

PRACTICAL NOTES.

Treatment of the Insane by Repose in Bed.—It has been found in St. Petersburg that insane patients are very favorably affected by being kept in bed, and the system has been introduced on a large scale for noisy, excitable patients and cases with psychic depression and general debility. Neither force nor narcotics are used, but the patients are merely habituated to remain in bed, although they take their walks and physical exercise every day as usual. It is not necessary to keep them in separate apartments and the economy of space and trouble to the attendants renders the practice a great convenience.—*Presse Méd.*, December 29.

A Case of Fatal Hysteria.—The *Ravista Med. de Sevilla* for October contains the description of the case of a young woman who after a brief married life and separation was attacked with all the "algias" known to science, with functional disorders in every organ and phantom tumors, etc., a most distressing case which was diagnosed as hysteria. This diagnosis was confirmed when after years of suffering the patient dreamed that if she received the communion she would be freed from her troubles, as proved to be the case. It was the first time anything had passed into her stomach for weeks, as a constriction in the esophagus had prevented her taking food. This miracle of her complete restoration to health continued for some months, when her former state returned in an aggravated form, accompanied by serious gastro-intestinal disorders and a peculiar pigmentation of her face, as if she had been tattooed with blue paint; fever and complete insomnia rapidly terminated her life.

Salubrol, a New Antiseptic Powder.—Salubrol and Salubrol gauze (20 per cent.) are designed to substitute iodoform, and are proving successful on small abscesses, boils, burns, etc., as they dry the surface rapidly and promote the formation of the scab to such an extent that small abscesses do not require dressing after being sprinkled with the powder. Experimental tests on animals demonstrate that it is completely non-toxic, while its bactericidal power is so great that it not only prevents the development of bacteria, but kills already flourishing developed colonies of staphylococci, anthrax spores, etc. It is made by the action of bromin on methyl-bis-antipyrin, and corresponds thus approximately to a tetrabromin derivative. It is not adapted to use on large surfaces as it dries them so fast that fresh granulation does not occur to the desired extent. There is no irritation of the skin from its use, but it causes smarting in some cases, when applied as a powder, but not as a gauze.—M. Silber in the *Deutsch. med. Woch.* December 24.

The Influence of Antidiphtheria Serum on the Kidneys.—In *Virchow's Archiv*, for November and December, appears a clinical and experimental study of the influence of Behring's diphtheria serum on healthy and diseased kidneys by Dr. F. Siegers. He finds that slight transient albuminuria and albumosuria are often induced, and that although occasionally acute parenchymatous nephritis and hemorrhagic nephritis have been observed in association with the injection of the serum,

the dependence of the renal lesion upon unaltered serum has not been proved. Suppression of urine has been observed experimentally as well as clinically. Preëxisting albuminuria is not unfavorably influenced by the use of the serum, the employment of which, if its specific value in diphtheria is proved, ought not to be set aside on account of any renal effects.

The Bacteriology of Colitis.—Before the Liverpool Medical Institution, Dr. A. W. Campbell showed specimens and cultures of a bacillus isolated from the cases of colitis occurring in Rainhill Asylum. The organism is a small short rod morphologically allied to the bacillus coli communis and others of that genus; it grows freely on agar-agar, gelatin and potato; it does not liquefy gelatin, its growth is not stopped by potassic iodid, it forms gas abundantly, it coagulates milk and is motile. So far cultivations from the feces of three cases suffering from the disease have been made, and some initial experiments performed in Professor Boyce's bacteriologic laboratory seem to point to a causal relation between the bacillus isolated and the disease in question. In case No. 1 the cultivations were made when the disease was at its worst, the patient being severely purged, prostrate and pyrexial, and a rabbit inoculated subcutaneously with 3 c.c. of a broth culture died in nineteen hours after showing signs of commencing diarrhœa. At the necropsy of this animal the intestinal canal was in a condition of acute catarrh, the feces were liquid, the mesenteric glands enlarged, and the blood teemed with the organism. In case No. 2 cultivations were obtained from another acutely suffering patient and inoculation into another rabbit produced severe diarrhœa, along with general prostration lasting for four days. The animal was killed at the end of a week, when it was showing signs of recovery, and on postmortem examination, though there was no catarrh of the intestinal canal, still the Peyerian patches, the solitary glands in the large intestine and the lymph glands in the mesentery were swollen and the organism was present in the blood. In case No. 3, cultivations were made from the feces of a patient recovering from the disease, and it was interesting to find that a rabbit inoculated with some of the growth presented no signs of the disease other than edema round the seat of inoculation. Dr. Campbell mentioned that the next step in the investigation would be to endeavor to produce the disease in swine, because he had observed in pigs which had died from "swine fever," in addition to the specific lesion, a condition in the large intestine which bore much resemblance from an anatomic point of view to the change in the large intestine of the human being dying from colitis.—*London Lancet*, December 19.

Hydrotherapeutics.—W. Winternitz states that in various epidemics of infective diseases in which he has treated some patients with antipyretics, others with hydrotherapeutics and others expectatively, the proportion of mild cases was larger with the hydrotherapeutic than with the others. He claims that the failures in hydriatics are due to the incorrect application of the baths. He always decides the indications for them by a test sponge bath of a small portion of the surface of the body. The reaction from this shows the condition of the heart and cutaneous vessels. The latter are exceedingly excitable in typhus and pneumonia, while in measles and scarlet fever there is almost a paralysis of the peripheral vessels, and the strongest thermic excitation scarcely produces any reaction. If the test bath results favorably, he gives baths of 25 to 20 degrees C. in typhus and pneumonia, while in measles and scarlet fever, and also in the eruptive stage of variola, short baths at a low temperature are indicated. In regard to the indications for cooling, heating and stimulating packs it is important to bear in mind that leucocytosis is established by cold baths, while with stimulating applications a moderate leucocytosis is accompanied by a strong erythrocytosis. Stimulating applications

should not be covered with a moisture proof covering as the heat is drawn from the skin to dry the cloths, which does not occur with impregnated material. If the wet cloth is about the temperature of the blood, the skin under it will feel cool although an active hyperthermia is being excited by the stimulating application. He disapproves of Germain Sée's theory that it is best to wait before beginning the hydrotherapeutic treatment until the disease has advanced to a certain stage as it renders the diagnosis so difficult, remarking that the life of the patient is worth more than the diagnosis.—*Wien. klin. Rundschau*, December 27.

Negretto's Radical Cure of Ischuria from Hypertrophied Prostate by Cauterization through the Rectum.—The annoyances of castration are avoided by this method, which does not interfere in any way with the genital organs. It is simple, effective, and free from any danger, and Negretto considers it superior not only to castration and section of the vas deferens, for various reasons, but also to all other methods suggested to date, including Bottini's thermo-galvanizing process. It is described in the *Gaz. degli Osp. e delle Clin.*, of December 27, with the reports of five cases treated. Rapid and permanent cure was invariably secured, and this experience was confirmed by numerous experiments on animals. It is especially indicated in the congestive stage, as it is sure to produce atrophy of the prostate. His instrument consists of a sharp, slightly curved hook, 1 cm. long, on the end of a straight graduated stem about three inches long, with a slanting handle. The evening previous to the operation or the night before that, a saline purgative is administered, and one or two rectal injections are given an hour before the commencement of the operation. After chloroform the patient is placed in the peritoneal cystotomy position with the pelvis raised very high. The rectum is dilated with the Collin or Weir speculum, and a short distance above the gland the rectum is plugged with iodoform gauze to prevent fouling the site of the operation with fecal matters. After this the speculum is removed and with the left forefinger the center of the prostate is located, and the hook introduced, guided by the forefinger, and inserted in the center of the gland, a slight traction serving to hold it in position. The figures show the exact distance the stem has penetrated in the rectum and also any displacement. It is then entrusted to an assistant to hold, warning him to continue the traction. The speculum is reinserted and any scraps of the rectal mucosa are removed with a wad of gauze. The prostate is then cauterized with the Paquelin cautery or with the galvanocautery, around the hook, the extent depending upon the case. The operation is completed in two minutes on an average. If necessary the assistant can render the region of the prostate more prominent by pressing on the suprapubic abdomen. After the operation a large dose of bismuth subnitrate with opium is administered, to keep the bowels from moving, and a permanent Nelaton catheter is inserted in the bladder. It is changed in a few days and the bladder periodically disinfected. The sixth or seventh day an oil purgative is given and the gauze plug is expelled with the discharge. At the end of ten or twelve days the catheter is finally removed and the patient henceforth urinates without difficulty.

Insufficiency of the Bacteriologic Diagnosis of Diphtheria.—Dr. Spronck in *Semaine Médicale*, Sept. 4, 1896, points out that although a bacteriologic diagnosis of diphtheria is very easily and certainly arrived at, nevertheless cases exist in which bacteriologists disagree. Cultivation in serum, followed by microscopic examination, shows that there are three varieties of the diphtheria bacillus. On the serum these are differentiated only by size; the short bacillus, however, closely resembles the pseudo-diphtheria bacillus described by German authors. As regards virulence the short bacillus is regarded as extremely benign, the intermediate as less so, and the long bacillus as

the most toxic of all. It might be thought that the small bacillus described by French writers was identical with the pseudo-bacillus of German authorities, but doubt is thrown on this by the results of experiments on guinea pigs. Though benign, the small bacilli in cases under observation differed in their degree of benignity, though none of the animals affected died. The cultures used were in all cases pure. To determine whether or not two pathogenic specimens were true diphtheria bacilli recourse was had to antidiphtheria serum. If the true diphtheria bacillus had been present, this should have been capable of protecting a guinea-pig from ill effects. This was not found to be the case. Spronck concludes that there exists a pseudo-diphtheria bacillus, which is pathogenic to guinea-pigs, hitherto unknown or mistaken for the short bacillus. Researches on the but slightly pathogenic pseudo-diphtheria bacillus showed that in time the cultures lost their virulence, and when spontaneously attenuated could not be distinguished from von Hoffmann's pseudo-diphtheria bacillus. This proves that the relationship said to exist between the latter and the diphtheria bacillus can not be admitted without reservation. Probably von Hoffmann's bacillus is derived sometimes from the true diphtheria bacillus, at other times from a slightly virulent pseudo-diphtheria bacillus. It seems justifiable to think that microscopic examination of the colonies is adequate, and it is necessary to control the diagnosis by the experimental use of antidiphtheric serum.—*British Medical Journal*, December 26.

Tuffier's Technique of Intravenous Injections.—According to Tuffier the facts to be borne in mind in these injections are that there is no toxic dose, but only a toxic speed, and that the kidneys must be sound. The intravenous method is not difficult nor dangerous, as no harm results if air gets into the veins, while the absorption is certain and the effect apparent at once. It is applicable in hemorrhages and medical infective diseases, but is of especial value in surgical and obstetrical infections. It increases the intravascular tension and is an almost indispensable preliminary to an operation after part of a member has been crushed. It has been found effective in cholera and recently in two cases of tetanus. Infection of the kidneys is the only contraindication. The formula used is: Water, 1 liter; sodium chlorid, 8 grams; sodium sulphate, 10 grams. The serum is boiled or better still sterilized in the autoclave at 115 degrees C. for ten minutes. The chances of infection are reduced to a minimum by Voisin's contrivance for keeping the serum in balls with two openings; the rubber tubing is attached to the shorter small tube, at one opening, and the ball placed on some suitable support. At the moment of the injection the serum should be about 40 degrees C. The preferable injecting point is the internal saphena just in front of the internal malleolus, where it can be easily palpated. An incision two centimeters in length exposes the vein, which is then taken up on a grooved director. The vein is seized with the forceps and a small pointed flap cut with the bistoury in its wall, the adherent base on the side toward the root of the member. As the blood starts, without letting go of the venous flap, held with the forceps in the left hand, the trocar is taken in the right hand, and after letting the serum flow to expel the air, the trocar is inserted in the wound in the vein for about two centimeters. The receptacle is raised 1.50 meter above the level of the bed, which allows the liquid to flow at the rate of 1,500 grams of liquid in twenty-five to thirty minutes. When the injection is completed, an antiseptic compress is all that is necessary, as the same opening in the vein may serve for future injections, only the trocar must be inserted a little deeper in the vein to avoid the clot that has formed. The amount of liquid injected can without inconvenience be as much as 2,000 grams twice a day, until the arterial pressure is entirely restored. The pulse becomes perceptible, the temperature rises in hemorrhages and falls in infections with hyperthermia, and diuresis is established, accompanied by salivary secretion and diarrhea.—*Presse Méd.* from *Gaz. Hebdomad. de Méd. et de Chir.*, Nov. 22, 1896.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the ASSOCIATION living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, FEBRUARY 13, 1897.

THE DECENNIAL REPORT ON THE VITAL STATISTICS OF THE REGISTRAR-GENERAL'S OFFICE OF ENGLAND.

The successor of FARR and OGLE as Superintendent of Statistics, in the Registrar-General's office of England, is Dr. J. F. TATHAM, formerly of the Health Office of Salford. He is the author of the fourth decennial report on the vital statistics of England, being a supplement to the fifty-fifth annual report. That report covers the decennium 1881-1890, and is technically known as "the Registrar-General's Decennial Supplement." This report contains the third English life-table that has been published by that office. The first was drawn up by Dr. FARR, based upon the seventeen years period 1838-1854; the second was constructed by Dr. OGLE for the ten years 1871-1880. The period 1881-1890 has been the basis of Dr. TATHAM's new life-table, contained in the decennial report recently published. The last report is, like its forerunners, the result of most laborious research and has numerous improvements respecting mortality and its causes.

Regarding the general death-rate of England and Wales, the report shows that the rate has declined from 21.27 per 1,000 in the former decade to 19.8 in the period 1881-1890. The rate for males declined 12.6 per cent., that for females declined 10 per cent. There has been found a decrease of mortality in both sexes and at every age, except at one period, that for males aged 65 to 75 years, the rise for the age period being less than one per cent. In the decennium con-

sidered in Dr. TATHAM's report there were many thousand faulty certificates of death, requiring the sending to medical practitioners of over 22,000 letters for purposes of correction. The life-table of Dr. TATHAM is constructed for both sexes, for each sex, and for every year of age, with comparisons with the two foregoing life-tables of Drs. FARR and OGLE. This table is of sufficient interest to medical examiners for life insurance and to practitioners generally as to call for a partial reproduction of the findings of Dr. TATHAM. In the following brief tabular statement is given the mean after-lifetime, or "expectation of life," for males, at birth and at fifteen other selected age periods, in England and Wales with comparative columns for the corresponding data of the periods studied by Drs. FARR and OGLE:

MEAN AFTER-LIFETIME, OR "EXPECTATION OF LIFE," FOR MALES IN ENGLAND AND WALES.

AGE.	LIFE-TABLE OF—		
	DR. FARR. 1838-54	DR. OGLE. 1871-80	DR. TATHAM. 1881-90
At birth	39.91	41.35	43.66
Five years	49.71	50.87	52.75
Ten years	47.05	47.60	49.00
Fifteen years	43.18	43.41	46.47
Twenty years	39.48	39.40	40.27
Twenty-five years	36.16	35.68	36.28
Thirty years	32.76	32.10	32.52
Forty years	26.06	25.30	25.42
Forty-five years	22.76	22.07	22.06
Fifty years	19.54	18.93	18.82
Sixty years	13.53	13.14	12.88
Seventy years	8.45	8.27	8.04
Eighty years	4.93	4.79	4.52
Ninety years	2.84	2.66	2.37
One hundred years	1.68	1.61	1.24

From these figures we learn that the English male infant, of the last decennium, had 2.31 years added to his life-expectancy as compared with his ten-year old brother; and 3.75 years more than his father born in period of Dr. FARR, say from 27 to 44 years before. Improved expectations of life are shown up to 26 years of age; but from 27 to 44 they are less favorable than in the oldest table, and better than that of 1871-1880; at 45 years and over they are lower than in both the earlier tables. The chief improvement, therefore, is noted within the working period of life—namely, from about the twentieth to the sixtieth year. It is, therefore, satisfactory to observe that the average number of years lived between these limits of age by each male born are 20.92, 22.00, and 25.56 years respectively, according to the three successive life tables; an increase in the working period of life has therefore been shown within the last two decennia, amounting to an average of more than a year and a half for each male in the population. Among females the expectation of life at birth, which had been 41.85 years and 44.62 years respectively in the two earlier tables is further increased 47.18 years in the new table. The expectations of life at the several ages up to 54 years are greater by the new life table than by either of its predecessors. At all ages beyond 45 the expectations of life are less by the new table than by

either of the earlier tables. The average number of years lived between the ages of 20 and 60 years by each female born according to the three life tables are respectively 21.65, 23.48 and 25.12 years.

The report shows a heavy sacrifice of life by small-pox, namely, 12,280 deaths in the decade. Of these 2,145 were returned as having been vaccinated, 3,370 unvaccinated, and 6,765 of which the certificates failed to give the requisite information. The much-needed information was lacking in over 50 per cent. of the death certificates—a rather bad showing for the paternally governed “tight little island.” An encouraging fact brought out in this report is the conspicuous and progressive reduction which has recently taken place in the death-toll levied by pulmonary phthisis. The life-saving represented by this reduction during 1881–90, as compared with the previous decennium, is equal to 392 lives in each million of the population, and the lives saved are mainly those of young adults, who are economically the most valuable to the State. In the course of the last twenty years the crude mortality from phthisis has decreased by 30 per cent. Among males the rate of decrease has been equal to 25 per cent. and among females to 35 per cent. A very remarkable change in the sex incidence of phthisis has been observed within the last forty years. From the year 1851 to 1865 the phthisis rate was greater amongst males, although the difference gradually diminished as time went on. Since the year 1866, however, the mortality has been uniformly in excess, not amongst females, as formerly, but amongst males; and in the last two decennia (of the forty years) the excess of the male rate over the female rate was greater than had been the excess of the female over the male rate in the first decennium (1851–60). From information obtained since 1890 it appears that this remarkable change in the sex incidence of phthisis is still being continued. The mortality from this disease showed a decline during the recently ended decennium amongst males as well as females at all ages of life.

Scarlet fever, which has been sometimes termed “the English pestilence,” has shown a declining annual mortality during the last three decennia. The proportional decline being as 972 to 716 to 334 per million for the periods ending respectively in 1870, 1880 and 1890. It is not easy to ascertain whether this gratifying ebb has been due to a diminished prevalence of the disease or whether the malady has assumed a milder form in recent years. The returns from the fever hospitals, however, would seem to support the latter view. The deaths have been higher among males than females; especially is this true of children under 10 years old. It also appears that the mortality by scarlet fever is less among infants under one year of age than those in their second to fifth years.

A PSYCHOLOGIC STUDY OF THE THREE PROFESSIONS.

Recently some very interesting studies have been made by lawyers, clergymen and physicians, in two of the great metropolitan cities of the country. The object was to ascertain if possible the intellectual status of the different professions, compared with each other. It was assumed that each profession would be found intellectually rising, or perhaps merely holding its own along the levels of general development. Or possibly one profession might be at a lower level of comparative growth or far beyond the others in point of attainment. The data from which such studies could be made must include not only a history of each professional man, but a fair estimate of what he had accomplished in his intellectual life. This was ascertained in the numerous biographies and separate personal studies of professional men. A comparison of these histories would give a general answer to the inquiry. The results so far of these studies are very suggestive. Of the three professions, physicians appear to have made the most progress. Intellectually they are rapidly ascending, and the records of their actual achievements surpass all others. Every year more college trained men are entering the profession, and signs of progress along lines of literature and arts are rapidly increasing. The immense development of scientific research, no doubt has reacted on medicine more than other professions. But beyond this the profession has moved with greater rapidity, following broader lines of inquiry, with less reverence for the teaching of the past. In the studies of physicians in these two cities, a large number have made substantial progress in the discovery of new facts, and the new application of old ones to new conceptions of science. Many of these medical men are scientific students working out and testing new problems of medicine continually.

Next to the physicians come the lawyers, who seem to be making but little progress. Some of these men as judges have given broader interpretations of the law, and some new technical applications to practical life, but the greatest intellectual strain seems to be to adjust the law to the new conditions of life and living. As politicians and legislators, but little new work is accomplished, every thing seems to bend to preserve the harmony of the past and present.

In other circles a slow advance is apparent; in literature and the arts they occupy a prominent place, and in humanitarian circles they have barely kept pace with business men. The heavy weight of prestige and theories of the past outweigh and keep down much of the progress in the present.

The clergymen came last in the list. While intellectually, in general culture and scholastic training, they have probably exceeded both law and medicine, yet in real original work they have fallen back in the

march of progress. Few rise to the levels of the age in their teachings, or cut loose from the past, but like lawyers, spend a great deal of energy to keep in harmony with both present and past. The clergymen in those cities were very active in humanitarian work, but along old lines. They had contributed freely to the literature of the day, but little or nothing to the new life and new conditions of living. As a class they had not held their own in the march, but had broken up into extremists and doubters. In these two cities are to be found many of the ablest men of the country in the three professions. Yet from records of actual achievement intellectual progress and evolutionary development, medicine far exceeded both law and theology.

While these studies are not complete, and perhaps open to many sources of error and correction, they call attention to possibilities of attainment not often considered. Doubtless there are many towns of the country where the medical men are far back in real attainments, and are exceeded by both lawyers and clergymen. But the fact remains that scientific rational medicine, as a field for new discoveries that will raise the levels of life and living, offers the widest opportunity for intellectual development. Studies of this character are very practical, not only in giving us high points of view from which to estimate the direction of the real progress, but bringing incentives to the individual life of physicians not obtained in other ways.

The sociologic and anthropologic aspect of medical life furnishes many facts, a knowledge of which would be of great value in many ways.

THE MEDICAL ASPECTS OF THE MODERN "SKY SCRAPER."

The semi-revolution in urban architecture of the past few years, to which we owe the lofty structures that make a distant view of even the flattest of our cities picturesque, has a side that perhaps calls for some attention to be given it by the medical profession. The guardians of the public health have a right to investigate and, if needs be, pass judgment on any novelty that may directly or indirectly affect it, and it is quite possible that there exist in these sky-scraping structures, with all their advantages in economy of ground surface, some serious disadvantages that call for our professional consideration. As yet they are not universal even in limited districts, but the tendency is toward their multiplication, and the first natural suggestion is to query what will be the result of so materially affecting the ventilation and sunlighting of our streets when they have become as they may only deep narrow canyons, which are already strongly suggested in some even of the wider streets of our newer cities. A clever writer of fiction has even utilized this suggestion in the title of a novel and his

description of the bird's-eye view of the modern town and comparison of it to the bad lands of the West is an apt and striking one. In the narrower streets of the older cities of the Eastern border of our country, where buildings of only ordinary height produce some of the evils spoken of, the modern high structures can only aggravate them, and yet it is there that the craze, as we may call it, is just at present in its most pronounced phase. While in Chicago, where this modern construction can be said to have originated, there is now a restriction as to the height, and the day of the excessive sky scraper may be said to have past, in New York they are reported to be projecting thirty or forty story structures and exceeding the most extravagant ideas of the past. It would seem to be time to call a halt from motives of even ordinary prudence if for nothing else.

The dangers of public health are possibly not limited to the obstruction to the ventilation of the public streets, though that in itself is a sufficiently serious matter. The free sweep of the wind and consequent change of air and sweeping away of impurities is a very important matter in large centers of population and goes far to compensate for many sanitary deficiencies. The high buildings, however, are accused in some quarters, of having positive sanitary disadvantages of their own, entirely independent of their effect on the general health conditions of the streets and the city. A sanitary engineer, speaking it may be a little strongly, has called them "gigantic cupping glasses," sucking up and diffusing impure air and foul odors, and it is, in fact, not difficult to conceive that defects in sewerage, etc., may be amplified and exaggerated by the height of the building, unless special arrangements are made to meet such possibilities. Again, in their present generally isolated condition, standing alone among lower structures, it is claimed by some that the occupants of their upper stories are especially liable to injury from emanations from the chimneys, ventilation flues, etc., of the lower buildings around them. Cases have been reported of serious disease caused in this way, and it would appear to be a matter for consideration, at least by sanitarians, in the case of tall apartment buildings intended for residence purposes.

There is still another question, not strictly a medical one, but one that may involve human life and welfare; that of the durability of these constructions. They are practically frame structures, but the steel frames are almost everywhere concealed by solid masonry, tile and cement. Steel is a perishable material unless absolutely protected from erosion, and engineers have stated that its condition in these structures is one of the most serious questions of the present day. Even if these buildings are no more likely to fall or give way in parts than those of the older styles of construction, their great height makes

the risk more serious. Another matter to be thought of carefully is their possible behavior in case of serious conflagration. While they are themselves, it is to be presumed, comparatively fire-proof, what would be the effect of the intense heat, from fires in adjoining buildings, upon their metallic framework? These are engineering questions more particularly, but they have also, in their way, a sanitary bearing and can be mentioned here.

Tall buildings of the modern type are as yet an experiment, and it is too early to say with assurance whether the predictions of those who condemn them will be fully justified. It is always time, however, to note their possible sanitary defects with a view to obviating or amending them for the better. They certainly offer some problems for the sanitarian.

PRE-ENLISTMENT OF OPINION CONDEMNED.

In a murder case, after stating that, upon the trial, medical experts were examined on either side, and gave their answers to hypothetic questions as prepared and propounded, the court of appeals of New York uses this language: "The usual conflict of opinion occurred, which is constantly seen upon such trials, and which tends not only to bring discredit upon a learned profession, but, more seriously, to embarrass the search after the truth, in which the tribunal is engaged, by confusing and darkening the minds of the jurors with opinions upon the scientific questions before them, which are expressed as previously pledged to either side. The fact that the rule which permits expert testimony in such cases works, in practice, badly for the interests of justice, can not be so much attributable to the inexactness of the science in which the witness is assumed to be skilled as to the preënlisment of his opinion by the party." That the procedure in such respects is defective, the court admits, is also true. However, the issue of sanity having in this case been submitted to the jury, who were to finally determine it upon the evidence and having been determined against the defendant who plead insanity, the court holds, *People v. Hoch*, decided October 13, 1896, that their determination will not be interfered with where the evidence was in fair conflict, and permitted of opposing inferences. It also holds that it was a competent way to probe the mind of a medical witness, and to test the merits and value of the opinion he had expressed of defendant's insanity on the assumed state of facts, to ask him, on cross-examination, to give his judgment, from his examination under his employment by the district attorney as to whether the defendant was sane or insane while awaiting trial on a previous charge, some years before, the hypothetic question having embraced his conduct while serving sentence. Besides, the court holds that, it having appeared that the witness's examination had not been made while attending the

defendant as his physician, but at the special employment of the people, for the purposes of their prosecution, he was not disclosing any information acquired in attending a patient in a professional capacity. Furthermore, while the issue turns upon the prisoner's mental condition at the time of the homicide, whether he was laboring under such a defect of reason as to render him incapable of knowing the nature and quality of the homicidal act, or was incapable of knowing that it was wrong, the judge writing the opinion says that there is no apparent reason, and he is aware of no authority, for holding that, in addition to all the other facts, the jury may not be informed, by one competent to speak, as to the mental condition of the defendant at the time of his trial.

SURGERY OF ONE HUNDRED YEARS AGO.

Some time since, the Editor was very much pleased to obtain a copy of the wonderful history of *Surgery of One Hundred Years Ago*, by the learned Dr. GEORGE FISCHER, of Hanover, Germany. His great and exhaustive study of the development of modern surgery, and superior opportunities for obtaining unusual information, made the book one of very great interest and led the Editor to write for permission to translate the work for the benefit of the readers of the *JOURNAL*. Dr. FISCHER in a pleasant letter kindly granted the desired permission.

The work of translation has been committed to Dr. CARL H. VON KLEIN, of Cleveland, Ohio, who has been in ill health since he returned from Europe, but has fairly recovered and is now sojourning in Chicago.

We begin with the table of contents and translator's preface and introductory in this issue and will continue weekly until the entire work is published. Some of the chapters are as interesting as a romance and we advise our readers to preserve every number, as no extras will be printed.

A CANDIDATE FOR MAYOR.

We are informed that the lay Health Commissioner, Hon. WM. R. KERR, is a candidate for Mayor of Chicago. He bases his claims for consideration on the excellent record of the Assistant Commissioner, Dr. FRANK W. REILLY, to whom is due the first-rate administration of the Health Department.

If the affairs of that Department have been conducted with such skill as to entitle any one to consideration as a candidate for mayor, why not choose the actual person who has made the plans and performed the service? On that basis the candidate would justly be Dr. FRANK W. REILLY and not WM. R. KERR.

TO TRY THE SERUM.

The French Government has appointed Dr. YERSIN of Paris, to proceed to India and use his anti-plague serum. The French do not expect Dr. YERSIN to

conduct his investigations by letter. That method is peculiar to Washington. Let us have a Department of Public Health!

CORRESPONDENCE.

The Poor Physician.

NEW YORK, Feb. 1, 1897.

To the Editor:—While we are discussing the question of capital and the farmer, why not touch on the interesting question of the poor physician? His case is truly, if you look at it closely, which nobody seems inclined to do, a very, very lamentable one. Think of this: A man who has made his millions, by fair means or else by hook or by crook, it does not matter, feels that he has done nearly enough for this world and that some of his thoughts and deeds might be now reasonably employed to do something to result in dividends in another world possibly to come. The recipe for the cure of such morbid anxieties is an old and hackneyed one. No necessity for breaking one's head, as he had done before on Wall street matters, or about Standard oil wells in the West. Oh, no; there is a panacea! Let's found a hospital, or if we are very high-toned, let us endow a college. The hospital staff is filled by the founder's beneficiaries, or perhaps such of his friends, especially of such as are willing to contribute more influence and more money for the institution. To the clinics of this hospital only the poor are supposed to go. Such as appear there, and are not poor, are treated also and pay a monthly fee. We may naturally expect that some of the staff physicians, who, be it understood, receive no pay, as they are simply helping in a friendly way the rich man to pay his debt to heaven and his conscience, will divert some of the latter patients to consult him in his own office. But what becomes of the poor physician, the general practitioner of the community, while so much good is being done around him? He has to eke out his existence, support his wife and children, with what these good charitable people have left him. Only some of the very poor are left to him and these he can not, without public condemnation and a kind of dishonor, refuse in case of urgency to treat *gratis pro Deo*. This poor physician is not so perplexed as the rich man may have been, before beginning his great charitable career, as to the means of insuring to himself a livelihood in heaven, but he would be very much pleased if the admirable philanthropy of others allowed him to make one in this valley of tears.

I can not help making here two remarks which seem to me exceedingly curious, and I believe that anybody with a tolerable modicum of humor in him must be struck by their piquancy. First, the anxiety of doing good is sometimes so great that the thing is monstrously overdone. What will you say of a hospital intended for 700 patients that can only recruit 35? But now comes the second point: In order to come as near as possible to the number of patients which their colossal structure requires, they have the unspeakable naïveté to send around inviting the poor physicians, whom they have already deepoiled, to help them complete the spoliation by sending to the hospital clinics the few poor patients whom they have left them. The man in the hospital whose specialty it is to care for a certain fraction, or a certain casualty of the human body, wants the poor physician to send him *all those of his patients* (if this way of speaking is not ridiculously grandiloquent) who are affected with the complaint to which he has devoted his genius. Another who watches over a different point makes a similar request; they want their clinics to be well attended and interesting, whatever the poor doctor's dinner may be. For, you see the rich man must read reports which show that his work is prospering on earth, as his spiritual wheat is in heaven.

ALBERT S. ASHMEAD, M.D.

The Roentgen Ray in Ophthalmology.

PHILADELPHIA, PA., Jan. 29, 1897.

To the Editor:—In the issue of the JOURNAL of January 16, the proceedings of the Chicago Academy of Medicine are reported. Dr. Casey A. Wood, in the discussion of Dr. E. H. Lee's paper on "Dermatitis following the Roentgen Ray," is quoted as saying "So far as the diagnostic value of the X rays in ocular diagnosis is concerned the subject may be dismissed in a few words. . . . But it was found that inasmuch as the eyeball is surrounded by a bony casing . . . the experiments were found to be of little value." In experiments made in Chicago to determine the presence and location of a foreign body in the eyeball "the X ray was found to be of little or no value." In Philadelphia our experience has been quite the reverse. Within the past two months, two instances of the detection of steel in the vitreous have been reported in the Transactions of the Ophthalmic Section of the College of Physicians, the first by myself and the second by Dr. G. Oram Ring. Dr. G. E. De Schweinitz has verbally communicated to me the history of the third case in which, after the presence of the foreign body was determined by the X rays, it was extracted by the Hirschberg magnet. Thus it will be seen that the bony walls of the orbit and the coats of the eye are permeable to the rays. By comparison of the shadow of the metal with that of the margin of the malar process of the superior maxillary bone and the knowledge of the relation of the Crooke's tube to the sensitive plate the location of the foreign body can be closely estimated. The three radiographs of the cases above referred to were taken by Dr. Max J. Stern in the laboratory of the Philadelphia Polyclinic. Dr. Wood's hope "that we shall be able to make use of the Roentgen ray for purposes of this sort" has been realized.

Very truly

HOWARD F. HANSELL, M.D.

Blindness and Quinin.

COLUMBUS, OHIO, Feb. 2, 1897.

To the Editor:—In your issue of Nov. 7, 1896, Dr. H. B. Ellis, of Los Angeles, Cal., reports a case of total blindness, "possibly due to an overdose of quinin." I have read his report with interest, although I can not but regard the quinin as a very improbable factor in the production of the blindness.

The report, however, reminds me of a case which occurred many years ago in the practice of my preceptor, Dr. J. C. Reeve, of Dayton, Ohio. A young man came to the office complaining of symptoms which lead to a diagnosis of malaria. A prescription, containing quinin as the chief ingredient, was given him. A few hours later he reported that he had become suddenly and entirely deaf. This deafness was absolute and permanent. He had, however, not taken a single dose of his medicine. Had he taken the quinin I have no doubt the case would have gone on record as an undeniable one of permanent deafness produced by the administration of quinin.

There are so many things happening in this busy world that many events which seem to be sequences are really only coincidences, and I think the blindness in the case reported was of this nature.

J. F. BALDWIN, M.D.

A Case of Temporary Amblyopia from Eucain.

GALESBURG, ILL., Feb. 6, 1897.

To the Editor:—The new succedaneum for cocaine—eucain—has, I believe proved so useful and so nearly free from danger that its continued employment is not a matter for doubt. I have frequently used it in cases where its points of difference from cocaine have seemed to indicate its employment in preference to that drug, and I have often been struck, in such cases, by its excellences.

Recently, however, there fell to me an experience of a kind to teach us that eucain certainly has its dangers. The case was

that of a man, a physician, aged 32, who came to me with a moderately large hypertrophy of the anterior extremity of the right inferior turbinated bone. Ordinarily, before applying galvanocautery to the turbinated bones, I produce anesthesia with cocain. In this case, however, from the fact that the hypertrophy was seated so far forward, I did not think it necessary to produce the shrinking of tissue that follows the use of cocain, and hence merely secured anesthesia by means of eucaïn. The strength of the solution I used was 5 per cent.

Immediately after the cauterization, the patient complained that his sight was growing dim, and a few minutes later, he said that it had entirely left him. There were no stongly marked constitutional effects, though the pulse was rather rapid and the patient seemed talkative and a little incoherent. The amblyopia was of exceedingly short duration, having almost entirely disappeared at the end of four hours. Neither while it continued nor afterward were any changes perceptible by the ophthalmoscope. The return of vision has been perfect and permanent.

I have read of at least one case of amblyopia from cocain, but as yet no other case from eucaïn has come to my notice.

Yours, etc., THOS. H. SHASTID, M.D.

A "MILL" Graduate in Indiana.

PERU, IND., Feb. 8, 1897.

To the Editor:—I see in the *JOURNAL* of February 6, a reference to the Illinois Health University, now Independent Medical College, of which one J. Armstrong is president, secretary, treasurer, etc. We have had here a little experience with one or more of his graduates, one Dr. Elmor (?) who struck our town last summer, with long hair, a good supply of cheek, but little money and glowing advertisements, prepared as he thought to bluff everything in sight; but for once he over-looked his hand. We made him lie down, shut up, and get out, as we have all other advertising quacks of similar qualifications, coming to our town. If you will send J. Armstrong and his college down to Peru, we will turn his college into a hospital and make him the leading patient.

My idea about his college is to suppress his graduates, and that can be done in almost every State in the Union with the now existing laws. Indiana has a very weak medical law; but we find that a weak law strongly used is better than a strong law weakly used. Now if the profession will go to work and enforce the different laws effectually against all such quacks and graduates as of the Illinois Health University or Independent Medical College, in two years time there will be no such institutions. One thing is sure, such rot does no go in our section.

J. O. MALSBURY, M.D.

The Journal Gives Post-Graduate Instruction.

LEOMINSTER, MASS., Feb. 3, 1897.

To the Editor:—Let me thank you for calling my attention to the *JOURNAL*. I received my medical education forty years ago and it was an old garment that fitted nothing in the earth beneath or the heavens above, so I had decided to take it to some post-graduate school for reconstruction, when the *JOURNAL* came with its wealth of knowledge, up to date and exhaustive, yet within the limits that any busy practitioner could compass, and I soon made the discovery that a reader of the *JOURNAL* OF THE AMERICAN MEDICAL ASSOCIATION is receiving a post-graduate course in his own study.

Yours truly, C. A. WHEELER, M.D.

PUBLIC HEALTH.

The Epidemic History of the Sandwich Islands.—The *Medical Examiner* has compiled the following statistics regarding those islands: Some time ago I came across a rather rare epitome of history of the Sandwich Islands. In connection with our

line of business, I noticed that in 1805 there was an epidemic of cholera, which swept off half the inhabitants of Hawaii. There was no census between 1836 and 1850, but the decrease of population in that period was very rapid. In 1848 the measles were introduced from California, and spread through the group—10 per cent. of the population died. In 1853 there was an epidemic of smallpox. Census taken about that time gave a population of 73,137—a decrease of 11,027 in three years. In 1853 leprosy was first found in the islands; in the year 1864 leprosy had begun to spread to an alarming extent. In 1865 an Act of Isolation was passed; a peninsula on the north side of Molokai was selected for the purpose of isolation. In 1872 smallpox again appeared, but was easily suppressed. In 1881 smallpox came in from China, but was confined to the Island of Honolulu. Total population in 1890 was 99,990.

Valid Garbage Ordinances.—No argument is needed, says the appellate division of the supreme court of New York, to show that garbage in a decayed or decaying condition is a substance deleterious to health, the keeping of which may properly be prohibited by a municipality in the exercise of the police power. And it holds reasonable and valid, in *Town of Newtown v. Lyons*, Dec. 22, 1896, an ordinance which forbids any person from having or keeping at any place within the town any garbage or refuse vegetable or animal matter in a decayed or decaying condition, and prohibits boiling or cooking it at any place within the town in any open vat, kettle or caldron, or in any manner so as to permit the vapors or exhalations from such boiling or cooking to escape into the surrounding air. But a reasonable construction, it goes on to state, requires it to hold that a cooking vessel shut into a closed building would not be "an open vat, kettle, or caldron," within the meaning of the ordinance.

Public Health in Michigan, January, 1897.—For January, compared with the preceding month, pneumonia increased in area of prevalence. Compared with the average for January in the eleven years, 1886–1896, erysipelas, consumption, diarrhea and pneumonia were less prevalent. Including reports by regular observers and others, consumption was reported present in Michigan in the month of January, 1897, at 209 places; diphtheria at 94 places; measles at 77 places; scarlet fever at 63 places; typhoid fever at 42 places and whooping cough at 37 places. Reports from all sources show consumption reported at 7 places more; diphtheria at 9 places less; measles at 37 places more; scarlet fever at 22 places less; typhoid fever at 29 places less, and whooping cough at 4 places more in the month of January, 1897, than in the preceding month.

Contagious Period of Whooping Cough.—Dr. Weil of Lyons asserted in 1894 that whooping cough is not contagious during the period of paroxysms nor during its decline, but only in the earliest stages, when it is still unsuspected unless the child is known to have been exposed. He now confirms his revolutionary statement by an imposing array of statistics, collected in his hospital experience, where 865 child patients in the various wards were in close contact with fifty-nine cases of whooping cough in the paroxysmal period, without a single case of contagion occurring. Thirty little patients in the most intense stage of whooping cough, but convalescent from other diseases were accustomed to play among the other convalescents (195 between 2 and 5 who had never had the whooping cough), without the appearance of a single new case. Léon has recently published an observation of the contagiousness of the disease in its catarrhal, bronchial stage. The prophylaxis of the disease, therefore, assumes a new phase; the prompt isolation of every child at the first appearance of a cold during an epidemic of whooping cough, and the inutility of further isolation when the paroxysms have made their appearance. According to Roger, the incubating period is six to seven days, and not until this time has elapsed without the manifestation

of any of the specific symptoms of the disease, should the child with a simple cold be allowed to mingle with others, when there is reason to suspect that he has been exposed to whooping cough.—*Bulletin Méd.*, January 10.

Low Mortalities in New York State.—An interesting account of the recent death rate in that State is given in the *Bulletin* of the New York State Board of Health for November. Ten large cities, with a population ranging from 36,000 to 1,995,000, present for the month of November an annual average death rate of 16 per 1,000 inhabitants. The small cities and rural sections present a rate of 13.5 per 1,000; and the State at large 14.75. Of these ten cities, Buffalo with a population of 350,000 had the lowest rate, 10.6; Troy, having 65,000 population, the highest rate, 20.5. The combined cities of New York and Brooklyn, with 3,095,000, had 15.9 per 1,000. Among the ten cities, also, are Rochester with a rate of 12.6; Syracuse with 14.2, and Yonkers, 14.7. The aggregate population of the ten cities is very close to 4,000,000. The number of deaths reported for the month is 7,888, which represents a death rate of 14.75 per 1,000 living; this is the lowest death rate for years. Compared with the preceding month, in which the mortality was unusually small, the number of deaths is less by 800; there were 500 fewer than were reported in November, 1895. November is uniformly the month of lowest mortality in the year in this State; the average daily mortality for the ten preceding months of this year has been 340, while that of this month was 265, and for the past ten years there has been an average daily mortality during November of 280, a death rate of 15.75. The infant mortality is unusually low, 27.5 per cent. of the total deaths having occurred under the age of 5 years. The same is true of the zymotic mortality, which caused 11.3 per cent. of the total deaths in the preceding month, and likewise in the month of November, 1895; 13.0 per cent. of the deaths was from these causes. From all the diseases of this class the deaths were less than they were last month except diphtheria, which, however, has caused fewer deaths than during the corresponding period of last year.

Admissibility of Opinion Evidence of Exposure to Disease.—Under the interpretation which has been placed upon the general New York statute relating to local boards of health, the mere possibility that a person may have been exposed to a contagious or infectious disease is not sufficient ground for requiring his isolation, but he must have been exposed to it, and the conditions actually existed for a communication of the contagion in order to bring into operation the power to isolate. It may be common knowledge that one coming in personal contact with another affected with a contagious disease or occupying the same room with him is exposed to it. But, beyond that, whether, in a particular case, conditions so exist for the communication of the contagion to a person as to render him exposed to the disease, the appellate division of the supreme court of New York says, may be a question of medical science and skill. So it holds, Dec. 15, 1896, in *Smith v. Emery*, an action against the Acting Commissioner of Health of the city of Brooklyn for false imprisonment, that it was error to exclude evidence of how many cases of smallpox there were at a certain time in a certain district and their location, as well as to exclude the testimony of a member of the medical profession as to the infectious and contagious character of smallpox, how the contagion of the disease is conveyed, that it is conveyed by the air, absorbed in the respiratory tract, conveyed in clothing and utensils, and by atmospheric contagion, and how long the poison of the disease retains its vitality; this evidence being offered with a view to a hypothetical question to the witness, calling for his opinion whether the plaintiff was exposed to smallpox, which it is also held was erroneously excluded. On these grounds, the judgment which the plaintiff obtained is reversed and a new trial ordered. But Mr. Justice

Bartlett, while concurring in the result, says he entertains considerable doubt as to the propriety of permitting hypothetical questions in such a case, which call out opinion evidence to the effect that a given series of events constitutes exposure to a disease.

The Imperial Commission on Vaccination for Germany.—Another important recommendation of bovine vaccine for official purposes has been put upon the sanitary records of Europe. The Prussian government recently decided to investigate certain questions connected with vaccination, and for that purpose appointed a commission, presided over by Dr. Schmidt-mann of the Government Medical Department, and composed of bacteriologists such as Professor Koch, Professor Pfeiffer and Dr. Frosch of the Berlin Royal Institution for infectious diseases, together with practical vaccinators. The commission was consulted as to the possibility of ascertaining without bacteriologic examination whether a sample of lymph is in good condition or not, also whether there is any ground for the belief that vaccination wounds are specially liable to erysipelas. The report of the commission has just now appeared and supplies information on the following subjects: Number and species of bacteria found in the lymph, difference between the bacteria found in animal and in human lymph, connection between the symptoms of reaction following vaccination and the concentration of the lymph, the method followed by the vaccinator, and the idiosyncrasy of the person vaccinated. The commission came to the conclusion that there is an essential connection between the bacteria of the lymph and the inflammation of the tissue at the place of insertion; erysipelas and gangrene are due to secondary infection and are always caused by want of care either on the part of the vaccinator or in the subsequent management of the case. It is impossible for lymph to be absolutely free from all bacteria. The best lymph is calf lymph, in the collection of which no blood has been drawn and which has been treated by subsidence, centrifugation and solution. Such lymph is the least likely of any to induce excessive reaction.

The Secretary of State for Health.—The *Public Health Journal*, December, admonishes us that the health of the nation and the saving of human life is paramount to all other questions, and deserves a national consideration. No foe of the government is so widespread in its effects as that which attacks a nation's health, permeating all parts of the social and political structure. Its dangers can not be exaggerated. Empires have fallen because of neglected moral physical laws of health. Sickness brings weakness and poverty. Health develops strength and wealth. Therefore public health is of great commercial value. That which obstructs business and sacrifices lives that are valuable to the State is worthy of its earnest attention. Epidemics, though confined to our section of the country, affect the life and finance of the whole nation. Millions are given for the advancement of commerce, thousands spent in the interest of agriculture, and they are deemed worthy a place in the councils of the nation, while that which paralyzes trade, wastes strength, causes loss of labor and its earnings is neglected. In this enlightened land there are annually sacrificed to preventable disease 250,000 human beings. War, with all its dread calamities and horrors, does not bring such desolation, suffering and despair as disease. And yet millions annually flow from the treasury for the maintenance of army and navy, and two cabinet officers faithfully watch their interests. The time for temporizing has passed, makeshift ways must give place to the practical and scientific. The needs of the hour demand a concert of action against disease, with a well-equipped army of assistants, and a master mind at Washington to guide the attack. As we near the close of the nineteenth century let the united medical profession, with a full realization of its necessity, by a power that shall place in the

national council one whose scientific eye shall ever watch for threatened danger. Let us have a Minister of Health, and set an example to the great nations of the civilized world in this important direction.

How Dr. Kinyoun Escaped Typhoid Fever.—In the January *Bulletin* of the North Carolina Board of Health appears a report of a Health Conference, as it is called, held at Charlotte. Dr. Kinyoun participated in the discussion of milk-borne diseases. He stated that he had for several years adopted the plan of sterilizing or Pasteurizing all the milk used in his own home. His family had been obtaining milk from a dairyman living outside of Washington. "One morning he was missing. We did not think anything of that, but day after day passed, and upon inquiry of the man delivering the milk he said he was sick at home with typhoid fever. 'How long has he had it?' 'He was taken sick about ten days ago. His wife also has typhoid fever.' I asked, 'has his wife been away from home?' 'No; she has not been off the place,' admitting that she had not gotten typhoid fever from somewhere else. Immediately the question was asked in our family: 'Shall we abandon the milkman and get milk from another place?' I said, 'No; we have been exposed to the infection for three weeks and have no typhoid fever.' Upon inquiry, I found upon this milkman's route there were five cases of typhoid fever and it was traced to the milk. Herein is this apparatus for Pasteurizing extremely simple, it does not require an extraordinary knowledge to handle it, an intelligent cook can fill an ordinary bottle with milk and do it as well as yourself. I believe if I had not used this precaution, described in your hearing, some of my family would have had typhoid fever. I have advised all my friends to use some such apparatus. The beauty of it is this: It does not change the quality of the milk; very slightly if any at all. The digestive property of the milk taken from the cow remains the same, whereas in boiled milk it is exceedingly changed. It has another beauty. It removes the animal odor from about it, which is very disagreeable to many persons."

"Return Cases" of Scarlet Fever. The Mortality by Measles.—Dr. Thorne Thorne, of the Local Government Board, gives an explanation of the term "return cases," as applied to infective diseases, that is not infrequently met with in English journals and reports, and that is comparatively unknown to Americans. According to his explanation the use of the term is at present restricted to scarlet fever. *Pari passu* with the growing practice in recent years of isolating scarlet fever patients in hospitals, this disease has, in not a few instances, shown a tendency to reappear in households shortly after the return thereto of persons who had resided for some time in hospital as scarlet fever patients, and the term "return cases" has come to be applied to such instances of secondary infection. The hospital belonging jointly to the Bromley and Beckenham district councils seems to have come under the notice of the board in this connection during 1894, and the late Mr. T. W. Thompson was instructed to confer with the representatives of the combined hospital authorities on the subject. The circumstances are clearly set out in Mr. Thompson's report, which shows that a certain number of "return cases" appear to have been caused in the way above indicated as a result of the operations of this hospital; but in consequence chiefly of the smallness of the figures concerned Mr. Thompson did not profess to have discovered any definite solution of the matter under investigation. The report, however, which is included in Dr. Thorne Thorne's appendix is full of interest to those who, as practical sanitarians, have to deal from time to time with return cases of scarlet fever, for it will readily be understood that these unfortunate accidents interpose difficulties of no light kind in the way of those whose duty it is to secure the prompt isolation of first cases of infectious disease. Dr. Theodore Thomson contributes a valuable report, which is included in the

same appendix, on the subject of the prevalence and fatality of measles. It is quite clear to sanitarians that the mortality from most of the diseases of the so-called zymotic class has been slowly but steadily decreasing in recent years. Measles forms an important exception. This disease kills annually, on the average, nearly thirteen thousand persons, mostly, if not exclusively, young children, and it unfortunately shows a tendency to increase. Even in the quinquennium 1890-94, the death rate from measles was higher than that from any other zymotic disease except whooping cough and diarrhea. The mortality from measles is always much greater in towns than in country places, the disease being more frequently epidemic in towns where the opportunities for direct infection from person to person, in schools and elsewhere, are unusually frequent.

Although it is well known that uncomplicated measles is a comparatively mild disease, as it occurs generally among the children of well-to-do persons, the case is far otherwise among the poor. The importance to sanitary authorities of being able to devise measures for the control of measles among the latter class on its first appearance in their districts is apparent on consideration of the tender age at which measles is mostly fatal, namely, during the second year of life. "If," says Dr. Thorne Thorne, "measles, which formerly was epidemic every other year, be so far discouraged by preventive measures as to acquire epidemicity only every fourth year, it is clear that a larger number of susceptible children will, when the epidemic arrives, have reached ages at which the disease is little fatal, and that in this way many lives will be saved which formerly were sacrificed to measles." In discussing the measures likely to prove serviceable in the face of an epidemic of measles, Dr. Thorne Thorne naturally turns to notification and endeavors to learn how far this expedient has been adopted by the sanitary authorities of the country and with what results. Here, it must be confessed, the returns are disappointing. The notification of this disease has not been required under the Act by any considerable number of authorities, and it appears from the report to be questionable whether any great amount of good has been obtained in those cases where the disease has been scheduled. "Unfortunately, it is impossible," says Dr. Thorne Thorne, "to point to any one district as having systematically adopted all practicable measures of precaution for the prevention of measles; but the facts recorded go to indicate that in so far as in particular districts the difficulties of the problem have been realized . . . by so far have the results obtained been found encouraging to the sanitary authorities concerned."

For the facts and deductions in the above statements, we are indebted to the review of the last Annual Report of Dr. Thorne Thorne, medical officer of the Local Government Board of Great Britain, in the London *Lancet*.

Health Report.—The following reports of mortality from smallpox, cholera, yellow fever and plague have been received in the office of the Marine Hospital Bureau of the Treasury Department:

SMALLPOX—FOREIGN.

Bombay, December 22 to 29, 2 deaths.
Cairo, November 12 to 18, 1 death.
Cardenas, January 9 to 16, 26 cases, 5 deaths.
Genoa, January 9 to 16, 4 cases.
Gibraltar, January 3 to 10, 7 cases.
Madrid, January 6 to 13, 20 deaths.
Messina, January 9 to 16, 1 case.
Moscow, January 2 to 9, 7 cases, 1 death.
Nogales, January 16 to 23, 1 case.
Odessa, January 2 to 9, 25 cases, 10 deaths.
Osaka and Hioga, December 26 to January 2, 67 cases, 39 deaths.
St. Petersburg, January 2 to 9, 3 cases, 2 deaths.
Warsaw, January 2 to 9, 12 deaths.

CHOLERA.

Bombay, December 22 to 29, 1 death.
Calcutta, December 12 to 19, 30 deaths.
Colombo, December 12 to 15, 30 deaths.
Singapore, November 1 to 30, 12 deaths.

YELLOW FEVER.

Cardenas, January 9 to 16, 19 cases, 1 death.
Matanzas, January 6 to 20, 9 deaths.

PLAGUE.

Bombay, December 22 to 29, 390 deaths.

NEW INSTRUMENTS.

A NEW STETHOSCOPE.

PARIS, Ill., Jan. 25, 1897.

To the Editor:—Being unable to find a stethoscope that was efficient, simple and portable, I devised the one here represented, compared it with Camman's different styles, the Denison and the phonendoscopes, and found it the best instrument for general use. It is easily carried in the pocket, in a tight box to exclude dust, etc., which is much in its favor, as I know

from having carried a cumbersome stethoscope for nearly twenty years. My last purchase was a phonendoscope, which transmits sounds perfectly, but does not locate them satisfactorily, besides being uncomfortable to the patient and too heavy to carry in the pocket. The above instrument is made by Geo. Tiemann & Co., New York city. If the ear pieces do not fit, they will either admit external sounds or cause roaring.

Respectfully, W. H. TENBROECK, M.D.

ANTITOXIN SYRINGE.

Mulford's 5 c.c. antitoxin syringe is especially designed to inject concentrated antitoxin. The syringe case is solid metal, nickel plated, provided with a movable rack, thus permitting

of thorough sterilization. The plunger is expanded by a new and highly improved method. By simply turning the piston head to the right the packing is easily adjusted at any point in the barrel.

NECROLOGY.

PERRY H. MILLARD, M.D., of St. Paul, Minn., dean of the College of Medicine and Surgery, at the State University, died at Johns Hopkins Hospital in Baltimore, February 1. He was born in the State of New York in 1848 and was graduated from the Ogdensburg Educational Institute. He was graduated in medicine from Rush Medical College in 1872. He then spent several years in the practice of his profession at Stillwater, Minn., afterward removing to St. Paul. He was an aggressive advocate of higher medical education and it was mainly through his efforts that the present laws regulating the practice of medicine in Minnesota, were enacted. He rendered the ASSOCIATION valuable services while a member of the Board of Trustees. Following are resolutions passed by the College Faculty:

The Faculty of the College of Medicine and Surgery of the University of Minnesota record with sincere regret the untimely death of its dean, Dr. Perry H. Millard. In his death, a loss is sustained—not by this Faculty alone, but by the medical profession of the State of Minnesota and by the cause of medical education throughout the country. He was a self-made man—of large natural resources, of indomitable energy and perseverance, of unswerving devotion to his chosen purposes. And those purposes had, at heart, the good of his profession. To that profession he devoted twenty-five years of his life, achiev-

ing an enviable success in its service. He filled many positions of trust with faithfulness and places of honor with modesty. His services to the State of Minnesota are written upon her statute-books and in the history of her medical institutions. He was the author and inspirer of the laws which have governed the practice of medicine in the State and, particularly, of that progressive measure known as the Minnesota Medical Practice Act, which has become the type of legislation for over half the States of the Union. He was one of the most active organizers and promoters of the American Medical College Association, a body which has done much to elevate the average standard of medical teaching in this country. His most signal service was in the projection, organization and development of the Department of Medicine of the University of Minnesota. It was in his brain that this institution, which has taken rank among the foremost professional schools of America, first took shape. It was his influence which secured the surrender of the charters of those private colleges which united in its establishment. It was largely through his unceasing labors and his persistent enthusiasm that it was placed upon the University campus beneath

the roof of Medical Hall. It was his first ambition, his daily duty, his well justified pride to forward its interests throughout the years of his fatherhood of its Faculty. He passed from its immediate service under the inevitable compulsion of a death-warning he had too long refused to heed, to a death-summons which commands the sorrow of his associates and inspires this memorial "to the duty he has wrought."

CYRUS NORTHROP, LL.D. Pres't.

JOHN F. FULTON, M.D.

PARKS RITCHIE, M.D.

R. O. BEARD, M.D.

A. W. ABBOTT, M.D.

C. L. GREENE, M.D.

H. M. BRACKEN, M.D. Committee.

RICHARD JOHN HALL, M.D., of New York City, died January 24, at Santa Barbara, Cal., after an operation for appendicitis. He was a son of the Rev. Dr. John Hall of that city, and was born in Armagh, Ireland, forty-one years ago. He was graduated in arts, from Princeton College in 1875, and three years later from the New York College of Physicians and Surgeons. He took a surgical course of instruction in Vienna, and upon his return to New York joined the House Staff of Roosevelt Hospital, and became subsequently an associate of the late Prof. Henry B. Sands of that city. In 1886 he was appointed lecturer upon the principles of surgery, at his alma mater, and so continued until near 1888, when to recuperate his health, he went to Santa Barbara. While there, he established a hospital. He leaves a widow and two daughters. His brother Rev. Thomas J. Hall of Chicago had summoned his father to his own bedside just before the news of the death of Dr. Hall had arrived, and he is regarded as being still in a precarious state of health; the mother also is grief stricken and is shattered in health.

SIR THOMAS SPENCER WELLS.—The death of Sir Thomas Spencer Wells is announced as having occurred at Antibes, in the south of France. He was born in 1818 and educated at Trinity College, Dublin. He was a Fellow of the Royal Medical and Chirurgical Society, and surgeon to her Majesty's household, and at the third centenary of the University of Leyden and the eighth of the University of Bologna he received the degree of an honorary M.D. Queen Victoria in April, 1883, conferred upon him a baronetcy in acknowledgment "of the distinguished services which he has rendered to the medical profession and to humanity." He was the author of several important surgical works, on those branches of operative surgery to which he specially devoted himself, and was widely quoted as an authority on this continent.

CHARLES A. STARK, M.D., died at Marshfield, Mass., January 22, aged 35 years. Dr. Stark was a native of Manchester, and a graduate of the Dartmouth Medical School. He was for a time connected with the staff of the New Hampshire Insane Asylum, and then went south, practising his profession in Louisiana and holding the post of division surgeon on the Illi-

nois Central Railroad. In 1889 he was compelled by failing health to return to the north and in the following year established himself at Marshfield, where he acquired an excellent practice. He only gave up active practice when the progress of his last illness enforced retirement. He married, in 1886, Miss Harriet O. Walker, of Chelsea, who with a son, survives him. He was a great-great-grandson of General John Stark. Dr. Stark was a member of the Massachusetts and New Hampshire Medical Societies.

LAWRENCE J. McNAMARA, M.D., Bellevue College, New York, 1882, aged 37 years, died in New York City January 28, leaving a wife and five children. He was an "original" member of the New York County Medical Association and a member of the New York Pathological Society as well as Visiting Physician to the Hospital for Nervous Diseases. He had also served on the House Staff of St. Vincent's Hospital before entering upon general practice, which subsequently became both large and profitable.

FRANCIS MORELAND LORETTE, M.D., College Physicians and Surgeons, New York, 1843, born in London, died at his home in Brooklyn, N. Y. January 29, aged 84 years. He retired from practice about ten years ago. Three children survive him.

WM. S. ROLAND, M.D., University of Pennsylvania, 1835, of York, Pa., died January 23.

FREDERICK M. TURNBULL, M.D., Jefferson Medical College, 1877, died in Boston January 16 after a long illness.

OLIVE DEWEY ALDRICH, M.D., Woman's Medical College, Pennsylvania, 1874, died of pneumonia, January 11, at her home in Philadelphia.

Dr. F. F. MORAWITZ of St. Petersburg, famous as an entomologist. His collection of insects is considered the most complete in the world.—Dr. J. H. Thiry, professor of surgical pathology at Brussels.—Professor Plucker of Liège, president of the Société de Médecine-Chirurgie, in his 46th year.—Dr. J. M. Carminhoa, professor of medical botany and zoology at Rio Janeiro.

ASSOCIATION NEWS.

Semi-Centennial Meeting of the American Medical Association.—The Committee of Arrangements for the Semi-Centennial Meeting of the AMERICAN MEDICAL ASSOCIATION, to be held in Philadelphia June 1, 2, 3 and 4, 1897, desire to announce that in addition to the regular order of exercises during the meeting of the ASSOCIATION there will be for a week preceding and a week succeeding the ASSOCIATION Meeting, special courses and clinics given in the various large teaching institutions of Philadelphia, without cost to visiting physicians. This course has been organized in response to a generally expressed wish that opportunities might be given to visiting physicians of taking clinical courses, for it is believed that many physicians from distant points would be glad to spend a week or two over and above the time occupied by the Meeting, in this manner. A schedule and roster describing the course in detail will be published shortly before the Meeting. Further information may be obtained from Dr. Edward Martin, 415 S. 15th St., Philadelphia, the Chairman of the Committee on Hospital Courses.

H. A. HARE, M.D.,

Chairman of the Committee of Arrangements.

SOCIETY NEWS.

The British Medical Association.—The *Montreal Medical Journal* for January has the following items of news regarding the coming meeting of that Association. The president-elect of the Association, Dr. T. G. Roddick of Montreal, has departed for England, where he will devote some weeks to the business of the Association. "His visit seems to have been very well

timed; not only will he be able to post the officials of the Association with all necessary information concerning what has been done in Canada, but he will, we trust, be able by personal interviews to secure the attendance and active coöperation of many who are first and foremost in the profession." As an indication of the hearty coöperation of all parts of the Dominion, we are pleased to note that the following leaders of the profession have accepted positions upon the Executive Committee and have offered their coöperation: Dr. W. Tobin, president of Halifax Branch British Medical Association; Dr. G. L. Milne, president of British Columbia British Medical Association; Dr. C. R. Church, president of Ottawa Branch British Medical Association; Dr. A. Catellier, president of Quebec Branch British Medical Association; Dr. J. A. Duncan, president of British Columbia Medical Council; Dr. J. McLeod, president of P. E. I. Medical Board; Dr. V. H. Moore, president of Canadian Medical Association; Dr. D. W. Daniel, president of Maritime Medical Association; Dr. Coventry, president of Ontario Medical Association; Dr. H. H. Chown, president of Manitoba Medical Association; Dr. J. P. McDonald, president of Nova Scotia Medical Society. There are yet more names to be added to the Committee. In the absence of any official year-book of the profession of the Dominion, the secretaries have found some difficulty in determining the present holders of official posts in connection with the leading medical bodies of the Dominion, and as consequence the invitations to join the Executive Committee have been delayed.

Iowa Central State Medical Society.—The meeting of this society was held Dec. 16, 1896. Drs. Cora Williams, Merrill and E. M. Singleton were elected members. Upon balloting, Dr. W. S. Devine, Marshalltown, was elected president; Dr. W. E. Whitney, Eldora, vice-president; Dr. F. S. Smith, Nevada, second vice-president; Dr. C. C. Cottle, Marshalltown, secretary and treasurer; Drs. F. H. Boucher, H. L. Getz, G. W. Dobson, trustees. Committee, Drs. W. S. Devine, Marshalltown, W. E. Whitney, Eldora, F. S. Smith, Nevada. Dr. H. L. Getz, in a timely speech, introduced Dr. W. S. Devine to the society as the in-coming chairman. Dr. Devine responded in a few words and was installed as president. First paper by Dr. Singleton on the "Superiority of Inunctions in the Treatment of Syphilis." Discussed by Drs. Kierulff, C. C. Cottle, F. S. Smith, G. W. Dobson and H. L. Getz. Second paper by Dr. B. F. Kierulff on "Progressive Myopia in School Children." Paper discussed at length by Drs. Cottle, Singleton, Dobson, Getz, Smith and Devine. Two cases (recovery in both) presented by Dr. H. L. Getz. First case hysterectomy and ovariectomy; second case, removal of appendix and double ovariectomy. Discussed by members. Committee on revising Constitution made final report as follows: We, your committee on revising Constitution recommend the following: 1, that the date of regular meeting shall be on the second Tuesday of June and December. 2. That all of the words in Section 1, Article 5, previous to the word "present" be stricken out, leaving it to stand as follows: This Constitution and the following By-Laws may be amended by an affirmative vote of two-thirds of those present.

Report accepted and on motion the amendments were carried. On motion the society adjourned.

BOOK NOTICES.

Twentieth Century Practice. An International Encyclopedia of Modern Medical Sciences. By Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. In Twenty Volumes. Volume X. "Diseases of the Nervous System," pp. 859. New York: William Wood & Company. 1897.

The manuscript for Volume IX of this series not being entirely finished, Volume X has been published in its place, and the pub-

fishers announce that Volume ix will be issued in April, 1897.

The volume begins with diseases of the brain properly so called, and is then followed by chapters on intra-cranial hemorrhage, tumors of the brain, diseases of the meninges, hysteria, epilepsy, the spasmodic neuroses, neurasthenia, the disorders of speech and the disorders of sleep. The contributors to this volume are Sanger Brown, M.D., Chicago; Joseph Collins, M.D., New York; Chas. L. Dana, M.D., New York; Chas. Samson Féré, M.D., Paris, France; Howell T. Pershing, M.D., Denver; and Bernard Sachs, M.D., of New York.

The great changes that have been made in works on the nervous system in the last few years are due to more correct notions of the anatomy and physiology of the nervous system.

"The birth of the neuron theory," says Dr. Collins, "has been accompanied by a flood of light in the interpretation, not only of the physiology of the brain, but of the pathology as well. . . . We are nearing the time, if indeed it be not already at hand, when the nosology of disease shall be built upon or in unison with the neuron theory, and already some workers in the science of neurology have heralded the advent of such classification."

In the preparation of this volume such has been the deep sense of responsibility of the authors that "current medical literature and not previous treatises, has been the source where information has been sought."

The work then will be seen to embody the fruits of the latest teachings, and those wishing to keep *au courant* with neurologic literature should possess this volume.

Report on America's Relief Expedition to Asia Minor Under the Red Cross. By CLARA BARTON. Paper, pp. 143, illustrated. Washington. 1896. (Price thirty cents.)

This report is published for the benefit of the Armenian sufferers, and is an interesting narrative of the expedition. The illustrations are numerous and instructive.

Miss Barton and her corps have placed here an enduring record of her latest and best work in the cause of humanity. Nothing is set down in malice, nor are the instances of misgovernment by the "unspeakable Turk" shielded. The constant courtesy and respectful treatment of the Turkish Government is acknowledged.

The report is a plain unvarnished tale of human misery and suffering, phenomenal cruelty of the Mussulman, and heroic efforts of relief by a philanthropic society.

MISCELLANY.

Mirror-Writing.—Professor Richet states in the *Progrès Méd.* that the great genius, Leonardo da Vinci, was accustomed to write in this way. His notes and letters were absolutely illegible until they were held before a mirror.

New York Polyclinic.—The trustees of the New York Polyclinic Medical School and Hospital have decided to rebuild on the site of their former building, Nos. 214 to 218 East Thirty-fourth Street. The work will be begun immediately.

The Mignonette as a Vermifuge.—The *Journal de Médecine de Paris* for October 4, states that in Russia the mignonette (*reseda luteola*) has long been held in great popular esteem as a remedy against tapeworm, and tells of a woman who, fasting, took a very strong decoction of the flowers and then a large dose of castor oil, and three hours afterward voided the tapeworm in the form of a ball.—*New York Medical Journal*.

The Earliest Men.—Dr. Ranke, of the German Anthropological Society, recently undertook to describe the physical characteristics of the earliest men, as ascertained from the examination of prehistoric graves. They were of a yellowish color, he said, and had coarse hair. Their heads were peculiarly shaped, the part of the skull which contains the brain being large relatively

to the face, while the face was small. They had other peculiarities, among which was the rudimentary or undeveloped condition of the third molar, or back grinder tooth. The Doctor believes that the first men originated in Asia.

Disqualified for Appointment to Make Examination.—If, in any case, a litigant, suing for the recovery of damages for alleged injuries to his person caused by the negligence or the wrong of the defendant in the suit, can be, upon motion of the defendant, compelled to submit to an examination by a surgeon, the court of civil appeals of Texas holds, *Houston and Texas Central Railway Company v. Berling*, Nov. 12, 1896, that such surgeon should be one agreed on by the parties or selected by the court and not one who has already testified in the case adversely to the plaintiff.

Waiver of Privilege as Part of Contract.—Where the statutory law in force at the time a contract of insurance is entered into permits the insured to waive the benefit of the provisions of law preventing any physician from disclosing any information acquired in attending patients, and such a waiver is incorporated in the contract of insurance, the court of appeals of New York holds, in the case of *Foley v. Royal Arcanum*, Dec. 15, 1896, that a subsequent amendment of the law allowing waiver only when made upon the trial does not affect the waiver already made as stated, because the legislature can not pass an act impairing the obligation of contracts, and such a waiver is not in and of itself contrary to public policy.

Filling of Child's Teeth not Urgent Necessity.—While extracting of a tooth in relief of a toothache may be reasonably within the agency of a person with whom a child is temporarily residing apart from its parents to require, and thus obligate the father to pay for, the appellate term of the supreme court of New York holds, in *Ketchem v. Marsland*, Nov. 25, 1896, that such agency does not extend to the employment of a dentist to fill and regulate the position of such a child's teeth, it not being deemed such an urgent necessity as to warrant such a course. However, the court holds the father liable in this case because of his ratification of what was done by not communicating any dissent to the dentist during three years that elapsed after he sent in his bill.

Opinions on Qualifications of Experts.—One who has personal knowledge of the qualifications of an expert, the supreme court of Michigan holds, *People v. Holmes*, Dec. 24, 1896, may speak to the fact, based upon such knowledge; but reputation can not be shown, nor can an opinion as to the qualifications of an expert be based upon reputation. Thus, to ask a medical witness whether he regards another one as good authority, the court declares objectionable, on the ground that the opinion called for might be based upon mere reputation. Nor does the court think it proper to attempt to show the effect of an injury upon a person's mind by showing the effect of a somewhat analogous injury on the mind of another person.

Anstomic Foundation of Acute Delirium.—Prof. N. M. Popov recently had an opportunity to study the cerebral lesions in the case of a woman who had died from acute post-puerperal delirium. The nerve centers showed important modifications, the cerebral parenchyma was also affected, the pia mater and the superficial layers of the cortex were full of vascular lesions like small interstitial hemorrhages, while the neuroglia and nerve cells were perceptibly altered, the whole resembling what occurs in cholera, presenting the picture of a diffuse meningo-encephalitis with hyperplastic alteration of the cerebral substance itself. The conclusions to be drawn from these facts are that the conditions are undoubtedly due to some infection as in the case of cholera.—*Bulletin Médical*, December 23.

Can Olive Opinion Before Facts.—When it is shown that a medical expert has made the proper professional examination of the patient in order to ascertain the existence of some physical or

mental disease, the court of appeals of New York, in the case of *People v. Youngs*, Dec. 15, 1896, that he is then qualified to express an opinion on the subject, though he may not yet have stated the scientific facts or external symptoms upon which it is based. At the same time, the court thinks it undoubtedly the better and safer practice to require the witness to state the circumstances of his examination, and the facts, symptoms or indications upon which his conclusion is based, before giving the opinion to the jury. But, if the opinion is given first, all the facts or symptoms upon which it is based may be drawn out also either upon the direct or cross-examinations.

Jubilee of Dr. Theodore Roussel of Paris.—The beautiful custom of celebrating the fiftieth anniversary of prominent persons with appropriate ceremonies and speeches is more customary abroad than in this country, where we usually wait until a man is dead before we express our appreciation of him and his services to mankind. Dr. Roussel's jubilee was celebrated with great brilliancy by a grand meeting in a large hall presided over by the Minister of the Interior, and the addresses were brilliant homages to the work accomplished by this well known physician, senator and hygienist. The laws for the protection of unfortunate children from infancy to maturity are recorded as the Roussel laws, and the deliverance of the country from pellagra, which still devastates the fairest provinces of Italy, is another debt France owes to Roussel. He remarked in his response that this jubilee was not the festival of a single man, but rather the rejoicing at the culmination of the collective labors of many at home and abroad, which have resulted in laying a firm and broad foundation for the "protection of unfortunate childhood."

The Epitaph of Yale's Founder.—It is not generally known that Elihu Yale, the founder of Yale University, lies buried in the churchyard at Wrexham, North Wales, about ten miles from Hawarden. The following lines are inscribed on his tomb in the front of the church door.

"Born in America, in Europe bred,
In Africa traveled and in Asia wed;
Where long he lived and thrived, in London dead,
Much good, some ill he did, so hope all's even,
And that his soul through mercy's gone to heaven."

These quaint lines had become almost effaced by the "tooth of time," when, a few years ago, a party of Yalensians visited the church and seeing the state of things, had the lettering recut. The church itself is a very old one, more than five centuries, it is said, and the curfew is rung from its bells every evening.

Surgeon-General Robert Adair.—The hero of that fine ballad, "Robin Adair," was a dashing young Irish surgeon who, about the middle of the last century, finding his way into London society, was fortunate enough to secure the affections of Lady Caroline Keppel, daughter of William, second Earl of Albemarle, and his wife, Lady Anne Lennox, daughter of Charles, first Duke of Richmond. The match was naturally looked on with disfavor by the family of the young lady, and it was during a period of temporary separation that Lady Caroline is said to have written the words of "Robin Adair," and set them to the old Irish tune of "Eileen Aroon," which she had learned from her lover. At length, however, love triumphed, and the pair were united on Feb. 22, 1758. Within a few days Adair was appointed inspector general of military hospitals, and subsequently, becoming a favorite of the king, was made surgeon-general, king's serjeant-surgeon and surgeon of Chelsea Hospital. He died in 1790.—*Medical News*, January 2.

The Will of the Inventor of Dynamite.—The *Progrès Médical* states, January 16, that Alfred Nobel, the recently deceased Swedish engineer, who invented dynamite, bequeathed a large part of his immense property to establish a fund the income from which is to be divided into five equal parts and awarded each year to the five persons who during the year have made

the most important discovery or improvement in physics, chemistry, physiology or medicine, or, in the domain of letters, the most exalted production in the ideal sense, or contributed the most or the best to the brotherhood of peoples, the suppression of standing armies or the propagation of peace congresses. The prizes are to be awarded irrespective of nationality and if the provisions of the will are carried out, each of the five annual prizes will amount to 300,000 francs.

Experimental Tests of Subconjunctival Injections.—After having produced an ulcer in the center of the cornea in rabbits by injecting cultures of staphylococci, Von Sicherer treated one eye with subconjunctival injections of the various medicaments used for the purpose, leaving the other eye untouched. He found that the injections produce in fact a slight salutary effect, by causing a considerable leucocytosis around the infected focus. The simple 2 per cent. salt solution is equally effective with the more irritating salts, and deserves the preference for these injections. But there is no necessity for the injections at all, as the same effect is produced by the simple application of a salve of the yellow oxid of mercury, followed by an occlusive dressing. The leucocytosis thus produced is equal in extent to that by any other method, and the ulcer heals as promptly. Von Rothmund reserves galvano-cauterization for the supplementary treatment of ulcers of the cornea that are decidedly progressive and serpiginous.—*Rev. Gen. D' Ophthalmologie*, November.

Advance Waiver of Privilege Under New York Law.—The New York law providing that information acquired by a physician while attending a patient in his professional capacity, and which was necessary to enable him to act in such capacity, shall not be disclosed by him, was amended, in 1891, making the exception where such provisions are "expressly waived upon the trial or examination" by the patient. An application for insurance made in 1893 stated that the provisions of the New York law, and of similar provisions in the laws of other States, were thereby waived, and that it was expressly consented and stipulated that, in any suit on the policy applied for, any physician who had attended, or might thereafter attend, the insured, might disclose any information acquired by him in any wise affecting the declarations and warranties made in such application. This, the appellate division of the supreme court of New York holds, in *Hoiden v. Metropolitan Life Insurance Company*, Dec. 2, 1896, was a good waiver of the patient's privilege, which would preclude his legal representatives from afterward objecting to the admission of the testimony of his attending physician as to his having previously had bronchitis.

Connection Between Word Deafness and Deafness.—Word deafness has hitherto been ascribed to a cerebral lesion, but Keller and Freund have recently been impressed with the important connection between it and disturbances of the ears, especially of the labyrinth, which is able alone to cause word deafness. They urge the necessity of investigation of the ears in such cases. Keller asserts that isolated speech deafness with retained ability to comprehend other sounds, often corresponds with bilateral affections of the labyrinths, and is dependent upon tone-gaps in that portion of the tone scale which is physiologically important for the comprehension of speech. It sometimes happens that bilateral ear affections which in themselves are not sufficient to cause word deafness, produce it by a secondary degeneration of the nerve tracts and auditory centers. It requires such supreme efforts of attention then to hear that the patient gradually renounces the attempt, and lack of use hastens the degenerative processes. This is demonstrated by Urbantschitsch's system of ear gymnastics, which does not so much improve the hearing as it arouses and practices the faculty of comprehending what is heard. Pick's case is instructive in this respect. The patient was exceedingly hard of hear-

ing with word deafness also, and yet no lesion of the ears could be ascertained. The necropsy revealed, however, great alterations in the temporal lobe, to which the sensory aphasia was undoubtedly due.—*Deutsche Med. Woch.*, January 14.

Declarations of Cause of Injury not Evidence.—Whatever the rule may be in other jurisdictions, the supreme court of Illinois holds, in *Globe Accident Insurance Co. v. Gerisch*, Nov. 23, 1896, that the declarations of an insured person, as to the cause of his injury, made to his physicians at different times from several hours to three days after the supposed accident, are not proper or competent evidence in an action brought to recover upon a policy of accident insurance for his death, though had his statements related only to the part of his person that was hurt, his sufferings, symptoms, and the like, it would have been competent evidence.

Want of Skillful Treatment no Defense in Murder Case.—In the murder case of *State v. Edgerton*, the supreme court of Iowa holds, Dec. 9, 1896, that the trial judge properly stated the law when he charged the jury that if they found from the evidence that the defendant inflicted wounds which caused or contributed to cause death, then he could not avoid the consequences of his act on the ground that the wounds were not treated according to the best and most approved methods of medical and surgical treatment for wounds of that character, and that the judge properly excluded certain expert and medical testimony, as well as some medical and surgical books offered by the defendant, tending to show that by proper treatment of the wounds of the deceased his life might or could have been saved, it being especially contended that if the physician called had resorted to "laparotomy" his patient might have recovered.

Alloxur Bodies and Leukemia.—Gumprecht (*Centralblatt für allgemeine Pathologie und Anatomie*, Vol. vii. p. 820, 1896), taking the term "alloxur bodies" in Kossel and Kruger's sense as meaning those bodies which have an alloxan and a urea nucleus and therefore as meaning beside uric acid, also xanthin or nuclein bases (xanthin guanin, hypoxanthin adenin, or their derivatives) found that in leukemia in the cases where uric acid excretion is normal or diminished (it is generally increased) the alloxur bodies are increased, and that their amount varies directly with the amount of leucocytosis. He gives one case of his own in which this is shown very clearly, and points out that it forms an additional support to Horbaczewski's view that uric acid comes from degeneration of leucocytes, being formed from their nuclei. The "alloxan nucleus," or erythric acid, is a substance obtained from uric acid by the action of nascent chlorine or nitric acid, in the form of colorless crystals, large and small, that impart a red color to the skin. This substance has been found in the intestinal mucus of catarrhal enteritis.—*British Medical Journal*, December 26.

Formol.—Its synonyms are formaldehyde, formic aldehyde, formyl hydrid, mehanal. Preparation (Trillat process): Vapors of methyl alcohol are passed through coke or retort charcoal heated red hot, in a copper tube. This results in the production of formol in an aqueous solution, mixed with methyl alcohol with possibly traces of formic acid. The alcoholic and other products are expelled by distillation. The formol solution is then concentrated to 40 per cent. and in this form is commonly called formalin. Formic aldehyde is gaseous. It is usually employed in the 40 per cent. solution. It can not be concentrated beyond 50 per cent., as it undergoes in that case a polymerization which transforms it into a solid substance, trioxymethylene or triformol. In the 40 per cent. solution it is a colorless liquid with a strong, pungent odor, resembling that of the mouse, and a peppery taste. Reaction neutral. Formol dissolves readily in water. It is a powerful antiseptic, preventing fermentations and putrefaction of the urine. It is not toxic. It is used in surgery in a solution of 0.25 to 1 gram per

1,000. As a disinfectant it is evaporated in the infected rooms in shallow dishes containing a liter of formol diluted one-tenth. Traces of formol causes a characteristic white cloudy disturbance in diluted solutions of anilin. It is incompatible with ammonia, alkaline bisulphates, silver and copper solutions and gelatin. Formol deodorizes the hydro-sulpho-combinations.—From the *Annales de la Soc. Méd.-Chir. de Liège*, December.

The "Itchy Man" at Guy's Hospital.—The *Lancet*, November 28, quotes from a recent book, "The Girlhood of Maria Holroyd," who was the daughter of Lord Sheffield, the president of Guy's Hospital, about a century ago, to illustrate the "pull" of a peer, in those degenerate days. "Papa has got into Guy's Hospital four Frenchmen, gentlemen and officers, who perhaps you may recollect something of their having been a long time confined on board a ship and at last escaped by swimming to shore; I forget the particulars. How melancholy to think that these gentlemen are most thankful for admittance to the hospital; but one of them, a very genteel young man, is almost eat up by the 'itch'; and as it is a very extraordinary complaint, and they had no other proper place to put him into, he is now in the same apartment with the lunatics. They have hardly a shirt to their backs and neither shoes nor stockings. With the greatest difficulty they (four in a hackney coach) collected amongst them twopence to pay the turnpike. James went to the hospital to receive them and recommend them to the steward, and offered them money by papa's desire. They refused accepting it, saying they should want for nothing there. What uncommon generosity of mind, for men who are not above entering into an hospital can not be accused of false pride. Papa has sent Walpole today to get a lodging for the itchy man if he finds himself at all incommoded by his situation among the madmen. It really makes one's blood run cold to think what extremities hundreds are reduced to and what a number of melancholy stories there are that come to our ears." What a howl would be raised now were such a thing to be done. But it is a charming story and one hardly knows whom to pity most, the itchy men or the madmen. Perhaps the former is the more fit subject for compassion, since a lunatic ward at the end of the eighteenth century was not a desirable habitation.

Large Roentgen Apparatus.—Dr. R. A. Fessenden of Western University has just completed what is believed to be the largest apparatus of this kind in the world.

The machine is enclosed in a neat oak cabinet, four feet high and two feet wide, and weighs but 175 pounds. Handles are provided on either side to carry it. The most important feature is the coil, which rests near the base, between the legs of the cabinet. This is composed of seventeen coils and is wound with fifty miles of small wire. It is arranged to give a spark over twenty inches long, while the capacity of the machine reaches thirty inches. The current is received from two portable storage batteries, the ordinary direct or the alternating currents. The main circuit is broken by a revolving contact breaker which makes about two hundred breaks a second. This is important when it is known that the sparks are produced when the current on the large wire is broken. The contact breaker is immersed in ordinary petroleum, and is adjacent to a magnet, both of which put out any light produced in the breaker. This is encased in a small box on the top of the cabinet and is driven by a small one-horse power motor placed beside it. The suddenness of the breaking of the sparks is regulated by an adjustable condenser, also on the cabinet top. It is simply an alternation of tin foil sheets and paraffin paper. It arrests sparks and makes the break more sudden. Fastened to the side of the cabinet is an adjustable arm for holding the Roentgen ray tube. This is so constructed with several elbows that it can be placed in any position. If necessary, it can be placed beneath the bed upon which the patient lies and the photograph taken without moving or disturbing the sick one. A drawer is also inserted in the cabinet for the storing of assorted sizes of tubes. The tube is of Professor Fessenden's own discovery and represents the latest and most economical principles. It was worked out six months ago and has been in successful operation. It was designed

in accordance with a principle that the positive electrode must not be nearer any part of the fluorescent glass than the length of spark the coil will give. The positive terminal is, therefore, enclosed in a long tube connected with the main bulb. The coil is the most powerful ever successfully made. A photograph can be taken through the thickest part of the body in fifteen minutes, and the surgeon can easily see through every part of the body with the fluoroscope.

The New York Maternity Hospital Receives a Princely Gift.—We envy men of large wealth in one particular only, or chiefly, let us say, and that is in respect of their luxury of liberal giving to worthy causes. Such a luxury has Mr. J. Pierpont Morgan of New York, recently indulged in, in a gift of a ton of money, more or less, to suffering womankind. He purposes to donate \$1,000,000 for a new building, ten stories in height and fire-proof throughout, to the New York Lying-in Hospital. Wealthy women have given largely to churches and art, but it has been left to a man, already known for his generous gifts in other quarters, to seize the opportunity to qualify the parturient suffering of the poor. The following comment in the *New York Herald* explains gracefully and cunningly the concomitants of the generous gift:

"Mr. Pierpont Morgan has done so many things with his right hand which his left hand knew nothing about that it gives us a peculiar pleasure to congratulate him on an act of beneficence concerning which he is compelled to take the public into his confidence. There are many men in New York who are not only princely in the extent of their fortunes, but equally princely in their gracious generosity. Among these Mr. Morgan occupies an enviable place. He has bestowed a large sum on a most worthy institution. There are in this city tens of thousands of women who while passing through the ordeal of child bearing are dependent on charity for nursing and medical attendance. The Lying-in Hospital has done what it could to alleviate their sufferings, but Mr. Morgan's beneficence increases its power for good at least one hundred fold. The condition on which this gift is based—namely, a sufficient endowment to keep the institution in perfect running order—offers another opportunity to our citizens to assist a cause which makes a very pathetic appeal to the community."

The influence of a physician, Dr. Thomas M. Markoe, is said to be back of it all. The annual income of the hospital is \$47,000, inclusive of \$12,000 that the city is in the habit of apportioning to it. It is stated that no donor during his lifetime has given an equal sum to a charitable institution. Five of the junior physicians on this hospital's staff have been traveling and investigating the home and foreign hospitals, their expenses having been defrayed by Mr. Morgan, and this has been going on in a quiet way, for fully two years. The new building as at present designed is to be a ten-story fireproof structure of steel framework and a body of granite and light brick. It is to be ten stories high and capable of accommodating six thousand patients yearly, as against the present capacity of about 2,768. In the cellar floor will be the laundry, furnaces, dynamo rooms, a disinfecting room and rooms for servants and attendants. The basement will contain a student's dormitory and sitting room, drug store, instruction room and clinic and examination rooms. The kitchen and dining room for attendants will be on this floor.

Etiology and Treatment of Puerperal Eclampsia.—Dr. William Warren Potter of Buffalo read a paper on the above subject at the 91st annual meeting of the Medical Society of the State of New York, Albany, Jan. 26, 1897. He said, in part:

"Though the pathogenesis of eclampsia is still unsettled, we are certain that it is a condition *sui generis*, pertaining only to the puerperal state, and that to describe, as formerly, three varieties—hysterical, epileptic and apoplectic—is erroneous as to pathology and causation, as well as misleading in treatment. The kidney plays an important office in the pathology of the eclamptic. If it fail to eliminate toxins, symptoms are promptly presented in the pregnant woman. Renal insufficiency is a usual accompaniment of the eclamptic state. Overproduction of toxins and underelimination by the kidney is a short route to an eclamptic seizure. However, many women with albuminuria escape eclampsia, and many eclamptics fail to exhibit

albuminous urine. The microbic theory of eclampsia has not yet been demonstrated. The toxic theory, in the present state of our knowledge, furnishes the best working hypothesis for prevention or cure. Treatment should be classified into 1, preventive; and 2, curative. The preventive treatments should be subdivided into medicinal and hygienic, and the curative into medicinal and obstetric. A qualitative and quantitative analysis of the urine must be made at the onset. If there is defective elimination, something must be done speedily to correct a faulty relationship between nutrition and excretion. One of the surest ways to control progressive toxemia is to place the woman upon an exclusive milk diet. This will also serve to flush the kidneys and thus favor elimination. Distilled water is one of the best diuretics; it increases activity and supplies material—two important elements. In the pre-eclamptic state, when there is a full pulse with tendency to cyanosis, one good full bleeding may be permissible, but its repetition should be regarded with suspicion. If there is high arterial tension, vaso-motor spasm, glonoin in full doses is valuable. When eclampsia is fully established the first indication is to control the convulsions. Full chloroform anesthesia may serve a good purpose. If the convulsions are not promptly controlled the uterus must be speedily emptied. This constitutes the most important method of dealing with eclampsia. Two lives are at stake, and by addressing ourselves assiduously to speedy delivery of the fetus we contribute in the largest manner to the conservation of both. Rapid dilatation first with steel dilators, if need be, then with manual stretching of the os and cervix, followed by the forceps, is the nearest approach to idealism. Only rarely can the deep incision of Dührssen be required. Cæsarean section should be reserved for extreme complications, as deformed pelvis, or to preserve the fetus when the mother's condition is hopeless. *Veratrum viride* is dangerous, uncertain and deceptive in action. In eclampsia of pregnancy, *i. e.*, prior to term, the aseptic bougie, introduced to the fundus and coiled within the vagina, may be employed to induce labor. Finally, to promote the elimination of toxic material diuresis, catharsis and diaphoresis should not be forgotten; neither should the hot air bath nor the hot pack be overlooked."

Tetanus.—The following four cases of traumatic tetanus, all under treatment at the Cook County (Illinois) Hospital at the same time, make a remarkable record in the treatment of this fatal malady. Three out of the four recovered, while the one that died was prognosed the most favorable of the quartet on admission to the hospital.

The first case was in the service of Dr. A. F. Lemke. The patient was a boy of 17 years, who stepped upon a nail and received a puncture in the sole of the right foot. He was admitted to the hospital on Sept. 20, 1896, and had general tetanus of the most pronounced type. On the 22d, he was given 50 cubic centimeters of the Pasteur Vaccine Company's tetanus antitoxin, which was followed by a decided amelioration of the symptoms. On the 23d he was given 20 cubic centimeters more, and on the 29th a third dose of 20 cubic centimeters. This was the last dose of the antitoxin used and his recovery was uninterrupted.

The following three cases were in the service of Dr. L. Dy-sart, who kindly furnished the notes herewith given. The first patient was a colored boy of 14 years, admitted to the hospital on Sept. 24, 1896. He had convulsions of a general character, most marked in the upper extremities and thoracic regions—the spasms occurring about every five minutes, and were of a severe type. The trismus in this case was well marked and accompanied by some *risus sardonicus*. Four days after the development of the tetanic symptoms, and not yielding to the ordinary means of treatment, the boy was given 30 cubic centimeters of antitoxin. Three days later another similar dose was administered. The convulsions ceased, convalescence was established and the patient is practically well, a little more than three weeks from the date of the attack.

The next case was a laboring man of 42 years, admitted on October 7. Nine days after receiving a wound on the right malleolus by being struck with a staple, symptoms of tetanus were developed, being the most pronounced in the arms and muscles of the chest, with trismus of a severe type. On the third day after the development of the symptoms he received his first antitoxin, 50 cubic centimeters. On the following day he was given a dose of 30 cubic centimeters, since which time there has been such a continued and gradual decline of symptoms that it has not been deemed necessary to repeat the dose. His recovery is now assured.

The last case of the series is that of a boy 8 years of age. On September 26 he was kicked by a horse on the left side of the head. Soon afterward facial paralysis was noticed, and ten

days after receipt of the injury the first symptoms of tetanus appeared. These were confined to the head, neck and upper part of the thorax, but were of great severity. Four days after the spasms commenced he was given 50 cubic centimeters of antitoxin, and again four days later another dose of 60 cubic centimeters. The convulsions were partly controlled in the beginning of the treatment, but became more severe toward the last, and he died on the 14th of October, four days after his admission to the hospital and eight days after his first tetanic spasm. Owing to the age of the patient, the late appearance of the first symptoms, the limited area affected and the absence of any notable complications, this case was regarded as the most favorable one of the four. But it must be remembered that the antitoxin was not used for four days after the development of the disease; whereas to secure the best results from any antitoxin, it should be employed at the earliest possible moment. The physician in charge of the case at the hospital used the antitoxin immediately upon his admission, but the disease had already been running four days, and its speedy termination in death shows that it must have been of a very grave type.

The Microphonograph.—Professor Dussaud of Geneva has invented a microphone placed directly on the membrane of a phonograph, attached to a battery and telephone receiver, which transmits sounds to the ear greatly magnified, and promises to be to the ear what the microscope is to the eye. When the receiver is held to the ear the sounds repeated by the phonograph can be regulated by increasing or decreasing the current or manipulating the microphone. A volume of sound can be secured sufficient to produce violent pain to normal ears, while deaf persons with a little practice can learn to distinguish melodies with it, beating time to them and distinguishing them, showing a preference to this or that tune, etc. The value of such an instrument in teaching the deaf to converse is inestimable, and it can also serve as an audimeter, determining the more or less absolute deafness of the subject, and improvement or the reverse in hearing. It will also serve another purpose in registering sounds inaudible to the ear, such as the pulsations of the heart, the sounds produced in respiration, the steps of an ant, etc., and reproduces them magnified for scientific study. As sound is so eminently fleeting, it must be fastened and held to be studied with scientific accuracy, which Professor Dussaud has succeeded in accomplishing. Microphonography is destined to an important rôle in the study of the at present inaudible sounds of normal and pathologic organs. He states the four following principles as the foundations of his investigations, and the source of his success: 1. The sounds transmitted by means of the microphone undergo an important transformation in their character, and become more accessible to defective hearings as they assume in some respects the characters of noise. 2. The microphone is the only means of increasing the power of acoustic waves to a point where the sense of hearing, even the most blunted, is able to perceive them as long as there is a vestige of the sense left. 3. The mechanical vibration of the microphone caused by the vibrating membranes of the phonograph produces an acoustic power several hundred times superior to that obtained by transmitting atmospheric waves on the microphone. 4. By placing the wooden receiver in contact with the ear the mechanical vibration of the wood, varying with each note or syllable transmitted by phonograph, produces a mechanical effect on the ear, which approximates in the case of the deaf and dumb what we call the sensations of sounds.—*Bulletin de l'Acad. de Méd.*, December 29.

Husband can Recover for Sale of Laudanum to Wife.—The supreme court of North Carolina has handed down a decision, Nov. 24, 1896, in the case of Holleman v. Harward, for which it says it was able to find no precedent in the English Common law courts or in the courts of any of our States, save only in the New York case of Hoard v. Peck, 56 Barb. 202. It holds that an action will lie at the suit of a husband, to recover damages from druggists for injuries sustained by him in consequence of the sale by them to his wife of laudanum and similar prepara-

tions, in violation of his express orders, and knowing that his wife was using the drugs in large quantities as a beverage to the ruining of her health. It bases its decision upon the broad principle that, "whoever does an injury to another is liable in damages to the extent of that injury." A married woman, it says, still owes to her husband, notwithstanding her greatly improved legal status, the duty of companionship and of rendering all such services in his home as her relations of wife and mother require of her. And so it holds that the defendant druggists owed the husband the legal duty not to sell to his wife opium in the form of large quantities of laudanum as a beverage, knowing that she was, by using them, destroying her mind and body and thereby causing loss to the husband. Under the circumstances stated, it declares they were just as responsible as if they had forced her to take the drug for they had their part in forming the habit in her, and continued the sale of it to her after she had no power to control herself and resist the thirst; and that, too, after the repeated warnings and protest of the husband, who said that he was trying to counteract the habit, which he alleged was the outgrowth of taking opium in different forms, principally laudanum, as a medicine. There is no difference, the court insists, between the principle involved in this action and the principle upon which a husband can recover from a third person damages for assault and battery upon his wife. Nor will it admit that, because there is no statutory provision in North Carolina prohibiting the sale of laudanum as a beverage or as a medicine, it must therefore follow that a sale of it under all circumstances is lawful. It is a well known poisonous drug, which can not be drunk as a beverage without injury to the body, affecting the health of the physical and moral powers, as all druggists know. So it reverses a judgment which held there was no cause of action stated in this case, laying down the law as above.

1896 at the Paris Academie de Medecine.—The retiring president, Dr. Hervieux, in his address stated that each year has certainly had its share in the progress accomplished in these last years of the century, and 1896 deserves honorable mention. . . . Perfection in asepsis has reduced the mortality in our lying-in-hospitals from 13 per cent. a few years ago to a fraction of 1 per cent. Surgeons now approach the most audacious operations with perfect confidence, extirpating the larynx or a kidney, a portion of the liver, several centimeters of intestines, the bladder, the uterus, the ovaries, and think nothing of opening the abdomen to solve a diagnostic question. Not a meeting takes place without some remarkable surgical achievement presented. Our hospitals are overcrowded with patients, and this crowding, which a few years ago would have produced the most deplorable epidemics, now has no effect on raising the mortality. . . . The present is an age of facts, as is shown once more by the absence of theoretic discussions and the preponderance of practical questions in our meetings this last year. . . . The year 1896 has added another to the list of microbial diseases, and Nocard's discovery of the bacillus of psittacosis has established its infective character. Yersin's serum has triumphed over the plague. Henriot has discovered a new ferment in the blood which solubilizes the fats. Lannelongue has secured brilliant success with his sclerogenic treatment of inguinal hernia with chlorid of zinc. The Roentgen ray has been utilized to discover foreign bodies in the organism, and radioscopy with the fluorescent screen has enabled Fournier to study the displacement of the liver during each respiration and the cardiac revolution as it commences with the auricles. Cornil has also added to our knowledge by his important study of the mode of reunion of the serosa in intestinal operations. He fastened the serous surfaces of two intestinal loops together and watched the histologic processes, finding that they are due entirely to the multiplication and displacement of the cells

of the endothelial and connective tissues by movements of their protoplasm, anastomizing and forming the definite cicatrix by the formation of new vessels, which result from their activity. A similar process occurs in the fibrinous effusions in aseptic pleurisy, and he also states that the cicatrization of vessels after a ligature is the same as after suturing. Francois-Franck has succeeded in establishing the vasomotor action of the nerves of the pulmonary vessels. Stimulation of the filaments emerging from the superior thoracic ganglion increases the pressure in the pulmonary artery while it diminishes it in the left auricle.

Medico-Literary Notes.

PREMATURE BURIAL.—Mr. W. Tebb, an Englishman, and Col. Vollum, an American, have thought it to be worth their while to get up a book on this subject, published in London, by Swan, Sonnenschein & Co. It is a grewsome subject and it will grow still more hideous when the Sunday newspapers have their attention called to the theme.

A BRINTON CALENDAR.—The publishing house of Jacobs & Co., Philadelphia, has upon its list "The Pursuit of Happiness" Calendar for 1897. The writings of Dr. Daniel G. Brinton have been drawn upon, in many happy selections, to make the calendar instructive. A portrait and decorative drawings give it added attractiveness.

AN AMERICAN BOOK COMMENDED.—The *Lancet* speaks quite highly of an American book, namely, Norris and Dickinson's Text-book of Obstetrics, issued in London by the Rebman Publishing Company, at 42 shillings. The book has 900 illustrations of a high order of merit that were contributed by Dr. Robert L. Dickinson of Brooklyn as art editor. On this subject the *Lancet* says: "There is generally something attractive about a fresh presentment even of familiar facts, and to this attraction there are added in the work before us several features that in no small degree contribute to make it a welcome addition to the literature of the subject. We may more especially instance the illustrations, many of them beautifully colored, for which we have nothing but praise. There is, we think, no work on midwifery in which the illustrations are so numerous and excellent. The figures are all drawn to scale, usually one-third or one-sixth life size." The American publisher is W. B. Saunders of Philadelphia. Another reviewer has written: "In the wealth and excellence of its illustrations, this work stands alone."

THE COMMENTARY OF APOLLONIUS.—An important contribution to a revival of interest in ancient medical literature has appeared in a magnificent edition of the Commentary of Apollonius of Kitium on the Hippocratic treatise, *περὶ Ἀρθρῶν*, "On the Joints," by a German scholar—Hermann Schöne. Apollonius, like another physician of note, Apollodorus, taught and practiced medicine at Kitium, a town on the south coast of Cyprus. He flourished about the date 60 B. C. A still further confirmation of his date is the fact that his commentary is dedicated to Ptolemy—not the King of Alexandria, but almost certainly Ptolemy Auletes, King of Cyprus. Little more is known of him, but his commentary has always been prized by medical scholars and has been carefully studied by Bandini, Kühlewein, Ilberg and others. The manuscript on which the text before us is based is in the Laurentian Library in Florence, and its history as given by Schöne is of peculiar interest. Schöne assigns it to the second half of the ninth century. It was bought on April 3, 1492, in Candia by John Lascaris, on his second voyage to Greece, at the instance of Lorenzo de' Medici. It next received hospitality in the Bibliotheca Medicæ under Piero de' Medici; then it was passed on to Rome at the request of Pope Clement VII. We next find it in the hands of Guido Guidi, physician to King Francis I. of France, who translated it into Latin; and then a copy of it was made for the library at Fontainebleau. It can be next traced to the library of Cardinal Ridolfi, from whose keeping it was transferred to that of Marshal Strozzi, and once more to that of Catharine de' Medici, from whom it finally found its way into the Laurentian Library before 1571. It constitutes the "fons et origo" from which the Parisian and other manuscripts are derived. All this and a good deal more related with admirable

lucidity by Schöne leads up to the text, of which he presents us with a careful recension, which is likely to remain the "textus ab omnibus receptus" for a long time to come. Hardly less important are the plates, thirty in number, which illustrate the text beside conveying to us a vivid appreciation of the anatomic science of the first century B. C. These are executed with consummate skill, thanks in the first instance to an able photographer, then to a not less competent lithographer, in whose hands the facsimiles of the manuscript and diagrams, clear, effectively colored and highly artistic, gives the book a value of their own. The whole volume, published at Leipzig by Teubner, is indeed honorable to the medical scholarship of Germany and leads us to hope for other contributions to the elucidation of Hellenic healing art from the same editor.—London *Lancet*, December 12.

THE PUBLIC SERVICES.

Army Changes. Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from Jan. 30 to Feb. 5, 1897.

Major Edward B. Moseley, Surgeon, ordered upon the expiration of his leave of absence to Benicia Bks., Cal., relieving Major Curtis E. Munn, Surgeon. Major Munn, on being thus relieved, is ordered to Ft. Logan, Colo., for duty, relieving Major Augustus A. DeLoffre, Surgeon. Major DeLoffre, on being thus relieved, is ordered to Ft. Sam Houston, Texas, for duty.

Major William C. Shannon, Surgeon, will upon expiration of his sick leave be relieved from duty at Ft. Custer, Mont., and ordered to Jackson Bks., La., for duty, relieving First Lieut. Robert S. Woodson, Asst. Surgeon. Lieut. Woodson, on being thus relieved, ordered to Ft. McPherson, Ga., for duty, relieving Capt. Philip G. Wales, Asst. Surgeon. Capt. Wales, on being thus relieved, ordered to Ft. Niobrara, Neb., for duty.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the two weeks ending Feb. 6, 1897.

Asst. Surgeon H. LaMotte, granted sick leave.
Asst. Surgeon C. E. Riggs, detached from the "San Francisco" and ordered to the "Detroit."

Change of Address.

Crowley, P. F., from Dunning to Jefferson Park, Ill.
Dayles, W. H., from Maquoketa, Iowa, to San Bernardino, Cal.
Gallagher, Thos. J., from 1321 Race St. to 605-606 California Bldg., Denver, Colo.
Halse, Ellen H., from Irving Park to 204 N. Main St., Canton, Fulton Co., Ill.
Hickman, Henry, from 3586 to 3624 S. Broadway, St. Louis, Mo.
Reynolds, Dudley S., from 3d and Chestnut Sts. to 304 W. Chestnut St., Louisville, Ky.
Van Cleve, A. H., from El Paso, Texas, to Silver City, N. M.

ADDRESS.

RETROVERSION OF THE UTERUS.

Address delivered before the Central Illinois Medical Association at
Streator, Dec. 1, 1896.

BY FRANKLIN H. MARTIN, M.D.

CHICAGO.

Retro-displacement of the uterus is one of the most important conditions which the gynecologist and the family physician are called upon to remedy in the treatment of female complaints. It is important because the condition frequently exists, because it produces a long train of symptoms which frequently end in invalidism, and because it is frequently ignored if discovered at all by physicians whose experience ought to teach them better.

Because the uterus is a movable organ, because it is behind the bladder which must fill and empty, and in front of the rectum which must distend and contract, because it is subject to the intra-abdominal pressure with every inspiration and expiration of the woman; because it is fixed with elastic and muscular supports which protect it from sudden jars; because of all of this it does not prove that there can be no normal position of the uterus and hence there can be no pathologic displacement. A man's arm has a normal range of movement in order that it may accommodate itself to its environment and perform its function, but that does not argue against a possibility of pathologic dislocation of the arm.

APPROXIMATE NORMAL POSITION OF THE UTERUS.

In order to diagnose and treat a dislocation of the humerus one must know the normal anatomy of the parts. While I have reason to believe that there are physicians of reasonable appearance who do not apply this same rule in the practice of pelvic disorders, I affirm that every family physician or gynecologist who depends upon his own knowledge for making diagnosis of pelvic difficulties should not only know pelvic anatomy but should also be able by repeated practice to detect abnormalities.

The uterus, Fig. 1, in its normal location is suspended in the pelvis with the fundus lying a fraction of an inch below a line drawn from the top of the symphysis pubis to the promontory of the sacrum. With the subject in the upright position the body of the uterus inclines forward on an angle of about 45 degrees with the horizon. The cervix lies within an inch and a half of the sacrum. The body of the uterus projects from the top of the vagina in a forward direction at about right-angles to that muscular tube. The fundus of the uterus occupies such a position in the pelvis when normal that the intra-abdominal pressure deflected from the anterior abdominal wall strikes it just posterior to its crest in a direction to force it, if at all, in an anterior direction.

The supports of the uterus are the broad ligaments which suspend it with side expansions, the vaginal

tube resting upon the peritoneum supporting the cervix, the two folds of peritoneum called the sacro-uterine ligaments holding the cervix near the sacrum with the anterior vaginal wall acting as a counterpoise suspending it in front. The round ligaments act as stays preventing the uterus from being forced into retroversion by sudden impulses or jars. So that it has supports from almost every point, and in no case are the supports immovable and fixed. It is surrounded with cushioned supports and elastic guys, while its free fundus is embraced in a canopy of soft ever-yielding intestines. No organ in the human body is more carefully protected from violence from without or from its immediate environment from within.

THE FEMALE PELVIS.

The female pelvis upon which the destinies of the human race so much depend is not only a box of wonderful security, but it is a stronghold of marvelous nervous mechanism. The uterus is connected with and has extensive automatic control of almost every organ in the body. No other organ except the heart has such universal sway over the whole economy. From the time that puberty begins in early maidenhood until the well-earned rest is secured at the menopause the immense network of sympathetic nerves surrounding the uterus is ever ready to perform herculean tasks. If conception occurs it must automatically, at once, begin a work which is the most remarkable thing in the world. It compels the heart to send more blood for nourishment of its new life, it compels the brain to create an appetite in the individual, it compels the stomach to digest larger quantities of food and the intestines to increase assimilation. It strengthens and expands the peritoneum, it softens the cartilage of the pelvis, it expands its own supports, it enlarges its environment without pathologic consequences, it develops the breasts and fills them with fluid, and when at a certain hour on a certain day the climax of gestation is reached it touches the spring which sets in motion all of the awful machinery of labor, which contracts its own powerfully developed walls, relaxes and lubricates the soft parts through which the child must pass, compels abdominal contraction at the proper time and when finally the labors are finished it telegraphs less blood to the pelvis, more to the breasts. It contracts its own walls, narrows its blood supply, furnishes an antiseptic fluid of soothing quality for the soft track of its outlet and in a remarkably short time has returned to its normal size and position.

When we stop to think a minute of the wonderful accomplishments of this uterus, and realize that its functions of menstruation or gestation are constantly maintained for thirty years it does not seem unreasonable that a displacement of the organ with a consequent disturbance of its sympathetic nervous connection will produce disastrous results.

Retroversion of the uterus produces *local* and *remote* subjective symptoms.

The *local symptoms* are produced by the disturbance the dislocated organ produces by pressure on neighboring parts. Constipation may result from direct pressure of the uterus on the lower bowel. Sacralgia or backache may be produced by direct pressure of the displaced fundus on the sacral nerves. This (displaced fundus) may draw upon the support of the bladder or the displaced cervix from forward pressure, may too disturb the function of this organ. This displacement of the uterus frequently forms flexures of the broad ligaments which interferes with the return venous circulation of the organ and produces a passive congestion with symptoms of heaviness. Pain in the ovaries and tubes may result from the same cause.

Figure 1.

The organ from its increased weight and from lying with its long axis parallel with the vagina (Fig. 2) slides into a lower plane of the pelvis and gives rise to the distressing symptoms of "bearing down." These symptoms are all aggravated by exercise of the patient and the upright position of the body because these things exaggerate the displacement. Menstruation is invariably disturbed and more or less pain is seldom absent.

Remote symptoms.—The remote symptoms may be as multitudinous as the nerves which connect the organs of reproduction with other organs of the body. While the uterus in health has such positive influence on the functions of other organs, it is easy to understand how, when in distress, just this intimate connection might disastrously disturb the normal functions

of these neighbors. Such is the case. Palpitation of the heart, poor digestion, nausea, intestinal disturbance giving rise to imperfect assimilation, bladder irritation, backache and almost invariably severe headaches are a few of these symptoms.

General symptoms.—After the suffering woman has been allowed to bear the constantly harassing symptoms from month to month, with the cause becoming more and more fixed, with poor assimilation leading on to anemia, with rampant reflexes gradually endangering the balance of the nervous system, we find the subject growing thin in flesh, we find her despondent in spirits, especially aggravated each month when the labor of painful menstruation is superadded, her will forces become less resistant to the nerve storms, hysteria supervening and what was once a healthy woman is transformed into a thin, weak, white-skinned, aching, despondent, hysteric invalid.

Figure 2.

Diagnosis.—While the subjective symptoms already rapidly recited must give us a clew to the local condition, it is the objective signs as gained by an examination of the pelvic organs which must make or confirm our diagnosis.

With a knowledge of the normal conditions well fixed in his mind the physician should proceed to make a thorough examination of the pelvis. The patient is placed on an office table or a bed with her legs flexed and her feet supported in a pair of stirrups, or on two chairs if the examination is on a bed. The examiner with the index finger of his left hand well soaped or otherwise lubricated, standing or sitting close in front of the patient, between her separated knees, should proceed to make a vaginal digital examination, reserving the strong right hand for external

palpation. In an instant he will determine if the perineum is lacerated, whether the anterior or posterior vaginal walls are projecting. He immediately reaches the cervix. If it is well back in the pelvis it would be well nigh impossible for retroversion to exist, because the overhanging sacrum would throw the fundus forward, and by placing the finger in front of the cervix it can be proved by grasping the fundus in front (Fig. 3). If the cervix is well forward and low in the pelvis, then look out for the retro-displacement of the fundus, for then by placing the finger in front of the cervix the hand from above will approach it with no fundus to be felt between (Fig. 4). By placing the finger behind the cervix in such a case if the fundus is retroverted it can be palpated in that position, thus proving conclusively that the uterus is retroverted (Fig. 5). While the uterus is grasped

Figure 3.

in such a position any irregularities of its surface, its size and something in regard to the amount of its mobility can be ascertained. In fact an expert in bimanual palpation of the pelvis can easily by some such systematic course as described above determine not only the position, shape and size of the uterus, but also the condition of the appendages. If the parts are tender, or the patient a virgin, or the pelvic walls unusually resisting or thick, an anesthetic should always be given in order to accomplish a thorough examination. In fact it should be followed as a rule that an anesthetic should be given when an examination without one leaves any doubt. Whenever the uterus appears fixed in retroversion an anesthetic should be given in order to confirm the diagnosis as frequently an apparently adherent

uterus becomes dislodged and movable under the relaxing influences of ether.

Treatment.—Without going more fully into etiology, more minutely into methods of examination, or into a more exhaustive study of the anatomy of the pelvis, than the foregoing hasty discussion will allow I must hasten to the more practical part of my subject, viz., treatment. And here, too, I can but touch on general principles with the elucidation of but one or two important practical applications.

For the treatment of simple persistent retroversion without adhesions or with laceration of the perineum or diseased appendages two possible means of cure may be adopted.

Without Operation.—One can not safely promise a cure in any case of retroversion without finally resorting to an operation but after taking the precaution to explain to a patient before treatment is begun that

Figure 4.

non-operative treatment *may fail*, one is justified in making an attempt (with patients who can wait) to cure without operation.

The treatment here should be the replacement of the uterus and the retention of the organ in place by a well-fitting Hodge-Smith pessary, or the replacing of the uterus at each treatment by means of well placed tampons, keeping them in position until just before the next treatment, and all this supplemented by a judicious application of local tonics and stimulants.

To be more exact, my method is as follows: I replace the uterus by bimanual manipulation, by forcing the cervix backward and drawing the fundus forward (Fig. 6). I then select a pessary which will lengthen the vagina, thereby keeping the cervix back

in the hollow of the sacrum, and whose posterior bow will force the fundus forward.

I then place in the vagina a vaginal electrode and over the replaced fundus an abdominal sponge electrode and apply a slow break faradic current of electricity, applying it as strong as the patient will bear without pain and for a period of five minutes. This stimulates all of the muscular supports of the uterus and that, too, when they are in a state of relaxation. The patient is then instructed to get into extreme knee-chest position three times a day and when in that position to open the vagina so that it will be distended with air by retracting slightly with her finger the perineum. This reverses temporarily intra-abdominal pressure, throws the uterus forward by gravitation, and forces the cervix into the hollow of the sacrum by ballooning the vagina with air. The patient takes the local stimulation of faradization

Figure 5.

three times a week and at each time the uterus is examined to make sure that it remains in place. The surgeon should by bimanual manipulation stretch the shortened supports and force the uterus into extreme antiversion at each treatment. After a month's treatment the pessary is carefully withdrawn, the patient is instructed to avoid violent exercise, is cautioned to assume the knee-chest position religiously, in order to avoid a relapse, and to report the following day. At this time the parts are examined and if the uterus has remained in place for the twenty-four hours without support one should be much encouraged. The ordinary treatment should be applied and a two days' respite given. And so, carefully, these cases should be nursed and about one out of five will reward you with a final cure.

Frequently after withdrawing the support the

first time at the next visit the patient will announce a failure, her symptoms having already convinced her of that fact. Another month or even two months' treatment should be advised.

If a well-fitting pessary will not be tolerated, then at the end of each treatment, after the uterus is well in position, the patient should be placed in knee-chest position and with the aid of a perineal retractor and a pair of dressing forceps an elastic wood tampon should be placed in front and below the cervix (Fig. 7). This should be allowed to remain until the following evening when it should be removed by the patient and an antiseptic douche given. The patient should remember to assume the knee-chest position at least three times a day during the time she is receiving this treatment. All forms of violent exercise should be avoided and corsets should be abandoned.

These tedious forms of treatment will yield a gratifying result in about one case in five. This small percentage is well worth fighting for, however.

Figure 6.

Alexander Operation.—What shall we do with the failures under this head of non-adherent, but persistent retroversions? Unhesitatingly I say: Shorten the round ligaments. These cases require the slightest tension on the part of the round ligaments to make them permanently normal. The operation is safe and by my method of ligament fixation it is sure.

RETROVERSION WITH ADHESIONS.

Adhesions of a retroverted uterus without concomitant disease of the appendages is a rare complication. However, cases will occasionally be found where adhesions have occurred from destruction of the epithelium of the opposing peritoneal surfaces as a result of pressure and friction without the intervention of a septic process. These adhesions occasionally I believe I have been able to separate by manipulation under anesthesia. If they do not yield by one manipulation under ether, we may hope by repeated massage, local stimulation of faradism and hot water and depletion to cause frail adhesions to give way without operative interference. After once overcoming the adhesions the case should be treated exactly

on the principles of those cases of non-adherent retroversions.

Adhesions of a permanent and unyielding character complicating retroversion where there is not serious disease of the appendages requires more radical treatment. While by an examination under anesthesia (and all of these cases should have such) one can not invariably say that the appendages are not seriously diseased, it is possible for one of experience to arrive at a pretty satisfactory conclusion. If then posterior fixation exists and the appendages, in the opinion of the surgeon, need not be sacrificed, he should proceed to break up the adhesions through the posterior *cul de sac*, after first cleaning the uterus with a curette, ascertain the true condition of the appendages, replace the uterus and retain it in position by shortening the round ligaments by Alexander's operation.

Figure 7.

RETROVERSION WITH DISEASED APPENDAGES WITH OR WITHOUT ADHESIONS.

Retroversion with diseased appendages, with or without adhesions, can, in my opinion, be successfully treated by laparotomy only. A small incision usually suffices. The uterus is sought for and the fundus freed by sweeping the finger between it and the adherent peritoneum. The diseased appendages are sought and treated by removal if necessary, or if simple cysts only exist they should be excised, disinfected and drained and then the uterus is brought well forward and suspended.

Method of Suspension.—I have adopted Fowler's method of ventral fixation or a modification of his method when the urachus is absent. The urachus, which ordinarily may be seen lying parallel with the abdominal incision on the peritoneum in the sub-peritoneal space, is avoided in making the incision and when the uterus is freed and ready for attachment the urachus is stripped from its surrounding tissue until a cord of two and a half or three inches is obtained, then the umbilical end is severed, leaving it attached low down in the pubic end of the abdominal incision. The uterus is drawn well up into the abdom-

inal incision and the blades of a Cleveland forceps are passed from behind forward through the fundus just posterior to its crest. The points of the blades are separated and are made to grasp the free end of the urachus and by withdrawing the forceps the cord-like urachus is drawn through the top of the uterus. Now by grasping the free end of the urachus the uterus is slid along the ligament into extreme antiversion well below the lower angle of the wound. An antiseptic catgut suture secures the uterus in place and the free

Figure 8.

end of the urachus is buried in the whole length of the abdominal wound as the wound is closed with its permanent sutures. This succeeds in suspending the uterus on an animal living ligament taken directly from the surrounding tissues, and the fact that the cord-like tissue is again immediately reburied in succulent, well nourished, living tissues insures its integrity. The uterus, therefore, becomes successfully fixed without the intervention of any kind of an artificial permanent or temporary suture which are always liable to become infected and give rise to troublesome fistulæ.

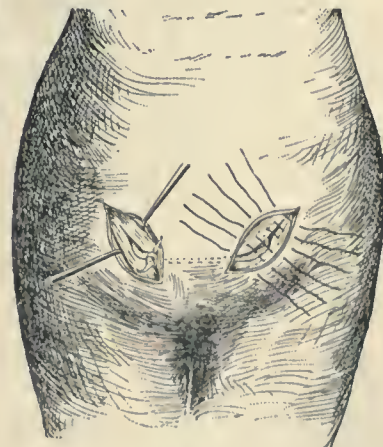

Figure 9.

When the urachus is absent, or divided and scattered as it occasionally is, I take a strip of peritoneum about one-half inch wide from the side of the incision, twist it into a cord and leaving the pubic end attached I treat it exactly as I do the urachus. It is in every way as efficient as the urachus.

I have done these two operations at least thirty times within the last year, and in no case has there been the least tendency to weakness of support. I consider it superior to any other method I know.

THE AUTHOR'S ALEXANDER OPERATION.

With my method of doing Alexander operation some of you are already familiar, as I published it over a year ago. It is unique only in the method of fixation of the ligaments. As in my ventral fixation operation, in fixing the shortened round ligament I do not cumber my wound with any permanent or temporary buried sutures. I make the ordinary incision from the spines of the pubes, two inches in length, in the direction of the anterior superior spine of the ilium, exposing the external rings (Fig. 8). I separate the rings and draw out the strong round ligament. I then pass the closed blades of an artery forcep from the lower end of one wound beneath the skin, fat and superficial fascia over the pubes to the lower end of the wound of the opposite side. I then open the closed blades of the forceps and grasp the freed end of the ligament of the farthest wound and draw it through to the other wound (Fig. 8). The two ligaments are then drawn taut and tied tightly together over the pubes in a strong hard knot. The free ends of the ligaments are tacked by means of antiseptic cat-gut to the ligament on either side in such a way as to prevent the knot slipping until adhesions have occurred (Fig. 9.) This method of tying effectually and evenly shortens the ligaments and the knot thoroughly fixes them without the necessity of resorting to any kind of objectionable permanent suture. The wound is then closed over the ligaments in the ordinary way with temporary silkworm gut sutures.

SUMMARY.

1. Continuous retroversion of the uterus is a condition which frequently leads to serious pathologic consequences.
2. Retroversion without adhesions can be cured without operative interference in about 20 per cent. of the cases in which it occurs.
3. A small percentage of retroversion with adhesions can be cured by massage, electricity and depletion.
4. Retroversion with unyielding adhesions should be freed through the Douglas *cul de sac* and the round ligaments shortened at the same operation.
5. Retroversion with diseased appendages should be treated through an abdominal incision and the uterus brought forward and suspended on the urachus or a ligament constructed of peritoneum.
6. When the Alexander operation is performed the ligaments should be secured without resort to a permanent buried suture, and this can best be accomplished by tying the two ligaments together in a hard knot over the pubes beneath the integument.

THE TECHNIQUE OF OPERATIONS FOR ACUTE APPENDICITIS.

BY WELLER VAN HOOK, A.B., M.D.

PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY IN THE NORTH-WESTERN UNIVERSITY MEDICAL SCHOOL; PROFESSOR OF SURGERY IN THE CHICAGO POLICLINIC; SURGEON TO THE GERMAN HOSPITAL.

The technique of operations for acute appendicitis has been studied and discussed by a splendid array of the world's best surgeons. Nevertheless opinions continue to differ not only as to the immediate objects of operative interference but also as to the technical methods by which these objects are to be accomplished.

Some of the operators whose lists are longest and whose statistics make the best showing are extremely vague when it comes to a working description of their methods. The incision which each writer affects is carefully described; the statement made that the intestines are carefully protected by gauze; the appendix carefully removed or carefully left in and a few sutures inserted. But in my opinion the most important part of the operation consists in the protection of the normal serosa from infectious matter and the application of the gauze drain. These points are not carefully dwelt upon as a rule and one prominent writer says he fears he can not give an accurate idea of the method he employs.

This paper is not intended to exhaustively treat of technique in all the multitudinous forms and anatomic varieties of appendicitis, but rather to discuss the common forms, if possible, in a way to suggest the principles upon which the infinite variety of morbid anatomic conditions may be dealt with.

The minds of those who have not operated at all, or of those who have only operated "occasionally," should first be disabused of the notion that operations for appendicitis are easy or simple affairs and a wholesome conviction should be entertained that they are not unassociated with danger. It is impossible for me to withhold an expression of surprise and almost of horror that most writers either leave an opposite impression or like Sonnenburg¹ state boldly that the operation is a simple one. It is my firm belief that a hundred cases of acute perforative appendicitis will show a much higher percentage of recoveries under a uniform "medical" treatment of rest and hot applications with "lancing" of pointing abscesses than will be the case with a hundred patients similarly affected and operated upon by a hundred or even twenty surgeons gaining their first experience. I am confident that the loss of life from weak or faulty operations for appendicitis is proportionately much greater than is the case with operations in pelvic abdominal work. The reason for this greater danger is that a surgical operation in the course of appendicitis is an act of supreme violence—supreme because inflicted just at the critical point, the seat of virulent infection with the deadly inhabitants of the intestine. No surgical calamity can be more appalling than the uncontrolled distribution of pus from appendicitis to previously uninfected peritoneum. When this accident has occurred the fear of the patient's death is before us, no matter what surgical technique or detail of subsequent medical management be resorted to. It is the prevention of this accident, the unnecessary distribution of pus to normal serous membrane, that in these operations marks the man of surgical skill.

No medical man objects to the acquisition of experience by the tyro; he must make a beginning at some time. But ethics demand that except in cases of the utmost urgency the inexperienced operator abstain from drawing blood. Experience can be gained without much loss of life by assisting an older surgeon. A second proposition of equal importance is that none should begin operating on these cases who has not the inclination and opportunity to follow up his work and to so perfect himself in the beneficent art that his later cases may fare better than his earlier ones.

¹ "Die Operation bei der Appendicitis perforativa ist eine einfache, und jeder, der mit den anatomischen Verhältnissen bekannt ist, wird sie leicht erlernen koennen." Deutsche Zeitschrift fuer Chirurgie, Bd. xxxviii, Hefte 2 und 3.

The *objects to be accomplished* in these operations should be clearly defined and borne in mind at the bedside and at the operation. None will deny that the first great goal to be reached is the saving of life. It is the cry of danger to life that has aroused the profession to the importance of operating at all and it is this which gains for us the consent of the patient to submit to a procedure which *is in itself dangerous*, although if indicated and properly done not so dangerous as the disease itself.

We can not conscientiously permit any departure from those technical details which most strongly promise the saving of life. In consequence we must subordinate to *this prime object* considerations of future comfort and convenience.

The *secondary objects* are, first the prevention of fistulæ; second the avoidance of recurrent appendicitis, and third the diminution of the risks of hernia.

The *preparation* for the operation by the surgeon, if the patient be not in hospital, involves in the first place obtaining the best nurse to be had, since her services will not only be required during the operation but will accordingly be of the greater importance in the after-treatment. A trustworthy assistant to stand opposite the operator is essential to the best work, to aid in preventing escape of pus into the uninfected abdominal cavity, to arrange sponges and keep them warm, to prevent breaks in the chain of antiseptics, to place and hold retractors, etc. An operating table must be provided suitable for the application of the Trendelenburg principle, if conditions are present before or arise during the operation to make it desirable. An ordinary kitchen or dining table will do in an emergency if the patient's feet are fastened to the end in such a way as to prevent his slipping toward the head of the table. A box or chair placed under the end of the table will raise its feet sufficiently. Elaborate preparation of the patient is usually impossible for lack of time. The cleansing and disinfecting of the skin should not be done in such a way as to jeopardize the integrity of the abscess wall if adhesions have taken place. Transportation of the patient even to a neighboring hospital is an extremely hazardous procedure. Every jolt and jar causes the patient to suddenly contract the abdominal muscles, menacing the normal peritoneum with a flood of infectious matter from perforated bowel or abscess.

The *position of the patient* should be subject to the varying demands of the operator as modified by the pathologic conditions encountered. Should pus be met with at the pelvic brim it may be necessary to prevent its flowing into the pelvis by quickly tipping the patient into the Trendelenburg posture. If the pus tends to flow toward the median line the patient may be rolled upon the right side. These two maneuvers may be practiced simultaneously if desired. The site of the incision must depend largely on the site of the appendix and the morbid anatomic conditions present. It must be so located as to give the most free and direct access to the seat of disease, except where we desire to avoid opening the free peritoneum. The median incision has been discarded except for the rare cases in which the cecum and appendix lie behind the linea alba.

The most rational *method of opening the abdomen* when the appendix lies in one of its more usual positions, is that of McArthur and McBurney. McBurney recommends that the skin incision, about 4 inches

long, should cross a line drawn from the anterior iliac spine to the umbilicus nearly at right angles, about 1 inch from the iliac spine, and so situated that its upper third lies above that line. The aponeurotic structures are divided with the knife, but the muscular fibers are separated by blunt dissection. In this way a wound is produced at whose edges are muscular fibers running in different directions. These fibers, held apart by retractors during the operation, close the wound almost perfectly when the operation is finished, by overlapping. Unfortunately this method can not be applied except where an abundance of good assistance is at hand and where the wound need only be a small one. The general principle involved should be respected in all incisions involving the lateral regions of the abdomen, *i. e.*, the direction of the incision should follow the general trend of the fibers of the external oblique muscle and the fibers of muscles should be cut as rarely as may be possible. In this way nerve trunks may be avoided. It is to avoid nerve injuries that Kocher recommends our making only transverse or slightly oblique incisions except in the median line. Hence the old Langenbuch incision at the side of the rectus muscle, and the various longitudinal incisions over the colon must be given up. With Kocher's recommendation we must heartily agree, partly because the nerves supplying the rectus muscle should be held sacred, for fear of weakening that part of the abdominal wall by paralysis, but chiefly because the oblique incision gives perfect access to all ordinary foci of appendical inflammation and at the same time making the wound parallel with the general traction lines of the abdominal muscles prevents yawning of the wound and diminishes the tendency to hernia at the seat of operation.

The *length of the incision* must be adequate for all the manipulations required in the abdominal cavity. The wound should always be long enough to facilitate and not to retard intra-abdominal work. There is no essential advantage in operating through openings of especial shortness. On the other hand, making the wound unnecessarily long conduces to prolapsus of intestines and increases the liability to hernia.

Before going further a few *diagnostic points* demand brief consideration, since they concern most intimately the manipulations to be undertaken later. They are as to the site and the morbid anatomy of the appendix and of the adjacent structures. No diagnostic study of a case of appendicitis can be considered complete until these points are if possible determined. The *site of the chief pathologic activity* can be determined in the majority of instances, especially when a tumefaction exists or when tenderness is found. To discover these signs a *rectal* or vaginal examination *should never be committed* since a pelvic location or extension of the inflammation is by no means rare.

[I can not agree with Fowler, who says, "Generally speaking, it is not possible to demonstrate by means of a rectal examination in these cases anything which can not be made out much more satisfactorily by external examination; if the examining surgeon is to be the operator in the case he will do well to keep his finger out of the rectum." In several instances I have been able to make or to strongly confirm the diagnosis by this mode of examination; while in other cases the exact site of the primary or secondary focus has been made out.]

Pain at the end of urination is a sign of much value

in the diagnosis of inflammation of the vesical peritoneum.

In the cases of the gangrenous appendicitis, or in the perforative cases in which diffuse peritonitis takes place, the absence of a tumefaction and the presence of widespread tenderness makes a *diagnostic localization of the appendix* impossible.

A preliminary determination of the *relation of the inflammatory focus to the ascending colon* and to the ileum is also of great import. These structures, ileum and colon, act as barriers, water sheds so to say, tending to limit or retard the spread of inflammatory fluids. Abscesses to the outside of the ascending colon generally occupy a position well toward the flank and tend to extend as they grow larger toward the renal and hepatic regions. Moreover the tympanic colon can often be detected by percussion, nearer the median line.

Inflammatory activity *below the mesentery of the ileum* tends to extend into the lesser pelvis and can often be located by rectal or vaginal touch. Our gravest apprehensions are excited for the patient's recovery when the site of inflammation is *mesial to*

brought about much adhesive proliferation. On the other hand, acute and violent symptoms lead us to suspect no such delimitation of the process by adhesions. And combining these general propositions, an inflammation which has existed for some time, but which has at the last advanced by sudden exacerbations, may be suspected to have become limited at first, but to have extended later by successive fresh invasions of previously normal serous membrane. Uncertainty in respect to the state of these new-formed barriers to the spread of inflammation is greatest between the third day and the end of the first week. No reliable diagnostic signs are as yet at our disposal to aid in deciding this important clinical question. Our efforts result only in a prediction of probabilities. From signs of violent activity of the disease, we assume the local extension of the inflammatory process. A tumefaction not apparently enlarging, in the presence of mild general symptoms, would of course suggest the limitation of the process by adhesions.

Fig. 1.—A B, Poupart's ligament; A, anterior superior spine of ilium; A C, line joining umbilicus and anterior superior spine; D E, line of incision recommended by McBurney, parallel with the course of the fibres of the external oblique muscle and its aponeurosis.

the ascending colon and above the mesentery of the ileum. The percussion relations of the colon are here of some value, but our chief dependence must be upon the situation of the tumefaction and tenderness well toward the median line.

The abnormal positions of the appendix are usually not determinable before operation unless the focus of inflammation can at once be located at a point remote from the usual site of the caput coli and be recognized as appendical.

The Morbid Anatomic Conditions to be encountered can be determined before operation only to a limited extent. It is partly on account of this very uncertainty that appendicitis operations may prove far more difficult after the abdomen is opened than they appeared beforehand.

The duration of the inflammation and the size of the tumefaction are points which often, not always, give a suspicion of the morbid changes to be encountered. Obviously a suppurative process of long standing (one to three weeks) can be considered to have

Fig. 2.—To show the appearance of the gauze strips before they are turned over to the right side of the patient's body.

Edema of the skin is usually an indication of the adhesion of the abscess to the abdominal wall and the operator in that case has the opportunity of simply draining the abscess without even seeing the free peritoneum. In one case I was able to push about in the abdominal cavity the caput coli with the abscess mass for a distance of three-quarters of an inch in each direction. The operation disclosed the fact that the omentum covered the coils of adherent intestines enclosing the perforated appendix. And as the omentum was not inflamed upon its anterior surface, the whole mass could be slipped about by external pressure.

An additional subject upon which to exercise our diagnostic acumen in future is as to the *amount of tension* present in the abscess-cavity. Much prognostic importance would attach to this knowledge if we could in any way gain it. Unfortunately we can only draw from our clinical study the vaguest inferences on the subject.

Having decided, as nearly as possible, these pre-

liminary diagnostic points we have to ask ourselves, *what is the technical task before us* when we undertake an operation for acute appendicitis. It is, we may say briefly in answer, to expose and drain an area of serous membrane surrounding the appendix, which is infected, usually with enormous quantities of bacteria of many species and often of the utmost virulence acting with the aid of most irritating fluids. If this were all—if the damaged tissues and the invading microorganisms lay beneath the skin or even immediately below and in contact with the abdominal wall, the case would be surgically simple. But this drainage has to be effected over a membrane the progressive infection of which means death to the victim of the disease.

Of what properties of this delicate serous membrane can we take advantage in attempting a practical solution of the difficulties to be met? First, our most important aid, our ever present help in time of need, is the enormous resisting power of infection presented by the peritoneum. No other tissue in the human body can so powerfully annul the pathogenic power of bacteria or so quickly and effectually remove disease producers as can the peritoneum. One-tenth the filth often cast into the peritoneal cavity without

Fig. 3.—To show the relation of gauze strips to the cecum (A) and the stump of the appendix (B), when the appendix lies between the cecum and the outer abdominal wall.

harmful results would cause fatal infection in the cranial cavity. In operating for appendicitis under the conditions assumed, we take advantage of this resisting power of the peritoneum and *deliberately inoculate a portion of the serous membrane*. Inoculation, however, is fortunately not always tantamount to progressive infection. But traumatism, such as mechanical and chemical irritation, drying and cooling of the serous surface, tend to diminish resistance. These things can not be wholly avoided, and for that reason it is strongly urged that these operations are not, as is so often maintained, devoid of danger or even only slightly dangerous.

Our main surgical resource is found in *drainage by capillarity*. In the unopened abdomen the normal serous surfaces are not separated from one another by layers of gas or ordinary air. They lie in contact with one another, lubricated by a thin layer of serous fluid. A foreign fluid poured out between these surfaces is disseminated with extreme rapidity, partly by the action of gravity, but chiefly by capillary action. This force, which lifts the sap to the tops of the highest forest trees, is aided also by the vermicular action of the intestines. When about to open a *dépôt* of infectious matter it has been the usual custom to pro-

tect the intestines from contact with this material by means of large compresses. When the infected cavity has been evacuated as well as possible, the compresses were removed and pieces of gauze applied in their place to be left as drains, with the purpose of opposing the capillary action between serous surfaces and the action of gravity with the capillarity of the cotton fibers. I wish to urge the *preventive* application of this capillary drain. Before defilement has taken place in that part of the peritoneal cavity lying between the anterior parietal serous layer and the *dépôt* of infection, the operator should apply gauze sterilized and, if not required in too great quantity, iodoformed, in such a way that it will attract fluids away from the intestinal interstices and not into them. This gauze, instead of the peritoneum beneath it, must henceforth be the surface to be protected by gauze compresses. The ends of the pieces of gauze are to be inserted into various spaces, as will be dwelt upon later in order to prevent by occlusion as well as by capillarity the dissemination of poisonous fluid. The strips of drainage gauze are not to be replaced by fresh gauze at the close of the operation for three reasons, to wit: 1. The repeated manipula-

Fig. 4.—To show the application of the gauze when the appendix (B) lies in the midst of the small intestines, to the left of the cecum (A). This and the preceding drawing were made from photographs of frozen sections made by the writer after having performed the operation described in the text upon the cadaver.

tions of the intestinal serosa favor the ingress of the bacteria into the tissues. 2. The handling of the parts transports bacteria to previously clean areas. 3. The gauze, if properly applied, will carry outward, through the very long strips employed, the infectious matter contaminating their surfaces, which has escaped the carefully applied gauze compresses, that of course have been replaced as often as desired by the operator.

It is maintained by Gubaroff that the beneficent action of the absorbent gauze extends a distance of two and one-half inches on each side of its margin. This must be at least approximately true, since by no other assumption can we explain why capillary drainage enables us continuously to withdraw infectious fluids across the serous membrane without wide-spread inflammation. A recent autopsy by Dr. Fuetterer upon a case of my own, operated upon after general peritonitis had set in, confirms Gubaroff's opinion, Dr. Fuetterer says that for at least a distance of two and one-half inches on either side of the gauze the peritoneum presented all the evidences of recovery from the violent inflammation.

For practical purposes it is of the first importance for the operator to decide before operation whether he has to deal with: 1, a morbid process not mechan-

ically limited. 2, a pus *dépôt* shut off from the uninfected peritoneum by delicate adhesions; or 3, a well marked abscess-cavity without strong adhesions.

Once a positive diagnosis of appendicitis has been made a probable determination of these morbid anatomic points must be reached by consideration of the points already mentioned, the most important of which is the duration of the disease. In a first attack of moderately severe perforative appendicitis effective adhesions may be considered absent up to the fourth day. Between the fourth and tenth days the bands of new connective tissue are becoming resistant and may be utilized in the operative treatment. After the tenth day the abscess (if it has not enlarged by successive ruptures) may be expected to have strong walls, requiring distinct pressure to break them down.

TECHNIQUE.

In the absence of adhesions, the proper preparations having been attended to, an incision is to be so made as to place the operator in full command of the region involved. It is important that the incision be made long enough before manipulations are begun within the abdomen. This having been accomplished, the first thing to be done is to apply a gauze barrier about the

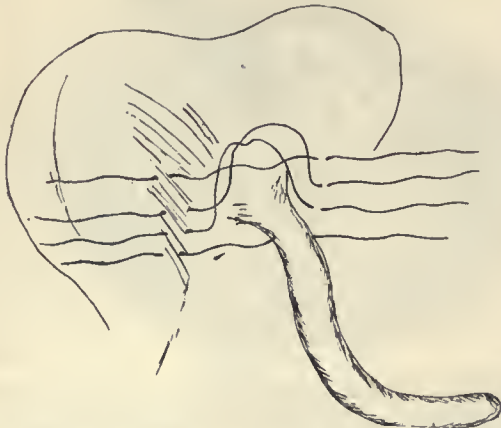

Fig. 5.—Lembert sutures applied before the appendix is cut off.

wound, so that exudate and feces may not soil the normal peritoneum. For this purpose, strips of plain sterilized gauze and of iodoform gauze will have been prepared by the nurse, two and a half inches wide, fifteen to eighteen inches long and four layers in thickness. The iodoform gauze will be used for all packing if the quantity required is not so great as to threaten iodoform intoxication. If this is feared plain gauze will be used for preventive packing and the iodoformized material reserved for the immediate drainage of the disease focus. An assistant now places a large dull-edged retractor under the abdominal wall at the edge of the wound and by strong traction perpendicularly to the abdominal parietes lifts the wall upward and away from the intestines. The operator then pushes the end of a ribbon of gauze under the abdominal wall between the parietal peritoneum and the intestines for a distance of one to three inches, in a direction at right angles to the line of incision. This piece of gauze is to be flattened out rather neatly. The retractor is now moved aside in either direction for a short distance and another piece of gauze inserted by the side of the first one, with whose edge it lies in contact. This process is repeated if free peritoneal surface surrounds the wound, in every direction, so that as the operator looks into the

wound, the edges of the incision are seen to be covered by gauze extending out into the abdominal cavity. If the inflammatory focus lies in contact with the lateral parietes, the gauze barrier must be applied with great care to prevent infection of the pelvic cavity below or the hepatic region above. For this purpose the incision must be low enough to enable the operator to get well below the appendix. Strips of gauze are then passed down toward the pelvic brim until the surgeon is sure that this avenue of infection is reasonably well closed. This maneuver may be facilitated by the temporary use of the Trendelenburg position. Equal care must be taken to guard the hepatic fossa by a similar method. For, while a patient may escape with his life, if this large area be infected, since it is in a sense isolated from the rest of the peritoneum, the extent of the surface is so great that even the primary intoxication due to flooding with feces and pus is of most serious import, especially as the chief resorption area of the peritoneum, the *centrum tendineum* of the diaphragm, is located here.

The object of this packing is, 1, to prevent as far as possible infection of the peritoneum when the disease focus is disturbed; 2, to set up enough peritoneal irritation to determine a serous discharge, so that outward capillarity along the strips of gauze may conduct infectious matter away from the free peritoneum²; and 3, to favor the formation of adhesions

Fig. 6.—Lembert sutures tied after removal of the appendix.

about the tract through which drainage is to be effected.

The second step has for its purpose the finding of the inflammatory focus and its immediate treatment. The operator carefully covers the visible parts of the gauze strips with gauze compresses wrung out of warm (105 degrees F.) salt solution, and with the edges of these compresses he presses aside loose coils of bowel until he reaches the seat of most active disease. If the location of the offending part has not been determined by palpation before operation and if a real search is necessary the longitudinal muscular band of the colon is an infallible guide, leading the surgeon at once to the seat of trouble. The appendix having been found, a quantity of feces, pus or sero-pus will gush upward almost invariably and must be caught on compresses, which, as fast as they are replaced by fresh ones, must be carefully discarded to prevent their being used again. The cecum is not to be lifted from its original site, if by so doing the least additional danger of infection is to be incurred. Before removing the appendix the operator carries his strip of gauze packing well down to the infected region surrounding the dangerous area, thus completing the well of gauze through which the work is done. Far

² See paper by the writer, Amer. Obstet. and Gyn. Jour.

better would the surgeon leave the base of the appendix closed by a strong catgut ligature at the bottom of such a well protected cavity, than by lifting out the cecum from the wound, spread the virulent bacteria often present over uncontaminated serous membrane. But if the cecum can be thus lifted up without risk of infection, *i. e.*, without risk of pouring infectious matter into parts of the peritoneal cavity unprotected by adhesions, a piece of gauze is slipped under it, the appendix is amputated by incision between a thin but strong temporary ligature on the proximal side and a compression forceps on the other. The projecting mucosa is then touched with a drop of carbolic acid and a row of Lembert sutures passed from side to side over the stump of the appendix. These sutures are not tied until the temporary ligature has been removed. But when this has been done the stump is inverted into the cecum and the Lembert sutures knotted. A second row of sutures may be placed if desired. This elaborate technique is rarely practicable in acute appendicitis.

Hemorrhage from the arteries of the mesenterium is controlled, if need be, by ligatures or suture ligatures. If the cecum has not been lifted, drainage of the deeper cavity is effected by some additional strips of iodoform gauze and, if the operator chooses, by a tubular drain. If it is found that the infectious fluid has already traveled between the intestines in any direction or to any extent, it is carefully followed with sponges, cleansed away by gentle pressure with gauze sponges and gauze drains left in contact with the infected serous membrane. The practice of lifting extensive masses of intestine from the abdominal cavity to clean them seems to me illusory. They are much better treated by surrounding them with gauze drains which can be subsequently removed, if necessary under anesthesia. The ends of the gauze strips are to be left very long so that they may hang over into hydrophile dressings at the side of the patient, since the writer has shown that the dependent part of the gauze strip delivers fluid partly by gravity and partly by capillarity at an exceedingly rapid rate, thus enabling the intra-abdominal portion of the strip to lift fluid against gravity without the embarrassment of imperfect delivery upon the surface of the abdomen. This method of placing the gauze drains almost all the fluid to the patient's side. I have often found the gauze and cotton dry at a distance of two inches from the wound on the left side, while on the right side of the body toward which the strips were directed, not only the dressings but the bedding and mattress were soaked with exudate.

The last step consists in the partial closure of the wound. The point at which the drains are to project is determined, the gauze being made to emerge in as short a line as possible from the site of inflammation. Silkworm gut or silver sutures are inserted above and below the drainage opening and tied. The same material is to be used for secondary sutures, the threads being introduced at the sides of the gauze mass but not tied until the drain is removed.

It is *when adhesions exist* in easily recognizable degree and mass but while they are still easily broken down by the finger-tip that the technique is as yet farthest from being settled. All are agreed that the appendix is to be removed if it be near at hand on exposing the focus of inflammation. Others say it may be removed if in the operator's opinion this can be done without breaking down the abscess wall; some say

if the appendix do not constitute a part of that wall.

Shall we remove the inflamed appendix at all hazards, as advised by still another set of clinicians? There is at present no more popular clinical problem in all surgery or one, perhaps, better worth consideration. Some bold operators say it is always to be removed; that operations without its extirpation are "incomplete;" that undiscovered abscesses may be left undrained; that recovery is slow; that fistulae and sinuses remain and recurrences are to be expected. Unfortunately statistics can not help us at present, for our clinical classification of cases is so poor that a reported death rate of 15 per cent. by one operator may be an index of no better work than would be indicated by a mortality rate of 20 per cent. by another man whose run of cases is different. Of course the man who operates on all cases, even the mildest, will make a better showing than will he who chooses for the knife only those of well marked severity. He who gets his cases on the third day will have a brighter list than will the man whose patrons call him in council on the fourth. Statistics of appendicitis operations indiscriminately gathered furnish no trustworthy information.

The question that arises in our minds when we approach our cases of appendicitis for operation is, How can we operate to save life? All other questions are secondary. All considerations of surgical nicety and personal satisfaction must give way. What is the main anatomic object to be accomplished by operation *when adhesions have formed?* You will agree that it is to relieve by outward drainage the tension in the abscess cavity—to make a safety-valve. When this has been properly done our chief excuse for interference is exhausted. Further work in the abdomen is dangerous. To what extent is it justified by securing to the patient immunity from other ills? The "aggressive" surgeon says, if we do not find the appendix we may leave a secondary abscess unopened. The "conservative" operator replies that secondary abscesses do not very frequently occur; that he does not consider removal of the appendix necessary to the discovery or drainage of the secondary abscess; and that the manipulations necessary to effect extirpation necessarily disseminate pus and, by injuring the peritoneal surface, invite infection. The aggressive man urges that recovery is prolonged if the offending member is not plucked out, that fistula or sinuses may remain, and that the patient is exposed to recurrences. His opponent argues that even if the first statement is correct, a few more days spent in bed can not be so serious a matter as the additional operative risk; that fistulae and sinuses do not often occur, and can be cured with comparative safety by an operation instituted when virulent pus has well nigh disappeared; that tenderness and occasional pain over the appendix region will usually warn the patient after the acute attack is over, if a chronic inflammation exists which is capable of being lighted up into a new acute attack, so that the part may be removed during the quiet stage. The percentage of recorded recurrences after drainage seems to be small. Fitz placed it at 11 per cent. No one should underestimate the value and satisfaction of leaving the patient freed of the dreaded appendix; but it seems to me we should not too strongly urge the operator, especially if inexperienced, to go too far toward this ideal. The conservative ground is here the safest to advise. Remove the appendix when you feel confident that by so doing

you will not scatter pus or destroy the wall of adhesions which encloses the *dépôt* of infection. Success in these operations depends largely on the use of a proper system of gauze packing. On opening the abdomen the wound is first carefully surrounded with gauze strips, as already described, passing between the abdominal parietes and the superficial layer of intestines wherever they are not adherent. The next step consists in the application of the gauze about the coils of intestine which are matted together to retain the infectious material. The operator should palpate with the utmost gentleness to ascertain what portions of bowel are non-adherent and therefore to be isolated from those nearest the appendix by the protective packing. These deeply seated strips of packing material are to be carried well back to the posterior parietal layer of peritoneum. They must touch one another from side to side and must be spread out evenly. All knots and coils of gauze must be avoided with great care. This can be accomplished most easily where the end of each gauze strip can be carried to its destination on the tip of the finger. No strip is to be folded longitudinally upon itself in order to fill up cavities. When spaces are to be filled in, additional pieces of gauze are to be used, each one coming to the surface of the abdomen by as a direct a route as possible. The infected area is not to be encroached upon for any purpose, diagnostic or therapeutic, until the peritoneum is protected by gauze. Once the operator is sure of his protective gauze the infected area is to be opened and drained. This is done deliberately by working the finger gently between the adherent coils of intestine until the exudate is reached. Direct drainage to the cavity is then affected by a strip of gauze which may enclose a tubular drain if the operator desires. If removal is not practicable, the intestines are carefully retracted with gauze compresses or strips and the drains inserted deeply enough in the track of the pus to assure the operator with reasonable certainty that no pockets of pus are without a vent. It is much safer to carry the drainage down to the appendix itself, even if it is not removed.

The location of the inflammatory focus with reference to the great barriers to the spread of infection is of the first consequence in estimating the safety and justifiability of these manipulations.

Foci situated between the ascending colon and the right lateral abdominal wall offer conditions relatively very favorable to manipulation, since the colon acts as a watershed to turn the course of infection from the main part of the abdominal cavity. Before opening such a focus the surgeon takes care that the space between the anterior surface of the colon and the abdominal wall, if not obliterated by adhesions, is protected by gauze strips and that the upper and lower boundaries of the infected area are well protected by packing to prevent the infectious matter from traveling upward toward the liver or downward toward the pelvis. This technique needs but slight variation when the appendix lies farther down *i. e.*, in the internal iliac fossa.

It is when the inflammatory disturbance lies mesially to the colon and above the ilial mesentery that the greatest difficulty exists in protecting the peritoneum during the operation and in draining adequately afterward. In the language of Harris, "However well we may pack around with gauze, it is often impossible to prevent pus escaping into the general

cavity with a resulting fatal peritonitis."³ Presupposing that adhesions are slight or altogether absent, it is absolutely essential that the patient be placed upon a table which can be adjusted to the Trendelenburg position. The pelvis being elevated, the abdomen is opened, the gauze strips having been adjusted as usual about the wound, aseptic compresses are so placed as to receive any infectious matter emanating from the appendical region, and if any adhesions are present at all, the most delicate manipulations must be made in order to leave them intact and a drain of gauze, with perhaps also a tubular one, is to be passed down to the appendix. Should delicate adhesions be disturbed peristaltic action may carry the liberated small intestines to a distant part of the abdomen in a few hours together with the actively infectious matter adherent to their walls.

It should be mentioned that transperitoneal drainage has often seemed to various surgeons more hazardous than direct drainage of pelvic accumulations through the vagina or rectum. One of these routes may occasionally be used with advantage. If the inflammation has existed for a length of time sufficiently great to allow strong adhesions to form, binding an abscess wall to the abdominal parietes, it is the surgeon's duty to seek the most direct route to the abscess interior, the incision through the abdominal wall being made in such a way that the free peritoneum will not be injured. When abscesses are situated in the right iliac fossa adhesions will oftentimes be firm between the walls of the abscess and the outer abdominal parietes, even though the anterior wall be free. The incision in such a case should be made well to the outside of the focus of inflammation or even in the lumbar region.

The gauze drain should not be removed until five to eight days have elapsed, giving ample time for adhesions to have walled off the infected area.

AN IDEAL SUTURE FOR THE CLOSING OF ABDOMINAL INCISIONS, CUTS ON THE HANDS, FACE AND BODY GENERALLY.

BY W. H. HAUGHEY, M.D.

BATTLE CREEK, MICH.

The ideal suture is one that, first, can be most readily and easily introduced; second, that holds the parts in perfect apposition with the least possible interference to the circulation of or at the edges of the wound; third, that is the least apt to become septic; fourth, that requires the least possible amount of suture material; fifth, that leaves the least possible scar; sixth, that can be relied upon to fulfill these requirements and after fulfilling them, can be removed.

The old interrupted *en masse* suture, while fulfilling the first requirement of introduction well enough, utterly fails in all the rest except the last, *viz.*: removal, for by including the tissues from one-half to one inch on each side of the wound and tying them, the circulation is materially interfered with, thus preventing healing and promoting sepsis by reducing the blood supply and depriving nature of its best means of keeping the wound disinfected and promoting its rapid repair.

The buried animal suture is objectionable because

³ See the admirable paper of Harris, *Journal American Medical Association*, Dec. 1895.

of its proneness to become septic despite our very best efforts at cleanliness and antiseptics.

In silkworm gut and silver wire we find the nearest approach to the ideal suture material that science has yet produced; either can be rendered aseptic and when so rendered, are almost absolutely non-irritating to living tissues. The problem is to so introduce them that they will meet the six requirements above stated. I have solved this problem thus: With a straight, sharp-pointed needle about one and three-quarters to two inches in length, threaded with silkworm gut (of the very best variety), I begin at the lower angle of the peritoneal incision on the left side, and with a simple spiral continuous suture rapidly close the entire peritoneal cut, bringing the end of the suture out about one and one-half inches above the upper angle of the incision in the skin, pass it through a thin aluminium plate and fasten by means of a perforated shot, then threading the needle on the other end, bring it out and fasten in the same manner about the same distance below the lower angle of the wound. Do not make too much tension, but fasten just tight enough to avoid a slack suture.

In exactly the same manner introduce the suture in the muscular aponeurosis; here you may, if the cut

is long, with advantage use silver wire about No. 23 or 24, as it is probably stronger, and can be left as long as necessary with no danger of disintegration, though I have left silkworm gut five weeks and had no trouble in this respect. The skin suture is introduced in the usual manner of a buried skin suture. Fasten ends same as the other two. It will thus be seen that the first or peritoneal suture will be the longest and will be fastened farthest from the extreme angle of the cut at each end; the muscular suture is second longest and fastened in the center at each end, the skin suture shortest and fastened nearest the incision at each end.

No difficulty will be experienced in removing either the peritoneal or skin suture if they have been properly introduced; simply grasp the shotted lower end, lay the open blades of the scissors on the aluminium plate, draw on the suture, make counter pressure with the scissors until about one inch of suture is withdrawn, then clip, grasp the other end and draw the long or remaining end of suture out. The muscular suture will be found to offer, in many cases, much resistance, and if too strongly pulled on will break. This is not necessary. Simply draw what will come easily and fasten by means of a split shot and wait

twenty-four hours, when you can easily draw more; fasten and leave again, and so on until the entire suture is removed.

I have also been using this suture for the past year in cuts, wounds and operations about the face, hands, or any part of the body. It leaves the least possible scar, offers the least possible interference to circulation, thereby promoting the healing process; can be left as long as you wish, can be readily and easily removed, and in fact possesses all the requirements as yet known to man of an ideal suture. Only the very best, smoothest and strongest silkworm gut should be used. This suture was exhibited to the Calhoun County Medical Association in Albion, January 14, 1897.

REPORT OF A CASE OF CHRONIC NEPHRITIS COMPLICATING PREGNANCY, LABOR AND THE PUERPERIUM.

Read at the meeting of the Obstetric Staff of the Chicago Health Department, Nov. 2, 1896.

BY LAWRENCE H. PRINCE, M.D.

CHICAGO.

I regret very much that more accurate observations were not made in this case, and also that many of the notes recorded were lost. However, I trust that the main facts as here reported will be of interest:

Mrs. H., of Irish descent, a bright, intelligent woman, 28 years old, I saw for the first time the latter part of December, 1895. She gave me the following history: As a girl she was always well and strong. She became pregnant shortly after marriage and the child was stillborn at term. When four months pregnant with this first child she began to suffer from sleeplessness, dizziness, edema and momentary attacks of blindness. After the seventh month all these symptoms became aggravated. The edema was general, even extending to the lips and to the tissues of the back. The lips and finger nails were often cyanosed. The urine was scanty throughout pregnancy. Labor was rapid, lasting about an hour, and unaccompanied by convulsions, or any other complications that the patient knows of. There was severe epistaxis, lasting one hour, the day following labor. Patient remained in bed three weeks, the edema gradually disappearing. She got up anemic, emaciated and weak. Her general health improved and there were no further subjective symptoms of kidney disturbance. Menses returned in two months.

Three months after the birth of her first child she again became pregnant. She remained in fairly good health up to the sixth month. From this time on she suffered as she had during her first pregnancy, though less severely. She was delivered of a living child at term, the labor lasting two hours. There were no complications at time of labor and for one week the puerperium was normal. She then had a chill, followed by three days of fever and abdominal pain. She remained in bed for three weeks, getting up weak and anemic, but improved rapidly afterward for a few months. She nursed her baby for fourteen months, the child growing stronger and the mother weaker after six months. After weaning the baby she became stronger. The child is still living and robust. Menses returned after the weaning of the child.

The patient's third pregnancy began eighteen months after the second child was born. She aborted

at three months. There was no edema prior to the abortion, but she had frequent "weak spells" and attacks of dizziness. Immediately afterward she suffered from nausea and vomiting and attacks of weakness, and had rather a severe hemorrhage after seven days. She did not fully recover from the results of this abortion for three months. Menses remained regular and patient's health remained fairly good for two years, when she became pregnant for the fourth time. This, the fourth pregnancy, began in October, 1895. At the time of her first visit to me she was about three months pregnant and in fair health. During the second week in January, 1896, she suffered from a severe attack of quinsy. A couple of weeks later her husband died of pneumonia complicating typhoid fever. During the ten days of his illness Mrs. H. assisted in the care of her husband and she received very little rest or sleep. I did not see the patient after this until she was six months pregnant, that is, in April, 1896. She said she had been feeling fairly well up to within a few weeks, and that she had voluntarily placed herself upon a diet consisting largely of milk, knowing from past experience that such a diet was best for her. Her feet and legs were becoming more and more edematous and she had begun to suffer from headaches, sleeplessness, dizziness and occasional momentary loss of vision. Examination of her urine at this time, and at intervals afterward, showed generally less than one litre passed in twenty-four hours, with a diminished amount of total solids and of urea. There was always present considerable albumin and large numbers of waxy and granular casts. There was also some pus in each specimen of urine. The treatment consisted in placing the patient upon an almost absolute milk diet, laxatives, and an occasional sweat. Her condition remained nearly stationary until two or three weeks before labor began. The old symptoms became aggravated with temporary relief after a profuse sweat or catharsis. Edema of the neck was especially marked, although there was no portion of her body that was free from swelling. On account of the edema of the neck there was difficulty in lying down, the patient thus securing little rest.

Labor came on the night of July 14, 1896, lasting but an hour, although there had been for a few days occasional preparatory pains. Aside from extreme nervousness and considerable muscular twitching, the labor was normal in every respect, and a living, though small and feeble child, weighing four and one-half pounds, was born. A few hours after labor, the patient was catheterized and the urine thus secured found to contain 5 grams of albumin to the litre. During the first few days of the puerperium the edema became gradually less, the patient's temperature remained normal, and the lochia was normal in amount and character. Patient complained of no pain and was quite cheerful, but slept little and was restless. She was very anemic. The urine was scanty, highly albuminous and deficient in urea and other solids. From two to four copious watery stools were produced daily by means of cream of tartar. A strictly milk diet was adhered to. At 3 P. M. of July 16, the third day of the puerperium, patient had a severe chill lasting about fifteen minutes. At the completion of the chill the temperature was 101.6 degrees F. The chill was almost immediately followed by profuse perspiration and by 6 P. M. the temperature was normal. The following two days the

patient's condition was practically the same as it had been prior to the febrile attack. On the morning of July 19, the sixth day of the puerperium, patient had another chill, lasting a full hour, the temperature at the end of chill being 104.5 degrees; pulse rapid. Profuse perspiration followed almost immediately, with rapid lowering of the temperature. An examination of the blood was made with a negative result, except that on one slide was found a single body bearing a strong resemblance to a malaria plasmodium. The spleen was very much enlarged. There was no headache, no abdominal nor pelvic pain nor tenderness, and the lochia was normal. There was no pain on micturition. In the absence of evidence of cystitis, or of pelvic inflammation, a provisional diagnosis of malaria was made, and accordingly quinin was administered, 2 grs. every two hours. At 3 P. M. of the same day, July 19, patient had another paroxysm, this time the temperature reaching 105 degrees, which again subsided in a few hours to 101 degrees. The urine was scant and contained 7 grams of albumin to the litre. On the following day the patient had three or four paroxysms, the chills becoming less severe with each. The temperature rose to 106 degrees the afternoon of this day, apparently without affecting the patient's general condition more than as already stated. The lochia ceased the next day, July 21. After this the daily temperature curve ranged between 100 and 104 degrees, sweating following each rise, which occurred from two to four times during the twenty-four hours. There was a gradual lowering of the temperature curve from day to day and the normal was reached at the end of the third week of the puerperium. The lochia reappeared before the temperature reached normal. The odor was faint and free from evidence of putrefaction.

About July 24, the patient complained of some pain in the right side below the ribs. An examination showed an easily palpable right kidney, enlarged and a little tender.

Up to this time the urine remained scanty, the amount for twenty-four hours varying between 250 and 750 c.c., containing much albumin but little pus. On July 24 there was an increase in the amount of urine and a sudden increase in the amount of pus, which was at first large and then gradually diminished. There was also an increase in the amount of total solids eliminated. There was some edema of the lungs and an irritable cough, worse at night, resembling whooping cough, from which her son was suffering.

The patient's general condition gradually improved; she soon was able to sleep better, and in three weeks was able to change from her bed to the couch. However, she remained emaciated and anemic for some time after. On the first of August her urine contained 1 per cent. of albumin, considerable pus and granular casts.

The patient works every day at her business, that of hairdresser and manicurist. She is living on a non-nitrogenous dietary, as for seven months past, and is slowly improving in strength and flesh. She has occasional spells of dizziness and blindness, nevertheless. On Nov. 13, 1896, she passed 1024 c.c. of urine, acid reaction, sp. gr. 1015, containing 1½ per cent. albumin, 10 grams urea, some pus and a few granular casts.

The child, which has been bottle-fed from birth, has made a desperate struggle for existence, and now

after four months, gives fair promise of making a success of it.

After a careful study of all the facts in the case, I feel confident that the puerperal febrile disturbances were due to pyelitis complicating chronic nephritis.

51 Lincoln Ave.

OPERATIONS FOR THE RADICAL CURE OF HERNIA IN PERSONS OVER SIXTY YEARS OF AGE.

BY A. E. ROCKEY, A.M., M.D.

PORTLAND, OREGON.

Illustrative case.—Man aged 72. Ruptured forty years. Retention with truss always difficult and painful. For two years the hernia had not been reduced and had grown to enormous size. During examination the intestinal portion, representing about three fourths of its bulk, was reduced by taxis with some difficulty but an omental portion remained irreducible. A truss was adjusted but the hernia could not be retained. The man had chronic bronchitis and the paroxysms of coughing soon sent the intestine under the truss. Radical cure by operation was recommended and accepted. Previous to operation the patient was kept in bed for two days and the cough much allayed by an anodyne mixture.

Chloroform was administered, the sac opened and a large mass of omentum, the lower end of which was firmly incarcerated in a small pouch, was removed after ligation with fine silk. The operation was finished after the manner of Bassini, using silk ligature and sutures. The patient made a rapid recovery and now after ten months the hernia remains perfectly cured and the general health, comfort and ability to exercise are much improved. No truss has been worn since the operation.

Appended to this article is a table of 144 cases, most of them unpublished, for which I am indebted to the courteous letters of surgeons I have the pleasure of meeting personally, both in this country and abroad. The list will suffice to illustrate the purpose of this paper in pointing out the advisability of the more general adoption of operative treatment for the radical cure of hernia in persons whose disability from rupture increases with advancing age. Under what circumstances should an operation for the radical cure of hernia be performed in the aged? It will be almost universally admitted that when strangulation makes herniotomy necessary it should be followed by an operation for radical cure except when contraindicated by gangrene or exhaustion. Beyond this point there is a wide divergence of opinion as to the propriety of performing operations for radical cure in the aged.

Jonathan Macready in his most admirable "Treatise on Ruptures" says in describing the indications for radical cure operations, "Whatever divergence of opinion there may be as to the kind of cases which call for an operation there is none in regard to the unfitness of aged and cachetic individuals." On page 367 of the same work is a table, the perusal of which may well suggest the question as to whether we have as surgeons, done our whole duty by the aged when we have dismissed them with this dictum, and then wait for them in the hospital, until the occurrence of strangulation removes all doubt as to the absolute necessity of operation.

This table is compiled from the statistical reports of St. Bartholomew's, St. Thomas', St. George's and the University College hospitals, for varying periods during twenty years and comprises in all, the records of 1063 operations for strangulated hernia.

Of these 749 were under 60 and there were 525 recoveries leaving a mortality of about 30 per cent.

There were 314 strangulated hernias in persons over

60 requiring operation for relief and but 146 recovered, leaving a mortality of 53 per cent. Observe the greatly increased mortality in the last class. A considerable part of this table antedates the general adoption of antiseptic surgery and for this reason and also that operations were then longer delayed than at present the total mortality is high. This, however, does not affect the relation between the two groups of cases and the fact remains that the mortality after strangulation in the aged is very great.

In the table which I have compiled we have the results of 144 operations for the radical cure of hernia in persons over 60 years of age done since the general adoption of antiseptic surgery. Of these eighty-three were strangulated, and there were sixty-five recoveries leaving a mortality of 23 per cent. I have tabulated these cases for the purpose of contrast with the results of radical operation in non-strangulated hernia where the operation is one of choice and not of necessity.

There were sixty-one of these operations with but two deaths, or mortality of 3.5 per cent. The fatal cases are Nos. 11 and 24 in the table. The first by Dr. W. T. Bull. Patient aged 80. Double inguinal complicated with hydrocele. Death by hemorrhage from atheromatous artery cut by ligature in omental stump. Here the cause of death was distinctly incident to age and what would have otherwise proved a complete success was defeated by this small yet significant accident. The lesson is an important one and has not passed unheeded. I recall vividly the emphasis which Dr. Bull placed on this source of danger in his paper and the fact that several times when scrutinizing an omental stump previous to returning it to the abdominal cavity, I had his words in mind. On one occasion an omentum had been ligated in four or five portions and was about to be returned when I discovered that one of the ligatures had slipped and the artery was leaking. Haste at this point would have lost the patient, and it is but right to give Dr. Bull the credit of having saved him, for I had learned the lesson of care by reading his paper. By a more general exercise of this care I believe that we may eliminate entirely this source of danger. In case No. 24, by Dr. Le Bec, the patient, aged 70, had an enormous scrotal hernia with adherent omentum, uncontrollable, with pad. Death occurred on the fourteenth day from pneumonia, the autopsy showing the peritoneum to be normal. Under these conditions the fatal result can only in a very indirect way be ascribed to the operation. This leaves us fifty-nine recoveries, which means much for the comfort of the time remaining to life after 60. How many of this number have been saved the greater danger of strangulation?

There are important factors, both of body and mind, the direct result of senility, predisposing to strangulation, and as the principal cause of mortality, they should not be overlooked or regarded as trifles. First of these may be mentioned diminished peristalsis incident to age. If we examine and give credence to the elastic strangulation theory of Sir Astley Cooper and the older writers, or to the *abknikung* theory of Busch, and admit that strangulation is even occasionally the result of fecal occlusion as stated by Kocher and Röser, then it must be conceded, that on account of diminished peristalsis the aged are in greater danger. More important than this, however, is the constantly increasing disability to reduce the rupture

No.	Operator.	Ref.	Sex and Age.	Kind of Hernia.	Reason for Operation.	Kind of Operation.	Result.

104	H. O. Marcy.	1	F. 63	Left inguinal.	Strangulated.	First case where closure was made with buried animal sutures; catgut; Lister dressing; carb. plaster	Union primary, remained perfectly cured until death, six years after.
105	Same	1	F. 67	Left inguinal.	Uncontrollable by truss. Deliberately decided upon for cure.	Closed with buried sutures.	Union primary and cure remains perfect.
106	Same	1	F. 68	Rt. inguinal.	Same patient (105) demanded operation for smaller hernia.	Marcy's.	Union primary and cure remains perfect.
107	Same	1	F. 62	Umbilical.	Large. Strangulated.	Closed with catgut buried sutures	Union primary, cure perfect, think still living.
108	Same	1	F. 63	Umbilical.	Strangulated.	Resected 7 inches of necrosed small intestine; sutured with catgut tendon.	Death some days after from exhaustion; primary union, intestines united without peritonitis, specimen held column of water without leakage.
109	Same	1	M. 70	Enormous ser. left inguinal.	Strangulated.	Removed sac by suturing at base and closing with kangaroo tendon suture; collodion seal.	Recovery, union primary, cure permanent.
110	Same	1	F. 66	Rt. Femoral.	Strangulated.	Closed with tendon sutures.	Union primary and permanent
111	Same	1	F. 62	Rt. Inguinal.	Non-strangulated.	Removed large omental mass, closed wound without drainage, sealed with collodion.	Union primary and permanent
112	Same	1	F. 62	Left inguinal.	Non-strangulated.	Same as above	Union primary, cure perman't.
113	Same	1	M. 65	Left inguinal.	Uncontrollable by truss	Marcy's	Union primary, cure perman't.
114	Same	1	F. 67	Large ventral.	After a suppurating Alexander's operation.	Resected and closed in layers of tendon suture; sealed.	Union primary, cure perfect.
115	Same	1	M. 65	L'rge l't ser't.	For radical cure	Marcy's	Union primary, result perm't
116	Same	1	M. 83	Left serotal.	Strangulated, containing twelve inches of large intestine.	Marcy's	Union primary, result permanent until death 3 yrs. later.
117	Same	1	F. 61	Large umb'cal	Irreducible.	Resected large mass omentum and elliptical portion about umbilicus; joined with layers of tendon.	Union primary and result permanent.
118	Same	1	M. 65	Rt. inguinal.	For radical cure	Marcy's	Union primary, result perm't.
119	Same	1	M. 65	Left inguinal.	For radical cure	Marcy's	Union primary, result permanent, cord a long time tender
120	Same	1	F. 62	Large umb'cal	Enormously fat woman. Uncontrollable	Resected and removed large mass of adherent omentum; closed in layers with tendon sutures; sealed	Union primary, result perfect.
121	Same	1	F. 65	Left femoral.	Strangulated.	Closed in layers and sealed.	Union primary, result perm't.
122	Same	1	F. 70	Left femoral.	Strangulated.	Closed and sealed.	Union primary, result perm't.
123	Same	1	F. 63	Left inguinal.	Uncontrollable.	Marcy's	Union primary, lost sight of.
124	Same	1	F. 78	Rt. femoral.	Strangulated five days.	Resected, closed and sealed.	Union primary, result permanent, living at date.
125	Same	1	M. 62	Rt. inguinal.	For radical cure	Closed and sealed	Union primary, result permanent, died in 1895.
126	Same	1	M. 67	Enormous rgt. serotal.	Old congenital. Uncontrollable by supports.	Large mass of omentum adherent to testicle; testicle diseased and removed	Union primary and permanent
127	Same	1	M. 71	Large right serotal.	Uncontrollable.	Testicle diseased; removed.	Union primary and result permanent.
128	Same	1	M. 61	Rt. inguinal.	For radical cure	Marcy's	Union primary and result to date permanent.
129	Same	1	M. 61	Left inguinal.	For radical cure	Marcy's	Same as above.
130	Same	1	F. 62	Rt. femoral.	Strangulated.	Sealed	Union primary, died of pneumonia some weeks later.
131	Same	1	M. 61	Rt. inguinal.	Very imperfectly retained by truss.	Closed and sealed	Union primary.
132	Same	1	M. 61	Left inguinal.	Very imperfectly retained by truss.	Closed and sealed	Union primary, 9 months later slight yielding of internal ring.
133	Same	1	M. 61	Large rt. ing.	Irreducible.	Closed and sealed	Wound infect'd and superficial fatty structures sloughed, union strong at date.
134	E. J. Senn.	20	M. 67	Inguinal.	Difficult retention and annoying	Bassini's modified.	Cure.
135	W. T. Bull	21	M. 67	Left inguinal.	Irreducible.	Czerny's	Wound healing, suppuration, relapse in one month.
136	Same	21	F. 60	Umbilical.	Sac contained omentum, colon and loop of small intestine. Irreducible.	Omentum resected; wound closed in layers with kangaroo tendon	Primary union, except small stitch-hole abscess.
137	Same	21	M. 63	Rt. femoral.	Irreducible.	Omentum reduced; ligation of neck of sac; ring not sutured	Primary union.
138	Same	21	M. 61	Inguinal.	Strangulated.	Same as above	Death on tenth day, autopsy showed 1½ ft. of ileum nearly black, no perforation, fatty heart, tubercular deposits in lung.
139	Same	21	M. 63	Dbl. inguinal.	For radical cure	Canal sutured with kangaroo tendon	Well eleven months later, no relapse.
140	Same	21	F. 60	Rt. inguinal.	For radical cure	Bassini's	Primary union.
141	Same	21	M. 62	Dbl. inguinal.	For radical cure	Double Bassini's.	Primary union.
142	Same	21	M. 72	Inguinal.	Strangulated.	Double Bassini's.	Death 11 hours after operation.
143	W. B. Coley.	21	F. 62	Om'til ventr'l	Irreducible. Frequent attacks of incarceration and local peritonitis. Hernia about size of a fist.	Incision of omentum	Primary union, slight relapse about one year later.
144	Same	21	F. 68	Rt. inguinal.	Of many years' duration. Irreducible for six months. Considerable pain.	Incision of omentum	Perfect primary union.

and properly adjust the truss. This may be due to lack of intelligence or to a lowered sensibility. There are many persons whose tactile sense and mechanical ability are poorly developed and it surely does not improve in advanced age. Lack of intelligence in matters of this kind in those otherwise capable may be caused by want of proper instruction and to the confusion brought about by the failure of the many inefficient appliances which fill the markets. Some months ago I was called to attend a man over 70 years of age who was wearing three trusses and a suspensory loosely applied at various points over a large unreduced rupture. An efficient truss was adjusted, he was properly instructed in its use and has since retained his rupture without any great difficulty though not without some inconvenience.

Unfortunately all ruptured persons do not have ready access to skillful surgeons or clinics and truss societies where they have the best attention the world affords to prevent or cure strangulation. These are facilities afforded by large cities and yet the great number of strangulated hernias occurring where they are to be had and the fatal results in the vicinity of immediate assistance, might suggest that additional aid in their prevention would be desirable. I believe that remoteness of the ruptured from skillful surgical aid in the emergency of strangulation should be considered a reason for operating in those cases that both theory and experience have shown to be in such danger.

Lowered sensibility in the parts implicated in a rupture does not necessarily mean a lack of sensitiveness. In both the sensitive and the obtuse there may be an inability to discriminate and it frequently happens that the hernia protrudes and the truss is worn for a time making pressure on the contents at the neck of the sac thus greatly predisposing to strangulation. Liability to protrusion under the truss or to forcing a greater quantity of intestine into the sac from straining incident to enlarged prostate may be another cause of strangulation.

There is no inconsiderable proportion of cases of entero-epiplocele in which the omental portion is irreducible on account of firm incarceration in a pouch which in an early stage in the development of the rupture formed a purely omental hernia, but as the ring increased in size and a larger sac was pushed down from the peritoneum, the intestine was admitted to the upper and larger pouch alongside of the omentum now held securely fast below. There are also others in which the intestine has formed adhesions to the sac wall and are for this reason irreducible. In Bull's table of 134 operations of all ages there were forty-two irreducible. Of a total of 176 cases of irreducible hernia seen at the London Truss Society in the years 1888 to 1890 inclusive twenty-five were in persons over 60 years of age. These hernias it is true may be sometimes held satis-

factorily and frequently reduced by the hinged cup truss of Mr. Kindon. On page 221 of Macreadie's Treatise we find the following significant sentence: "A person wearing a hollow truss for irreducible hernia can not be deemed secure, for at any moment a descent of intestine may occur and he may suffer strangulation."

The considerations so far named have been for the safety of the patient but if it can be shown that the danger of operation is not great, are we not justified in taking some risk for his comfort? Inability to bear a sufficient degree of truss pressure to retain the rupture may often be due to poorly fitted appliances. Frequently it is caused by a tenderness and intolerance to pressure in all the tissues. Not only is the pressure of the pad poorly borne but points of counter pressure on the back are much complained of. This is especially true when we have associated an impatient disposition and is aggravated when the extrusive force is increased by chronic cough or enlarged prostate. Under these circumstances the desire of the patient to be rid of the pain, discomfort and annoyance of wearing a truss should surely have some weight in favoring the performance of a radical cure operation provided that it can be done with a reasonable degree of safety.

Permanence of cure is an important question that our inquiries have not entirely answered, for the reason that so many cases are not seen again after immediate recovery. Bishop reports one recurrence in his seven cases, but that was after strangulation. Some of his cases though have been under observation for years and have remained well. Bull reports recurrences when the method was ligation and excision of the sac. But that was in operations done years ago, before Marcy or Bassini's or even Macewen's or Bishop's methods were in vogue. Other things being equal I believe that permanence of cure may be as readily attained after 60 as in younger subjects. Success in this important particular depends on the method employed. The operation, though, must be well done. Slouchy work will not give good results.

From time to time I have tried most of the operations in vogue for the radical cure of hernia.

My conclusions are that Marcy's operation will give the best results in inguinal hernia. When I say Marcy's operation I mean the operation by closing the internal ring under the cord with kangaroo tendon. It is displeasing to me to have this operation called Bassini's because the operator does not happen to use Marcy's needles or cobbler's stitch.

Bassini's operation with silk gives equally good results, but when suppuration does occur, as it has sometimes in my operations and occasionally with others also, then the buried silk proves to be a nuisance by perpetrating a nidus for pus microbes. I believe with absolute care in all points of technique this will be very rare. In femoral hernia Bishop's method will fill the canal easier and firmer than any other method and I always employ it.

In umbilical hernia I believe the buried mattress suture of silver wire will give the best results. The pressure on the closed ring is stronger and more unremitting than in other hernias and the presence of the wire must be a continued benefit.

The prognosis as to recovery is well set forth in my table. Sixty-one cases of operation for radical cure for seasons other than strangulation and but two deaths.

Bull's seven and Le Bec's nine cases seem to have been a matter of serious discouragement to these operators. Bull says in the article already quoted: "This fatal result is worthy of notice in so far as it serves to emphasize my conviction that old and feeble subjects should not be subject to operation in reducible cases."

Le Bec says in his letter: "I dislike to operate for the radical cure of hernia in the aged as it is scarcely necessary in those who do not labor and the results are doubtful." His nine cures to one death, and that from pneumonia fourteen days after the operation, the peritoneum being normal, should be regarded more favorably.

Mr. Edmund Owen says "Age is an indefinite term and no barrier to the performance of an otherwise successful operation."

N. Senn says: "I have operated on a number of persons over 60 years of age for radical cure of hernia, usually after operation for strangulation. Age did not seem to interfere with a good result. The last patient was 78 years old. Strangulation of sigmoid flexure. Complete recovery in four weeks."

In reviewing the table and giving attention especially to the experience of H. O. Marcy, G. Stanmore Bishop, W. T. Bull, Le Bec, Arthur T. Barker, Aug. Broca, J. D. Griffith, W. W. Keen and Jos. Ransohoff, it would seem to me that precedent was established and prognosis sufficiently favorable to warrant us in recommending the operation to the aged in suitable cases as a matter of increased safety and comfort to those in whom reduction is impossible or retention difficult.

NOTE.—Recent experience with formalin catgut leads me to believe that it may entirely supplant kangaroo tendons in hernia operations. An autopsy one month after an exploratory laparotomy in a case of cancer of the stomach, where the peritoneum had been closed with a continuous suture of fine formalin catgut, showed it still firm enough to maintain support, but undergoing absorption. Previous to the appearance of Professor Senn's article (See JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION for Dec. 12, 1896, p. 1219) I had exposed catgut for one week, instead of twenty-four hours, to the formalin solution. Before boiling it is brittle, but after boiling has great strength. It requires a longer time for absorption, as I have proved in frequent trials of both methods.

ABSCESS OF THE SEPTUM NARIUM.

BY W. E. CASSELBERRY, M.D.

CHICAGO, ILL.

Chairman of the Section on Laryngology and Otology of the American Medical Association; Professor of Laryngology and Rhinology in Northwestern University, Medical School; Laryngologist and Rhinologist to St. Luke's Hospital; Laryngologist to Wesley Hospital, etc.

The condition which, for the sake of simplicity in nomenclature is designated "Abscess of the Septum," only occasionally presents the typical characteristics of acute circumscribed suppuration. When caused by traumatism the first stage may be an effusion of blood beneath the muco-perichondrium of the cartilaginous septum which is termed "Hematoma of the Septum." In time the blood degenerates, perhaps becomes infected by pyogenic microorganisms and changes to a brownish yellow fluid which when evacuated appears neither like blood nor typical pus. In this state it has been called "Cold Abscess," and again when it does originate without traumatism and runs an acute course with pain, fever and obstructive swelling terminating in ideal suppuration, it has been spoken of as "Acute Perichondritis." Jurasz¹ has described a form in which the contained fluid is at first serous, termed serous perichondritis. Some sort of abscess is the culminating stage of all these conditions.

Although it might be possible for the bony portions to be affected, the usual seat of the disease is the cartilaginous part of the septum and it may be either unilateral or bilateral.

Etiology.—The most frequent cause is believed to be traumatism, e.g., blows or falls upon the nose, yet in many cases it is impossible to establish this relationship; slight contusions, readily forgotten, can determine a hematoma of the septum. This may run an insidious course, endure for days or weeks and undergo spontaneous absorption, having been little noticed, but in other instances the blood changes to sanguinolent pus and the cartilage itself disintegrates, the contents being retained by the bulging muco-perichondrium. Pyogenic microorganisms could excite suppuration in these and also in so-called idiopathic cases by gaining an entrance through excoriations which frequent these surfaces. The disease may occur also during the course of typhoid fever or smallpox, and Scheck calls attention to the frequency with which facial erysipelas proceeds from abrasions upon the septum and infers that abscess of the septum can be caused by infection by the streptococcus erysipelatis. In many cases still it is quite impossible to assign any definite cause.

This was true in the following case which is a typical example of the variety termed cold abscess.

Case 1.—Master G., aged 16 years; while away from home at school began to suffer from nasal obstruction which he attributed to an acute exacerbation of his customary "catarrh." No history of traumatism could be elicited, the disease having seemingly commenced as a cold and continued several weeks before it received serious consideration. But nasal obstruction, and swelling within and without the nose gradually grew so serious that he was sent home where he was confined to his bed, supposed to be suffering from asthma. On examination the diagnosis was at once apparent, for from each side of the septum bulged a fluctuating tumor which completely blocked both nostrils. The enveloping mucosa was unbroken, somewhat inflamed, and the nose generally reddened and edematous. A brownish yellow liquid was withdrawn by a hypodermic syringe, and this was followed by a free incision toward the base of one side and gentle curetting of the cavity. The central portion of the cartilage had liquified, but it redeveloped from the muco-perichondrium and perfect recovery ensued.

Symptoms.—In case of the transition of a hematoma into an abscess, the disease may manifest itself either quite insidiously or the suppurative change may ensue quickly and be associated with sneezing, nasal irritation and slight fever. In either event the salient symptom ultimately complained of will be obstruction to nasal respiration together with the discomforts of mouth breathing.

When the abscess arises in the form and in conse-

¹ Journal of Laryngology, etc., Nov. 1896, p. 266.

quence of acute perichondritis it is ushered in during a few days by symptoms indicating a high degree of inflammation, *e. g.*, chill, pronounced fever, pain, swelling and redness of the whole organ. Spontaneous rupture is more apt to occur quickly in this than in the former type, although it may be much delayed after the subsidence of the inflammatory symptoms, leaving again nasal obstruction as the salient symptom.

Case 2 exemplifies the latter type.—Mr. B., aged 26 years; thought he had contracted a severe "cold in the head," the condition commencing with chilly sensations followed by headache, fever, local sensitiveness and redness extending to the bridge of the nose. These symptoms gradually subsided but were replaced by nasal obstruction and what he now supposed was chronic nasal catarrh. The examination was not made till the third week when a fluctuating tumor was observed to bulge from each side of the septum. Typical pus was evacuated by an incision and the cavity curetted. The destroyed central part of the cartilage ultimately redeveloped without deformity. He positively denied the least probability of traumatism as a cause.

Diagnosis.—By simple inspection with the head tilted backward, the semicircular tumor may be seen bulging from one or both sides of the septum. Palpation by a probe will cause deep pitting or even fluctuation, and aspiration by a hypodermic needle will provide a sample of the contents. It may thus be readily distinguished from polypus for which it is most commonly mistaken by novices, but which occurs but rarely in this situation, and also from syphilitic gumma which commonly develops at just this spot. I have seen one case of gumma in which the central part had liquified before the occurrence of superficial ulceration, in which the diagnosis would have been impossible, had not other syphilitic signs been present.

Prognosis.—If recognized reasonably early and the abscess evacuated, the prognosis is very good. Notwithstanding complete liquefaction of the cartilage itself, if the muco-perichondrium be preserved, another cartilaginous septum will develop and this usually without deformity. However, if the disease be unrecognized or if the inflammatory action extend to the antero-superior border of the septum, the line of junction of the septum with the lateral cartilage and nasal bones, softening and depression of these which constitute the dorsum of the nose will result. Apart from this "saddle-back" deformity or in conjunction with it, perforation of the septum can also ensue.

Treatment.—When the initial stage is a hematoma cold applications would be suitable. In any event as soon as pus is present a rather free incision should be made low down on one side and the contents expressed. This should be reopened daily with a probe until the cavity has been effaced. It is probably not necessary to curette, wash out or pack the cavity with gauze although one or all of these may seem desirable at times.

FIBROUS NASAL POLYPUS.

BY D. R. SILVER, M.D.
SIDNEY, OHIO.

As a contribution to our knowledge of nasal polypi, I venture to report this case, which, in one respect at least, may be unique. The growth developed in a boy, 12 years old. He had the characteristic mouth-breathing at all times on account of the complete closure of the posterior nares. On inspection, a tumor the size of a man's thumb could be seen in the naso-

pharynx below the line of the soft palate. To the touch it was hard and seemed firmly attached; so firmly, indeed, that to remove it by twisting was out of the question. Its point of attachment could not be made out. Its large size made the passage of anything through either nostril nearly impossible. As a preliminary step, a threaded needle was passed through the lower portion of the growth so that it could be pulled well down and forward, after which it was found possible to pass a small rubber catheter, to which was attached a string, through the right nostril and out of the mouth, as in the operation for closing the posterior nares. By means of the string a heavy silver wire, doubled, was drawn through and slipped over the tumor, fortunately encircling the point of attachment, which could hardly be called a pedicle, since it was found to be nearly as large as any other portion of the neoplasm, and fully three-fourths of an inch in diameter. The wire attached to a strong screw cut its way through in an hour.

It proved to be a three-lobed affair, very hard and fibrous, and was drawn out through the mouth by means of the thread which transfixed the growth at its lower end. Its dimensions were $2\frac{3}{4}$ by $1\frac{1}{2}$ by $\frac{3}{4}$ inches. The pain produced by the constricting wire was considerable, but there was no hemorrhage to occasion alarm. Notwithstanding the fact that the point of attachment was well cauterized a large mucous polypus sprang up in a few weeks. This was removed by twisting and did not return. The specialist trained in the manipulations of rhinologic work may not find the removal of nasal and post-nasal polypi very difficult. But when these growths are very large or very small the general practitioner finds their management quite perplexing. For this reason the subjects of nasal polypi furnish a large contingent of the army of victims who fall an easy prey to the catarrh "specialist." Nostrums, whose only recommendation is their nastiness, are bought and used for years by persons whose rather fashionable complaint could be removed by a twist of the forceps.

HEMORRHAGE FROM THE LARYNX, FOLLOWING AN ATTACK OF MEASLES, IN AN ADULT.

Read before the Section of Otolaryngology of the College of Physicians, Philadelphia, Pa., March 3, 1896.

BY FRANK WOODBURY, M.D.

Instructor in Laryngology in the Philadelphia Polyclinic; Attending Physician to the Medico-Chirurgical Hospital, etc.

PHILADELPHIA, PA.

On January 24, Martin S., 27 years of age, born in Ireland, a laborer by occupation, presented himself at the laryngologic dispensary of the Polyclinic Hospital with an acute inflammation of the fauces and pharynx and with almost extinguished voice, requiring considerable effort in speaking. He gave the following history: About nine weeks previous, or about the first of December, four sailors were admitted to the Naval Hospital suffering with measles. Three cases developed subsequently among the employes of the institution, where he was engaged as a fireman, and all the cases recovered. The patient was taken sick January 3, or about two weeks after the first patients were convalescent, and had been allowed to go around the grounds. He said that he had fever, eruption, conjunctivitis, cough, and subsequently there was much desquamation, especially from his face

and hands. The cough continued and was attended by hoarseness and free expectoration. He was confined to bed for only one week, but had been feeling poorly ever since. The notes in the case book state that three days before the visit to the hospital, he woke up in the morning feeling his throat obstructed and, on clearing his throat, expectorated mucus and blood, followed by a small quantity of pure blood. He stated further that he had spit blood each morning since, but none during the day. He indicates a spot in the trachea, just below the larynx, as the place which he considers the source of the hemorrhage, as he has more or less pain in it all the time. He has also sore throat and pain in speaking and in swallowing.

On examination, the fauces, soft palate and uvula and part of the pharynx were found to be intensely hyperemic and his throat was so irritable that it was impossible to make a complete laryngoscopic examination at this time or on several subsequent visits. On February 5 the throat was so much better that an examination was made, when hyperemia of the larynx and vocal bands was recognized but no ulceration was found. There has been no hemorrhage since his first visit and his general condition has steadily improved.

The treatment was by inhalations of benzoinated steam, a gargle of chlorate of potassium and rhus glabra, with the internal administration of muriate of ammonia (gr. x every three hours) and milk punch. he was instructed to use his voice as little as possible and to remain in the house the greater part of the day.

SHOULD CULTURES FOR BACTERIOLOGIC EXAMINATIONS BE TAKEN FROM THE NASAL CHAMBERS AS WELL AS FROM THE THROAT IN CASES OF SUSPECTED DIPHTHERIA.

Read before the Section of Otolaryngology of the College of Physicians, Philadelphia, Pa.

BY E. LARUE VANSANT, M.D.

Professor of Diseases of the Throat and Nose, Philadelphia Polyclinic; Laryngologist and Aurist to the Howard Hospital; Fellow of the College of Physicians, Philadelphia; Fellow of the American Laryngological, Rhinological and Otolaryngological Society.
PHILADELPHIA, PA.

Recently I commenced to take cultures for bacteriologic examination from the nasal chambers as well as from the membranous deposits in the throat in cases of suspected diphtheria. The nasal cultures were made by pushing the swab back to the posterior portion of the nasal chambers, but not going through to the pharynx. Those from the throat were made by rubbing the swab over the surface of the membranes before any remedial application had been made.

In the following two instances the bacteriologic examination showed diphtheria bacilli in the cultures from the nose, and gave negative results in those from the throat. The bacteriologic examinations were made by Dr. W. J. Gillespie, to whom I acknowledge my indebtedness:

Case 1.—Mr. M. II., age 46 years, seen Nov. 25, 1896, has a history of several attacks of quinsy during his life. His present illness dates from a chill three days ago; since then he has had fever, chilliness and exhaustion, pain on swallowing, with swelling of the left side of his throat. Examination showed the left tonsil swollen and hypertrophied, the peri-tonsillar tissue of the same side greatly swollen. A velvety, dirty yellowish-white membrane covered the left tonsil and extended over the palatine arches. Upon removing a portion of this membrane a granular, slightly bleeding surface was seen

beneath. There was no membrane visible in the vault of the pharynx or nose. The nasal septum was deflected to the left and the nasal chambers contained considerable muco-purulent secretion. The bacteriologic report was: for the nose, numerous diphtheria bacilli; for the throat, large cocci, numerous spores and long slender bacilli, no diphtheria bacilli.

Case 2.—I. L., aged 18 years; seen Dec. 2, 1896. Has been in good health until two days ago, since then has suffered from chilliness, fever and sore throat. He comes from a neighborhood largely infected by diphtheria. Examination showed both tonsils swollen, with an extensive yellowish-white exudation from the crypts. This exudation in several spots spread over portions of the tonsils. The pharynx was dry and glazed with a whitish membranous appearance at the vault. Nasal inspection revealed an advanced atrophic rhinitis, but no membranous deposit. Bacteriologic report: The culture from the nose contains a few diphtheria bacilli; that from the throat contains numerous organisms resembling the bacilli subtilis, no diphtheria bacilli.

It is a well-known fact that it is not infrequent to receive negative results from bacteriologic examinations in clinically well marked cases of diphtheria. Thus, Dr. B. Meade Bolton, in an abstract from the first annual report, bacteriologic laboratory, Bureau of Health, Philadelphia, Pa., read before the Philadelphia County Medical Society, June 10, 1896, states that in 557 cases diagnosticated as diphtheria, bacteriologic examination showed the presence of diphtheria bacilli in 507, or 90.2 per cent.

Here, then, is nearly 10 per cent. of negative bacteriologic examinations in 557 cases where positive diagnosis of diphtheria had been made. There can be no doubt but that carelessly made cultures would account for some of these negative results. Still, when we consider that the membrane in the throat in diphtheria quickly becomes loaded with many other bacteria found in the mouth, and further that the diphtheria bacilli are rather under the membrane than in it, we can readily see how a carefully made culture may have the typical growth of the diphtheria bacilli obscured by that of foreign germs, and how a culture taken from the surface of a diphtheritic membrane may contain only partially devitalized diphtheria bacilli, incapable of giving a good culture for bacteriologic examination. The normal nasal secretion, however, seems to retard the formation of the membranes; cultures, therefore, taken from the nasal chambers may in some instances give more accurate results than those taken from the throat.

The embarrassment to the attending physician caused by receiving a negative bacteriologic report in cases clinically so well marked as to cause him to make a positive diagnosis of diphtheria and the lessened carefulness and insufficient isolation on the part of the patient after receiving such a report, should certainly cause us to use every means to insure accurate results. I, therefore, would suggest that in all cases of suspected diphtheria, cultures should be taken from the nasal chambers as well as from the site of the membranes in the throat.

INFANT MORTALITY DURING LABOR, AND ITS PREVENTION.

BY Z. LINCOLN WHITMIRE, M.L., M.D.

URBANA, ILL.

(Continued from page 294.)

Uterine inertia.—This brings us to uterine inertia, which is a peculiarity the uterus has sometimes of suspending operations and refusing to further assist in the delivery of the child. It most commonly occurs in protracted cases, accompanied by great prostration in the patient, and coming on near the

termination of labor, though it may occur at any time, it is more apt to occur at a time when its presence most endangers the child's life, as when the head or cord or both are passing over the perineum, and are undergoing great compression irrespective of the uterine contractions; so that for the child to be left in this position would be certain death if continued for any great length of time.

Uterine inertia is also apt to appear in excessively painful cases and in those in which the patient is weak and emaciated, a condition resulting from disease or from an ever-present dread of the approaching and inevitable ordeal of labor. The chief consolation to the physician is that this trouble may be anticipated and often prevented, and when the above-mentioned indications are present the patient should be put on a tonic and alterative treatment at once. If we see her for the first time in this condition when we are called to attend her through confinement, we have nothing left to do but to fortify her against the probable results by a judicious administration of stimulants. But in cases of high nervous tension, sedatives may be indicated. Sometimes it happens that her health is in a perfect condition, but circumstances are such that the case bids fair to be a long and tedious one; as, for instance, when the membrane has ruptured early or in a case of breech presentation, and particularly when both these conditions are present. In such cases also we should fortify her against the probable occurrence of uterine inertia.

Unless properly attended to, uterine inertia is apt to prove fatal under the following conditions: 1, in a breech presentation when the body is born and the head and cord are passing together over the perineum; 2, in a head presentation when the head has reached the outlet and the crown is exposed to the cold air. In both these cases the child's life may be lost by the head being too long in this contracted condition while passing through the outlet; and also the cold air upon the exposed part may cause the child to inhale sufficient mucus to strangle it after the cord is tied and the child is dependent upon its lungs for oxygen. In a breech presentation the cause of death is the compression of the cord, and it will be fully discussed under the head of breech presentation. When uterine inertia occurs under either of these conditions, a prompt delivery is necessary to save the child. Forceps must be used, if indicated, where there is time to apply them.

Ante-partum hour-glass contraction of the uterus is not an uncommon complication to labor. It is usually caused by a premature rupture of the membrane, for when the amniotic fluid escapes the uterus has to contract upon the irregular surface of the child's body. This causes an uneven distribution of the uterine force, and the uneven contractions resulting are apt to assume the hour-glass variety. Under such circumstances the child can not pass out of the uterus, and unless the pressure is relieved or normally applied the child's life will be lost. For the purpose of stopping this abnormal and dangerous condition such remedies are indicated that tend to relax the muscles of the uterus. A dose of ipecacuanha is very good for this, but a trifle slow in its action. A hypodermic injection of morphin sulphate or a very small injection of apomorphia are also good remedies, but should be given with care. Inhalations of chloroform, however, are perhaps the most commonly used and are far the safest. Whatever is determined upon must

be administered promptly and with due consideration for the patient and for the circumstances attending upon her case. After the contractions have assumed their normal state, if there is a disposition on their part to return to the abnormal type, the physician may use as prophylactics the remedies he formerly used as a cure, though in most cases he will find that an immediate delivery is far preferable.

Displacement of the uterus.—Of the various displacements of the uterus, anterior displacement occurs most often in pregnant women; and a description of it will answer for a description of each of the others—except as to the location of the os and the fundus. The principal cause of anterior displacement of a gravid uterus is the weakness of the walls of the abdomen and their inability to support the weight of the uterus. It tips forward therefore and distends the abdomen, while the os is tipped backward and out of sight, as an examination of the vagina will disclose. It is quite evident that while the os is in this hidden position it will be impossible for the uterus to expel the child, and the pressure is sure to either rupture the uterine wall or kill the child, or both. To prevent such a calamity it is the duty of the physician to correct the displacement and to maintain the uterus in its normal position till labor has progressed far enough to prevent a recurrence of the trouble. This is easily done. To replace the uterus, govern the fundus with one hand, from without the abdominal wall or from within the rectum, according to the direction of the displacement, and with the other hand in the vagina, guide the cervix with your fingers. After it has been replaced it can be kept in its proper position by bandages around the body of the woman or by her assuming an appropriate position. It is then best to hasten delivery; but do not use forceps unless especially indicated.

Premature rupture of the membrane is next in order in this discussion. This complication may happen at any time during gestation, though it rarely happens before the fifth month. When the membrane ruptures before the last two weeks of gestation, the length of time thereafter till the occurrence of premature labor is proportional to the amount of amniotic fluid that escapes. This rule applies only to those cases where the membrane has been ruptured by accident, or ruptured intentionally. When it has been ruptured by the expulsive force of the uterus in trying to expel the child the rule does not apply; only applying where the rupture of the membrane produces the pains.

The normal time for the membrane to rupture is after the os has been expanded and dilatation is almost, if not quite, complete. The premature rupturing of the membrane with which the physician has to contend, and which comes under this class of complications, is that in which the membrane ruptures near the completion of gestation and before the os is dilated. The principle use of the unbroken membrane in labor is the service which the sack performs as an entering wedge in dilating the os; a use for which its conical shape is particularly adapted. When it breaks, its conical shape is lost. But the breaking of the membrane does not always mean the loss of the fluid, for the presenting part sometimes hinders the escape of the fluid that is behind it; hence the bad results that sometimes follow it are prevented; for instance, ante-partum hourglass contraction of the uterus. It may be stated as a rule

that the earlier the membrane ruptures the more fluid escapes and the more serious are the resulting troubles.

When a child is born at full term and the fluid has escaped several weeks previous to the delivery it is commonly called a dry birth or a dry labor; and such a labor is usually a slow and tedious one. The first stage is slow because (in the absence of the conical-shaped sack) the os can not easily be dilated by the blunt skull or flabby and yielding breech; while the rest of the labor is retarded by the uneven distribution of the uterine force, due to the uterus having to contract upon the irregular surfaces of the child's body. This slowness subjects the child to the pressure a long time, and may of itself be the cause of the child's death. This is particularly true when the head is passing over the perineum, where it undergoes great contraction. The uneven distribution of the uterine force may result in ante-partum hourglass contraction, which has been discussed.

As mentioned above, the cases in which the membrane ruptures early in confinement are slow and tedious and especially so when nearly, if not quite, all the fluid has escaped; but, nevertheless, they should be allowed to take their course and should not be interfered with till it is seen that the life of the child is in danger. In that case delivery must be hastened as much as is consistent with existing circumstances, but always bearing in mind that the forceps must not be used until they are indicated.

In the second class of complications, those located in the cord and placenta, there are five kinds, as follows:

Short cord.—By this term is meant a cord that becomes taut before the child is delivered. It may occur in several ways, of which the two main ones are: 1, its entire length may be too short; 2, its shortness may be acquired. Examples of the second may be found in cases where the cord is wrapped around some part of the child a sufficient number of times to make it too short, or where the cord is tied in knots enough to produce the same effect. The cases are very rare in which the cord is naturally too short, but when such a case does occur it is a most difficult one to handle. The diagnosis of a short cord is not very easy, and on a correct diagnosis depends the success of the delivery. When the child descends during a pain and then goes back with a jerk, and keeps up this by-play without any ground being gained, one may be fairly certain that he has a case of short cord to contend with and should proceed at once to determine the cause of shortening. This can usually be done by inserting the hand past the presenting part and feeling carefully with the fingers to determine if there are any knots in the cord or if it is wound around any part of the child; one of which conditions will be found, as a rule, to cause the shortening of the cord. If these are excluded, then the only conclusion remaining will be that the cord is naturally too short.

The dangers from a cord that is naturally too short are, that it may break or that the placenta may be torn off before the child is in a position to breathe, or before the cord can be tied. Before the child can be born the cord must be divided or the placenta must be separated from the uterus; hence it is the duty of the physician to strive to have the child as nearly delivered as possible before that time, in order that no time may be lost in completing the delivery and ligating the cord, and he should also cut the cord, if

possible, rather than allow it to break wherever it may happen to, or to allow the placenta to be torn off. The cord will stand a great amount of tension before it breaks, and may be stretched to nearly five-fourths its original length. However, stretching the cord in utero has its dangers. An umbilical hernia may be produced, and in some cases it may retard the circulation sufficiently to asphyxiate the child. The umbilical hernia may be prevented if the hand can be placed inside the uterus so as to grasp the child by the abdomen and allow the cord to pass between the fingers. This is impossible with a head presentation, and can rarely be accomplished when the breech presents.

When the shortness of the cord is caused by its being wound about some part of the child or from its being tied in one or more knots (though it may not be naturally too short to allow the child to be delivered) the dangers are the same as those above mentioned, but the danger of stopping the circulation is greater. These cases will be discussed separately.

(To be continued.)

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

CHAPTER I.—DOCTOR AND BARBER.

Social relations in the first half of this century; Prejudice; Physician's dress; Family physicians; How soon can one become a great and renowned physician? Education of physicians; Dissensions in consultations; Title; Drinking, physician's income; Beard and barber; Lepers and bathers; Education of the barber-surgeon (*des Wundarztes*); His social position; Country barber-surgeons; Consultations between physicians and surgeons; Various classifications; Surgical fees; Separation of surgery from medicine; Extinction of barber-trust.

In the eighteenth century family life among the Germans was very rigid. Housekeeping was recognized as the highest destiny for the wife and daughters and the simplest as well as the poorest homes were kept in the best of order. The husband demanded respectful obedience from his wife and children; even the brothers exercised a certain amount of superiority over their sisters. There existed but little general culture in these homes, but plenty of mother wit and wholesome cheerfulness. On holidays, the wealthy citizen appeared in a velvet coat, richly embroidered in gold and silver, broad cuffs and fine lace jabots; and shoes and silk stockings were the correct style in ladies' company. Father and son carried a sword at the side. The apparel worn by the women resembled the fashions of the present day; the hair was dressed high on top of the head, adorned with ribbons and flowers; the heels on the shoes were very high, whalebone corsets which compressed the waist and forced the bosom together were worn, and large hoopskirts and trains. The faces were painted, *tout comme chez nous*; there are only the little beauty spots of court-plaster lacking on the cheeks and chin of our beautiful women. A strict formality controlled all social intercourse. Congratulations and compliments were so rigidly regulated, that with the numerous little rules of propriety the entire intercourse maintained its unchangeable solidity. No woman was allowed to attend a concert or theater without an escort, nor to go promenading;

even on her way to the church or store she had to be accompanied by her servant-girl. The German peasant often boisterously scolded about this constrained formality, yet he frequently lacked strength of character and will-power. Money and external honor exercised so great a power that about the year 1750, among the best citizens there was scarcely a single man in Germany who would have refused an anonymous bribe; for example, even Gellert, professor at Leipsic, who served as a model of delicate feeling and unselfishness for his contemporaries, yielded to the temptation. The height of ambition was to obtain a title.

About the close of the seventeenth century the absurd custom of giving mechanics court titles sprung up, and if the rank of the court tailor exceeded that of the court gardener, the latter received the distinction of wearing a sword. These things increased the feeling of inferiority among the poorer middle classes and created in their characters the deference and self-constraint paid to the upper classes. The system of protection flourished. Those who had noted and influential acquaintances were envied; an intercession was demanded from every friend of the family, and to kiss the hand of a patron was deemed good form. On account of this lack of self-consciousness, vanity, on the other hand, grew to such an extent that those without rank, title, or station in life were recklessly thrust aside or spurned. Recognizance by the influential and not merit was brought to account. An enlightened public press and strong public opinion were wanting in the German citizen, and his interests in political economy were at a standstill. Most of the gentry of every city belonged to the learned professions, and the theologians, jurists and physicians represented the culture of the times. Every morning they met at their favorite resort, the apothecary's, for a social chat. While enjoying a glass of aquavit (liquor) here they talked over the news of the day, caring little about the skeletons of sharks, stuffed apes and abortions in alcohol which adorned the tops of the cases. This custom grew so that the Mayor of Hanover (in 1784) prohibited the sale of whisky and liquors at the town apothecary's, because the drug clerks were detained in their work and liable to make mistakes. Only physicians and surgeons were admitted, but no longer than necessary for their usual morning drink. The next important event of the day was the arrival and departure of the mail coach, and when a stranger came to town, what an unusual occurrence! Every two weeks only, in the year 1750, did the mail coach go from Dresden to Berlin. The usual stage coach fairly crept along through the country, there being no highroads built until after the Seven Years' War. Those who had to travel a great distance, generally purchased a conveyance, which was sold at the end of the journey. The fastest horses got over the ground at the rate of five miles a day. (G. Freitag.)

About this time the upper classes began to show an interest in science. The boys collected butterflies and beetles and then mounted them; chemistry, distillation, etc., were pursued with pleasure. Superstition, however, still prevailed among the laity. In the graveyard they imagined they saw ghosts, and old cats they took for witches. In the village of Hechingen, in 1725, the lord high forester offered five florins to every countryman or peasant who delivered any of the evil spirits, dead or living, to him. During a thunder storm the church bells were rung, but this was forbidden in Prussia in 1783; in the Rhenish

hamlets, however, this superstitious notion still exists. Throughout Germany, as well as England, bleeding was allowed only on certain days. Crowds of peasants migrated to the cupper, who abused them outrageously. The Greeks and Turks, at that time nearly all having the festering cut on the arm (Fontanelle), had a few incisions made in the vicinity of the ear for the bleeding, after a bandage had been tied around the neck to stop the flow of blood, all on account of a little headache. In Pavia existed the barbarous custom of bringing all the horses into the public square of the church, where one after the other they were bled in honor of the holy Antonius, the father of the monks. Purgatives were taken on certain days, the dog-days being particularly dreaded. The result of the physic depended upon the sign of the zodiac in which the sun chanced to be, but in the fall and spring of the year it was very necessary for the maintenance of good health to cleanse the system thoroughly. It was thought that the blood during the period of menstruation contained poison, so a number of surgeons forbid the use of linen articles belonging to women. Amulets and conjuring were in high favor and served as a cure for dead bones. With the formula "abrakadabra," fever was treated; the bite of a mad dog by the Hubert's key.

If clothes make a man, the German physician's appearance during the middle of the eighteenth century proclaimed him one of the worthiest of men. Imagine him with a wig high in front and falling in curls halfway down the back (allongeperücke) powdered white as snow, with a scarlet red coat embroidered in gold and adorned with a jabot and broad lace cuffs, silk hose, white or black, and with flashing knee and shoe buckles. Under his arm he carried a small black silk chapeaubas and in his hand a large bamboo cane, which was indispensable in supporting his chin when pondering over critical cases. When Frederick William I. condemned the allongeperücke and introduced the braid in the Prussian army on account of its simplicity, the fashion set was soon followed by all the men, even the colleague adopted the plait.

But this mode continued only until the French Revolution, when there was no time for curling and dressing the hair; on the other hand, however, the style of dress-coat worn by the North American ambassador in Paris was adopted. Not every German doctor could, without punishment, cut off his braid to be more comfortable, did he not wish to be decried as a Jacobite by the nobility and lose their patronage. It was evident that the physicians speculated to retain the confidence of the public by means of the changes they made in their apparel. This circumstance was well remembered by Napoleon I., who, when suffering from cancer of the stomach while at St. Helena, not wishing to have two diseases, nature's and the physician's, and refusing every internal remedy, wrote his Italian physician the following: "You know, Doctor, that the science of medicine is nothing more than the art of putting to sleep and soothing the imagination; for this purpose the ancients clothed themselves in long coats and flowing garments, which attracted attention and forcibly impressed the sick; but since this Galenic delusion is out of practice, you no longer exercise your former power over them. Who knows but what I would take you for the god of Health were you to appear suddenly before me, attired in a flowing toga and a large wig with a long braid. Unfortunately you are no more than the god of Remedies." The

position occupied by a physician grew to be a most honorable one. He obtained a certain amount of superiority among the upper classes because they were sadly deficient in the knowledge of sciences, and his importance grew more and more when, in the eighteenth century, the family physician came to occupy the confidential relations to the family formerly held by the minister of religion. Soon the former learned all the weaknesses and secrets of the family, binding him more closely, and the relationship between physician and family was considered a great blessing. Thus during the latter half of the eighteenth century the doctor occupied a position only inferior to the nobility. The State also aimed to elevate the position of the physicians. In 1748 they were ranked between the knights and the nobles. The latter loudly disapproved of this classification, so the emperor settled the matter in favor of the doctors, who of their own accord had expressed their desire not too closely to approach the birthright of the gentry in writing. Joseph II. abolished an old law existing in Galicia, that any nobleman who practiced medicine should be deprived of his rank. Afterward the physicians partially lost their high esteem, principally on account of those who, by means of pride, charlatanerie or grossness, which had become typical of our class, ingeniously tried to force their rank. To attain this end they employed many little devices, for as in all ages the laity judged the physician more from appearances than by his scientific knowledge and talents. He who hastened to a bedside and remained a long time, chatting to the patient and those surrounding him, wrote a new prescription at every visit, bowed low and kissed the hand, was the most highly respected, and as long as there are physicians it will never be otherwise. Even Galen complained that he had noticed many doctors by paying compliments in the morning and attending a social dinner in the evening, rose to the rank of a "Doctor of Fashion."

The layman valued the physician with gray hairs the most, for he reasoned thus: The greater the age the greater the experience; a correct inference, providing he was a capable critic. But if he lacked this talent of observation then his experience was of as little value as an old shepherd dabbling in our science.

In answering the question: How can one soon become a great and noted physician, a fine set of rules for success is found in Gruner's Almanach of 1782, which are as follows:

1. Enjoy as long as possible all pleasures of academic life; study a little of everything and for the rest depend upon your good head and your glib tongue.

2. On your return to the Fatherland be the wise-acre and derive all your wisdom from journals and newspapers.

3. Give your opinion on everything as if you were an adept in the art whether you understand the matter or not.

4. Praise yourself and your merits, your successful cures and operations, on every occasion, especially when meeting those incapable or not desirous of criticizing you, and all other know-nothings treat with contempt.

5. Be governed by those who wish you well, flatter them, please them in all respects, and as the occasion demands be most courteous.

6. Don't continue your studies, but all the more find fault with learning, journals and bibliomania.

7. Begin early in the morning to stroll through the streets and so persuade the inexperienced ones to believe you the greatest and busiest physician.

8. Give yourself the appearance of a busy man even if you are doing nothing.

9. Mention with pride the important observations and discoveries you have made to your friends so often until they believe it.

10. Become a naturalist or a researcher of nature, because it is the fashion and purchase an elegant case for natural products filled with all kinds of bric-a-brac.

11. Invest in a splendid library and a fine collection of instruments and prepared articles, anatomic, chemic and pharmaceutic; cause a bust to adorn your entrance and your renown as a collector to be spread everywhere.

12. Become the editor of a journal or paper, otherwise a co-worker. If neither, appoint some one to laud your deeds in them.

13. When attending a social gathering see to it that you are called away several times and after your return remark how great the afflictions of a famous man and physician are.

14. Procure a court title or one of some scientific society. It will insure you respect and a reputation.

15. Strive to gain the patronage of the aristocracy.

16. Meddle in everything, undertake everything and promise everything and, like a man of rank, keep only as much as you can and desire to do.

17. Go on a trip if possible. Knowledge gathered in Paris or Edinburgh is better than German wisdom.

18. Condemn all medical books that do not come from London or Edinburgh and purchase the original copies, even if unintelligible to you. The possession of them looks so very learned.

19. Keep up a correspondence with the learned and employ your money in obtaining patrons and friends.

20. Be a friend of the superficial colleague, of the ministers, the druggists, barbers, and of the midwives; also of the merchant, if he can be of use in attaining your purpose.

21. Be religious and a strict observer of ecclesiastic tenets, if you can thereby add to your reputation and increase your income.

22. Manufacture secret medicines, and effect, like Ailhand, the publication of letters of convalescents who never wrote you any.

23. Write some paradox article, clothed in modern style, if forced to copy from the practice of the ancients, and confirm your work by invented or false observations, regardless of the connoisseur and independent thinker.

24. Marry the daughter of an eminent man (distinguished relatives increase purse and mind) or of a rich man, be he of superior or inferior rank. For money encourages one and occasionally makes fame.

25. Have your photograph taken several times and have steel engravings made, accompanying them by your titles, whether merited or unmerited.

26. Assist wherever you can gain honor, money or reward, unmindful of right or wrong.

27. Make it a point to intertain the public with the latest news, with the introduction of novelties, with modern changes in art, with various rumors, etc., and cause them to feel your great value in diverse ways.

28. Boast of the many professional offers you have received from all parts, and if necessary, have some

relative prepare some plausible papers for the purpose. The following instance of Dr. Faust shows us by what means some of the colleagues sought to draw on the people. When Dr. Faust settled in a village he sent out printed sheets offering his aid to the peasantry. He introduced his circular by: "My dear countrymen! It is well for us to know the man with whom we are to have anything to do, so I say to you that I am a just, good and upright man." Then he advertised that his price for a prescription was only a groschen (about 2½ cents), that the medicines he dispensed could be had at cost price or prepared for a groschen; the real poor would be benefited without paying the groschen. In conclusion the advertisement read: "And now, dear fellow-men, I hope that you will not need my services. But if you do you will find that I am an honest and sensible man. Farewell! Altmorschen, the 6th of November, 1785.—B. C. Faust, Dr."

The number of physicians in the beginning of the century was limited, but greatly increased toward the latter half. This increase was partly caused by the growing dislike for the ministry and the abandonment of many cloisters, and partly by the greater number of public offices being filled by the sons of the nobility, making it difficult for the middle classes to obtain any of these positions. The very easy examinations also contributed thereto. On account of the superfluity of young physicians, no more than six inland candidates were allowed to graduate in Vienna every year (1789). The greater mass of the profession was comparatively ignorant; there were as many titled dabblers as real quacks. Aside from the complaints of the great men, that there were not twenty out of a hundred physicians, who had intelligently read Hippocrates in the original language, and that many had never even seen his works, the studies of the practitioner were at a stand-still. They never changed their views, read nothing, obtained no information on anything and followed their old rut of practice. But a few had such an excessive thirst for knowledge, that they continued their studies while out on the street. Stoll, who had a large practice in Vienna, put several volumes, especially Boerhaave's writings, into his buggy, which he read while driving. No one concerned himself much about literature and the younger physicians knew little of what had been written prior to the beginning of their studies; most of them cured palliatively; not knowing the nature of the disease, its origin, or its symptoms. They had but little knowledge of pharmacology, for many mixtures prescribed decomposed, soured or turned into a poison. These were extremely expensive prescriptions—"but physicians and druggists ought not to foster an unlawful and secret agreement." (Austria, 1872). Hieroglyphics in writing prescriptions were still used, as: ∇ was the sign for water, † tr. pur. for saltpetre, ⊖)-(ac. crud. for sal-ammoniac, and others. Not until about the end of the century a greater interest was taken in the study of materia medica, as well as a preference shown for the same, and those in possession of many approved prescriptions were thought to have invaluable treasures. The physicians became druggists. An idea of the amount expended for medicines in the various hospitals may be gleaned from the following: In the year 1796, at the clinic in Jena \$680 worth of medicines were needed for 540 patients; and for the Kieler Hospital in 1797, the total of the apothecary bill was \$711 for 343 patients. On

account of their low degree of education, disputes among the physicians were common occurrences. Often these became so heated, that they were discussed in public and the most absurd measures planned to extirpate such an evil. According to the opinion of theologians there was no class of professionals in the whole of Germany who contradicted each other oftener than physicians. Whether they attended the same university, were instructed by the same teachers or learned at the bedside of the same patients, was a matter of indifference to them, but when practicing they met at the home of a patient, the spirit of opposition arose. A code of ethics was not followed by physicians in consultation, for if an improvement resulted in the patient's condition, the consulted physician received the credit, while on the other hand, if the patient died it was considered due to the treatment of the regular doctor. Hence ensued the aversion for consultations among physicians, particularly the older men. If a slight shake of the head was noticed by some member of the family, a little wrinkling of the forehead, or a scarcely perceptible smile on the part of the consulted colleague, then the confidence of the family physician was irrevocably lost; although he may have been incapable of correctly diagnosing the disease in the first acute stages, the nature of the same was readily understood the moment the second physician was called in. There accrued an intolerance of sects and advocates of different methods of practice. If a patient died, the one party cried out that the other had beaten him to death. The animosity toward the learned physician was often vented in such expressions as: "He cured his patients in Greek. . . . they died from the influence of too much Hippocrates," and such. The opinions of others were not tolerated and it was believed that there was only one saving and infallible church of medicine, which was defended with an amount of arrogance and animosity, which had no equal. But systems and hypotheses were subjected to so many sudden changes, that the younger generation seldom held the same opinions as the older, although the difference was often only apparent, not real, being clothed in a different language. In large cities, where many consultations were held, the practitioners made an agreement, something like Molière's axiom: *Accordez-moi la purgation, je vous accorderai la saignée.* What the family physician prescribed was good and the drift of the whole consultation was that everything was sanctioned in a friendly manner, but silently conditioned to enjoy a similar collegiality, should the case be reversed. He who was not loyal to this party was excluded from the consultation, or a great tumult arose, if it was absolutely demanded. The conduct of physicians toward each other professionally, was not an honorable one, for they were very envious of each other. They could not endure to see the financial conditions of a physician in great demand improve day after day, when they themselves were remaining far behind. Envy combined with an over-estimation of self, made them uncharitable and intolerant, and even if the merits of the more remote were willingly acknowledged. Those of the nearer colleagues were ignored and underrated. The mass of medical students has been without means from the very beginning, which is very detrimental when entering on their practice. In Vienna it was a common occurrence that medical students, in order to live, accepted a position as tutor or steward in some

wealthy family. Maria Theresa decreed that only the most talented of the laity be admitted to the study of medicine. For some time practitioners among the higher classes were honored with titles by the State. Beginning often as private surgeon, they soon advanced to the position of private physician, and if made privy councillor, reached the highest round of earthly happiness. Among these climbers there was a wild chase after titles. If you made yourself ridiculous by being addressed as "Mr. Counsellor of Justice" or Mr. "Counsellor of the Superior Court of Justice," whether P. Frank, himself privy councillor and private physician, called to mind how absurd it would have sounded to say Privy Councillor Hippocrates and Private Physician Galenus, was immaterial. This "miserable chase after titles by physicians," which Kurt Sprengel also severely criticised, this inequality, which was thereby carried over into the social standing and not tolerated by the weaker characters, caused much ill-feeling. If the privy councillor believed that his higher title also gave him a scientific preference or rank, the position of the lower ranks of the profession was hard indeed, and these often showed their spite by contradictions at the consultations. At the beginning of their practice the younger physicians had to battle with all these disadvantages. They soon perceived that scientific knowledge alone did not reap the greatest harvest, but that the artifices of flattery and ostentation were the most profitable. In consequence many intelligent men cursed their thankless profession, lived in poverty, or very early in life resorted to by-ways to obtain a practice by means of which they could support themselves. Others, like the quack, proclaimed their skill and corrupted the position of their colleagues in a malicious way. The rules prescribed by the state as to the proper conduct of physicians availed nothing. The Austrian physicians "ought, at all times, to lead a good, decorous and righteous life; deport themselves toward every one, as well as toward each other, in a quiet and modest manner; not derogate one another as to his skilfulness nor as to his profession, nor by underrating one of his colleagues obtain his patients; carefully investigating their condition and constitution, ought not to disclose the secretly discovered wants and frailties of anyone, and in consultations necessary to ascertain the recovery of a patient, should unite their jurisdiction and skill to further the same; not prescribe for a patient secretly, without the knowledge of the regular professor, nor give him medicines prepared by himself, unknown to the regular physician, but be especially impressed with the importance of their calling when following the same, and bear in mind that every carelessness perpetrated by them conceives a subtle murder for which they will some time be held accountable to God." (1753.)

The measures taken to prevent the quarrels of physicians were poorly chosen. Prominent men gave well-meant advice to the young physicians how they were to conduct themselves toward patients and colleagues and what would be of advantage to them in their pursuit. But they overlooked the fact that the young men revealed no inclination to accept such precepts and conducted themselves with the same spirit of independence as heretofore. Fines were imposed upon the physicians in Jülich-Berg, who quarreled during a consultation in the presence of a patient, or slandered an absent physician. A man who gave the provocation had to pay a fine of ten

dollars, the one who took it up in a similar temper, five dollars—physicians fared no better, the fine for slandering an absent colleague and corrupting his good name was fifty dollars. Peter Frank believed that this nuisance might be abated by a more extensive education of the practitioner, therefore proposed the establishment of public libraries to promote greater facility for study, the contributions for which would be small in comparison to the expense of a private library. Circulars were to be sent out in the city and the country. He also recommended the formation of medical societies, to induce physicians to be more sociable and to meet once a week for the discussion of serious cases. Stieglitz did not share his opinion when a young man; deemed a true spirit of friendship among physicians more valuable and more beneficial than all medical associations, in which he did not believe.

The drinking habit, it is well known, was common among the physicians as well as the members of other social circles. The German has ever done honor to the cup and foreigners have not, without cause, held up this thirst as a general disgrace to him. In Venice it was customary to offer the physician a cup of coffee when paying a visit to a patient of nobility, so the busy doctor was obliged to drink on an average of twenty cups of coffee a day; in Southern Germany, however, the courtesy offered was a pint-glass full of wine.

The laity drank much brandy, the abuse of which gained such ground that Heister made the proposition to allow its sale only at apothecaries' where it was to be retailed in small quantities. To prove his assertion that brandy was unnecessary, Heister said that the Grenadiers at Potsdam were fine-looking men, although they were prohibited from indulging in a draught, by the King of Prussia. The number of practicing physicians being small in the first half of the century, their income was sufficiently large and lived however in modest circumstances, corresponding to those of the peasantry. During the reign of Friedrich Wilhelm I. of Prussia, doctors were not allowed to charge exorbitant prices for their services, especially when attending the poor; they "must diligently strive to make them as moderate as possible." In Austria a patient was not allowed to change his physician or surgeon, unless he had paid him well, yet "to contract for big wages was forbidden." Later on, the increase in the number of physicians impaired their incomes; many scarcely made a living in spite of their great exertions. At that remote period, complaint was made that deceased physicians' wives received no pensions, although their husbands had died from contagious diseases contracted in hospitals or during epidemics. Accordingly a Medical Widows Association was formed in Vienna, in 1758. The rules prescribed were:

	Braunschweig. Lueneburg. 1719	Grafschaft. Lippe. 1789	Prussla. 1815
Daily prescriptions	3 Mgr.	3 Mgr.	1/8-1/4 Thlr.
1 visit	24 Mgr.—1 Thlr.	12 "	2/3-1 1/2 "
1 visit after 10 o'clock	1 Thlr.	24 "	2-3 "
Every succeeding day-visit	6 Mgr.	4 "	1/2-2/3 "
Every succeeding visit after ten		12 "	1-2 "
A visit, one mile out, without traveling expenses of board	1 Thlr.	2 Thlr.	1-2 "
A visit at night, one mile out, without traveling expenses of board		Besides the inflage 8 Thlr.	5-4 Thlr.
To attend a surgical operation		1 "	1-3 "

One Thaler equaled 73 cents; one Mgr., 23,85 cents. (The Swedish physician had a right to demand one German specie dollar.)

On New Year's Day the druggists were wont to make valuable presents to the physicians and surgeons; it

was also the day for rendering bills. On account of the long interim, the laity did not remember how much they really owed for services rendered; the consequence was many complaints about the amounts charged. The following is the main substance of three contemporary protest letters written in the year 1760 in Hamburg: "Think of it! the Doctor has sent me such a bill that I'd like to put him in the pillory for it! I had a little hemorrhage of the lungs, in two days coughing up scarcely more than a little pailful of blood. A few times he called at night, and for such a visit, the distance being only a step, the impudent fellow charges me a rix dollar, and beside that for every other visit he put down one mark. Aye, truly, he earns his bread very easily."

A consumptive woman, worth about 40,000 marks, who had received sixty-two professional visits, and a number of bottles of medicine beside, writes: "Sir, here are the hundred marks of Lubec; but never enter my door again! I will not pay a mark of Lubec (legal) for a visit, and for the 38 marks charged for medicines, I might have kept house a long time or made myself some fine presents. My life is so dear to me and my cough is not so intolerable that I must allow myself to be reduced to a beggar."

"Is it right, that I should pay a bill to the Doctor for my husband who died, when he ought to have helped him? I am now tired of paying bills. Besides, I don't want to throw my money out on the street. He suffered with dropsy. Three times the water was tapped, but it did no good. An hour before his death he said: My dear wife, it is of no use, I must die, so don't give the fellow a dreyling (penny), for he is letting me waste away. Now he has died, so he shall not have a single penny."

Only a few physicians, principally the private physicians in the large cities, had royal incomes, being handsome paid for the cures they effected. The Courts of Vienna, Berlin and St. Petersburg made the first private physicians privy counsellors, thereby imitating a custom which had existed in France for a number of years. When Joseph II. suffered from an ulcer (fistula) in the rectum, which was successfully removed by the Knight of Brambilla, he made him and his body physician von Stoerk, a present of 1000 sovereigns and a diamond ring worth 6000 florins; the younger Brambilla received 6000 florins and a ring worth 2300 florins, and the private physician Kollmann 4000 florins and a ring valued at 1300 florins. A few days before the death of Joseph II. Guerin was called in for a consultation, for which service the Emperor gave him a barony and 100,000 florins. The Emperor's royal brother, Frederick William II., of Berlin, gave Dr. Brown, who successfully vaccinated the princes and princesses of the House of Prussia, 10000 Prussian dollars (73 cents each U. S.) and pensioned him for life, the amount of 600 Prussian dollars being by and by raised to 1200. Not less generous was the King of England, George III., who for the treatment of his well-known trouble by Father Willis set apart 1500 pounds sterling for his yearly wants to run twenty-one years, and for the son, a life-pension of 650 pounds sterling. The other attendants received 30 guineas for every visit they paid in Kew. Occasionally the position of the court physician was abused, for instance, in 1780 when he had for many years attended the poor aristocracy of one of the German Courts, they gratuitously sent him testimonials of their friendship, accompanied by diplomas of recom-

mendation for services rendered, containing the gracious remark, that if he demanded as much as a penny for them, he would be disgraced with a dismissal.

PECULIARITIES OF THE SURGICAL DISEASES AND INJURIES OF THE NECK.

BY EDMOND SOUCHON, M.D.

PROFESSOR OF ANATOMY AND CLINICAL SURGERY, TULANE UNIVERSITY.
NEW ORLEANS, LA.

(Continued from page 308.)

PECULIARITIES OF THE SURGICAL DISEASES AND INJURIES OF THE INFRAHYOID REGION.

Congenital malformations.—It is in the lower part of the region that the orifices of the bronchial congenital fistulæ of the neck are most frequently met, near the head of the clavicle; they may also be met in the thyro-hyoid region. Median fistulæ below the larynx exist but their internal orifice is always pharyngeal, not tracheal. Median thyro-hyoid fistulæ also exist, but they are always secondary, resulting from the rupture of a cyst; there exists only one positively identified case on record.

Acquired malformations present no peculiarities.

Swellings of the region are mainly due to the various diseases of the thyroid body, which will be especially described further on.

Burns and the effects of cold are only peculiar in the possibility of being followed by cicatrices which bind the neck, and chin down to the sternum in a very peculiar manner.

Contusions are usually due to blows, to the passage of a carriage wheel, to garroting, to hanging; on account of the presence of the larynx and trachea they may be followed by great concussion effects altogether out of proportion to the severity of the blow. Contusion of the thyroid cartilage by a blow upon and close to it may cause death without any appearance of a lesion. Contusions may cause rupture of the larynx and trachea. In hanging the compression very often bears upon the base of the tongue, and the larynx with its vessels and nerves are not injured. In strangulation the traumatism is applied upon the larynx and the trachea, which may be torn by the fingers and the rope; all the structures are more or less torn. In some cases lesions of the skin of the neck, of the trachea and of the larynx may cause inhibition of the heart, of the respiratory organs, and of the brain. It is especially in cases of traumatism of the anterior region of the neck that we observe a complete loss of consciousness and a respiratory and cardiac syncope. This is what takes place in cases of death through incomplete hanging, which does not prevent the passage of air through the respiratory passages. In such cases the red blood of the arteries continues red in the veins, whereas in death by true asphyxia the blood becomes rapidly black in the arteries. Accidental wounds are rare; the most frequent are punctured wounds resulting from a fall on a sharp body.

Homicidal wounds are not so rare; they are usually incised wounds and a cutting instrument is used by the criminal to make believe they are self-inflicted or accidental. Suicidal wounds are the most frequent; they are seldom punctured; they are usually incised wounds; they are most frequent at the point of the thyro-hyoid ligament or below it; they are lacerated,

jagged, deeper on the left side; they are usually directed from left to right and obliquely downward or transversely across the neck; the large vessels are seldom injured. Usually the suicide, throwing his head back, cuts too high; the trachea and the rigidity of the sterno-mastoid protect the vessels. If the head is too much bent the larynx, the trachea and the sterno-mastoid also protect the vessels. There is usually a single gash. These wounds are more commonly fatal than the other wounds, because the victims are usually intoxicated or are laboring under delirium tremens or insanity; these patients should be watched closely because they often tear away their dressings and die of hemorrhage. These wounds sometimes present much hemorrhage, although none of the larger vessels are hurt, except the anterior jugular vein; there are cases on record where air has penetrated into it and to the heart, causing death. The edges of these wounds are often much separated and have a tendency to roll in on account of the action of the fibers of the platysma; coaptation therefore needs more care. Lacerated wounds are very rare. Gun-shot wounds are also rare. Balls may traverse the neck without wounding any important structures, because the tissues are round in form, elastic, movable.

Bites by dogs are comparatively common; the anterior region of the neck is the favorite aim of dogs, especially the bull-dog; they cause all the lesions of strangulation and of incised wounds.

Non-penetrating wounds, *i. e.*, not involving the larynx, trachea, pharynx, esophagus, recurrent nerves, are not peculiarly serious and should be treated as elsewhere, taking care to secure the divided vessels, etc. Penetrating wounds due to any cause involving the respiratory or digestive tract and the recurrent nerve are of course severe. Punctured wounds, especially in duels, may penetrate into the mouth, pharynx, esophagus, larynx or trachea; it is important to look for such penetrations and to keep the parts as thoroughly disinfected as possible because there is often risk of infection of the wound from within. The landmarks are the hyoid bone, the thyroid and cricoid cartilages; the laryngoscope should be used.

Penetrating wounds above the larynx are less dangerous than those of the larynx and those below it; the lower the wounds the more dangerous they are. Wounds through the thyro-hyoid membrane penetrate into the pharynx, injure the epiglottis, the aryteno-epiglottic folds, the cartilages, the vocal cords; they are less dangerous than below because they allow feeding; they are more liable to suppuration. Wounds of the larynx are comparatively frequent because of its prominence; they are usually very dangerous and may be diagnosed by the rushing sound of the air passing through. They should be treated like those of the trachea. Wounds of the trachea are commonly followed by great hemorrhage; because of the large vessels around it, which may also have been wounded by the same cause. When the severance is incomplete, there is slight gaping; when the section is complete, the lower end is drawn in deep at each effort of respiration, and the soft parts cover up the orifice, causing suffocation. In all cases keep the blood and foreign substances out of the respiratory tract until hemorrhage is checked. Rose's position may be of assistance. In incomplete wounds there is slight gaping and the wound should not be stitched; the head should be flexed on the chest and fixed in that position by a liquid glass bandage. In complete

wounds, when longitudinal, there is little gaping. In complete transverse wounds the retracted lower end should be searched for and a strong thread passed deeply through it, an attempt at stitching should be made; if it fails a tracheotomy tube should be placed in it; the tube should be longer than the ordinary one because the swelling may lift it out of the trachea; the head should be kept flexed also; a moist cloth should be placed over the tube; the room should be warm, at about 70 degrees, and a vessel with boiling water should keep the atmosphere moist; all this to avoid bronchitis and pneumonia. Later we should be mindful of the exuberant granulations which may obliterate the canal.

The sequelæ of wounds of the air passages are permanent contractions of these passages, aphonia, fistulous orifices, entire occlusion of larynx, the air passing through the external wound; fistulæ are hard to cure. Wounds of the pharynx and esophagus are usually done through the side of the neck by balls, knives, etc.; they cause much pain, spasms, hiccough, dysphagia, more or less suffocation; there is escape of food through the wound if this be of a certain size; the thirst is great. The patient should be fed by enema; if the use of the esophageal tube becomes necessary from insufficiency of the rectal alimentation, it should not be left in place, but introduced each time. In incised wounds stitch immediately; in lacerated wounds let the wound granulate. Rupture of the esophagus from contusions are rare; the special symptom is hematomesis. When the diagnosis is sure cut down upon the injured spot along the anterior edge of the sterno-mastoid; stitch the wound if possible; if not, pack and let it granulate.

The immediate dangers of wounds of the anterior region of the neck are death from hemorrhage; although the hemorrhage stops from syncope it may start again later; from asphyxia due to the tongue or epiglottis or a piece of cartilage obstructing the passage, or to blood and clots in the larynx and trachea; from penetration of air in the veins. Penetration of the respiratory tract is recognized by cough, blood expectoration, hissing or boiling sound. The secondary dangers are inflammation of the larynx, edema of the glottis, bronchitis, pneumonia, abscess and purulent dissections, emphysema, aphonia more or less complete, dysphagia; secondary hemorrhages are common and serious complications. In all injuries with solution of continuity of the mucous membrane the most frequent source of death may be mediastinal emphysema and inhalation pneumonia.

Wounds of the neck parallel to the longitudinal fibers of the muscles are more apt to be followed by emphysema. The remote effects and sequelæ may be exuberant granulations causing dyspnea; cicatrization, producing strictures of the larynx, trachea and esophagus; persistent fistula; paralysis due to inflammatory thickening, which may disappear later, or due to injury of recurrent nerves or the pressure of a bullet. All these complications should be treated here as elsewhere.

Dislocation of the hyoid bone is very rare. There is one case (Gibbs) in which the dislocation was muscular; it was accompanied by a peculiar click on the left side of the neck and a sensation of choking; examination showed displacement of the left horn of the hyoid bone; reduction was affected by throwing the head backward toward the right side, so as to stretch the muscles of the neck, and then suddenly

depressing the lower jaw, thus bringing the depressors of the hyoid bone into action. All the following fractures are usually due to violent contusions.

Fracture of the hyoid bone is rare, but it is well-known; its site is usually the great horn, near the body; it may be unilateral or bilateral; it is characterized more or less by hoarseness and dysphagia, according as it is without or with displacement and without or with deformity, it is accompanied by more severe symptoms, especially when swallowing fluids, which pass into the larynx, because of the imperfect action of the epiglottis; it is reduced by using the fingers inside the oral cavity.

Fractures of the larynx are less rare than fractures of the hyoid bone; they are due to great violence; they are usually accompanied by much pain and suffocation, often calling for immediate reduction or for tracheotomy. Each cartilage may be fractured by itself; the thyroid is most frequently the site; fractures without displacement are not so grave. Fracture of the thyroid cartilage is more common in old people, because of the ossification of the cartilage. Fracture of the cricoid is more dangerous than the others, perhaps because of its small size, which causes slight displacement to be followed by serious obstruction. Fractures or subcutaneous ruptures of the trachea without actual wound have been observed after great traumatism; they are less frequent than the others; they present the same symptoms and indications as the fractures of the larynx, but the lesions are lower down. The trachea should be opened below the fracture, and a long tracheotomy tube be introduced; when the fracture is low down, the lower end should be hooked, raised and sutured to the skin or upper fragment. Spontaneous ruptures of the trachea due to violent efforts, are admitted by some. All these fractures are more serious if accompanied by displacement which obstructs the air passages. The symptoms are those of obstruction and shock, plus those of fractures in general; crepitation, abnormal immobility, plus also aphonia, dysphagia and emphysema. The fragments should be replaced by external and internal manipulations; if necessary, the parts should be incised through and the fragments stitched. Tracheotomy is often indicated; it is well to perform the operation before grave symptoms develop, because these sometimes come on so suddenly that the patient may succumb before the surgeon can be had to operate.

(To be continued.)

Fourteenth Biennial Report of the Board of State Commissioners of Public Charities for the Years 1895 and 1896.

ARTHUR R. REYNOLDS, M.D., PRESIDENT.

(Continued from page 315.)

IMPROVEMENT OF ATTENDANTS IN HOSPITALS FOR THE INSANE.

We believe that the State hospitals for the insane may well excite the pride of the citizens of Illinois. Their material equipment is admirable and in the whole their condition has undoubtedly never been as good as it is at this time. Such institutions, however, can not stand still. They must either retrograde or continually improve.

The medical and nursing care should always command our greatest interest, and it is here as in educational institutions of the State, that there must be continuous progress if there is not to be retrogression.

Early in 1896 the State Board of Charities sent out a list of inquiries to superintendents of hospitals for the insane in the United States regarding attendants or nurses. We present below a condensation of the replies received, fifty-eight in number. The inquiries were made because of the belief of the board,

founded upon careful observation of hospitals in this and other States that improvements in what should be the nursing care of the patients is at present the greatest administrative need of hospitals for the insane.

In the condensed statement below it will be seen that out of the fifty-eight State hospitals considered less than one-half have training schools.

The general average monthly wage for working day of sixteen hours is from \$18 to \$30 per month for men; from \$12 to \$25 for women. It will be remembered that the State of Illinois considers eight hours a working day for clerks and others whose employment does not carry with it any great responsibility.

On the other hand it is, so far as the board knows, universally admitted that no work is more exhausting to the nervous system than caring for the insane. It requires a disciplined mind and high character to bear calmly and patiently with the violent or annoying conduct of many insane patients and to regard all their unreason and extravagance as symptoms of a disease, no more to be resented than a rise in their temperature. Ought the State to expect to obtain such qualifications when the hours are twice the legal working day and the compensation no better than that of city house servants?

For the most part the attendants both lodge and eat upon the wards, *i. e.*, practically in the society of their patients. The time during each twenty-four hours in which they are permitted to absent themselves from the ward is two hours or less in forty-seven hospitals, including four of those in our own State.

The proportion of attendants to patients, as it actually exists in the hospitals, is, with few exceptions, much below the number recommended by the different superintendents of the same institutions. The superintendents, however the conditions of their own hospitals vary or depart from the desired standard, recommend in thirty-eight cases: 1, training schools; 2, higher wage; 3, housing and boarding of attendants in separate buildings apart from patients; 4, separate night service for the wards—which is the necessary accompaniment of boarding and housing attendants in separate buildings.

A more general employment of women attendants upon men's wards is recommended. This recommendation comes especially from those superintendents whose standing best entitles their opinion to respect. There is practically unanimous testimony to the superior service obtainable from women. This is ascribed in part to their natural taste for nursing, and in part to the fact that more avenues of desirable and lucrative employment are open to men than to women. We would respectfully submit that since it is possible to obtain a better grade of service among women than among men for the same pay, there is good reason from an economic standpoint, for urging the most general employment of women practicable. Women are employed on men's wards in some of the most progressive hospitals—including one of the Illinois hospitals. This does not mean that there shall be no men attendants, but points toward a partial introduction of the system in the general hospitals, with nurses in charge and male orderlies. This system, so far as tried; has satisfied the humanitarian and the physician alike.

It seems evident to us that, in order to secure proper nursing, the wage must be raised; especially does the women's present wage seem to us inadequate and unfair for the service demanded. The wage paid can not invite or retain, with any certainty, the sort of ability demanded for the care of the insane. It appears to be the general opinion of the superintendents, as shown in the "Remarks," that by increasing the requirements for an attendant, and also the pay and dignity of the occupation, efficient and humane service can be obtained, and in no other way.

Four of our Illinois hospitals are included in the replies and probably present the average condition indicated in schedule. One of them has a training school for nurses and employs nurses upon men's wards. The one failing to report is in no particular superior to the four which appear in the condensation.

VISITING STAFF.

While as we have stated above, we must depend upon the general practitioner to keep people out of the insane hospitals, we must look to the alienist for improving their medical care after they are received into the hospital.

It has proved impossible in all the States to maintain in a hospital a medical staff of expert alienists. The superintendent, burdened as he is with the administrative work of the community of from 1,000 to 2,500 souls, which our various hospitals constitute, can not take personal charge, medically, of the patients upon the wards also.

We therefore would recommend a visiting staff of alienists

or specialists upon mental diseases, who, together with the resident physicians, shall constitute the medical staff of the various insane hospitals, such visiting staff to visit in turn, examine patients, hold clinics and deliver lectures to the resident physicians, internes and nurses. We believe that such physicians should be paid for their services.

PATHOLOGIST.

The Board believes that the pathologic work of every insane hospital in the State should be thoroughly done. This can only be done under competent direction, and the board recommends as the most effective and economic method of doing this the appointment of a State pathologist, who shall be a member of the visiting staff, but shall devote his entire time to the pathologic work of the hospitals, and shall make the same uniform in character throughout the State.

MERIT SYSTEM.

The Board recognizes that such suggestions as the above concerning physicians and nurses, must fail, even if nominally carried out, unless all the positions involved be placed entirely upon a basis of efficiency.

In fact the entire administration of these hospitals must, in the opinion of the board, depend upon merit, absolutely unmoved by fluctuations of political party fortune, if the institutions are to continue long free from grave disasters.

COMMISSION.

In view of the statements made above we would respectfully request the Governor to appoint a commission of three physicians experienced in the care and treatment of the insane, to cooperate with this Board in formulating and putting into execution plans for securing: 1. A general plan for the future care of all insane by the State. 2. For promoting the most efficient medical and nursing administration of the existing hospitals. 3. For placing the service of the insane hospitals upon a basis of merit only.

CIRCULAR AS TO TRANSFER OF INSANE TO HOSPITALS.

We append a copy of a circular sent out Sept. 1, 1896. This was followed by a letter to all county judges, calling their attention to the fact that under the provisions of the Lunacy Law, they have power to direct how insane patients shall be transferred to the hospitals. We have reason to believe that these efforts to improve the care of insane patients prior to arrival at insane hospitals have had some good effect, but the matter still needs earnest attention.

PRIVATE HOSPITALS FOR THE INSANE.

Under the Lunacy Law of this State the Board of Commissioners of Public Charities is directed to license all private insane hospitals and to formulate by-laws as to their administration. Such licenses are good for twelve months and must be renewed annually, in order that the institution may lawfully exist. If there is a change in the management of a private hospital, the law requires that the Board be notified and that the license be transferred in the discretion of the Board.

During 1896 application was made to this Board for permission to transfer from Dr. Anna McFarland to Dr. George C. McFarland the license granted by this Board to Dr. Anna McFarland to carry on the private hospital for the insane known as Oak Lawn and situated at Jacksonville. After a careful examination of the case the board declined to consent to the transfer of license to Dr. George C. McFarland. Notwithstanding the refusal of the board Dr. George C. McFarland has continued to carry on the hospital. The Board has therefore referred the matter to the Attorney General for prosecution as by law directed. Sec. 33, Lunacy Law.

It is plain that the provisions of the Lunacy Law in regard to licensing private insane hospitals are intended as a protection to the public and a guarantee of good conduct. Such a law is not only a protection to the public and to the insane patients received into private hospitals, but is also a protection to private hospitals which are carried on faithfully and humanely.

We trust that the decision of the supreme court may be speedily obtained as to the provisions of lunacy law covering the licensing of private hospitals, to the end that the law may be amended if necessary.

The private hospitals for the insane now licensed are: Bellevue Place, Batavia; Dr. F. C. Winslow's Private Hospital, Jacksonville.

SOCIETY FOR AIDING CONVALESCENTS DISCHARGED FROM STATE HOSPITALS FOR INSANE.

We commend to private benevolence the temporary care of convalescent patients discharged from insane hospitals. Persons thus discharged as recovered struggle under great disadvantages in many instances in trying to obtain opportunities to

earn a living; it is the observation of all superintendents that discouragement and disappointment have frequently brought on another attack of insanity and compelled a return to the hospital, which might have been avoided if on leaving the institution the patient had enjoyed a little friendly help. A small yearly sum and a moderate amount of personal interest would perform a most humane and useful service in carrying on a society for the assistance of patients discharged from the State hospitals, and we commend the subject of the organization of such a society to the attention of philanthropic citizens. There are two societies for this purpose in Paris, which are reported as most beneficent in their result.

THE AUXILIARY BOARDS OF COUNTY VISITORS.

These boards have proved valuable in some counties already, but have by no means reached their full measure of usefulness throughout the State. A pamphlet containing reports from such as had performed active service was issued by this Board during the year. We append a list of the visitors who made reports in July, 1896, together with statement of visits made. In some counties marked improvement in the equipment and administration of the almshouses has been secured and less frequently improvement in the jails.

We feel that it is for public interest that these volunteer and unpaid public servants should be encouraged in a wise and vigorous performance of their duties of visiting the county jails and poorhouses and keeping themselves fully informed as to their condition. Yearly conferences addressed by experts in the care of dependents and in preventive measures, and where full opportunity for discussion is allowed can not but prove most valuable, and are essential as a means of educating public sentiment in the State.

At the State Conference of Charities held in November, 1896, it was found that the attendance of auxiliary visitors was smaller than had been hoped, and in repeated cases the members of the auxiliary boards stated that they could not afford to attend. We would recommend that the legislature permit the State Board to pay the railroad fare only to the State conference of one delegate from each county.

STATE CONFERENCE OF CHARITIES AND CORRECTION.

As indicated above, the visits of members of the Board of Public Charities to the various counties of the State convinced them that an annual conference of the auxiliary boards of visitors, the superintendents of State institutions and of all others interested or engaged in the care of dependent and delinquent classes in the State would prove of much service in diffusing throughout the State a more general public interest in problems which are little understood, and which have a vital relation for every taxpayer, as well as an interest for humane citizens. Such State conferences have been held in various other States for years with good results. The State Board of Charities therefore called a State Conference of Charities and Correction, which was held in Springfield Nov. 12 and 13, 1896, of which we append program.

The conference formed a permanent organization with the following officers for the ensuing year:

President, Jenkin Lloyd Jones, Chicago; vice-president, Fay Lewis, Rockford; secretary, Mrs. John Lutz, Lincoln, executive committee.

Secretary of the State Board of Charities ex-officio Clerk of the Executive Committee.

The proceedings of the Board have been published and form a valuable contribution to the literature of the State upon the subjects presented.

DEPENDENT CHILDREN.

The State through its law of guardian and ward has long said to the rich child, when the normal family relations were for any reason destroyed: "You are a ward of the State; your name is upon the records of the court; you shall not be lost; your estate shall be used for your education, and the guardian appointed by the court shall report his stewardship."

Because the child deprived of natural family care has no estate there is not less but more reason for public watchfulness. From the ranks of neglected, untaught, unprotected children we have no right to expect that upright, self-respecting, self-sustaining citizens will grow.

The law of Illinois regarding dependent children presents anomalies which certainly have never been purposed by any one and which public interest demands should be eliminated.

The county court can find a child "dependent" under the Industrial School Acts, as follows:

Part of Sec. 3 in aid of industrial schools for girls.—"Every female infant who begs or receives alms while actually selling or pretending to sell any article in public, or who frequents any street, alley or other place for the purpose of begging or receiv-

ing alms; every female infant who shall have no permanent place of abode, or who shall not have proper parental care or guardianship, or who shall not have sufficient means of subsistence, or who from any cause shall be a wanderer through streets and alleys or other public places, or who shall live with, or frequent the company of, or consort with reputed thieves or other vicious persons, or who shall be found in a house of ill-fame, or in any prison or in a poorhouse."

And part of Sec. 3 of act to provide for and aid training schools for boys.—"Every boy who frequents any street, alley or other place for the purpose of begging or receiving alms; every boy who shall have no permanent place of abode, proper parental care or guardianship; every boy who shall not have sufficient means of subsistence, or who from other cause shall be a wanderer through streets and alleys or other public places; and every boy who shall live with, or frequent the company of, or consort with reputed thieves or other vicious persons."

The definition of "dependent child" under these statutes is probably sufficiently broad to cover all cases in which the child's normal family protection has been so broken down that public interest and humanity demand the intervention of the State.

The anomaly in the law is discovered when it is shown that after the judge has thus found a child dependent, he can, under the statute, dispose of the child in but one way, namely, by confiding it to the care of an industrial school—a private corporation. The school or some officer thereof becomes its guardian, having a right to retain during minority, or to discharge at any moment.

Again, it is found in practice that parents whose children are abandoned to almshouses, are nevertheless able to legally and successfully resist efforts to place the children in homes or give them for adoption.

As the counties are compelled by law to pay ten dollars monthly for each child placed in an industrial school, while the child may be retained in the almshouse at a much lower apparent cost, or it can be left in its bad surroundings at no immediately evident cost to the county, many counties object to the expense of placing the child in an industrial school, and when the supervisors or county authorities do so object, it is difficult or impossible to obtain commitments to the industrial schools.

Again, there is, as indicated above, no law forbidding the indefinite detention of children in almshouses, and many children pass through the almshouses of this State yearly through no fault of their own, receiving not only the stigma of pauperism, but the taint of poorhouse associations.

Our last report instances in detail some of the evils of bringing up children in the poorhouse, and it is unnecessary to again set forth special instances. It is true that the majority of children who are in the poorhouses do not grow up and marry inmates, as has sometimes occurred, but the history of pauperism in this State, so far as it can be traced, shows that the associations of the poorhouse in the parents breed dependency in the children, as has been demonstrated by long family histories in older communities.

The Board renews its former recommendation that the retention of any normal child between the ages of 2 and 16 years in any almshouse should be forbidden by law. It recommends that the County Court should have the power, upon finding the child dependent, to place him in an industrial school, or in a private family at no greater cost, or to make such other disposition as he may deem for the best interest of the child. It recommends that by agents, to be appointed by this Board, or by such other means as may be deemed wisest, the character of the homes into which children thus "placed out" are sent, shall be frequently and faithfully examined, and the education and proper maintenance of the child carefully supervised, and that the same shall be reported to the county from which the child comes, and to the body appointing the visiting agent. The States of Michigan and Massachusetts offer examples of State care of dependent children, which we can not afford to neglect or fail to imitate in such measure as best accords with our existing system of industrial schools. The State of Michigan maintains a State school; Massachusetts has abolished hers as unnecessary. In both States the essential feature is a system of "placing out" children by the State itself.

(To be continued.)

SOCIETY PROCEEDINGS.

Chicago Ophthalmological and Otological Society.

Regular meeting held at the Chicago Athletic Association Rooms, Nov. 10, 1896.

Dr. HENRY GRADLE in the chair.

The minutes of the last meeting were read and approved. The application of Dr. J. W. Heustis of Dubuque, Iowa, was read and referred to the Committee on Membership.

Dr. HOTZ showed a case of Thiersch grafting for pterygium. Four years ago Dr. Hotz had suggested the filling up of the space left in the conjunctiva after removal of a pterygium by Thiersch graft. In the ordinary pterygium the operation of excision with bringing together of the conjunctival edges is easy, but in certain cases the space left is so large and the amount of tissue removed so great that he thought it would be advisable to fill it up with a graft. He had used this method a few times about a year ago and showed a case to the Society. In this case the graft had not been fastened, but was simply laid over the sclera and during the first few days it shifted partially onto the cornea. The Doctor had seen the patient only a week ago and the small tag of skin was still over the corneal surface. In the case tonight the pterygium extended considerably beyond the pupil, was very large, measuring at the corneal edge about 8 mm. and at apex 5 mm. The operation was done on May 1. After the removal of the pterygium a small shaving of skin about 3 mm. wide and 9 mm. long was taken from behind the patient's ear. This was laid over the sclero-corneal junction and each end of the graft was fastened down by a stitch, in order to avoid the shifting. In spite of the fact that there was considerable disturbance of the cornea from infection, numerous small points making their appearance in the neighborhood of the wound, the healing of the graft was rapid. It shrank to about 2 by 7 mm. in size. The epidermis became macerated and could be rubbed off with a blunt probe after a few days, leaving underneath a pink membrane. At present the surface looks about like normal conjunctiva.

In reply to Dr. Robertson as to how many cases relapse, the President stated that Fuchs says there should be no recurrence of pterygium if it is possible to close the conjunctival wound.

Dr. PINCKARD referred to the method of removal by means of a grooved director and a small cautery knife, the director being passed under the neck of the pterygium and incision made with the knife from edge to edge.

Dr. GRADLE stated that he had done subvulvotomy once with a very good result.

Dr. MONTGOMERY said that he had in broad pterygia dissected off the head and body of the growth and simply allowed the head to roll under without fastening it with a stitch. He had found that the growth showed no tendency to recur under these circumstances. He laid particular stress on the fact that the dissection from the sclera must be very complete. He reported a case where the growth was tendinous in character and seemed to be fixed to the internal rectus muscle. Numerous operations were done but no permanent benefit resulted.

Dr. GRADLE—The allusion by Dr. Hotz to purulent infection of the cornea in his case induces me to bring before you a very sad result of pterygium operation within my experience.

A man had been treated by me for nearly a year for trachoma of three years' duration. He seemed entirely cured of his trachoma, one cornea had always been normal. The other one had been covered by a moderate pannus, which had thinned considerably under the treatment and now permitted V=15-50. On this eye there was a small pterygium on the inner side, apparently slightly progressive. I had deferred an operation until after the trachoma was cured. The head was then dissected off the cornea and the small conjunctival gap closed with a suture. There was more than the ordinary amount of inflammatory reaction of the conjunctiva for the first four days, then it subsided. Thereupon minute white specks of infiltration appeared in the cornea adjoining the wound and from thence spread in a circular path around the cornea, forming an incomplete circle about 3 mm. inside of the limbus. This was accompanied by increasing ciliary irritation and injection. The area between limbus and the line of infiltration became vascularized and hazy. On the twenty-fifth day the infiltration on the site opposite and furthest from the wound changed into ulceration. The original wound had healed long before this and the minute infiltrates nearest to it had receded considerably. The ulcer was now touched with the galvanocautery. This prevented extension of the ulceration, but did

Laughter.—Laughter is a most healthful exertion. It is one of the greatest helps to digestion with which I am acquainted and the custom prevalent among our forefathers of exciting it at table by jesters and buffoons was founded on true medical principles (Hufeland).

not prevent further infiltration in the form of minute specks in the same circular path. The disease had been very painful and the pain did not abate while the cauterized ulcer healed. A few days later it was evident that a relapse of the trachoma had occurred, as the conjunctiva of the lids now showed the characteristic appearance. For a few days the lids were touched with sulphate of copper, but without benefit. In spite of all customary local treatment (atropin, etc.) a hypopyon made its appearance, yet the individual specks of infiltration all receded after existing for a few days. The patient, worn out by his pain, went to the country for a week. When he returned the irritation had lessened very much but the cornea was uniformly hazy and vascular, and $V = \infty$. There was now a characteristic granular disease of the conjunctiva, which undoubtedly accounted for this unusual form of corneal affection.

Dr. J. E. COLBURN reported a case of

CYST OF THE CORNEA AND A CASE OF PIGMENT CELL SARCOMA OF THE CORNEA, FOLLOWING A PTERYGIUM.

Willie G., aged 15 years, was presented by Dr. E. M. Smith at the Chicago Polyclinic. About six months ago the patient's parents first noticed a pearl-like swelling about the size of a half pea, located midway between the cornea and inner canthus; it extended rapidly in all directions till it occupied the area indicated in the drawing. There has never been any evidence of inflammation.

FIGURE 1.

When examined by me the tumor presented a pearly semi-transparent appearance, somewhat irregular in form; there was a slight depression just at the sclero-corneal junction, which was marked by the vascular ring. The tumor had forced its way into the cornea, separating its layers. The outer layer was transparent enough to allow a good view of the sclero-corneal junction of the inner wall, and somewhat deeply into the sclera portion of the tumor. The tension of the tumor seemed to be the same as that of the eye in other parts of the globe.

The parents recall that in early childhood while at play with a Newfoundland dog the child received an injury to the eye, which was followed by a scar located near the center of the cornea. There was no change in the shape of the corneal scar.

FIG. 2.—1, base of tumor.

The eye was cocaine and the conjunctiva opened over the base of the tumor near its lower edge. The structure of the outer wall of the tumor was found to be continuous with the sclerotic. Fearing that there might be some connection between it and the cavities of the eyeball and the tumor, a very slight incision was made. This was followed by a rapid flow of clear water and a collapse of the tumor; the tension of the eye remaining normal, the incision was extended. The inner surface was carefully examined, for it had been suggested that it might contain a cysticercus. Nothing, however, was found to indicate that the cyst had been tenanted. The lining membrane was not vascular and could not be distinguished from the sclera; the outer wall was thin but firm and resisted the knife, cutting like a true scleral tissue. The inner wall was somewhat depressed and did not seem to be restored to the normal curvature by the removal of the tension of the tumor. After the conjunctiva had been dissected carefully back, the outer wall was entirely removed, the ocular surface carefully

denuded of the lining membrane and the conjunctiva made to cover the exposed surface. The central fibers of the internal rectus muscle were not disturbed. The wound healed promptly and the gray area which extended farther than the tumor upon the cornea, cleared up. The old scar, however, remained without change in appearance.

A careful search through the ophthalmic literature at my command is not rewarded by finding the counterpart of the above case.

In 1894 Wm. S. called my attention to a small, progressive pterygium which had made but slight advance upon the cornea. The growth was again examined by me in six months and a marked advance noted. Three months later the growth was removed by tearing it from the cornea, excising the central portion of the conjunctival thickening down to the sclera, together with the tongue of growth just removed from the cornea. The conjunctiva was now separated from the corneo-scleral junction, and freed from its subconjunctival attachments, and the upper and lower edges brought together by two sutures. The corneal wound was scraped, the eye flushed with a saturated solution of boric acid and a light bandage applied.

The wound closed quickly and three months after the operation nothing could be noticed upon the cornea, and the conjunctival section was smooth and non-vascular.

About six months after the operation the doctor called my attention to the eye, saying that the pterygium had returned. There was no change in the conjunctiva, but upon the cornea there had appeared a thick, dark, slightly vascular mass extending from the near median line upward, and limited by the corneal margin. Cocain was used and an attempt was made to raise and dissect it away. The forceps disclosed the fact that it was papillated and bled freely when torn. Fragments of the growth were taken off and examined by Dr. Hoadley. He reported columnar epithelium, spindle cells of a large size and a dark pigment with some connective tissue.

We decided to cauterize the whole surface with electro-cautery. This was done and but slight reaction followed. The wound closed and for several months close scrutiny was made, but no return of the growth was observed.

FIG. 3.—1, pterygium; 2, area of first growth; 3, area of second growth.

It was my intention to report the case in connection with some other cases of diseases of the sclero-corneal region. However, just as I was preparing my notes, the doctor called my attention to a greatly extended growth, similar to the one we had removed. This was of thinner structure, but covered all the area that had been involved before and extended to the equator on the opposite side, but not coming quite to the center of the cornea. (See Fig. 3.)

May 1896 I again burned the whole corneal surface involved, with galvano-cautery, using a low degree of heat, but burning much deeper and more thoroughly than before. The reaction was severe but the repair rapid and uninterrupted. The eye was irritable for some months. The corneal astigmatism became regular and glasses were given; these have had to be changed frequently; vision is now 20-30. The cornea is transparent and regular.

The report of the microscopist gave the same finding as in the first examination.

We have made frequent examinations of the eye during the past months and are unable to see any evidences of return of the growth. The doctor has had two tumors removed from the face, but no examination was made to determine their true character.

At the President's suggestion the January meeting was set aside for the discussion of "Asthenopia not due to Errors of Refraction."

On motion the society adjourned.

C. P. PINCKARD, Secretary.
103 State Street.

PRACTICAL NOTES.

Heredity of Gastritis.—An article in the *Bulletin Médical* of January 6, calls attention to the frequency of gastric disturb-

ances of the same type in different members of a family, as revealed by analysis of the gastric secretions. In most cases they are unsuspected by the subjects and only manifest themselves by secondary neurasthenia or other trouble. This hereditary tendency should be borne in mind and appropriate treatment instituted, especially in the case of persons with an arthritic inheritance. A number of interesting observations are cited to confirm the writer's statements.

Substances Incompatible with Antipyrin.—1. Those which precipitate the antipyrin, such as phenic acid in concentrated solutions, tannin and its preparations, tincture of iodine, chlorids of mercury, etc. 2. Those which decompose antipyrin when triturated dry with it: calomel, which forms with it a toxic combination, naphthol; chloral which forms an oleaginous liquid; sodium bicarbonate, which generates an odor of acetic acid; sodium salicylate, which also forms an oleaginous compound with it, and lastly the salts of quinin and caffeine, whose solubility is increased by antipyrin.—*Gazette Méd. de Liege*, December 31.

Effect of Chloroform and Ether Narcosis on the Liver.—Bandler of Prague performed a herniotomy on a hitherto strong, healthy man, who was however a hard drinker, using chloroform as the anesthetic. A few days afterward icterus developed and the patient died with cholemic symptoms. As leucin and tyrosin were found in the urine, *intra vitam*, the diagnosis of acute yellow atrophy of the liver had been made and it was confirmed by the necropsy. Bandler has been since studying the literature on the subject and experimenting on animals, to determine the exact effect of chloroform narcosis on the parenchymatous organs. He states that every case of chloroform narcosis showed degeneration of the liver cells afterward, while this degeneration was absent or very slight after ether narcosis. He therefore urges the importance of avoiding the use of chloroform in cases where there is reason to suspect that the liver is not perfectly normal, and using ether instead.—*Wien. klin. Rundsch.* from *Mith. a. d. Grenz. d. Med. u. Chir.*, No. 3, Vol. I.

Dilation of Strictures of the Urethra.—Wossidlo states that relapses are frequent and in his experience almost inevitable when the urethra is only dilated to a No. 25 or 28 Charr. but that they are very rare and yield promptly to treatment if the dilation is carried as far as a No. 30. Microscopic examination shows that in the former case the mucous membrane is not normal, the lumen is funnel shaped and the crypts are filled with an infiltration. Only when the dilation is carried beyond 30 does the color return to normal and the infiltrate disappear. This can only be accomplished by an Oberland or Kollmann dilator. The process must not be hastened, and the reaction following each dilation must be allowed to run its course, which requires ten days, sometimes three to four weeks. The reaction can be favorably influenced by a $\frac{1}{2}$ to 1 per cent. solution of nitrate of silver. Dilation accomplishes nothing with rigid, unyielding strictures and internal urethrotomy is indicated for them.—*Cbl. f. Chir.*, December 26.

A Case of Porro's Operation.—Schwartz reports, in *Centralblatt für Gynäkologie*, a successful case of delivery by this operation. The patient was a rachitic dwarf, aged 19 years. She was three feet, three inches in height, well nourished and muscular. There was lordosis with extremely pendulous abdomen. The pelvic deformity was remarkable, even in a dwarf. Between the iliac spines the measurement was seven and two-fifths inches, between the trochanters ten inches. The conjugata vera was one and one-half inch (4 centimeters or 1.56 inch). The patient was in the ninth month of pregnancy. Pains set in on Jan. 16, 1896; in a few hours the membranes burst spontaneously. Pains continued through the night, but were quite ineffective. Schwartz saw her early on the morning of January 17. The temperature was 104, the pulse 180.

Septic peritonitis was present. Porro's operation was at once performed with full precautions. The child was a fully developed female, 19.5 inches long and 5 pounds in weight. It was saved and reared. For two or three weeks the patient's life was in great peril through septic symptoms with peritonitis, followed by diarrhea. The stump of the uterus was treated subperitoneally. By February 5, convalescence was in steady progress.

Fish Diet in Chronic Nephritis.—J. E. Ferran describes in the *Archivos de la Policlínica* for December, his success in severe and prolonged chronic nephritis by suspending the classic treatment: potassium iodid, milk diet, etc., and putting his patients on an exclusive fish diet, selecting the fish that contain the most iodine, with once in a while a small amount of some vegetable. The improvement is prompt and radical. He mentions one case that had been treated in vain at Paris for two years, which had yielded in a few days to this treatment. He had seen the patient recently in magnificent health, after seven years, with no restrictions as to diet necessary. This treatment is based on Ferran's chemo-clinical studies and is invariably to be preceded by careful analysis of the urine, as he states that it must be limited to those cases that are in a generally satisfactory condition, without too large a proportion of granular cylinders, and in whom the urea, the density, the phosphates and phosphoric acid are normal or above, with over 800 grams of urine eliminated in the twenty-four hours.

Results of Thirty-Two Nephrorrhaphies for Floating Kidney.—The operations were performed in 1894 to 1896. The immediate results were all favorable; one patient died in a couple of months from fibrinous pneumonia, and another of fatty degeneration of the heart in four months; twenty-four are in the best of health to date, and the remaining six have been lost to sight. In twenty-three cases the operation was performed for pains, seven for dyspeptic troubles and two for neurasthenic disturbances caused by the wandering kidney. The patients were all women and in all but one case the right kidney was the one involved. In three cases there had been preceding trauma; enteroptosis was present in three; hydronephrosis in three and cysts in one. Ten were nulliparæ, the other twenty-two mothers. The suppuration was always restricted to the subcutaneous connective tissue and never interfered with the growth of the kidney to the *M. quadratus lumborum*. The peritoneum was not opened in any case.—*Tricomi at the Ital. Surg. Cong., Cbl. f. Chir.*, December 26.

The Latest in Organ Therapeutics; Extract of Lung Tissue.—The *Bulletin Méd.* of December 27, publishes the results of trials and experiments made by F. Brunet with aqueous glycerin extract of the lungs of sheep. Two grams of lung tissue, fresh, shaved thin, to 60 grams of glycerin; after soaking half an hour, 120 grams of sterilized water is added and the whole filtered through linen in another half hour. The liquid is then sterilized in the autoclave, and passed through a Chamberlain bougie and glass tube into the ball in which it is kept ready for use. The doses administered internally were 10 c.c. and in injections, 2 to 5 c.mm. Ten cases of pulmonary affections were treated with it and many animals experimentally. In each case the cough diminished rapidly; the patients increased in weight, and the extract seemed to possess a general tonic property. The pus disappeared from the sputa and the sense of oppression was relieved so that the patients could sleep undisturbed. The general results of the treatment were similar to those of other organ extracts, in respect to the increase in the secretion of saliva, decrease in the amount of urine and increase of urea. Brunet therefore recommends it as extremely beneficial in liquefying bronchial expectorations, and suggests that the technique of administering it should be based upon the experience acquired with other organ extracts. He had no opportunity to observe it in cases with fever.

Precautions in Using the Catheter.—Patients should be instructed in the antiseptic use of the catheter, when obliged to resort to it habitually, as the most serious vesical troubles may be caused by infection from this source. We quote the directions given by Dr. Marc, republished in *Memorabilien* for December. The hands should first be washed with soap and warm water and then a 5 per cent. solution of carbolic acid or a 1 per cent. solution of sublimate be poured copiously over and through the catheter, held perpendicularly over a basin, washed off afterward with warm or cold water poured over and through it in the same way, as traces of the acid left might produce irritation in the urethra or bladder. The catheter is then dried with a clean cloth, or better, with a piece of sublimate gauze and greased with a little vaselin kept in a tight tin tube. After having used the catheter it must be washed carefully in warm soapy water, to remove all the urine, vaselin, etc., and water poured over it to remove all traces of the soap, after which the disinfecting solution must be poured over it as before and, without being wiped, it should be wrapped in a clean cloth or sublimate gauze, which should be renewed every few days. The catheter should never be wrapped in a newspaper or kept loose in a paper box.

Chronic Intoxication from Trional.—Gierlich describes the case of a man who had been an excessive drinker of beer and afterward used morphin habitually, to a moderate extent. To relieve his insomnia he began to take trional, 1.50 gram every evening for two months, amounting to 84 grams in fifty-six days. At the end of a month he found he had some difficulty in writing. In a few days his speech was also affected, he staggered as he walked and required a support. The movements of his members resembled those in ataxia, with trembling of his hands, feet and facial muscles. He complained of a sensation of oppression, buzzing in his ears and spots before his eyes, while his spirits and mind were profoundly depressed and weakened. Several times he had involuntary mictions and evacuations. In speaking he transposed letters and syllables, and his writing was incoherent. With the suppression of the trional gradually all these symptoms passed away in the course of three weeks, but not until the fourth to fifth week could he write as before the attack. Gierlich advises against the prolonged use of trional. The doses should be rapidly diminished or interrupted for a day or two at intervals.—*Bulletin Méd. from Neurol. Cbl.*, 17, 1896.

The Toxins of Diphtheria and Tetanus in Amorphous Form.—In the London *Lancet* for January 9, is a note, taken from the *Deutsche medicinische Wochenschrift*, stating that Drs. Brieger and Boer have succeeded in separating the toxins of diphtheria and tetanus in an amorphous form. It is easy to precipitate these toxins from their solutions by means of zinc salts, but the further treatment of the compounds formed in this way presents some difficulties, for many of the usual chemic re-agents have a destructive effect on the toxins. In the preparation of the toxin the bacilli must be cultivated in a medium containing no albumin; human urine was the fluid selected. The specific toxin of diphtheria is described by the investigators as not giving the reactions of an albumin or a peptone; it must not, therefore, be classified as an albuminous substance. Alcohol, ether, acetone, and acids destroy it, but weak alkalies do not affect it. Oxidizing substances, such as potassium permanganate, also destroy the toxin, but reducing substances have no injurious influence on it even after twenty-four hours' contact. The indifference of the toxin to substances having a reducing effect is very important, for according to the researches of Ehrlich such substances are continually produced in the organism. It appears, moreover, that the pathogenic action of the bacilli is quite different from that of the toxin. Subcutaneous injections of the bacilli produce an intense necrosis at the place of injection without the internal

organs undergoing the alterations characteristic of diphtheria. It was already known that diphtheria bacilli produce local necrosis, but it now pointed out for the first time that this necrosis depends, not on the toxins elaborated by the bacilli, but on the actual bacilli themselves.

Improved Method of Vaginal Irrigation.—Prof. F. Ahlfeld believes that the frequency of infection from post-partum vaginal injections is due to the fact that the fluids injected wash the germs present up into the cervix as they rebound from the posterior wall. To avoid this he uses a glass canula, closed at the end, but bored with rows of small openings sloping obliquely from the top downward, so that the liquid injected is always flowing evenly and gently out of the vagina. With this instrument and the usual antiseptic precautions, these injections have ceased to be followed by accidents in his practice.—*Gaz. Méd. de Liege*, December 31.

Amylene Hydrate in Polyuria.—H. Brackmann had occasion to prescribe amylen hydrate for a young man mentally unbalanced, who had been affected with polyuria from infancy. 2.50 grams was given every evening, and under its influence the amount of urine fell from 7 to 2 liters a day, and the polydipsia ceased. These troubles returned as soon as the amylen hydrate was stopped, and ceased again when it was resumed. After a certain length of time permanent improvement was secured, so that the amount of urine never surpassed 5 liters a day, even without the medication. He therefore recommends the further use of this substance in diabetes insipidus.—*Semaine Méd.*, December 23.

Garay's Method of Operating for Crural Hernia.—The incision is made over the hernia and the sac opened and resected as usual. Then a second incision is made along the internal border of the sartorius muscle, which is opened up and divided in two by a longitudinal incision parallel to its fibers. The inside half is then cut and a lengthwise flap thus obtained. Another incision is then made in the skin, uniting the two others like the cross piece of an H, and the flap is brought through this third incision into the first, where the end is sutured to the crural arch, Gimbernat's ligament and the pectineus. The skin is then sutured. With slight modifications this method could be applied to inguinal hernia, by suturing the flap to the pillars of the internal ring. It is simpler than Bassini's method, and requires less time.—Reported at Pan-American Congress.

The Light Perception Power as an Aid to Diagnosis and Prognosis in Diseases of the Eyes.—The instruments hitherto in use to determine the light perception power have all failed in exactness as the standard of light used varied and the shape of the object was also a factor in the result. Henry Wall suggests a new instrument for the purpose, which consists of an oblong box, one end covered with a piece of cloth like a photographic camera. In the other end is an opening fitted with nine discs of ground glass, arranged so that they can be removed one by one. A candle stands thirty-three millimeters outside of the box in another box that prevents any flickering of the flame. After remaining five minutes in absolute darkness, the subject puts his head at the large open end of the box, one eye is bandaged and the head is covered with the cloth. The ground glass discs are then removed one by one and he is instructed to state the moment he perceives the sensation of light. The standard of measurement is the number of discs through which he can perceive the light. By this instrument the disturbances due to nicotin, alcohol, albuminuria, diabetes, etc., can be differentiated and the chances of recovery estimated. The greatest loss of light perception power is found in pigmentary retinitis.—*Rev. Gén. d'Opht.*, November, from *Opht. Review*, February, 1896.

Improved Method of Applying the Wet Pack.—The sensation of being bound down hand and foot by the pack is so unpleasant to some persons that the use of this method of hydriatics has

had to be renounced in many cases in which it was urgently indicated. The method has now been modified by Buxbaum in such a manner that the arms and head are left free, while yet the moisture does not escape, as is the case when only part of the trunk is enveloped. The wet cloths are wound around the trunk from the armpits downward, combined with broad pieces passing from around the trunk over the shoulders, crossing in front and behind, the same material used in all the pack. As the arms are thus left free, scientific investigations can be conducted with the sphygmograph, plethysmograph, etc. It also allows the introduction of a coil of tubing over the heart to regulate its action during the packing, conveying a liquid from a receptacle raised slightly above the bed to another on the floor. The article in the *Blätter f. Klin. Hydrotherap.* for December states that packing is one of the most excellent antipyretic methods we have, but it is contraindicated in cases of feeble heart action, or when collapse is to be feared from any cause. This disadvantage is obviated by the tubing mentioned, which removes the only drawback to its use.

Importance of Preventive Therapeutics of Syphilis.—Prof. E. Lang of Vienna ascribes great importance to the prompt arrest of syphilis with preventive therapeutics. In an article in the *Wien. Klin. Rundschau* of January 3, he remarks that internal mercurial medication can not be prolonged to the necessary extent, owing to injury to the digestive apparatus and the lack of precision in the doses, as it is impossible to determine the precise amount of mercury that passes through the intestines unused. Inunctions have the same disadvantage; the lack of exactness in the dosage and the varying rates of absorption in different people. Subcutaneous injections are therefore more reliable than any other method, and can be graduated to the case. The selection of the preparation is of great importance and requires discrimination, and it is necessary that the physician should be familiar with the different therapeutic methods. But whatever method is selected, the chief point is to limit the mercury and not administer too much. *The mercurialization must be mild.* Inunctions and injections with full doses do more harm than good. The eruptions may be postponed, but the later manifestations are inevitably more severe and prove unusually obstinate. A mild preventive mercurial treatment, combined with a rational mode of life and observation of hygienic measures, is one of the most precious therapeutic measures in our possession. The imminent danger of subsequent tabes, which he connects closely with syphilis, renders preventive treatment almost imperative, and the favorable results of mild mercurial therapeutics, especially in his private practice (private patients can be traced much more easily than hospital cases), have impelled him to urge its importance upon all anew.

Pneumopexy.—Prof. C. Bayer of Prague, states in the *Cbl. f. Chir.*, January 16, that he was performing an operation on a 13 year old boy, for the extirpation of a large sarcoma of the right thoracic wall, when the pleura adherent to the sarcoma in one place suddenly tore. The laceration was tamponed, when it tore again and the patient began to collapse. The larger tear was sutured, the portion of the sarcoma already detached was removed and the wound left open, with iodoform dressings. The operation was resumed and completed three days later, when the pleura tore again and this time the lung collapsed entirely and sank out of sight. The patient was succumbing when Bayer seized the superior lobe of the collapsed lung with a pair of forceps and drew it out of the thoracic cavity through the large hole in the pleura and fastened its lower border by three sutures about 3 cm. apart to the periosteum of the sixth rib, which was immediately above the end of the tear in the pleura. The patient revived at once and "we saw the fixed upper part of the lung breathing regularly." The inferior lobe remained collapsed, but he refrained from

attempting to suture this likewise, as he considered it best to utilize the opening for drainage. The after results were good. Dyspnea appeared only when the dressings were changed and he thinks that if he had been able to fasten the inferior lobe also no dyspnea would have occurred. The superior lobe continued its respiration to its full extent, and the lung did not seem to be at all injured by the sutures. The patient is now (twenty-seven days after the final operation) recovering finely. The wound is healing perfectly with a deep depression corresponding to the defect. He considers himself justified in recommending the process of fastening the lung in this way as a simple means to restore this vital organ to its functions, when in cases of extensive injury to the costal pleura it is impossible to put an end to the pneumothorax by merely closing the wound with all haste. It is simpler than the method proposed by Tuffier and Hallion, who have succeeded experimentally in similar cases by artificially filling the lung with air through the larynx or trachea. Their experiments on dogs were encouraging, but the operation has not yet been applied to man.

Whooping-Cough Complicated by Myelitis.—Bernhardt reports in the *Deutsche Medicinische Wochenschrift* a case where whooping-cough was complicated by spinal symptoms. A girl aged 5 years, who had been suffering from whooping-cough for about ten days, was after a severe paroxysm suddenly seized with tonic rigidity of the lower extremities, so that walking or even standing became impossible. The power of speech and the functions of the sensory nerves continued normal. The tendon reflexes were increased and the adductor muscles of both thighs were strongly contracted. Neither fever nor cerebral symptoms were present. In the course of several weeks the child's state gradually improved, so that after two months she could move her legs and flex her knee joints fairly well, but the spasms of the muscles and the exaggeration of the reflexes continued. After four months the power of walking was regained. A year after the first illness the child was attacked with double parotitis and the spinal symptoms once more appeared, so that she could only walk with difficulty and by a succession of spasmodic movements; slight urinary troubles also developed themselves. A course of baths at the Oeynhausensprings proved beneficial, and when Professor Bernhardt saw the child some weeks ago she was able to walk, run and jump, but the reflexes were abnormally strong and micturition was more frequent than natural. No atrophy of the muscles or other symptoms of degeneration were present. Bernhardt points out that the case is probably to be classified as spastic spinal paralysis owing to myelitis caused by the specific virus of whooping-cough. He does not consider that there was hemorrhage into the medulla, because the muscular paralysis which is characteristic of this affection, did not follow the spastic symptoms. He is also opposed to the view that the case might be a severe manifestation of hysteria, because the child shows no other hysterical indications whatever. Cerebral troubles complicating whooping-cough have been sometimes described, but affections of the spinal cord and the peripheral nerves are extremely rare in this disease. Möbius published two similar cases 1889; the first occurred in a boy of 3 years of age who after whooping-cough suffered from a paresis of the arms, the legs, the cervical muscles and the diaphragm. The tendon reflexes were diminished, but sensation and the functions of the brain and the intestines were normal. The lesion was evidently slight, no atrophy ensued, and all the symptoms soon disappeared; it is not improbable that the case was only one of peripheral neuritis. In the second case a girl aged 2½ years on the sixth day of whooping-cough was seized with paresis of the legs, loss of the tendon reflexes and incipient degeneration of the peroneal muscles. The nervous affection began with high fever, the paresis of the legs did not entirely disappear, and the case proved to be one of myelitis. It is evident, therefore, that whooping-cough is practically free from any tendency to originate affections of the spinal cord and the peripheral nerves.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the ASSOCIATION living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, FEBRUARY 20, 1897.

THE DIFFERENTIAL DIAGNOSIS OF LEPROSY
AND SYRINGOMYELIA.

A number of observers have of late pointed out the close clinical resemblance between syringomyelia and the nervous form of leprosy—in fact it has been contended that the former is but a variety of the latter. While not going so far, it must be admitted that the differentiation is at times not easy, although a careful consideration of anatomic, etiologic and symptomatic details will usually remove any diagnostic doubt. Little difficulty is encountered in the recognition of the tuberculous variety of leprosy, the characteristic cutaneous nodules being quite distinctive. The complexus of symptoms described by MORVAN as painless whitlow is not generally viewed as an independent disorder, but rather as the manifestation of some primary affection, which is most commonly either syringomyelia or leprosy. In view of the insidious and widespread dissemination of leprosy, its discrimination from the diseases which it most closely resembles is a matter of considerable importance, from both the prophylactic and the therapeutic, as well as the purely scientific point of view. The distinguishing and differential features of the disease are admirably depicted in a recent communication by LAEHR (*Deutsche med. Woch.*, Jan. 18, 1897, p. 45) from the clinic of JOLLY at Berlin.

It is generally admitted that leprosy is dependent upon the activity of the bacillus lepræ of HANSEN, which can usually be found in all recent lesions of the disease and in most old ones. The disease belongs to

the group of infectious disorders, and, while not contagious in the ordinary sense, is still communicable from person to person, directly or indirectly. It further appears that infection is favored by hereditary or family predisposition, by unhygienic surroundings, by filth, by insufficiency of food and possibly by climatic influences. The first pathologic changes are to be found in the skin and consist in cellular proliferations about the cutaneous vessels, in the midst of which the bacilli are situated. This process extends along the nerves in gradually diminishing degree from the periphery toward the spinal cord. It is most pronounced in the most exposed situations, such as that of the ulnar nerve at the elbow and the peroneal nerve behind the head of the fibula. Syringomyelia on the other hand is a complexus of symptoms dependent upon various lesions of the central portion of the spinal cord resulting in structural alterations that terminate in the formation of cavities. The usual causes of this condition are developmental defects, traumatism, and inflammatory and anemic softening. There is no evidence that syringomyelia is dependent upon hereditary or family influences or that it is an infectious disease.

From the nervous form of leprosy recovery may and not rarely does take place, leaving only the secondary changes to which it has given rise. Such a result from syringomyelia is not known, death, though sometimes long deferred, being the inevitable termination, generally through some intercurrent disease. Both leprosy and syringomyelia develop insidiously, although the first symptoms noted are usually observed earlier in leprosy and are more commonly preceded by prodromal manifestations, such as headache, malaise, obscure paresthesiæ and rheumatoid and neuralgic pains. Febrile symptoms also more commonly attend the onset of leprosy than that of syringomyelia in the absence of complications. Previous residence in a leprosy locality can not be viewed as conclusive evidence, and unfortunately the bacillus lepræ is not always detectable in the lesions. Syringomyelia may develop under the former conditions, while failure to detect the bacillus does not exclude the possibility of leprosy. Of great significance would be the presence of a thickened, spindle-shaped nerve, such as the ulnar or the peroneal. Only exceptionally has the bacillus been found in the blood or at the site of the inflammatory lesions in the skin.

The greatest diagnostic importance is to be attached to circumscribed anesthesia, muscular atrophy and vasomotor-trophic disturbances of the skin, bones and joints. In leprosy these manifestations appear regularly first upon the face, trunk and extremities, more commonly earlier upon the lower than upon the upper, and often upon both simultaneously. In the great majority of cases of syringomyelia the disease is located in the cervico-dorsal region of the cord and the symp-

toms first manifest themselves in the upper extremities, the lower remaining uninvolved for many years. Should the lower extremities be affected first extension to the upper does not take place until later. As a rule, the face escapes, or is involved only very late. Certain cutaneous manifestations are characteristic of leprosy, *e.g.*, multiple pigmented and partly unpigmented hyperesthetic and hyperesthetic spots; and peculiar bluish-red reticular markings upon the skin, especially in the gluteal region, which are accentuated by friction and by temperature-changes. In the course of leprosy there frequently appear acute recurrent painful swellings of the joints, ultimately leading to deformities. Arthropathies are not rare in syringomyelia, but they are mostly painless. Both leprosy and syringomyelia may be attended with extensive deformities of the fingers and toes from ulcerative processes, and also with spontaneous atrophy of bone, but these are always much more pronounced in leprosy. Sweating is absent from the cutaneous areas affected by the leprous process, while in syringomyelia hyperidrosis is common.

The muscular atrophy is much the same in both diseases, although it is more extensive in syringomyelia and is also associated with marked fibrillary twitching. With the spinal lesion the alteration in the response to electricity is more pronounced than the atrophy would lead one to anticipate. The muscular atrophy of leprosy usually involves the small muscles of the hands and feet, less commonly the parts supplied by the peripheral nerves of the forearms and legs; while the wasting of syringomyelia begins in the proximal portions of the extremities. The atrophy of leprosy corresponds in distribution with the cutaneous anesthesia; that of syringomyelia may be crossed. In leprosy there is relatively early involvement of the nerves of the face, especially those supplying the orbicularis oculi, with ulceration of the cornea, epiphora, etc. If the face becomes involved at all in syringomyelia it is so late. The resulting palsy is of nuclear type, the facial muscles being affected on both sides and only those supplied by the lower branches of the seventh nerve suffering. In addition there are likely to be symptoms of bulbar palsy, such as difficulty in speech and in swallowing. If similar symptoms attend leprosy they can be readily traced to local causes, such as inflammation of the mucous membrane of the mouth and pharynx. If ocular symptoms attend syringomyelia they are usually limited to narrowing of the palpebral fissure and of the pupil, frequently upon one side only. There may also be paresis of the external ocular muscles, more particularly of the external rectus, of central origin.

The anesthesia of leprosy includes, as a rule, in addition to loss of pain-sense and temperature-sense, also loss of tactile sensibility; while in syringomyelia tactile sensibility usually escapes. Exceptionally, however, tactile sensibility is retained in leprosy and

lost in syringomyelia. In leprosy the anesthetic areas vary in form and size. They are, as a rule, indiscriminately distributed all over the body. Often, however, the distribution of the anesthesia is peculiar on the extremities, involving the peripheral portions of the members like a glove or a stocking, the line of demarcation running at right angles to the axis of the limb. In rare cases the whole of the peripheral distribution of a cutaneous nerve is involved. The sensory changes of syringomyelia manifest themselves upon the trunk in the form of a girdle or in zonular arrangement. When present on the extremities, if the involvement be not total, the anesthesia pursues longitudinal lines; on the arms the inner or the outer margin is often affected; on the legs the anterior or posterior aspect. The sensory disturbance is segmental and corresponds to the portions of the cord involved in the disease, while the anesthesia of leprosy is dependent upon local cutaneous disease and at times upon disease of the peripheral nerves. When the anesthesia of leprosy has become so extensive as to occasion confusion, other characteristic cutaneous lesions appear that resolve any doubt in diagnosis.

Syringomyelia is often attended with slowly progressive spinal curvature (kypho-scoliosis), derangement of vesical and rectal function and spastic manifestations in the lower extremities. In leprosy the tendon-reflexes may be normal, or they are diminished or entirely wanting. In leprosy, as a rule, even before the appearance of manifestations of neuritis, it may be possible to detect peculiar spindle-shaped thickenings of peripheral nerves, especially of the ulnar and the peroneus. Not rarely the nerve-trunks are sensitive upon pressure, while in syringomyelia there is rather pressure-anesthesia. Leprosy is often attended with widespread glandular enlargement, while in syringomyelia only the glands adjacent to phlegmons or other complicating conditions of similar nature become enlarged.

From the foregoing it will be seen that while, as already stated, there is a good deal of clinical resemblance between leprosy and syringomyelia a careful analysis of all the manifestations in any given case will, as a rule, point the way to a correct interpretation of the symptoms present.

DR. YERSIN, THE DISCOVERER OF THE ANTI-PLAGUE SERUM.

Dr. YERSIN has recently been spending a few weeks in France and has returned to Annam with resources sufficient to enable him to produce a large supply of his serum against the plague. From the French papers we learn that while Dr. YERSIN is a naturalized citizen of France, he is a native of Switzerland, having been born there about thirty years ago. He is an officer in the Sanitary Corps of the French Colonies. He has energy and courage, and at the same time is

modest in demeanor and language. His birthplace was Morges, in Switzerland, his parents belonging to a French family that was driven from France by the revocation of the Edict of Nantes. At an early age he became distinguished for his wonderful thirst for medical science. In 1885 he was a medical student at the Hôtel Dieu, under Professor CORNIL. In the hospital there was a troop of Russian peasants who had been bitten by a mad wolf. They were sent to Paris by their government to receive the Pasteur treatment. One of them died, and while performing an autopsy on the body, Dr. YERSIN cut himself. He was sent to the Pasteur Institute, where he was vaccinated, and became the friend of Dr. ROUX, who made him his associate. The famous memoir of diphtheritic toxin, which marked the first step in the discovery of the croup vaccine was signed by ROUX and YERSIN.

The young doctor became a naturalized Frenchman, and in 1888 he was appointed professor in the technical bacteriologic laboratory, where he distinguished himself by his labors over the microscope. He applied for a place as doctor in the Messageries Maritimes, and set out for Cochin China. After a certain time spent in travel, he returned to the study of pestilential diseases of the far East, and obtained an appointment as doctor in the Colonial Service, while another disciple of Pasteur, Dr. CALMETTE, founded an institute in Cochin China and discovered a vaccine against the venom of serpents. YERSIN devoted his energies to the bovine pest and the plague. He received from the Colonial Ministry an order to go to Hong Kong to study the nature of the plague, the conditions in which it was propagated and to seek the most efficacious means of hindering it from spreading. KITASATO had previously discovered the bacillus.

When he arrived there, more than 3,000 Chinese had already succumbed to the Plague. They commenced to build, with great haste, temporary sheds, because the hospitals of the country were no longer sufficient to shelter the sick.

He found accommodations in a straw hut which he had made, under the authority of the British Government, and in the center of the principal hospital. The mortality was extreme, about 95 per cent., in the hospitals.

In his first experiments he isolated and studied the bacilli of the pest. "The pulp of the buboes," he says, "is in every case filled with short stumpy bacilli with rounded ends. Sometimes the bacilli appear as if they were surrounded by a capsule. They are found in great quantities in all the buboes and ganglions of the affected. The blood sometimes contains them, but in a lesser degree. We never find them in the blood, except in rare cases, which are rapidly fatal."

With these bacilli he made cultures which he used

in experimenting upon rats and guinea pigs. The first series of his experiments brought him to the following conclusion: "My observations, which were very suggestive, permitted me to suppose that the inoculation of certain varieties, but little or not at all virulent, with the specific bacilli would confer immunity upon the animals from the plague, and in that line I commenced my experiments."

He continued his new experiments in 1895, in Paris, and afterward at an isolated point on the coast of Annam, at Nha Trang, where he set up a laboratory. He inoculated the animals of the laboratory and afterward the horses, obtaining his serum for inoculating man.

The pest reappeared in China in the first months of 1896. Dr. YERSIN went there immediately with his flasks of serum. He landed at Canton, but the Chinese population would have nothing to do with the European doctor. In his autopsies he risked death, not only from contagion, but also from fanaticism. It was with the complicity of the grave digger, or the wagon driver that he was enabled to procure both the pus and the blood, and sometimes the bodies of victims of the plague.

Therefore, at Canton it was impossible for him to experiment with the new serum upon the numerous Chinese cases. But three seminarists of the mission were attacked by the disease. Dr. YERSIN cured them. Then he went to Amoy. There he inoculated twenty-three patients, out of which he cured twenty-one. After that everybody wanted to be doctored by him and all his serum gave out.

· IDIOPATHIC ARTERIAL HYPERMYOTROPHY.

It seems a fair proposition to view senility as fundamentally and essentially a process of arterial degeneration, which may occur early or late, may set in insidiously or abruptly and may advance rapidly or slowly. Whatever its mode of onset, whatever its course, its development is inevitable and its termination invariable. The changes in the vessels are followed in turn by analogous alterations in other tissues and organs of the body until in the absence of accident or complication functional and nutritive processes are interfered with to such a degree as to be incompatible with the continuance of life. These changes may from the first be widely distributed and general, or they may begin or be more pronounced in some one organ or other in consequence of local physiologic and pathologic influences. The symptoms present in a given case will be determined by the extent, distribution and intensity of the morbid process, and the clinical pictures will be correspondingly varied and variegated.

An interesting contribution to the literature of this important subject has recently been made by SAVILL (*British Medical Journal*, Jan. 23, 1897, p. 188), who

describes a condition of hypertrophic increase in the middle or muscular coat of the smaller and medium-sized arteries throughout the body in varying degree independent of, though frequently associated with, chronic renal disease. To this abnormal condition he applies the designation idiopathic arterial hypermyotrophy and he now reports two cases with autopsy in addition to ten others previously reported.

The affection is not uncommon, especially during advanced life and in those who are prematurely old. A certain degree of cardiac and arterial hypertrophy may be looked upon as normal in the aged and be unattended with symptoms, but more than this is morbid and obtrudes itself by more or less marked manifestations. Hypertrophy of the middle coat of the arteries may go on for many years without any evidence of its existence, so long as the cardiac hypertrophy compensates for the increased peripheral resistance; or the thickening of the vessels may be accidentally discovered. The change in the walls of the vessels is to be distinguished clinically from atheroma by the absence of beading and from the fact that atheroma attacks primarily the large vessels.

The characteristic feature of the pulse of arterial hypermyotrophy is its perpetual state of high tension, resulting from the increased peripheral resistance, in conjunction with the secondary cardiac hypertrophy. Another prominent feature is vertigo, coming on without warning, usually after assumption of the erect posture and lasting for but a few moments. Sometimes it is accompanied by a feeling of faintness, and syncope may actually occur. Vomiting also is usually present at some stage of the disease. Paroxysmal dyspnea is another symptom attending arterial hypermyotrophy. Headache is a feature in most cases. Hemorrhage is a frequent complication, particularly into the brain. The urine displays no distinctive features. The daily quantity is likely to be somewhat diminished and the specific gravity slightly lowered. Gangrene of the extremities and angina pectoris are observed in some cases. Dropsy is usually absent and the pulse is as a rule slow and regular, but when the heart fails the pulse becomes rapid and irregular.

The chief therapeutic indication is the reduction of high arterial tension. To this end saline purgatives and a dose of calomel are often of use. Bleeding will occasionally afford prompt relief. Rest in bed alone or in conjunction with massage and passive movements may be required to relieve the overburdened heart.

FAT-EMBOLISM ATTENDANT UPON PHOSPHORUS POISONING.

It has always been recognized that phosphorus poisoning is attended with profound alterations in the blood, the most striking physical characteristics being its incoagulability and its change in color. The blood

corpuscles have been found to be distorted and destroyed, while the amount of fat in the blood is increased. Drops of fat and fat-crystals also have been found in the blood and embolic infarcts in the lungs. The changes noted are peculiar to the subacute cases of poisoning, rather than to the extremely acute cases. By a series of experimental observations upon dogs PUPPE (*Vierteljahrsschrift f. gerichtliche Medicin u. öffent. Sanitätswesen*, 3, F. xii B., Suppl., Heft, p. 95) has succeeded in demonstrating that fat-emboli in the blood attend subacute phosphorus poisoning, but not the most acute cases. By a fortunate circumstance he was afforded the opportunity of comparing with these observations the changes noted in a girl 20 years old, who died several days after drinking an infusion of match heads. In addition to jaundice, multiple hemorrhages, fatty liver and acute nephritis, fat-emboli were found in the lungs, in both the pulmonary and the bronchial vessels. The fat from which these emboli are derived is supposed to originate partly in the fatty metamorphosis of the large parenchymatous organs, especially the liver, and in smaller degree from autochthonous fatty degeneration of the elements of the blood and of the walls of the vessels. The hemorrhages that attend phosphorus poisoning are to be attributed to the state of the blood and of the vessels in conjunction with venous stasis. It is thought, besides, that the fat-emboli are in part also responsible for the bleeding. They aid further in explaining the occurrence of superficial gangrene, which is sometimes observed in association with phosphorus poisoning. Sometimes cardiac weakness and peripheral vasomotor paresis are contributing factors.

PROFESSIONAL COMMUNICATIONS TO PHYSICIANS SHOULD BE PRIVILEGED.

Dr. F. L. HALL of Perry, Ill., a member of the Legislature from the 34th District, January 27 introduced into the Legislature the following bill:

A BILL

For an act to provide for secrecy in communications between physicians and patients in suits at law or in chancery where the patient is a party in interest to such suit.

SECTION 1. *Be it enacted by the People of the State of Illinois, represented in the General Assembly, That no person duly authorized to practice as a physician or surgeon shall be compelled or permitted as a witness in the trial of any cause at law or in chancery in this State wherein his patient is a party in interest to such cause, to disclose any information which may be acquired in advising or attending any patient in a professional character, and which information was necessary to enable him to advise or prescribe for such patient as his physician or to do any act for him as a surgeon, unless the consent of the patient to the making of such disclosure is first had and obtained.*

All physicians in Illinois should immediately write to their Senators and Representatives in the Legislature asking them to support this meritorious measure.

Let us have a Department of Public Health!

CORRESPONDENCE.

"The Despised Office of Motherhood."

NEW YORK, Jan. 25, 1897.

To the Editor:—In the issue of your JOURNAL dated April 25, 1896, now nine months since, appeared an article entitled, "The Despised Office of Motherhood."

I have waited this long time hoping some male member of the profession would be chivalric enough to reply to it. It is so manifestly unjust to a very large number of women.

I have been a physician for nearly twenty years, a member of the AMERICAN MEDICAL ASSOCIATION for several years and a constant reader of the JOURNAL. I also belong to the fraternity so unceremoniously assailed; hence it is my duty to take up my pen in defence of my sex.

Your writer starts out with an illustration that belittles his subject.

These creatures of fashion, whom he describes, did have one redeeming quality: They were fond of dumb animals and were evidently humane to them. He characterizes them as daughters of wealthy parents, fashionably clad, as though these were merits.

Whereas these dolls of fashion are generally lazy and incompetent, ready to become the tools of impulse, as you know the old adage: "Satan finds plenty for idle hands to do" and it comes in here appropriately. The fault should not always be charged up against these ignorant young women, but, to the mothers who have trained them, and neither should they be pitted against the brain and brawn of the overwhelming majority of good women, who are the earthly Saviors of the race.

I have had a large experience with women, as patients as well as every other relation of life. I can assure you I have had more women come to me to ask me to aid them in securing good healthy children than to prevent or destroy them. Now, please make that fact as emphatic and prominent as you have the converse, if you will be just. Before making such a wholesale charge, you should differentiate a little. Allow me to arraign your sex.

How many, on an average, of the men you are personally acquainted with and can vouch for, are fitted, mentally, morally and physically to become ideal fathers, particularly with that old effete idea, "That boys must be boys and sow their wild oats?" Too well do we, as physicians, know the harvest such a sowing produces. Right here I would like to refer to an article by Dr. Henry J. Garrigues in the *American Medical-Surgical Bulletin* of Oct. 31, 1896. It has so much bearing on this subject. The thanks of all honest men and women are due the doctor for having the courage of his convictions and uttering them so frankly. "Protection for future wife and children" should enlist our every energy. I can corroborate his experiences with much of my own.

Here let me assert another fact: Every case that ever insulted me with the desire for assistance in destroying the product of conception, was urged and backed by the man in the case—married or single—almost without an exception. It is a weak argument to bring the devotees of fashion in contra distinction with true women. A pretty doll face and a dainty dress will catch the average man every time—as against a sensible, thinking woman. I have in my mind's eye scores of cases where worth goes unsought.

The very parties your writer condemns the (daughters of wealthy parents) are the sources from which a large majority of men seek their mates.

Some of the most flagrant cases of opposition to child-bearing are among those who profess to be Christians. That, at least has been my experience. Ministers of the gospel are as derelict in duty, on these subjects, as the members of the medical profession.

As this is for professional eyes and ears, I will state other facts, *i. e.*, the crime of onanism, more than all others, is undermining the physical and mental well-being of both sexes, as well as stultifying the moral nature. Even members of the profession are not exempt from it, I am creditably informed. And what is worse yet, they teach the pernicious habit to the laity. When I have discovered the peculiar inflammation that results in such cases and attempt to remonstrate with them and show them the dire effects of such habits, they reply: "Why! Doctor So-and-so told my husband that was the best way to prevent conception."

This course will invariably destroy all natural desire for sexual relations in women where it is persisted in for any length of time as it is only a modification of masturbation. The latter, injuring only one party, while the first named injures both parties.

I am intensely interested in righting these sexual dissipations.

To accomplish the work as it should be done, we must begin with the children. Bring them to a healthy manhood and womanhood, free from any vices, with a thorough knowledge of the physical dangers that beset them. Prevent them from learning evil habits by giving them instructions in every line necessary to this end, dietetic, hygienic, etc. It has been asserted that man can be known by the food he eats. There is more to this than we at first think. Children should only have plain substantial nourishing food without condiments, tea or coffee, and no stimulants. Then give them a chart for the future to help them steer clear of the rocks and pitfalls that wreck so many lives. Teach them moderation in all things and their duty to each other, as husbands and wives, to their children, and the world at large. Too much meek modesty of parents has wrecked more lives than any pestilence which has ever visited this earth.

Parents allow their children to learn very important physiologic facts in a very unsatisfactory vulgar fashion, begetting idle curiosity and its train of mistakes and allowing them to drift away from parental surveillance. They read pernicious books appealing to the lower and baser nature, giving them distorted ideas of those functions that should be held sacred. Is it any wonder they go wrong?

To return to the office of maternity, we want physicians as a class to interest themselves in pregnant and parturient women. Instruct them and help them to accomplish this grand work with safety and comparative comfort, and then there will not be the aversion to it that is claimed. There are many hygienic and dietetic measures which secure this end; I am thankful to say that I have tried to do my duty in this direction with much success, as I have only had to use instruments twice in twenty years. One case of flattened pelvis, where the patient did not follow directions fully, and in the other case, weak heart action caused the expulsive force to be *nil*. I would like to quote from another brave article on "Social Purity and Marriage" by Dr. E. S. Bullock of New York in *The Polyclinic* of Dec. 15, 1896, but it would make my article too long. I trust, however, every member of the profession will read and profit by it. I assert, without fear of contradiction, another fact—there is not a woman who truly loves her husband, but wants children by him, and would go through fire and water to have them, particularly when she is allowed to choose the time and season. Where this condition obtains I will show you happy contented people. When they get ready for maternity they make a business of it. The children born under such conditions are models of health, happiness and fine dispositions. I have a number of such in my clientele demonstrating fully this proposition, and furthermore children thus born will do much to lift the world of humanity out of the "slough of despond."

I teach the mothers their duty to their children in no uncertain terms in regard to the physical care as well as the mental, of their bodies and, when they reach the age that renders them

amenable to physiologic law—they shall be made acquainted with every possibility that confronts them. This can be done with tact, in a manner and in language that would not offend the most fastidious ear. With knowledge hundreds may die, but ignorance will slay its millions. The patient quoted sounded the key-note when she said: "Give him bromid, do not dose me with damiana." Men should be taught moderation and to conserve their vital energies instead of wasting them as they do now. I remember seeing it stated in a medical work some years ago, that one ounce of semen was equivalent in vital force to forty ounces of blood. When you can fully impress men with this fact you will do a little toward stemming the tide of sexual dissipation that is well nigh appalling. If every physician will do his or her duty to right this fearful wrong as they become cognizant of its existence, it will be like throwing a pebble in the brook; we may not know where the ripples will end. Leave the results to a higher power.

Your hit at the new woman was rather pessimistic, to say the least. The bicycle, properly used, is no doubt the greatest boon yet devised for women.

The very fact that it develops the chest power and the muscles, increases the circulation as well as equalizing it, should commend them to us. Out of the many women I am personally acquainted with who ride wheels, not one has been demoralized, I am sure.

That bad people use the wheel is no argument against it any more than any other conveyance. It has been asserted by a great teacher: "That nothing improves morals better or more than good health."

If you will keep track of what you dub the "new woman" the best class of them, you will find them heart and soul engaged in trying to lift humanity up, God bless them; as types take Miss Willard and Lady Somerset. It is too late in the 19th century to try to impede their progress by sarcastic remarks. They do not weigh much with thinkers, be they men or women. In regard to the men who ride like monkeys, with constant pressure on the prostate gland! Is'nt that going to invalidate the parentage from the male side of the question ere long?

Poor women are blamed for all the short-comings on this maternity question. It is high time we have some X rays (so to speak) on the conditions of the opposite sex. Women are proud and loyal as a class. When they have made a bad bargain they try to shield those who have wronged them; and declare they did not wish children, when they learned to their sorrow they could not have them, through the incompetence of their husbands the result of youthful dissipation. Such sublime heroism merits a better fate. They will have it, too, when, as Dr. Bullock says, "Our intelligent women wake to the fact that our social law was not made for women alone—but applies in all equity to the opposite sex as well." Another thing; in securing offspring it is quality we want and not quantity. Parents have no right, human or divine, to invite guests they are not prepared to care for in every respect, physically, mentally and morally. It is brains that will count in the government of the world. Let capacity measure sphere of any and all people regardless of sex. "And may justice be done, though the heavens fall." I enclose a little article from one of our late magazines. It is a refutation in regard to time, and claims the aversion to children to be in the "long ago past." Therefore the "new woman" can not be charged with it.

I reiterate, if you canvass fairly you will find the male sex are keeping the children in abeyance. If it were proper to do so I could bring ample evidence to prove what I assert. And I am sorry to say it, many of our profession are in the category. In conclusion I would say: Give good women a fair chance and you will have no cause to accuse them of "despoiling the office of true motherhood."

Yours for truth and justice,

An old Subscriber and Constant Reader of the JOURNAL.

The Philadelphia Meeting.

BURLINGTON, IOWA, Feb 13, 1897.

To the Editor:—The communication of Dr. H. A. Hare in the JOURNAL of this date should, it seems to me, suggest to the Committee on Transportation the importance of getting a longer time limit for the return tickets of those attending the Philadelphia meeting. Let us have at least a fifteen day ticket, even if we have to pay relatively more for it. Truly yours,

H. B. YOUNG, M.D.

Professorial Chairs Vacant.

PHILADELPHIA, Feb. 5, 1897.

To the Editor:—Please announce that the Chairs of Anatomy, Clinical Surgery and Genito-urinary Surgery are vacant in the Medico-Chirurgical College. Only the Chair of Anatomy is salaried. All applications should be addressed to

ISAAC OTT, M.D., Dean.

Size of Dose of Tuberculin?

SEATTLE, WASH., Feb. 11, 1897.

To the Editor:—Will Dr. W. A. Weaver please explain what sized dose, and how he administers the tuberculin, as described in his article in the JOURNAL of January 16? Respectfully,

F. H. COE, M.D.

PUBLIC HEALTH.

Etiology of Ophthalmia Neonatorum.—Chartres contributes a long article to the December *Archives Clin. de Bordeaux* to call attention to a fact he proceeds to demonstrate, viz., that the serious ophthalmias are those produced by streptococci or by an association of streptococci and gonococci, or by these two and others. The gonococci alone are comparatively harmless and yield to treatment. The treatment should be prompt and powerful, consisting of copious irrigations with potassium permanganate, lime, boric acid and cauterization with nitrate of silver. This combination acts on all the various species of microbes which may be producing the ophthalmia. He concludes by insisting on the necessity of bacteriologic investigation.

The Milk Typhoid Epidemic at Kirkcaldy, Scotland.—In the report bearing on the late typhoid epidemic at that place, recently submitted by Sir Henry Littlejohn of Edinburgh, he states that in this epidemic just brought to a close there were 103 cases, with a mortality of 20, or 10.4 per cent. The origin of the outbreak was, in his opinion, clearly traced to a dairy. The Kirkcaldy town council have awarded to Dr. Mackay, medical officer of health, and Dr. Curror, £100 each, and Mr. Braid, sanitary inspector, £50, for the services rendered by them during the epidemic. Sir Henry Littlejohn, in his report, highly praises the ability and energy displayed by Dr. Mackay in coping with the epidemic.—*British Medical Journal*.

Governmental Regulations Against Imported Contagious Diseases of Animals.—The agricultural department has been taking steps to keep out of this country all animals that can in any possible way bring contagious diseases into the United States. Secretary Morton issued about January 20, a set of regulations providing for the inspection and quarantine of all animals imported from Canada into the United States, and the Federal officers at all the ports on the northern boundary have been instructed to look out for all future imports of cattle, horses, sheep, etc. Animals found infected with any sort of contagious disease are to be killed without compensation to the owner, or returned to Canada. The regulations provide that all animals shipped into this country from Canada must be accompanied by an affidavit made by the owner or importer, declaring the purposes for which the animals are imported. Horses for temporary stay, such as pleasure, exhibition and racing stock, are to be admitted without inspection.

Liable for Pay of Nurse.—While it may be that a request made by one person to perform service beneficial only to another may not alone raise the presumption of his intention to pay for it, when it appears that the requested service has been performed pursuant to such request, he, in the absence of authority from or ratification by such other person, is charged as upon an implied promise to pay the person so employed. This is illustrated in the case of *Ludlum v. Couch*. The plaintiff, who may be deemed to have been a professional nurse, was

requested by the defendant, a physician and village health officer, to go to the residence of one Peter Post, some of the members of whose family were sick with diphtheria, and nurse them. There was no evidence tending to prove that he was authorized by Mr. Post to employ the plaintiff for him or in his behalf, or that he was the family physician of Post, or had such relation to him. Under these circumstances, the appellate division of the supreme court of New York holds, Dec. 8, 1896, that the request of the defendant to the plaintiff was an employment of her to perform the services in question, and the only employment under which she performed them.

Encourage Every Worthy Health Officer.—Dr. Pemberton Dudley, in *Public Health*, January, expresses the opinion that the health inspector does not, as a rule, receive the coöperation to which he is entitled. He says, speaking to an audience of laymen and physicians: "We physicians—and we patients—ought to be very scrupulous and very intelligently careful about the way in which we receive and encourage and coöperate with our local health inspectors. They come to us when our homes are invaded by pestilential disease, just as much in the garb and character of a true friendship, as do our physicians and nurses. They ought to be welcomed as such, and their efforts furthered to the extent of our ability. There is, in the minds of some persons, a disposition to attach to the health officer and his inspectors, the responsibility for all the inconvenience and annoyance incident to the sanitation of contagious diseases, just as there are people who censure the weather bureau for all the cyclones. An intelligent patient of mine, into whose house scarlet fever had entered, determined that not a suggestion or direction of the inspector should fail of her cordial and energetic support and execution. Promptness, energy and persistence characterized every effort she made to prevent the disease from reaching other people. As a consequence, her three other children escaped the infection and, after a period of anxiety such as none but the maternal heart can know, her sick one recovered. Subsequently the inspector said to her something like this: 'Madam, your child caught the disease through somebody's mismanagement; but no other mother's child caught it through yours. So far as you had to do with the progress of this epidemic, it never got past your house, and if everybody would do as you have done, the disease would be quickly stamped out. No failure on your part has filled any other woman's home with mourning.' 'Well,' said the relieved mother, 'what a comfort it is to know that!'"

Valid Ordinance to Secure Pure Milk.—Chapter 203 of the General Laws of Minnesota of 1895, entitled "An act relating to the inspection of milk and of dairies and dairy herds, and to provide for the licensing and regulation of the sale of milk in cities," provides that the city council of any city may, by ordinance, provide for the inspection of milk and of dairy herds kept for the production of milk within its limits, and issue licenses for the sale of milk within its limits, and regulate the same, and may authorize and empower the board of health to enforce all laws and ordinances relating to the production and sale of milk for sale or consumption within such city, etc. This, the supreme court of Minnesota holds, in *State v. Nelson*, Nov. 6, 1896, authorizes the passage of an ordinance, such as one passed in Minneapolis, providing that any person desiring a license to sell milk in the city shall file with the commissioner of health of the city an application therefor, stating, among other things, the location or place from which the applicant obtains the milk, and, if he is not a producer of milk, then the name of the person from whom he obtains his milk, and also requesting the city to inspect his dairy and dairy herd, or the dairy or dairy herd of the person from whom he obtains his milk, for the purpose of carrying out the provisions of the ordinance, and providing that the commissioner of health shall

inspect such dairy and dairy herd, and cause an examination by the veterinarian of the department of health to be made of every animal producing milk for sale within the city, belonging to the applicant or the person from whom he obtains his milk, and further providing for the tagging of each animal examined and inspected. Such an ordinance, the court holds, has no extraterritorial operation, because it requires the applicant for a license to sell milk within the city to consent that the dairy herd from which he obtains his milk shall be so inspected, although such dairy herd is kept outside the city limits. The provisions in that regard go only so far as it is reasonably necessary to prevent the milk of diseased cows being sold within the city. This inspection is wholly voluntary on the part of the owner. If he does not choose to submit to it, the result merely is that he or the one to whom he furnishes milk can not obtain a license to sell within the city. So reasons the court. It also holds that a requirement of the ordinance that the applicant shall consent, as a condition precedent to obtaining such license, that the animals from which he obtains his milk shall be subjected to the "tuberculin test" is not unreasonable. Whether a license from a city under an ordinance passed pursuant to the foregoing statute is, as to the sale of milk in such city, a substitute for the license from the State dairy commissioner, provided for in Laws 1889, chapter 247, or whether it is merely supplemental and additional, the court says it does not decide. But, in either view, it holds the ordinance in question authorized by the act of 1895.

The Isolation Hospital Supplanting the County Pest House.—Dr. Benjamin Lee, secretary of the Pennsylvania Board of Health, has addressed that Board recently, regarding the replacement of the old style pest house by something more modern and attractive. He said that while almost all of our cities and towns of any size have some kind of a hospital, which they usually call a pest house, most unfortunately it is in reality a smallpox hospital which can be made use of in case of epidemics of that disease. "The institution, however, from its very name is looked upon with horror by the community. People would rather die at home than go to a pest house to be restored to health. I was greatly pleased in visiting your city yesterday to find so admirable a detached hospital for the treatment of contagious diseases. I found in your hospital private wards intended for the use of persons in good circumstances—not those who desire to be treated at the expense of the community, but persons of means suffering from illness, which could be best treated at a hospital, as is the case with the vast majority of surgical cases, so that such persons could avail themselves of the best medical skill under the best environment, with the best nursing, and in every way the best opportunity for recovery. You have also in your isolation hospital a hospital to which any mother should not object to going with her child suffering from a contagious disease. In so doing she would accomplish a number of good results for her own family as well as for the entire community. She would avoid the risk of contagion to the other children and other members of her family, and would make it unnecessary for the house to be kept quarantined. The breadwinners of the household would thus be enabled to continue to attend to business as usual. There is a movement on foot at present in Philadelphia which took its origin with the women of that city, through the association known as the 'Women's Health Protective Association,' for establishing a hospital of this kind to be reserved entirely for pay patients. It is intended to establish a hospital with every comfort and every facility for the treatment of contagious diseases, and every precaution for preventing the escape of germs of these diseases outside of its walls. It is intended, if I understand it, that while this hospital shall be under the supervision, to a certain extent, of the Board of Health of the city, that is to say, its officers must conform

strictly to the regulations of the Board of Health, yet, if the parents or relatives of the sick person so desire, such person may enjoy the attendance of the family physician. It would be necessary in this case for the physician also to be subjected to the regulations of the Board of Health, but the arrangements would be such that these could be followed with very little personal inconvenience. I feel that this is a matter of very great importance, and one that all representatives of boards of health and of local municipalities should consider. The State Board of Health has adopted a resolution recommending to the municipal authorities of every center of population of 25,000 or upward, that they should establish a separate hospital for the treatment of such affections."

BOOK NOTICES.

Anomalies and Curiosities of Medicine: Being an encyclopedic collection of rare and extraordinary cases and of the most striking instances of abnormality in all branches of medicine and surgery, derived from an exhaustive research of medical literature from its origin to the present day, abstracted, classified, annotated and indexed. By GEORGE M. GOULD, A.M., M.D., and WALTER L. PYLE, A.M., M.D. Imperial octavo, 968 pages, with 295 illustrations in the text and 12 half-tone and colored plates. Price, cloth, \$6 net; half morocco, \$7 net. Sold only by subscription. Philadelphia: W. B. Saunders, 925 Walnut Street. 1897.

We read the following in the author's preface with surprise: "A curious case is invariably reported and the insertion of such a report is generally productive of correspondence and discussion with the object of finding a parallel for it.

"In view of all this it seems itself a curious fact that there has never been any systematic gathering of medical curiosities. It would have been natural that numerous encyclopedias should spring into existence in response to such a persistently dominant interest. The foregoing volume appears to be the first thorough attempt to classify and epitomize the literature of this nature."

The surprise deepens when we examine the bibliography and find that the names of Millingen and Eve have escaped mention. Millingen, a British army surgeon, in 1837 wrote a work which was published in two volumes of 400 pages each, by Bentley in London. This work was entitled "Curiosities of Medical Experience." It was republished in Philadelphia by Haswell, Barrington & Haswell, in a single volume in 1838. There was little attempt at classification. Paul F. Eve in 1856 wrote a work, "A collection of Remarkable Cases in Surgery," a book of 858 pages, which was published by J. B. Lippincott & Co. in 1857. This extensive work was classified on the anatomic plan, that is to say all the cases were arranged according to the region injured or diseased.

In Eve's book the cases are reported as nearly as possible in the language of the original report. In the book under review a digest is made. Fournier's cases which he collected in the "Diction. des Sciences Médicales," article "*Cas rares*," is apparently made use of. Mr. Walter Dendy's pamphlet on the "Wonders Displayed by the Human Body," quoted by Eve, the writer has not seen, nor is it quoted by Gould and Pyle, nor in the Great Index Catalogue of the Library of the Surgeon-General's Office.

The scope of the work under review is much greater than that of Millingen, whose cases are irregularly arranged, and greater than the work of Eve, who limited his collection of cases to those of surgery.

The claim of the authors to have the only collection of rare cases in all branches of medicine holds good, and we can but admire alike the work itself and the wonderful industry that produced it. The book is more than a mere collection of rare cases, for the cases are not only systematically arranged, but instructively commented upon. Conditions, such as obesity,

are noted. There is also a chapter on epidemics. The illustrations are excellent.

The authors have rendered a very great service to writers and teachers, and many will have their labors greatly lightened by a reference to this storehouse of information. Practitioners will find here many a companion to the case that has puzzled them for months, and indeed there is no class of the profession who will fail to find the work useful.

Architecture of the Brain. By WM. FULLER, M.D. Illustrated: 8vo, cl., pp. 182. Grand Rapids, Mich. 1896.

This excellent work deserves to become very generally known. The plates are as good as they can be in black and white, and it is the most recent addition to the copious modern literature on the anatomy of the brain. The author has been a diligent and enthusiastic student of anatomy since his college days; for a number of years he was a successful teacher of this, the most important fundamental branch of medicine and although he has lived for a number of years in a rural city, he has pursued his favorite study with an ardor and originality that are refreshing in these days when physicians so generally employ all their time and energies in acquiring and increasing their practice. This treatise presents many features of great merit. The description of the anatomy of the brain is concise and clear.

The descriptions have been made "from dissections by the author, and have been carefully verified by comparison of longitudinal and lateral dissections, and by sections, all of which agree in proving the correctness of the representations herein described.

"These dissections have been permanently recorded by castings in plaster and the sections have been photographed and plates made, so that both the casts and the plates can be repeated at pleasure, thus enabling any who may take an interest in the anatomy of the brain to do so." They may also purchase reproductions of the casts if they wish.

The plates are interesting and instructive object lessons in studying the text, splendid substitutes for the actual dissections. The book will be alike valuable to the student and the practitioner; the former will find it the best instructor in obtaining an accurate knowledge of the structure of the brain and the latter the safest and simplest guide in locating cerebral lesions and injuries.

A System of Practical Medicine by American Authors. Edited by ALFRED LEE LOOMIS, M.D., LL.D., and WILLIAM GILMAN THOMPSON, M.D. Volume I. Infectious diseases. Illustrated; 8vo, cl.; pp. 985. New York and Philadelphia: Lea Bros. & Co. 1897.

The precision and accuracy of modern medicine in its practical applications have become such that few text books on systems accurately represent its present position.

"Such considerations," says Dr. Thompson, "render obvious the necessity for a systematic and practical work covering the entire field of general and specific medicine in its foremost state of development. To meet this want the late Dr. Alfred Lee Loomis, M.D., LL.D., undertook the authorship" and associated Dr. Thompson with him in its charge.

By omitting topics on hygiene, bacteriology, gynecology, *et cetera*, it "has been found possible to present a succinct and complete account of medical practice in its latest aspects, each article being a clinical monograph and proceeding from the cause and nature of a disease to its diagnosis, prognosis and treatment."

In the preparation of the work, the late Professor Loomis "secured the authors, apportioned their subjects, decided the arrangement and classification of the entire work, and discussed with Dr. Thompson many important details."

An inspection of the book shows that Professor Loomis made no mistake in choosing his associate editor, for the work is one which will reflect high credit on American medicine.

The contributors to the first volume are: I. E. Atkinson, M.D., Baltimore; John M. Byron, M.D., New York; Warren Coleman, M.D., New York; George Dock, A.M., M.D., Ann Arbor, Mich.; A. H. Doty, M.D., New York; Isadore Dyer, M.D., New Orleans; J. Crozier Griffith, M.D., Philadelphia; Walter B. James, M.D., New York; Thomas S. Latimer, M.D., Baltimore; Wm. Osler, M.D., Baltimore; Wm. Hallock Park, M.D., New York; P. Gervais Robinson, M.D., LL.D., St. Louis; George M. Sternberg, M.D., LL.D., Washington; James Stewart, M.D., Montreal; Wm. Sydney Thayer, M.D., Baltimore; Wm. H. Welch, M.D., Baltimore; Wm. M. Welch, M.D., Philadelphia; Hamilton A. West, M.D., Galveston; J. C. Wilson, M.D., Philadelphia.

The articles in this volume are: 1, Malaria; 2, Dengue; 3, Enteric Fever; 4, Typhus Fever; 5, Relapsing Fevers; 6, Yellow Fever; 7, Cholera; 8, Dysentery; 9, The Plague; 10, Influenza; 11, Epidemic Cerebro-spinal Meningitis; 12, Erysipelas; 13, Pyemia; 14, Septicemia; 15, Smallpox and Varioloid; 16, Vaccinia; 17, Varicella; 18, Scarlet Fever; 19, Rubeola—Measles; 20, Rubella; 21, Diphtheria; 22, Pertussis; 23, Epidemic Parotiditis; 24, Tuberculosis; 25, Syphilis; 26, Leprosy; 27, Tetanus; 28, Infectious Diseases of Obscure Nature.

The limitations of space will not permit us to do more than to content ourselves by a general and unqualified commendation of the book. We regret that the editor ignores the metric system of dosage in the prescription writing.

The publishers have done their part well.

Ophthalmic Operations as Practiced on Animals' Eyes. By CLARENCE A. VEASEY, A.M., M.D. With 56 illustrations; 12mo, cl., pp. 99. Philadelphia: The Edwards & Docker Co. 1896.

"This little work," says the author, "has been prepared in the hope that it may prove of assistance to those beginning the study of ophthalmology, by enabling them to become acquainted with the technique of the various operative procedures through practice on animals' eyes, thus removing a certain amount of timidity and affording a larger experience and more confidence when attempting the operations on the human eye."

Lest some antivivisectionist might set up a prolonged howl, let us take note that the author recommends sheep's and pigs' eyes removed from animals recently slaughtered. The book is well conceived and well executed.

City of Chicago Second Annual Report of the Civil Service Commission to His Honor, the Mayor, for the year ending Dec. 31, 1896. JOHN M. CLARK, R. A. WALLER and CHRISTOPHER C. HOTZ, Commissioners. Cl., 8vo, pp. 286. Chicago: Printed for the Commission. January, 1897.

The successful working of the Illinois Civil Service law is a source of gratification to all who have had the pleasure of witnessing the results of the Commissioners' labor in the city of Chicago.

It is evident that the much neglected science of government of our great cities is being rescued from obscurity and the problem is rapidly being solved.

The operations of the Medical Board are creditable. It will be remembered that this board was recommended to be appointed by the Chicago Medical Society, and the commissioners very wisely accepted their recommendation.

La Fol qui Guérit. Par T. M. CHARCOT. Tome VIII de la Bibliothèque diabolique in—80, de 48 pages. Papier vélin, prix 2 fr.; papier Hollande, prix 3 fr. 50; papier Japon, prix 4 fr. Publications du Progrès Médical. Paris, 14 Rue des Carmes.

This brochure, edited by the distinguished Bourneville, is one of the last works of the illustrious Charcot, and is published by permission of Madame Charcot.

This is a scientific exposition of the faith cure; the author freely concedes that certain cases belonging to the domain of hysteria, are sometimes cured by "suggestion," and the philo-

sophic reasons for such a result are given in detail. It is like carrying coals to Newcastle to praise anything written by a master of his art, and we can not do better than to advise our readers to get the pamphlet and read it for themselves.

NEW INSTRUMENTS. FORMALDEHYDE GENERATOR.

The apparatus shown in the above illustration has been designed by Chas. Truax, Greene & Co., for the safe, convenient and economic production of formaldehyde by the oxidation of methyl alcohol. This is accomplished by decomposition of wood alcohol and without the use of an open flame, and where used for disinfecting tightly closed apartments, it is free from the possibility of fire while in operation.

It is convenient, economical and simple in construction, compactly made and requires no nice manipulation to secure the desired result. An apartment having a capacity of 2,500 cubic feet may be thoroughly disinfected by the generator, together with the infected furniture, bedding, etc., with one filling of the reservoir and without previous preparation of the room or its contents.

Formaldehyde (CH₂O) in its gaseous form answers fully the above requirements, as it possesses the properties of ready diffusibility and great power of penetration.

It may also be used in connection with a sterilizer constructed for the purpose of sterilizing instruments and surgical dressings. It is destructive of all pathogenic organisms without acting injuriously on the higher forms of life, or on the material or color of the articles subjected to its action.

NECROLOGY.

THOMAS G. ROWAND, M.D., Philadelphia Medical College, 1850, died in Camden, N. J., aged 68 years, on January 25. In 1862 he was an assistant surgeon in the New Jersey Infantry Volunteers, 24th regiment serving with them until their muster out. Notwithstanding his modesty he held many positions of trust, including a professorship in the University Medical College of Pennsylvania, a deputyship in the Quartermaster General's Department of the New Jersey Militia, two terms as coroner of Camden, N. J., 1864 and 1868, and president of the Camden Board of Education, 1867-68. In his earlier career, he served acceptably as a hospital surgeon in the third division of the famous Second Corps at Potomac Creek, Va.

SAMUEL H. CHARLTON, M.D., of Seymour, Jackson County, Ind., one of the oldest and best known physicians in Southern Indiana, died Jan. 12, 1897, of uremia, aged 70 years. He was a graduate of Louisville Medical University, was assistant sur-

geon of 6th Indiana Regiment; in 1878 was president of the Jackson County Medical Society, also president of Mitchell District Medical Society; in 1881 was first vice-president of the Tri-State Medical Society of Indiana, Illinois and Kentucky; in 1882 was vice-president of the Indiana State Medical Society and in 1888 was president of the same; in 1887 became member of International Medical Congress, which met at Washington, and served as a member of the council of the Section on Diseases of Children; in 1890 was president of the U. S. Examining Surgeons on pension board. He was possessed of a genial, cordial nature, qualities that endeared him to all who knew him.

HENRY HARTSHORNE, M.D., University of Pennsylvania, 1845, died at the age of 73 years at Tokio, Japan, February 10. He was a graduate of the Haverford College in 1834. He was elected professor of the Institute of Medicine in the Philadelphia College of Medicine in 1853, and in 1859 was chosen professor of practice of medicine in the University of Pennsylvania. He became professor of hygiene in the latter institution in 1866, and in 1867 was elected to the chair of organic science and philosophy in Haverford College. He also held professorships in the Pennsylvania College of Dental Surgery, Girard College and the Woman's Medical College of Philadelphia. He was the first person to ascertain by experiments on himself and others in 1848 the safety and effects of the internal use of chloroform. Six years ago Dr. Hartshorne went on a tour of Japan. He remained a couple of years, and formed a liking for the country. Returning to the United States, he consented two years ago to return to labor in connection with the missions of the Society of Friends. He was a brother of vice-president Charles H. Hartshorne of the Lehigh Valley Railroad.

ROBERT M. DENIG, M.D., Jefferson Medical College, 1838, died January 17, in Columbus, Ohio, to which he came in 1849. He was at one time Professor of Medical Jurisprudence in the Starling Medical College, and later on became lecturer on Diseases of Children in the Columbus Medical College, which position he held until that institution united with the Starling College. He retired from active practice about five years ago.

CHARLES W. COOPER, M.D., Northampton, Mass., where he was in active practice for twenty-five years, was lost overboard from the Hamburg Line Steamer Columbia about 300 miles from Sandy Hook, during the first week in February. The vessel was stopped, but he never appeared above the surface. His health becoming impaired he made a trip to the Mediterranean about four months ago with his brother-in-law, Dr. Fred Tuckerman of Amherst. He was a graduate of Harvard Medical College, in 1877.

ABNER C. JONES, M.D., of Muncie, Ind., died January 28, aged 48, of acute Bright's disease. Dr. Jones enjoyed the distinction of having been the youngest soldier that served through the war. He was an ex-commander of the G. A. R.

ALBERT WELLS KILBOURNE, M.D., New York University Medical College, 1874, a practitioner of Albany, N. Y., of twenty years' standing, died January 14. Three years ago he returned to Liberty, N. Y., where he was born in 1851. A cardiac aneurysm was the cause of his death.

BENJAMIN B. ADAMS, M.D., University of Georgetown, D. C., 1876, died suddenly in Washington, D. C., January 25, aged 46 years.

JOHN KIRKER, M.D., Bellevue Hospital Medical College, N. Y., 1864, died at his home in Allegheny City, Pa., January 23. He was a member of the AMERICAN MEDICAL ASSOCIATION and had served as a surgeon in the Union forces during the war.

CHARLES A. STARK, M.D., Dartmouth Medical College, N. H., 1884, died at his residence in Marshfield, Mass., January 22, aged 35 years. He was for a time on the staff of the New Hampshire Asylum for the Insane, located at Concord and subsequently practiced in Manchester, N. H. He returned

from Louisiana in 1889 and in the following year established himself at his last address.

WILLIAM A. CAREY, M.D., University of Pennsylvania, 1886, died in Philadelphia, Pa., January 29, aged 35 years.

ANDREW L. VON WITTKAMP, M.D., Jefferson Medical College, 1876, died in Philadelphia, February 2, from a sequence of cerebral hemorrhage. He came from Germany when an infant.

EUGENE Z. BRIEVOGELLE, M.D., New York University, 1883, died at his residence, New York City, Feb. 12, 1897, of pneumonia, in his 47th year.

PHILIP HASTINGS FULLER, M.D., University Vermont, 1885, died at his home in Brooklyn, N. Y., of renal disease, February 12. He was born near Painesville, Ohio, in 1861 and came to Brooklyn with his parents when still a child.

MISCELLANY.

The *Laryngoscope*, published in St. Louis, has been selected as the official organ, for the year 1897, of the Laryngological Section of the New York Academy of Medicine. This selection, and the great probability of the same journal being chosen by other laryngological, rhinological and otological societies as their official organ, would indicate that the *Laryngoscope* has become what its proprietors stated they intended to make it, *i. e.*, the American Journal of Record for the specialties represented.

He Always Had Some "Small Change About Him."—A soldier wounded in the Franco-Prussian war recently evacuated a thaler through the rectum which had been in his body over twenty-five years. The bullet passed through his purse in his breast pocket and when it was extracted at the time a smaller coin was found with it. His health has since been good. The case has led to considerable discussion as to how the thaler could have found its way from the level of the seventh rib into the intestines without noticeable disturbance.—*Deutsche Med. Woch.* December 25.

Orchitis Implanted upon Prostatic Hypertrophy.—Dr. J. R. Gibson of Paisley writes to the *Lancet* concerning a case of the above character. His case was that of a man aged between 50 and 60 years, afflicted with enlarged prostate gland and requiring the use of the catheter before any urine could be drawn off, and who recently became afflicted with acute orchitis of one testicle, the orchitis being probably caused by the irritation of the catheter, as great difficulty was experienced in passing it. Almost immediately after the onset of the orchitis he could pass urine more or less freely, an act he had not performed for over a year, and the whole bladder symptoms underwent great improvement, an improvement which I am glad to state has continued since the orchitis got better.

Artificial Diphtheria Antitoxin.—Smirnoff has been continuing his efforts to produce an artificial substitute for the usual antitoxin and has succeeded. The liquid he prepares for the purpose is not so effective as antitoxin in the early stages of the disease, but later, when antitoxin loses its power, the artificial seems to display marvelous efficacy. It also works irrespective of the amount injected. His theoretical conclusions from his investigations are: 1, that antitoxin is only an oxidized toxin; 2, the electric current is only an excitant that can be modified according to the nature of the agent employed; 3, it acts through the chemic processes that occur during the decomposition of the salts. He is hopeful that it will be possible to manufacture antitoxins for tuberculosis, anthrax, etc., much cheaper than by the present methods. His process consists in electrolyzing toxin-bouillon in a U-shaped tube with a faucet at the lowest part, after the addition of .05 per cent. NaCl. The current passes through carbon electrodes. These

are replaced with silver electrodes, and .05 per cent. potassa is added to the liquid. The plates have to be changed once an hour, as the chlorid of silver that forms on them prevents their action. Four or five plates are necessary to neutralize all the chlorid. After 200 c.cm. of toxin have been thus electrolyzed for seven hours an antitoxin results that will cure guinea pigs fifteen hours after infection. Electrolysis for eight hours results in an antitoxin strong enough to produce its effect at the commencement, but too weak for later stages. If 1 per cent. of NaCl is added, electrolysis for three to four hours produces a very active antitoxin. This process produces antitoxin freed from every trace of toxins and of a standard strength and efficiency.—Russian correspondence of the *Presse Méd.* of December 23.

An Anecdote Regarding Erichsen.—The *Lancet* tells the following curious incident in the life of the late Sir John Erichsen: A serious fracture case occurred in a large hotel in the country and Dr. McNichol, of Dalnally, was called to it. When setting the limb, an old gentleman came to him and said he would be glad to give any assistance required, as he too was a medical man. He was thanked by Dr. McNichol and asked to use extension, etc., and to all the local man's directions the old gentleman gave ready obedience. The fracture was set and an adjournment made to the smoking room. "I must thank you for your assistance, sir." "Not at all; I was glad to be able to help in the matter. I think the case will do well, as the setting of the limb is perfect. That's my card." Dr. McNichol saw "John Eric Erichsen" on the card, and afterwards said he never felt so helpless in regard to making a remark fitting the occasion. "I'm glad," he said, "the fracture is set properly, for I learned the method out of your own book." There was a good humored laughter, and as they say about other pleasing functions, a happy evening was spent. Within a few weeks of each other they are gone, McNichol regretted in his small sphere as was Erichsen in his larger.

The Paris Night Medical Service.—According to *Médecine Moderne*, the public night medical service of Paris is maintained at a cost to the city annually of 145,000 francs, or about \$29,000. In return for this service the patients paid the city but 3,217 francs. One hundred and thirty-five doctors are employed, the yearly salary of each being 600 francs, or \$120. The *London Lancet*, January 16, in treating of a "strike" on the part of some of the physicians of this service, shows that the latter has in Paris, as elsewhere, been the subject of abuse. The service is highly appreciated by the population of Paris, but it is now maintained that persons who have means to pay for medical advice have availed themselves of its benefits. Such abuse, it is true, does not, as in the case of hospital abuse in England, represent a loss to the medical profession, for the medical men are paid eight shillings per visit by the municipality, but it is loss to the tax payers. The latter are therefore interested in preventing abuse, whereas if the proposal of the Prefect of Police were enforced there would be no check to the abuse. If the medical officers were paid a fixed salary it would not matter to any one except to the medical men themselves how many patients resorted to the night service or whether these persons were rich or poor. As it is, the payment being per visit, the authorities have every interest to watch and see that none but the poor avail themselves of the medical officers' service. It is proposed that the tax collectors should be employed to investigate the cases.

Two Surgeons and Their Fees.—Alfred Louis Velpeau, the greatest French surgeon of his time, had a severe lesson read to him by the mother of a patient, a young girl whose life he had saved in a critical case of croup. The mother brimming over with gratitude, went to see the famous surgeon, an abrupt and somewhat disagreeable person at the best of times, and reputed to be afflicted with inordinate greed. "I have come

to thank you for what you have done for us, and to offer you this as a token of our obligation," she said, placing a beautifully embroidered purse on Velpeau's table. Velpeau scarcely took the trouble to look at it. "I accept, Madame," he remarked in his ungracious way; "but, of course, this is without prejudice to my honorarium, which comes to 3,000 f." Thereupon the lady took up her present. "I am afraid I made a mistake then," she laughed; "there are five notes of 1,000 f. each in there. This makes us right then, Monsieur." And pocketing two out of the five slips of blue paper, she bowed, "I have the honor to wish you good morning." Sir Astley Cooper was wiser in his generation. The largest fee he ever received was in a less delicate but more original manner. He had been attending in his capacity of surgeon a West Indian millionaire, named Hyatt, with Drs. Lettsom and Nelson as physicians. The treatment was most successful, and in his joy Hyatt bestowed 300 guineas on each of the doctors. "But you," exclaimed the grateful patient, addressing Sir Astley, "you shall have something better." With this he flung his nightcap at the eminent operator. "Sir," replied the latter, "I'll pocket the affront." And he slipped the "affront" into his pocket. It contained a draft for 1,000 guineas.—*New York Times*.

Malpractice Question for the Jury.—*Moratzky v. Wirth* was an action to recover damages which the plaintiff alleged that she had sustained by the defendant's malpractice, while attending her as her physician during her illness due to a miscarriage, in not discovering and removing a remnant of the placenta. Unexplained, the evidence was sufficient to justify the conclusion that the defendant, in the exercise of that degree of care and skill which the law exacts of a physician, might and ought to have seasonably discovered and removed the remnant of the afterbirth. Wherefore, the supreme court of Minnesota holds, Dec. 28, 1896, that the question of his negligence in the premises was one for the jury, and that the trial court erred in dismissing the action. The evidence, it says, was practically plenary that the failure to remove the afterbirth materially aggravated and increased the blood poisoning of the plaintiff, even if it was not proved that it commenced after the defendant was called to treat her, and prolonged and intensified her pain and sickness. Such being the case, if the defendant was negligent in not removing the placenta, the court holds that the plaintiff was entitled to damages in some amount, and the case should have been submitted to the jury.

Privilege of Burial Can Not Be Limited to a Class.—The fact that the unlimited burial of the dead within a city is dangerous to life and detrimental to the public health may be a sufficient reason for the enactment of an ordinance fixing a term after which such burials shall cease within certain portions of the city; but, while burials are permitted within a district, the supreme court of California holds, *Ex parte Bohen*, Dec. 17, 1896, the privilege can not be limited to one class of citizens and denied to another class within the same district. In other words, the police power is to be exercised for the good of the entire public, and any restriction of the rights of the individual by virtue of this power must extend to all the individuals who might otherwise exercise the right. The right to prohibit burials within a certain district rests upon the proposition that any burial within that district is injurious to the public health and an ordinance permitting burials within a district to an extent greater in number than it prevents, as one allowing burial in lots already sold which have a greater aggregate capacity than those unsold wherein it is prohibited, can not be upheld as an exercise of police power. Nor can an ordinance forbidding the burial of human bodies within the city, or upon any designated portion thereof, as upon unsold cemetery lots, be sustained, if such burial be permitted upon other (sold) lots similarly situated; and the owner of land can not be restrained from selling it for the purpose of being used as a place of burial, if burial therein is not at the time forbidden.

Cincinnati.

AT THE MEETING of the Academy of Medicine Dr. Charles A. L. Reed read a paper on the "Sequelæ of Cholo-lithiasis."

Dr. J. W. PRENDERGAST, the health officer, is preparing an ordinance to prohibit promiscuous expectoration in street cars and other common carriers. He is also vigorously prosecuting his reforms in the direction of a pure milk supply for the city. His intention is to have the cows examined for tuberculosis by means of the administration of tuberculin, and then have them kept under rigid observation. A bacteriologic bureau as a department of the city health department, is another one of Dr. Prendergast's many progressive and commendable ideas.

THE ANNUAL REPORT of the staff of the Cincinnati Hospital was recently submitted and it shows that there were 4,812 patients discharged from the hospital wholly or partially recovered. The total number of patients received at the hospital was 5,254. This was an increase of 35 over the year previous. The death rate was 8.4 per cent. Of this Dr. Dandridge says it is to be understood that no less than 98 patients were received in a dying condition and did die within twenty-four hours. The pressing need of more commodious quarters for the contagious diseases, nurses, and another operating room was emphasized by President Dandridge. An appropriation of \$12,000 was made for the month of January and \$9,000 for the next five months to cover running expenses.

STEPS are being taken to have the legislature pass a law prohibiting the distribution of suggestive literature relative to diseases of the sexual organs.

Washington.

THE GEORGETOWN UNIVERSITY HOSPITAL.—Through the munificence of Georgetown University, the assistance of the medical department of the same institution and the generosity of several prominent citizens, Georgetown Medical School will have a modern hospital under its control for clinical teaching of its medical students. The hospital will have free dispensary, free emergency wards, chambers and wards for pay patients, operating rooms and lecture halls. The conduct of the institution when in operation, will be in the hands of a religious order of sisters, whose services have already been secured. The practical management of the scheme is now in the hands of a building committee, consisting of Dr. Joseph Taber Johnson, chairman; Rev. J. Havens Richards, S. J., president of Georgetown University; Drs. George Kober, C. H. A. Kleinschmidt and G. L. Magruder, ex-officio dean of the medical department.

REPORTED FAVORABLY.—The House District committee has reported favorably the following bills: House bill 9,821, authorizing the Commissioners to collect a fee of 50 cents for the issuance of transcripts from the records of the health department. House bill 9,976, to punish impersonation of inspectors of the health and other departments of the city government.

FOR THE CONTAGIOUS DISEASE HOSPITAL SITE.—The item in the District appropriation bill for the purchase of a site for a contagious hospital met with almost the unanimous approval of the entire House Appropriations Committee. The allowance of \$110,000 to be placed in the hands of the Commissioners for the purpose indicated, was voted upon separately. Members say there is little doubt that the item will be approved by the House. The Commissioners already have something like \$5,000 left of an appropriation made some time ago for the selection of a site.

TO CHECK POLLUTION OF WATER SUPPLY.—Mr. Gallinger has given notice in the Senate of an amendment he intends to offer to the sundry civil appropriation bill for the investigation of the pollution of the water supply in the city. The resolution is "To authorize the marine hospital service, under the direction of the Secretary of the Treasury, to investigate the sources of contamination of rivers and other natural sources of water supply, where the sanitary condition of the people of more than one State or Territory or the District of Columbia is affected or threatened to be affected by such pollution, and to report upon what legislation is necessary to remove such pollution, provided the first investigation shall relate to the Potomac River."

MARYLAND UNIVERSITY ALUMNI ASSOCIATION.—The first annual banquet of the Washington branch of the University of Maryland Alumni Association was held on January 29 at the National Hotel. Dr. J. H. Mundell was chosen president, Dr.

J. W. Bayne and T. Morris Murray vice-presidents, and Dr. I. S. Stone secretary and treasurer.

MEDICAL SOCIETY.—At the meeting of the Society held January 27, Dr. Bishop reported some physical and therapeutic facts on static electricity. Dr. A. F. A. King and Dr. Smart, U. S. A., reported cases of dermatitis from Roentgen rays; Dr. Dufour, a case of foreign body in the nose and presented the specimen. At the meeting held on February, Dr. Fry read the essay of the month, entitled "Report of the Obstetric Work of Columbia Hospital for the year 1896." Dr. Stone made remarks on the preparation of formalin catgut. Dr. S. S. Adams presented a polypus which he had removed from the rectum of a child, 3 years of age.

THE PUBLIC SERVICE.

Army Changes. Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from Feb. 6 to Feb. 12, 1897.

Major Robert M. O'Reilly, Surgeon, is granted leave of absence for two months, with permission to go beyond sea.
 First Lieut. Francis A. Winter, Asst. Surgeon, relieved from duty at Ft. Grant, Ariz., and ordered to Washington, D. C., for examination as to his fitness for promotion.
 First Lieut. William E. Purviance, Asst. Surgeon, will proceed from Ft. Columbus, N. Y., to Washington, D. C., and report for examination as to his fitness for promotion.
 Major James C. Merrill, Surgeon, will be relieved from duty at Ft. Sherman, Idaho, upon the arrival of First Lieut. G. A. Skinner, Asst. Surgeon, and ordered to report to the Surgeon-General for duty.
 First Lieut. Guy C. M. Godfrey, Asst. Surgeon, is relieved from duty at Ft. D. A. Russell, Wyo., and ordered to Ft. Sheridan, Ill., for duty.
 The following named medical officers will be relieved from duty at the Army Medical School, Washington, D. C., upon completion of the course about March 12, 1897, and ordered to take station as follows:
 First Lieut. Basil H. Dutcher, Asst. Surgeon, Ft. Leavenworth, Kan.;
 First Lieut. Leigh A. Fuller, Asst. Surgeon, Ft. Meade, S. Dak.;
 First Lieut. Franklin M. Kemp, Asst. Surgeon, Vancouver Bks., Wash.;
 First Lieut. George A. Skinner, Asst. Surgeon, Ft. Sherman, Idaho;
 First Lieut. Carl R. Darnall, Asst. Surgeon, Ft. Clark, Texas;
 First Lieut. William E. Richards, Asst. Surgeon, Ft. Grant, Ariz.;
 First Lieut. Louis P. Smith, Asst. Surgeon, Ft. D. A. Russell, Wyo.;
 First Lieut. Marshall M. Cloud, Asst. Surgeon, Ft. Sill, Okla. Ter.

Change of Address.

Alford, R. L., from Vadaia to Ladonia, Mo.
 Carter, R. H., from Lynville, Tenn., to Belton, Texas.
 Cooper, E. H., from Galesburg to Henderson, Ill.
 Carroll, C. C., from 509 Fifth Av. to 259 W., 75th St., New York, N. Y.
 Fullenweider, R. C., from 582 W. Madison Av. to 7100 S. Chicago Av., Chicago, Ill.
 Love, I. N., from 3642 Lindell Av. to 3507 Olive St., St. Louis, Mo.
 McDaniel, E. B., from Portland to Cove, Ore.
 Mullen, T. R., from Akrou to Marcus, Ia.
 Poehler, F. T., from Waseca to Morristown, Minn.
 Scates, D. W., from New York, N. Y., to 410 N. 12th St., Waco, Texas.

LECTURE.

ACUTE CATARRHAL INFLAMMATION OF THE STOMACH.

A Clinical lecture delivered in Rush Medical College.

BY HENRY M. LYMAN, A.M., M.D.

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE.
CHICAGO, ILL.

The patient whom I place before you this morning is, you see, confined to his bed. He was brought to the hospital three days ago, in a state of alarming prostration, vomiting and purging, and unable to retain anything in his stomach. This condition had been induced by a prolonged debauch, in which the usual accessories—wine and women—had been combined with almost fatal effect. Being only 22 years of age, and of a delicate organization, his stock of vital energy was insufficient for the occasion. Though considerably relieved, he can not yet tolerate the sight or smell of food; and ever since his admission to the hospital, he has been fed with nutritious enemata, and his stomach has been given perfect rest. His tongue is thickly coated; his breath is offensive; there is a small patch of herpes on his lower lip; his bowels, which were quite loose, on admission, are now only moved twice a day; his urine was scanty, high-colored, and acid. This specimen was passed shortly before leaving his ward; it is more copious than previously, and, now that it is cool, has deposited a copious brick-dust sediment that is composed chiefly of urates. The matters that were vomited when the patient first entered the hospital were very acid, slimy, and latterly of a greenish color and bitter taste. The acidity of the vomitus was found to be consequent upon the presence of lactic and butyric acids. Free hydrochloric acid was entirely absent. After the subsidence of vomiting there were frequent paroxysms of hiccough interspersed with belching of gas and the ascent of acrid fluids into the pharynx and mouth. These evidences of gastric uneasiness have now ceased to occasion any considerable annoyance, and will soon disappear, but the patient still complains of frontal headache with a feeling of intra-cranial fulness that is aggravated during each systolic impulse from the heart. On raising his head from the pillow, there is an overpowering sensation of dizziness. The special senses are painfully exalted, and there is tenderness all over the epigastric region when pressure is made below the xiphoid cartilage. The whole abdominal wall is morbidly sensitive to pressure, but the epigastrium is more susceptible than any other part. There is complaint of burning pain felt at intervals between the scapulæ, especially after an attempt to take food of any kind. When admitted to the hospital the bodily temperature was 102 degrees F., and the feeble pulse-beat was 118 per minute. This morning, however, the temperature is 98.2 degrees F., and the pulse

is quite normal, though rather weak and easily excited.

Since we can not open this man's stomach, and look into its cavity, I must tell you what would have been found had he died two or three days ago. The mucous lining of the organ would have been covered with mucus, and through its translucent layer would have been visible the reddened membrane itself. The pyloric extremity of the stomach is the seat of severest inflammation in such cases; and there the color is deepest, and the swelling of the mucosa is greatest. Some day Professor Hektoen will have the opportunity to show you such a stomach, and I ask you then to observe the manner in which the evidences of inflammation, redness and swelling, are intensified in the vicinity of the pylorus, where it is not unusual to discover actual ruptures of the small vessels in the mucosa, with general deep staining of the membranous surface, while in the cardiac extremity of the viscus the vessels are only slightly prominent, giving them an appearance of arborization upon a comparatively pallid background of nearly normal mucous membrane. In many instances the surface presents a patchy appearance, indicating local variations in the intensity of the inflammatory process. This local variation differentiates the appearances caused by inflammation from the uniformly diffused hyperemia that flushes the mucosa during the act of digestion. Microscopic examination shows that the active proliferation of cells that occurs during inflammation differs from what takes place during digestion chiefly in the tumultuous and excessive character of the process, and in the substitution of mucus for gastric juice as the final outcome of glandular action. The connective tissue also exhibits the results of exudation and inordinate multiplication of its elements. The blood and lymphatic capillaries present the usual changes that are witnessed in connection with inflammation in other parts of the body.

The history of this case refers the disease to excessive drinking of alcoholic liquor. But in many cases no alcohol has been taken. Some of the most violent cases of acute gastritis are excited by the use of tainted meats or sweets that have been accidentally transformed into culture media for the growth of poisonous bacteria. Several times I have been called to treat whole families who had been violently attacked with vomiting and collapse within a few hours after eating ice-cream or "floating island," which had been kept in a damp and moldy cellar. A few years ago nearly one hundred persons in the State of Iowa were thus prostrated on one of the hottest days in summer at a wedding feast at which the company had been regaled with chicken-meat in a condition of incipient putrefaction. In like manner, the disease is often induced by eating unripe fruit and coarse vegetables that produce mechanical irritation of the stomach. It is sometimes produced by accidental swallowing of coins or other objects which jugglers are wont to conceal in

their mouths. When occasionally by over-eating, it is not so much the result of excessive distention of the stomach as of the fermentations that are set up within the gastric cavity. The products of fermentation and decomposition irritate the mucous surface, and in that manner excite inflammation.

Acute inflammation of the stomach is frequently due to disturbances of the nervous system. To this cause must be referred the effect of sudden cooling of the body when overheated, either by exposure to cold air or by copious draughts of ice-water. Anxiety, lack of sleep, and inordinate sexual excitement are frequent causes of acute catarrh among neurotic and arthritic subjects. The disease is sometimes caused by disorganization of the mucous membrane through the introduction into the stomach of over-heated liquids, or chemical corrosives like acids, alkalies, corrosive sublimate, tartar emetic, alcohol, croton oil, colchicum, etc. Inflammation is also sometimes excited by the poison of gout, uremia and cholemia. It is a common incident in the course of the infective diseases, such as measles, scarlet fever, typhoid fever, erysipelas, etc. Among young children it is often noted in connection with acute intestinal catarrh as the result of bad feeding and exposure to various infections. After adult life has been reached it is observed among males more frequently than among females, and is often associated with ill health that is caused by tuberculosis, syphilis, cancer, chlorosis, hysteria, and chronic obstruction of the portal circulation dependent upon hepatic, pulmonary or cardiac diseases. It is sometimes due to infection with discharges that are swallowed from diseased oral, nasal, or pharyngeal cavities, such as are encountered in cases of salivation, syphilis, tuberculosis, and gangrene of the respiratory organs. Occasionally, it accompanies peritonitis; and it may result from an ascending inflammation of the small intestine.

Excepting the cases of young children and of violent toxic catarrh, the disease tends to recovery. Sometimes its duration is very brief, as after an occasional temporary excess in eating and drinking; but the duration is usually about one week. Relapses are frequent; and there is always danger that the disorder may be thus prolonged, and gradually subside into a condition of chronic gastric catarrh.

The treatment of these cases should begin with thorough evacuation of the stomach, so as to remove all local causes of irritation, and to procure rest for the wearied organ. Our predecessors, when called to treat a brawny rustic who was brimful of beer and cabbage, were in the habit of giving an emetic containing ten grains of ipecacuanha, ten grains of zinc sulphate, and half a grain of tartarized antimony. This was usually effectual, but the resulting commotion was extraordinary, and was sometimes productive of coolness toward the prescriber. For such a patient as you have before you, a hypodermic injection of one-tenth of a grain of apomorphia would be quite sufficient, and would have the additional advantage of avoiding all irritation of the gastric mucosa. If the stomach be distended with gas, so as to produce discomfort, and to be noticeable on percussion, it may be expelled by the aid of alkalies. To children and delicate females may be given dram doses of the milk of magnesia, or tablespoonful doses of Sir James Murray's fluid magnesia, frequently repeated until relief is procured. To more vigorous patients should be given five grain doses of sodium bicarbonate, or a

tablet of purified sodium salicylate, or a grain or two of resorcin, either singly or altogether, according to the severity of the case. These drugs should be administered in wafers or capsules, and may be washed down with copious draughts of Vichy water, or Selters water, or carbonated lithia water or plain diluted lime water.

If there be diarrhea or intestinal rumbling, indicative of the passage of irritating substances into the bowels, a cathartic should be administered. Drastic purgatives must be avoided, and the choice should fall upon mild cathartics, such as ten grains of calomel laid upon the tongue and followed by a five grain tablet of sodium bicarbonate—the ordinary soda-mint tablet of the shops. Or a teaspoonful of calcined magnesia, thoroughly moistened with mint water may be given every two hours until an operation of the bowels is procured. These remedies may be aided by a large enema, and, after the subsidence of vomiting, by the administration of an ounce of castor oil floating upon a mouthful of hot tea or lemonade, or disguised by the froth of fresh beer. It should not be given with whisky or other distilled liquor, for the reason that catarrhal inflammation of the gastric mucosa is always aggravated by alcohol.

For the relief of pain the abdomen should be covered with a large hot poultice of flaxseed meal into which have been stirred a dram each of chloroform and tincture of opium. If there be repeated vomiting and pain that is unrelieved by external application, a hypodermic injection, containing one quarter of a grain of the sulphate of morphia with the one hundred and twentieth of a grain of atropin, should be administered. If the patient finds the weight of a poultice disagreeable, it may be exchanged for light flannels wrung out of hot water and covered with oiled silk, or a large piece of spongio-piline similarly moistened may be applied to the abdominal surface. In this way the patient before you has been relieved of the most distressing symptoms of his disease. He now takes a little hot chicken broth every two hours, and is allowed rice-water, toast water or barley water for drink. Tomorrow, he will be allowed to take hot milk in addition to these liquids. As he is not suffering with diarrhea, the milk need not be boiled, but only heated to a temperature of 160 F. This will be sufficient to destroy all ordinary germs without detracting from its appetizing and nutrient qualities. He will also receive ten drops of dilute hydrochloric acid in four ounces of water after meals three times a day, for the purpose of stimulating the excretory organs of the body to effect the complete removal of the products of inflammation, and, incidentally, to replace the free hydrochloric acid which is absent from the gastric juice during an inflammatory attack.

IS THE INJECTION OF AIR IN HYPODERMIC MEDICATION A SOURCE OF DANGER?

BY CHAS. T. McCLINTOCK, M.D., PH.D.

DETROIT, MICH.

In concluding a paper on "The Cause of Sudden Death after Antitoxin," Seibert and Schwyzer (American Pediatric Society, May 24, 1896) say: "We here express our firm opinion that the sudden deaths reported after antitoxin injections were caused by

injected air and not by antidiphtheritic serum." I believe that this conclusion is without any justification whatever. It has been shown over and over again that relatively large quantities of air could be injected directly into the circulation in the lower animals without serious consequences. Senn, Hare, Adamkiewicz and others have reported experiments in this line with the conclusions that the danger from air injections is small indeed.

Nevertheless, it is believed by most practitioners that the accidental injection of even a small bubble of air may be followed by very severe consequences. Many of the older books teach this. The experiments and conclusions of Drs. Seibert and Schwyzer have been widely quoted and doubtless will add to the dread that many physicians have of hypodermic medication. As said before, I believe that their conclusions are wholly wrong.

The following experiments and the results agree substantially with those of Senn and Hare. In the production of antidiphtheritic serum it occasionally happens that a horse is paralyzed from the injection of the diphtheria toxin. In such a case it is customary to kill the animal with chloroform. Recently I had two horses so far paralyzed that they were unable to get on their feet. They were ordered chloroformed, but my assistants having read of the conclusions of Drs. Seibert and Schwyzer asked permission to try the effects of air injection. Horse No. 1, 20 c.c. air injected into the jugular, no effect; after five minutes 20 c.c., no effect; after five minutes 40 c.c., no effect; after five minutes 80 c.c., no effect; after five minutes 160 c.c., labored breathing. Horse No. 2, 320 c.c., into jugular; after one minute quickened respiration, spasmodic contractions of muscles; after four minutes, hiccoughs lasting ten minutes; fifteen minutes, uneasy but respiration slower, an occasional hiccough; two hours later no apparent effect. Several hours later this horse was given 600 c.c. air in the jugular; after one minute struggling, spasmodic respiration. It acted as if choking, profuse sweating, temperature falls 0.4 degree; after ten minutes, symptoms all gone. Fifteen minutes later 1,200 c.c. air injected; quiet, almost stops breathing; breathing stops ten seconds, then continues normal after a few minutes; after waiting twenty-five minutes and no symptoms appearing, the animal was chloroformed.

Dog, weighing about twenty pounds. The jugular was laid bare and with a 20 c.c. syringe, sixteen of these syringefuls (320 c.c.) were one after the other injected. One minute after the injections began, quickened and labored breathing set in; in fact the symptoms were practically the same as in the horse, dyspnea. A few minutes after the injections were stopped the animal recovered and normal breathing was reestablished. After an hour the injections were repeated with practically the same results.

Rooster, a small bubble of air injected; no apparent effect; then 1 c.c., the bird becomes somewhat dyspneic, acts just as a chicken that has run for some distance, gasps for air, soon recovers entirely.

Rabbit, injected with 20 c.c. air, decided action at once, quickened respiration, spasmodic contraction of muscles, etc. After two minutes, respiration less frequent and gradually stops, three and three-fourths minutes, dead.

Guinea pig, injected with small bubble of air, no effect; after three minutes 1 c.c., quickened respiration, etc., but animal recovers entirely.

These experiments were repeated on different animals with similar results.

In observing these animals one is struck by the similarity of the phenomena to those of dyspnea, and indeed they are dyspneic. The air entering the heart and remaining there as an air embolus, as some would say, stops the circulation; or it passes the heart and forms air emboli in the branches of the pulmonary artery; this for the time shuts off the blood from the portion of lung supplied by that particular vessel and the animal becomes dyspneic. It is easy to see that if enough air is injected, the circulation in the lungs may be so nearly stopped as to cause death, but one or several bubbles of air would merely temporarily close a few of the branches of the pulmonary artery. This air would be absorbed by the blood in a very short time, especially as it is in contact with venous blood and under arterial pressure.

The prevalent idea that if the ventricle is once distended with air it can not empty itself, owing to the fact that the air is perfectly elastic and during the contraction merely becomes smaller in bulk, without forcing open the valves and escaping, I do not believe is justified. While the air is perfectly elastic and its volume would decrease with the increasing contraction of the ventricle, so inversely its pressure would increase and as the ventricle practically obliterates its cavity at the close of the contraction, it seems to me that the pressure must open the aortic valves and force the air on.

The rabbit was killed in the above experiments with 20 c.c. of air, but a corresponding amount for a forty pound child would be 400 c.c., or far more than enough to occlude all the branches of the pulmonary artery.

As for ordinary hypodermic medication, or serum administration, I believe the danger from air injection is absolutely *nil*. In using the Koch syringe for giving small measured quantities of serums, toxins, etc., it is customary, in order to be sure that the entire amount of fluid is injected, to allow one or more small bubbles of air to escape from the needle. During the past six years I have made literally many thousands of such injections into rabbits, guinea pigs, rats and mice, and I have yet to see any harm come from it.

But there are sudden deaths following the injection of serums; how are we to explain them? Experiments seem to show that the serum *per se* is not responsible; the carbolic acid or trikresol does not deserve the blame, and if air can not be proved guilty, what is? It seems to me that the question is as yet unanswerable. I have read somewhere of a case, I think it was reported from Louisville, Ky., where a strong man, standing in a doorway, was stung on the forehead by a bee; he fell and expired almost instantly. Wood, in his "Therapeutics," says: "I have seen the injection of a sixth of a grain of morphin followed inside of a minute by complete unconsciousness, collapse, arrest of respiration, drooping of the jaw and apparent death."

As having a possible bearing on the case I record the following: I have made many hundreds of hypodermic injections into patients of nuclein solution. These injections varied in amount from two or three to two hundred minims. In some five or six instances I have noted immediate, marked, alarming symptoms. In these injections I was always scrupulously careful to see that the syringe contained no air. In one case

I gave a small injection to a young man in the back; he was standing half-stripped; I gave the injection and turned around to put away the syringe. The patient fell headlong on the floor. He arose immediately, and beyond feeling a bit faint, showed no other symptoms. This patient had just learned that he had tuberculosis and was nervous and disheartened. In the other cases, the patients were lying down; immediately following the injection the face became livid, and there was more or less unconsciousness for a few seconds. On recovering, which was complete in a few minutes, they would say that they became faint, or had a "gone" feeling. The phenomena, however, suggested cerebral congestion, rather than anemia. In each of these cases the patient walked home after a few minutes, and there was no apparent after-effect.

As said before, I have no explanation for the sudden deaths following the hypodermic administration of serum, but I feel sure that air is not responsible. It seems to me that it will be a gain to give definite form to our ignorance in the matter by calling these phenomena, shock.

ETIOLOGY OF DISEASES PECULIAR TO WOMEN.

Read at the Marion County Medical Society and at the Forty-Seventh Annual Meeting of the Indiana State Medical Society held at Fort Wayne, May 28-29, 1896.

BY MARTHA J. SMITH, M.D.

Member of the Marion County and Indiana State Medical Societies; House Physician in Dr. Frank Ferguson's Sanatorium for Diseases of Women and Abdominal Surgery.
INDIANAPOLIS, IND.

The object of this paper is to bring before you the most frequent causes of diseases peculiar to woman, which come under one's daily observation, and which are to a great degree avoidable. I shall discuss the habits and influences which deteriorate her power of endurance and diminish her capacity for resisting disease. Observation proves that women not exposed to degenerating influences, can compete in strength and endurance with men of their race and in some savage nations they are regarded as superior to them.

The truth of this statement is now being verified by the Cuban Amazons, who are taking a prominent part in the fights between the insurgents and the Spanish troops. These women, many of whom have husbands in the ranks of the Cuban army, have exhibited on frequent occasions, courage, endurance and fighting skill to a greater extent than many of the men. These women are not, as a rule, remarkable for personal beauty or cleanliness, but they are strong of limb, vigorous in action, and can use a rifle, revolver or knife with the best of the men, and whenever there is any fighting to do they go into the thick of it with energy and dash.

In the lower order of animals this equality in the female is still more marked. From such facts we can readily see that if women were properly developed and placed beyond causes which interfere with their physical well being, they would be in no great degree inferior to man.

There are two periods in the life of women in which they are peculiarly susceptible to morbid influences which, if not removed, will almost surely produce either structural or functional disease, oftentimes both, viz.: Puberty and menopause.

One of the most frequent diseases appearing at the age of pubescence is anemia, which oftentimes pre-

vents the appearance of the menses at the usual age and gives rise to grave forebodings upon the part of the mother and frequently leads to unwise attempts to force the establishment of the menstrual function. Amenorrhea during menstrual life, although treated of in most of our gynecologic works as a separate disease, is in all cases a mere symptom of disease, either constitutional or local, or an indication of the absence, or a rudimentary state of the uterus or ovaries, or of pregnancy. Among the most frequent constitutional diseases that produce amenorrhea in young girls and unmarried women are anemia and chlorosis and these may be produced by a long siege of sickness of any kind that destroys or impairs digestion and assimilation. Less frequently in our country they are produced among the poor by insufficient food and clothing and long hours of toil.

The most frequent local causes that produce cessation of the menses are as follows, viz.: Occlusion of the uterus or vagina, atrophy of the uterus, atrophy of both ovaries, cystic degeneration of the ovaries, pelvic peritonitis and ante flexion of the uterus. The cervical canal may also be congenitally or accidentally closed and the vagina may be occluded from congenital or acquired atresia.

There is a condition of the nervous system called by Dr. Hodge of Philadelphia, "Sedation," and by Dr. Thomas, "Atony of the Nervous System," that sometimes causes cessation of the menses. It consists in a decrease of the excitability, vigor and activity of the nervous agency which controls the functions of different organs and has for its cause physical and moral influences, such as mental depression, indolence and luxury, want of fresh air and exercise, etc. It is a very common thing to hear a physician say: "I have a case of dysmenorrhea which is giving me a great deal of trouble and nothing seems to do her any good." Probably it has never occurred to him that dysmenorrhea, like amenorrhea, is only a symptom of disease and may be produced by several separate and distinct causes and the treatment must be directed to the removal of the cause. Any condition affecting the structure of the uterine walls, or its appendages, or the peri-uterine structures, making the nerves supplying these parts morbidly sensitive, will produce pain at the beginning of the menstrual flow, while anything producing obstruction to the flow, such as stenosis of the cervical canal, flexions, etc., may produce pain during the entire period.

The desire to render girls accomplished at all hazards has originated a system of forced mental training which greatly increases the irritability of the brain and nervous system, while at the same time sedentary occupations are followed to the exclusion of active exercise out of doors. This powerful influence on the nervous system, and especially on the reproductive system, is quite frequently overlooked. No amount of mental training or degree of mental development will fit a woman for the physical duties of a wife and mother, or render her capable of bearing children competent to resist the inroads of disease.

The woman who neglects physical exercise is peculiarly susceptible to uterine and ovarian trouble at the menstrual period. Exposure to severe cold during menstruation without adequate protection from warm clothing, is liable to produce inflammation of the mucous membrane of the uterus. Such an inflammation once excited will oftentimes continue for years

and in time end in interstitial metritis, entailing in its progress, dysmenorrhea, sterility, pelvic pain, gastric disorders and impaired digestion and nutrition. Cases of pelvic peritonitis sometimes develop at this trying period of congestion and nervous exaltation.

The menopause is that period in a woman's life during which the menstrual function is gradually abolished through atrophy of the uterus and ovaries. It has been called the "critical period," because certain diseases, such as cancer of the uterus, are more likely to occur at this period than at any other time and diseases already existing are liable to be aggravated. There is a widespread belief among women that the "change of life" is necessarily accompanied with many distressing symptoms, which will cease when the change is fully accomplished and not before. This erroneous belief is too frequently fostered by physicians and has caused many a woman to refuse medical consultation until disease has advanced too far to be amenable to the physician's art. The menopause is a physiologic process and a woman whose general health is good and who has no disease of the reproductive organs, will usually pass through this period with almost uninterrupted physical comfort.

The most distressing and most fatal malady to which women are subject at this period of life, is cancer of the uterus, and so stealthy and insidious is its approach that many women pass beyond hope of cure before they experience any serious or alarming symptoms. Women should be taught by their physicians that the menopause is not necessarily accompanied by pelvic pain or uterine discharge of any kind; on the contrary, such symptoms are indicative of disease and should be carefully inquired into. They should be taught that pain is not present in the first stage of uterine cancer and that it is only when the disease has advanced to a hopeless stage that it produces pain. Every woman who has borne children should submit to frequent pelvic examinations while passing through the menopause in order that cancer may be detected in its early stage and early operation resorted to for its cure. If this rule were generally adopted, it would result in the saving of many precious lives that are otherwise doomed to a horrible death.

Constipation is a fruitful factor in the production of general as well as local diseases and frequently aids in the production, if it is not a direct cause, of displacements. The full bowel resting upon the body of the uterus will aid in the production of flexions and versions and in conjunction with other causes may produce pelvic inflammation and it certainly aggravates whatever disease may be present in the pelvis.

After the expulsion of the embryo, either at full time or at any period of pregnancy, the muscular structure of the uterus undergoes a process of fatty degeneration and absorption, which has received the name of involution. The process occurs rapidly after abortion, but after labor at term it requires six weeks under the most favorable conditions for its accomplishment. In order that involution may proceed with normal rapidity and certainty, perfect rest is essential. The woman who after parturition resumes her usual occupation before the completion of involution, invites subinvolution, displacements of the uterus and its appendages, and a general relaxation of the pelvic tissues, the occurrence of which will render her an invalid for months or for years, perhaps for life.

It is now universally recognized that lacerations of the pelvic floor are the chief cause of cystocele, rectocele and prolapsus uteri, and a large proportion of cases that consult the gynecologist are suffering from diseases that might have been prevented if the obstetrician had not neglected one of his most obvious duties, viz., the early repair of lacerations.

Lacerations of the cervix uteri are, in some cases, important factors in uterine pathology, but in many cases in which their existence is recognized by inspection, they produce no evil results whatever. Dr. T. A. Emmet first recognized the significance of the lesion and taught us how to repair it, and yet there are few who believe his statement that "at least one-half of the ailments among those who have born children are to be attributed to laceration of the cervix." That they do occasionally produce subinvolution and hypertrophy of the cervix, undergo cystic degeneration, produce sterility, dysmenorrhea, etc., there can be no doubt and the frequency with which cancer of the cervix appears upon the site of an old laceration is significant. But after cervical lacerations have been given due credit for all the mischief they are capable of doing, the fact remains that many times they have been wrongfully accused and as a result the operation of trachelorrhaphy has been greatly overdone.

That criminal abortion constitutes a prolific cause of many diseases of the uterus and its appendages, no one engaged in the practice of medicine can for a moment doubt. Dr. P. F. Chambers of New York, says: "In my experience the most frequent cause of pelvic trouble among married women is abortion and in the majority of cases abortion artificially or intentionally produced." Dr. Grandin says he is satisfied that fully 50 per cent. of the pelvic troubles of women can be traced to improperly treated abortions. Dr. Wm. M. Polk says abortions are the most common cause of disease of the appendages. Dr. Andrew F. Currier says the production of criminal abortion is probably responsible for more of the serious diseases which affect the pelvic viscera of women than any other cause. When we consider the vast multitude of women who habitually resort to the criminal abortionist to be relieved from the responsibility and inconvenience of child bearing, the wonder is that the crude and dangerous methods by which the act is usually committed, does not produce more chronic invalidism than superficial observation would lead one to suppose.

Specific vaginitis is one of the most frequent causes of pelvic and peritoneal inflammation. Many authors place it in percentage next to abortion and puerperal sepsis, but the frequency of this disease probably depends upon the character of the population in each particular community. The investigations of Noeggerath and the teachings of Tait have thrown a flood of light upon this subject. The fact is that until Tait opened up the realms of abdominal surgery and revealed the true character of the inflammatory diseases of the pelvic organs, very little was positively known of the ravages produced by this disease. Dr. H. W. Longyear of Detroit, Mich., says that latent specific vaginitis produces more cases of pelvic inflammation requiring celiotomy among women of the upper classes than any other cause. There was a time when this disease was thought to be of little importance, but it is now known to be a terrible and oftentimes a fatal scourge among women.

The mismanagement of the third stage of labor I believe to be one of the most fruitful causes of diseases of the reproductive organs. Undue haste in the delivery of the placenta is almost sure to result in leaving fragments of the secundines within the uterus, which may and sometimes do become the source of both present and future trouble. Dr. W. D. Porter of Cincinnati, in an article on the "Third Stage of Labor," says: "Efforts at expulsion of the placenta previous to its detachment are clearly wrong."

About twenty years ago Credé published his method of delivering the placenta, a procedure familiar to us all. Suffice it to say, that it has been grossly abused to the lasting detriment of a large proportion of women, who have been subjected to it too soon after the completion of the second stage of labor. The method scientifically applied at the proper time is a very safe and efficient one. Many physicians, heedless of the results that may be produced by interfering too soon, deliver the placenta before the uterus has regained its impaired contractility, caused by the long and oftentimes violent contractions of the uterus that finally result in the expulsion of the child. The probable results of undue haste in this most important part of the physician's duty, is the retention within the uterus of placental and membranous fragments, which not only cause frequent recurring post partum pains that fret and worry the patient, destroying her rest and protracting her convalescence, but frequently become the source of sepsis which, if it does not end fatally, is almost sure to cause subinvolution, chronic endometritis, metritis, salpingitis, peritonitis, displacements, etc.

Dr. Frank C. Ferguson, in an article published in the *Indiana Medical Journal*, of 1891, sums up the matter as follows: "The complications of incomplete abortions and the retention of fragments of secundines after labor, are primary and secondary. The principal primary complications are, 1, post-partem hemorrhage; 2, septicemia; 3, pyemia; 4, acute puerperal metritis; 5, lymphangitis. Should the patient happily escape these dangerous diseases, the principal secondary complications to which she may be subjected are, 1, subinvolution; 2, prolapsus; 3, versions and flexions; 4, long continued recurring metrorrhagia and menorrhagia, which sooner or later produce profound anemia, leading oftentimes to the development of tuberculosis or other maladies."

I have not attempted to enumerate all the causes that contribute to the ill health of women, but have spoken chiefly of the most prominent causes and those which are to a very large extent preventable. When proper attention is given to the physical training and education of our girls at the time of puberty; when a radical change is made in the social life of the wealthy; when women are thoroughly instructed concerning the evil results of improper dressing, the ill effects of constipation, and the terrible results of criminal abortion, and when physicians are universally held responsible for ill health produced by the accidents of parturition, the mismanagement of labor and the lying-in period, diseases peculiar to women will be far less prevalent than they now are.

ON INIENCEPHALUS.

Read at the Meeting of the Chicago Pathological Society, Dec. 14, 1896.

BY HENRY P. LEWIS, M.D.

CHICAGO.

St. Hilaire defines a monstrosity as a serious deviation from the specific type, complex, apparent on external view and congenital. His classification of anomalies and monstrosities has generally been followed by teratologists since his time. A large family of monsters is characterized by a defective closure of the cranial vault or the vertebral laminae. There are many varieties according as the defect is in the cranial bones, the spine, both cranium and spine, or parts of each or both. In a large number the brain is entirely wanting or rudimentary. Such are the anencephali or derencephali, the commonest of all, the so-called frog or owl fetuses. In another class the brain is present, although the mal-development of the bones has caused all or part of it to lie outside the cranial cavity. Sometimes the posterior defect is confined entirely or mostly to the vertebral laminae and we have spina bifida, through the defect in which meningocele usually protrudes. The class in which the brain is wholly or in part outside the cranium is the exencephalian. This is subdivided into those with and those without spinal fissure.

Without spina bifida:

1. Notencephalus; brain largely outside the skull through occipital defect with posterior encephalocele.
2. Proencephalus; anterior encephalocele.
3. Hyperencephalus; podencephalus; cranial defect in vault.

With spina bifida:

1. Exencephalus proper; cranial bones rudimentary and brain lies mostly or entirely outside on the back. The spinal defect may involve a few or all vertebrae.

2. Iniencephalus; considerable or all of the brain is covered by the cranial bones, but the tilting backward of the head makes the margins of the occipital defect come closely in contact with the margins of the spina bifida so that some of the brain lies upon the spinal cord and in the spinal gutter, although covered wholly or in part by the bones of the cranial vault, which act as vertebral laminae. There may be an encephalocele or not. Ballantyne states three cardinal characteristics of iniencephalus: occipital defect, spina bifida and fetal retroflexion. The dividing line between iniencephalus and exencephalus proper is not absolute and some few cases might be classified differently by different authorities. Taruffi groups iniencephalus, notencephalus and exencephalus proper into one species which he calls "mero-acrania postero-spinale."

Iniencephalus is a rare form of monster. Isidore Geoffrey St. Hilaire, writing in 1836, says that only three cases had been thus far reported. Taruffi, writing in 1889, says that only about twenty cases had been reported of mero-acrania postero-spinale. I have collected every case reported in accessible literature, including an exhaustion of the Catalogue of the

Surgeon-General's Office, U. S. A., and the Index Medicus, omitting one case undoubted and one doubtful which I can not find in original or abstract. To these I add one case delivered by myself and two from the museum of Rush Medical College, dissected by me with the assistance of Dr. L. J. Mitchell and with the permission of Prof. Ludvig Hektoen.

The cases recorded below divide themselves into three general classes. The first includes those without protrusion of the brain beyond the box formed by the cranial bones and the open vertebræ. This class may be called *iniencephalus clausus*. The second includes those having a small encephalocele and, with the first, comprises the typical iniencephalic class. The third includes those cases where the occipital opening is large enough to allow the escape of a large portion of the brain. The last two might be called *iniencephalus apertus*. Of the iniencephali clausi I have collected nine cases, viz.: By Fleck⁴⁵, Royal College of Surgeons of England⁶, Coffin⁸, Yocum⁹, Landucci¹⁰, Ballantyne^{11, 2} (two cases), my own case and one from Rush College Museum.

My case is as follows: Primipara, 25 years old, in sixth month of gestation, abdomen enlarged correspondingly, twins, male. One was normal and appeared to be five and one-half months along. This one lived for twenty hours in an incubator. It is 10 inches long, weighs 590 g., has finger nails half out to ends of digits and undescended testes. The second was dead and somewhat macerated, 6½ inches long, weighed 190 g. There was a common placenta and chorion, two amnia and two cords. The smaller twin presented the appearance of great shortening of the back. From back of head to anus is only ¾ inch, while from chin to pubes in front is 4¼ inches. The face looks forward and upward, while the cranium is turned sharply backward, covering most of the dorsum. The neck is edematous and has no furrow between chin and sternum. The abdomen is very protuberant. Dissection shows the parietals overlying the upper two-thirds of the spinal column. Cutting the fibrinous attachments of the cranial bones to the spine and turning the head forward reveals an extensive spina bifida as far as the second lumbar vertebra. All the cranial bones are normal except the occiput. The basilar portion articulates with the atlas, but the bone broadens out so as to leave a large foramen magnum, which opening is continuous with a large defect in the squamous portion and makes a figure eight with the latter opening. The squamous plates of the occiput are represented only by an acute triangle on either side of the opening articulating anteriorly with the parietal. The margins of the bony defect in the occiput are closely attached to the ends of the widely divergent transverse processes of the cervical, dorsal and first lumbar vertebræ. Thus it will be seen that the spinal canal is covered above by the remnants of the occiput and the parietals which form a sort of roof along the dorsum. At the bottom of the spinal canal lies the cord and over it, contained in the cranium, lies the brain. Thus we have an *exencephalus*, for while the brain does not escape into the outer world, yet it does lie partly outside of the cranium and in the spinal canal. The defect is in the occiput or "inion" and therefore the variety is "iniencephalus."

The cervical spinal column curves downward and forward, making a concavity with the dorsal portion which turns backward under the cranium. The cerebral hemispheres are apparently of normal size.

The first Rush College case is an unmarked specimen without history. Female, Beclard's center in the femur present, nails to ends of digits and otherwise apparently of full term. The length is only 12¼ inches, but the shortness is explained by the marked foreshortening of the back due to the tilting backward of the head. The face looks forward and upward, leaving very little furrow below the chin. There is an opening in the abdomen near the navel, allowing some of the viscera to be outside the body.

Dissection reveals a complete spina bifida to the tip of the coccyx. The cranium extends as far as the lumbar region, attached ligamentously to the transverse processes as in the former case and forming a roof over the spinal canal. There is no encephalocele. There is much lordosis of the cervical spine and right scoliosis of the whole column, so that the ribs are so irregular as to deform the chest. The opening in the occiput consists of a large foramen magnum 1½ x 1½ inches. The width of the spinal cleft is at its maximum 1½ inches. There is slight talipes varus of both feet.

Of *iniencephalus apertus* first come those with small encephalocele. Of this class I have collected eight cases, viz.: By Dugés^{12, 1}, Potthoff⁵⁴, Cruveilhier,^{13, 14} Drew and Jackson¹⁵, Lawther¹⁶, Vernier¹⁷, Remfrey¹⁸ and the second case found by me in Rush College.

This last is marked 140 and is without history. Female, toe nails less than half and finger nails two-thirds out to tips of digits; apparently about seventh month.

Beside the usual tilting back of the head and shortening of the dorsum there are two soft tumors upon the back. One protrudes from a bony defect in the skull to the right of the median line and hangs over the right shoulder, measures 2¾ x 2¼ inches and is shown by dissection to be an encephalocele. In the median line, and occupying the lower two-thirds of the dorsal region, is another tumor covered by membrane and allowing the cleft spine to be felt beneath. It measures one and one-fourth by fifteen-sixteenth inch and is shown by dissection to be a meningocele. The opening in the cranium through which the lateral tumor escapes is between the rudimentary plates of the squamous occiput which, in the form of acute triangles, are articulated with the parietals at the lambdoid suture. The bony defect here is continuous with the enlarged foramen magnum below and forming a figure eight with it. The margins of the foramen lie flat upon the spinal column and are ligamentously attached to the bony margins of the spina bifida. Thus the occiput covers the spinal canal, causing the shortening of the back of the fetus. There is complete spina bifida to the tip of the coccyx, widest under the cranium. There is lordosis of the cervical and kyphosis of the lumbar vertebræ. The axis of the spinal column is also turned to the right in the cervical and dorsal regions (right scoliosis).

Of the third class, namely, *iniencephalus apertus* with large encephalocele, I have collected five cases, namely: By Hull²⁰, Gros²¹, Budin²², Rogers²³ and Bonnaire²⁴. As in most classifications, the distinction between iniencephali and exencephali proper becomes indefinite at the boundaries. A few cases might, by different authorities, be classed in either category. One such case is reported by Poelman²⁵, but this seems to be an exencephalus proper with cyclops. Taruffi³, in the section on micro-acrania

posterior-spinal, mentions ten cases collected by him where the cranial defect was in the occiput. This class he considers synonymous with the iniencephalus of St. Hilaire. Only one of these do I think a true iniencephalus and that is one reported by Hull and already referred to by me. Beside these of Taruffi, I find reference to two whose original reports I am unable to find. One is a specimen depicted in Ahlfeld's Atlas⁵ and shows a skull with enlarged foramen magnum, therefore may be iniencephalus or notencephalus. Vrolik³² also depicts a skull with similar defect, but further particulars are wanting. St. Hilaire states that one of the three cases of iniencephalus reported up to his time was by Burkhardt³⁶ but I can nowhere find original, or abstract of the latter's article.

A résumé of the twenty-two cases collected by me shows a few interesting facts. In all cases there was a marked tilting back of the head and extension of the cranium on to the dorsum. The rhachischisis extends to the sacrum or farther in ten cases, to the last dorsal in two, to the middle dorsal region in four, through the cervical region in three and not stated in the rest. Anterior spina bifida in two, diaphragmatic hernia in four, hydramnios in six, club foot in three, hydrocephalus in one, umbilical hernia in one, celosomia in two, deformities or displacements of the alimentary tract in eight, myelocele in one. In one the external oblique took an origin from the clavicle and in another the gluteus maximus from the occiput. Four were born living, seven dead and the rest not stated; two were male, seven were born of primiparæ, four of multiparæ and the rest not stated. Only twice is it stated that there was twin pregnancy, in seven not stated and in the rest the language would imply single births.

The group of monsters exhibiting cranio-rhachischisis is a numerous one. Anencephalus occurs once in 7,143 births³⁷ and about two-thirds are female³⁹. Of the exencephalians the least rare is notencephalus; the proencephali are rather more rare and the podencephali rarest in the human species but common among animals. The exencephali proper and iniencephali are both very rare, the latter the most.

There are two important sets of views as to the etiology of such monstrosities. The pathologic theory explains the anomaly by disease of the fetus itself acting early in its history and depending for the different forms of anomaly upon the date of beginning.

The embryologic theory now held by the majority of authorities, explains malformations by arrest of development, usually from pressure at an early embryonic period. Dareste⁴⁴ considers the cause to be pressure and adhesion of the amnion to the tissues developing beneath it. He experimented with the eggs of birds, chiefly by unequal heating of different parts of the egg during artificial incubation, and was even able to a certain extent, by varying the point of greatest warmth, to produce different forms of monster at will. The arrest of development of the amnion, consequent on his treatment of the egg, modified the evolution of the different parts of the embryo by the compression it exercised upon them. The cranio-rhachischisis monsters he took to arise from compression and adhesion of the cephalic hood of the amnion which tended to shorten and flatten the cerebral vesicles.

Curious and interesting tales are told by ancient and medieval writers about all sorts of possible and fabulous monsters, but teratology practically begins

with St. Hilaire in the first half of the nineteenth century. His classification of monsters and anomalies remains satisfactory to almost all the wants of teratologists today. Later teratologists have devoted themselves to the etiology of the subject, as is evidenced especially in the experimental work of Dareste and his followers. The fields for experiment as well as for observation are relatively so small that the advance has been also small, still much has been and is being done. Teratology is pathologic embryology and the advance of the former must depend largely upon that of the latter. Although experiment will in the future, as in the past, do much to clear up these obscure problems, yet we will continue to be largely dependent upon careful descriptions of carefully made dissections.

A New Tapeworm.—In the journal of the College of Science of the Imperial University of Tokyo, Professor Ijimi of Tokyo, and Professor Kurimoto of Nagasaki, describe an enormous tapeworm which they denominate "bothriocephalus sp." It measured 10 meters in length and 25 millimeters in breadth at the broadest portion. Its expulsion was brought about with a dose of extract of male fern.—*New York Medical Journal.*

TUBERCULOSIS—INFECTION THROUGH MILK AND THROUGH BAD SANITATION.

Read before the Iowa State Medical Society, April 15, 1896.

BY W. E. HARRIMAN, B.S., M.D.

PROFESSOR OF PATHOLOGY, HISTOLOGY AND PHYSIOLOGY AT IOWA STATE AGRICULTURAL COLLEGE.
AMES, IOWA.

In the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION of Feb. 8, 1896, Dr. Edward F. Wells of Chicago announced the proposition that pulmonary tuberculosis is declining in prevalence, and supported the assertion by some very complete and carefully compiled statistic tables. These statistics seem authentic and it is hard to doubt the conclusions; yet our journals and periodicals in general are filled with startling statements of its prevalence.

Dr. J. Collins Warren, professor of surgery in Harvard University, says that tuberculosis probably affects more people than any other form of infectious disease, and estimates that one out of every five deaths is due to this disease.

Professor Law of Cornell University is quoted in Vol. xviii of *The American Veterinary Review*, as having said: "If the 5,490 deaths from tuberculosis which occur every year in the city of New York could be brought together in an epidemic lasting but one week, no smallpox, cholera or yellow fever scare would approach the panic which would thus be created."

From various statements we glean that the average ratio of deaths in the human family from tuberculosis, to the total mortality, is about 14 per cent., while in some localities it reaches as high as 40 or 50 per cent. Professor Law says "if we take the whole civilized world and compare with the tuberculosis mortality all the accumulated deaths from war, famine, plague, cholera, yellow fever and smallpox, we find that the latter wanes into comparative insignificance."

These astounding statements from men of national reputation, must carry no inconsiderable weight. Such appalling mortality as is here depicted enlists our interest in a search for the potent causes, and we find that it is a disease both of man and lower animals; that it is communicable from the one to the other; in fact, that it is intensely infectious, and in a plain sense contagious; that the conditions under which conveyance and transmittance of the infection occur, are numerous and variable in the extreme, and that once contracted it is terribly fatal. These complex conditions unite to cause the high mortality.

Of the various avenues whereby the tubercle bacilli gain entrance to the human economy, one of great importance is via the gastro-intestinal route.

As has been said, the disease is communicable from man to the lower animals and *vice versa*. Of all the lower animals, cattle are the most commonly affected; especially is this true of milch cows, and although Sims Woodhead finds some difference in the vital pathogenic characteristics of the two bacilli, recent investigation proves that bovine tuberculosis, or *Perlsucht* as the Germans call it, and human consumption are identic.

Fleming in his "Manual of Veterinary Sanitary Science and Police," in speaking of its geographic distribution among animals says: "Tubercular phthisis or tuberculosis probably prevails among the domesticated animals over the entire globe." In Mexico 34 per cent. of the animals slaughtered for food are found to be tubercular. In Europe and England it is exten-

sively present and has long been recognized as a common disorder among animals.

In the United States it is prevalent from shore to shore. Dr. Simonton in an article in the *San Jose Mercury* of January, 1896, states that 15 per cent. of the cattle in California are infected, while reports by the Cattle Commission of Massachusetts give the percentage in that State variously from 8 to 35. From results of tuberculin tests thus far made, the percentage in Iowa is from 12 to 14. We can safely put the average throughout the United States among cattle from 5 to 12 per cent.

Hence the question of infection of man through animal products assumes a colossal importance. Of all the animal products milk, being used so extensively in the raw state, is by far the most dangerous.

In the report of the Royal Commission on Tuberculosis in the *American Journal of the Medical Sciences*, September, 1895, experiments are reported in which pigs, guinea pigs and rabbits were fed on uncooked milk from tuberculous animals, and the disease was thus caused in a very large percentage of subjects used. Control experiments with animals kept under similar conditions but which received no tuberculous food, gave negative results. The uncooked food produced the disease in all of eight pigs, all of five cats, fifty-six out of eighty-four guinea pigs and eight out of ten calves that were fed with it. Prof. W. M. Late Coplin of Vanderbilt University, Nashville, Tenn., reports experiments with similar results. Dr. Palmer of Massachusetts reports equally conclusive tests. In experiments made at our Iowa Agricultural College over 60 per cent. of the animals fed upon the condemned milk contracted the disease.

In the human race it is known that children are most frequently affected with intestinal tuberculosis, and the *American Veterinary Review* of December is authority for the statement that over half the deaths of bottle fed children in cities are due to tuberculosis.

From all the above statements, we must conclude that the possibility of milk from tuberculous animals containing the infectious elements is undeniable.

It has been stated that only those cows having tuberculous udders are capable of producing bacilli in the milk. The unfortunate fallacy of this is shown by one of an exhaustive series of experiments conducted by the trustees of the "Massachusetts Society for the Promotion of Agriculture," quoted by Drs. Stalker and Niles in Bulletin No. 29 of I. S. A. C. Exp. Station, published in November, 1895; twenty-one healthy calves were fed on milk from tuberculous cows. At the conclusion of the experiment they reported: "Of the twenty-one animals, eight, or over 33 per cent., were shown to be tuberculous. That the cows from which milk for these feeding experiments was derived were free from tuberculosis of the udder is shown by an appended table of their history, and the results of the postmortem."¹

I am prone to believe, with the above society and Drs. Stalker and Niles, that "with the evidence here presented it is undeniable that milk from tuberculous cows with no appreciable lesion of the udder may, and frequently does, contain the bacilli of the disease."

Hence it is seen that milk from cows affected with the disease to any extent, whether the udders appear diseased or not, is very apt to contain the bacilli (and as a matter of fact, differential diagnosis during life

¹ Table not inserted with this article.

between tuberculosis of the udder and simple mastitis is often impossible).

When we consider the wide-spread prevalence of the disease among cattle, and the practically unrestricted public distribution of milk, and the enormous quantities yearly consumed in the raw state, we do not wonder at the high rate of mortality in the human race.

Sanitary science includes a consideration of all that can be done for the prevention of disease and promotion of the public health. The application of rules and enforcement of laws promulgated by this science is known as sanitation. If the sanitary rules are not rigidly applied, or the laws are disregarded, we have unfavorable or bad sanitation. The negligence shown in permitting the spread of tuberculosis by infected milk is bad sanitation. But more commonly we look upon the expression "bad sanitation" as meaning some condition of improper or inefficient sewerage or other menace to public hygiene.

The hygienic environments and state of sanitation have much to do with the tuberculosis problem, in so much as bad sanitation causes a lessened state of health and vitality, and hence renders the body easily invaded. Furthermore, conditions of filth and moisture, and decaying organic matter, such as is afforded for example, in some of the dark, damp, illy ventilated tenement houses of cities, are very favorable to the life and thrift of the tubercle bacillus.

No condition of bad sanitation can actually originate *per se* the germs, but various conditions of unfavorable sanitation are conducive to activity of the infection, which conditions, combined with some special predisposition on the part of the individual, result in his ultimate infection.

Perhaps the most frequent manner of infection in the human species, even more so than via the gastrointestinal route, is by inhalation of bacilli in the air, containing the dust of dried sputum expectorated unrestrictedly by tuberculous individuals. In the same manner, and from the same cause, public berths in sleeping cars and ships, cabs and other public conveyances are especially dangerous. Another source exists in use of contaminated water supplies, public baths, water closets, etc.

The practice of dealing in second hand articles, particularly clothing, is an especial menace to those so engaged. Along this line the Iowa *Health Bulletin* of November, 1895, calls our attention to the matter of infection through the sale and use of bed mattresses made of old rags.

The common procedure among children in our public schools, of cleaning the slate by fingers moistened in the mouth, and passing the slate to the next neighbor to repeat the operation, is one especially calculated to spread such a disease as tuberculosis.

The sale of tuberculous meat and of fruit which has been exposed to street winds and bacillus-laden dust are also matters of no mean magnitude in the spread of the disease.

In fact this disease has been transmitted from man to man, man to animal, animal to animal, animal to man, from place to place, until it would seem that man's life continues at constant hazard, and his survival is a momentous marvel.

Indeed, I believe were it not for that mysterious something within us, which Sternberg has termed partial immunity or "natural resistance," the already high mortality must needs be multiplied many times.

For the conditions have now become such that no doubt many of us inhale or ingest tubercle bacilli every day of our lives, while only those hereditarily predisposed, or in whom natural resistance is at a low ebb, become favorite seats for the development of the germ.

Woodhead has summed up these conditions necessary for infection as follows:

1. The presence of the bacillus tuberculosis in such a position and for such a length of time that it obtains a coign of vantage, so to speak, from which to attack the tissues of the body.

2. Some weak point in the epithelial surface, made by disease, or due to irritation or bad food, by which the organisms may attack the deeper tissues in sufficient numbers to insure their being able to hold their own in the struggle for supremacy that ensues.

3. The comparatively low vitality of these deeper tissues brought about by imperfect nutrition or irritation, the cells of which they are composed being no longer able to deal successfully with any large number of bacilli that can, under ordinary circumstances, find their way thus far.

Much has been done in various parts of the country toward controlling and preventing the spread of this disease, and our literature today is replete with conflicting plans for its complete eradication. A résumé of what has been accomplished and a discussion of the floods of contributions to our literature, on the subject, would be of intense interest and profit.

CHURCHILL'S METHOD APPLIED WITH SUCCESS IN FORTY-FIVE CASES OF PHTHISIS PULMONALIS.

BY T. BLANK, M.D.

ST. LOUIS, MO.

Too little attention is paid to "Churchill's method" of treating consumption, although it is still the best method, and if well studied and rightly applied will result in a cure in a great many cases. We can not expect much good from it at the last moment; it must be applied early. In the incipient stage and in the beginning of the cavernous stage, ninety cases out of a hundred can be cured by the Churchill method. But the physician, in order to succeed, must study it closely. He must be a good observer, otherwise he will fail or do harm. The Churchill method depends upon phosphology; if there is a decrease of molecular or intra-organic combustion, due to want of phosphid (oxidizable phosphorus) element in the bioplast (or bioplasmic principle, as Churchill calls it), then the tissue breaks down and the soil for the tubercle bacilli is prepared.

That the tubercle bacillus is the cause of tuberculosis no scientific man will deny. But considering the wide distribution of the tubercle bacilli and the many chances for infection, it is really wonderful that so many escape the disease. Koch himself drew attention to the slow growth of the tubercle bacilli, so that in many cases they are eliminated before they have gained a foothold.

Now we come to the point. What is the condition that favors a foothold of the tubercle bacillus? It is the deficiency of the phosphid (oxidizable phosphorus) element. If this element is not present in sufficient quantity in the tissue the oxygen we inhale with the air is not utilized to the fullest extent, owing to a lack of oxidizable phosphorus in the organism

which, acting by its chemic affinity, is necessary to secure its combination with the proximate principles of the blood and instead of normal bioplasmic material being produced, a broken down tissue is substituted—the soil for the tubercle bacilli. The Churchill method supplies this oxidizable phosphorus in the form of chemically pure hypophosphites.

It is really astonishing to see patients improve all around and gaining from one to two pounds per week by supplying the long-needed oxidizable phosphorus, a regular godsend as a drink of water would be to a dying man in a desert.

But the improvement consists not only in gain of weight, cessation of cough, night sweat, fever, etc., but in the lungs a process is taking place most interestingly. Dead cells, broken down tissue, millions of tubercle bacilli are expectorated, while under the influence of hypophosphites new normal bioplasmic tissue is formed, tissue which will resist the bacilli until the last one is expectorated.

I have made repeated microscopic examinations of cases, discharged as cured, and could not find a single tubercle bacillus; they were gone, though plentiful at the beginning of the treatment.

Churchill used the hypophosphites of soda, lime and quinia. He never combined any of these. He gave but one salt at a time, because each salt has a different action. For instance, in the incipient stage and in the second stage, where the expectoration is tight and the cough troublesome, the hypophosphite of soda is indicated, because it favors expectoration and clears the lung of dead tissue, but watch it closely; if expectoration is too free that means too rapid softening of the tubercular deposit, and then the lime salt must be given. The lime salt reduces expectoration and softening, as in Case No. 23, where the expectoration was reduced from a pint and a half per day to only a few tablespoonsfuls in measure. The action of these different salts is so distinct that it vexes me each time I see an advertisement of syrup of hypophosphites of soda and lime together, claiming to be according to Churchill. Such statements are false; Churchill never used these salts in combination in this disease.

The hypophosphite of quinia is given in the initial treatment of far-advanced cases, and later on soda or lime salt is given according to indications. Why is it that the brilliant results obtained by Dr. J. F. Churchill in the Parisian Hospitals are not generally obtained? This is due to several causes. 1. Most of the commercial hypophosphites are not chemically pure, therefore valueless. 2. If the chemically pure hypophosphite salt is not incorporated with pure syrup immediately after its manufacture it will be rapidly injured by age. 3. Many physicians have given a combination of different hypophosphite salts, believing that they apply the Churchill method. This is the most frequent cause of failure.

Of the forty-five cases I have treated within the past three years, I have given, at the conclusion of this paper, the history of the most important, barely mentioning, for want of space and because it would be tiresome to the reader, those, the history of which has been similar or identical with those published in detail.

I will say that the wonderful success which has resulted from my use of the Churchill method in this disease has so convinced me of its worth that I shall continue its use until, as I trust, we shall be able to cure 99 cases out of 100.

Before closing let me express my sincere gratitude to R. W. Gardner, New York, who does so much to spread the teachings of Churchill.

Case 1.—Mr. John W., East St. Louis, Ill., age 20 years; date of consultation June 19, 1893.

History: For about a year has complained of a cough, dry and hacking in the beginning; expectorated blood some months ago; lost considerable in weight during the last few months; there have been night sweats, but not severe; appetite failing.

Examination of lungs: Infra-clavicular region in left side sunken; inspiration in this region rough with dry rales; expiration blowing (bottle sound); on right side, same condition; percussion, cracked-pot sound. Microscopic examination of sputum (made June 23) showed tubercle bacillus.

Treatment: Syrup hypophosphite of soda (Gardner), half teaspoonful, t. i. d., after meals.

Report, July 1, 1893: Patient feels stronger already; expectoration not much increased; continued syrup soda, same doses; gave eight fluid ounce bottle.

Report Sept. 2, 1893: Patient has been in Kansas City; accepted work there, as he felt strong enough to do so; has gained in weight; appetite good; during the last two weeks of August, cough disappeared entirely, but now there is some cough again, continued syrup of soda hypophosphite, half teaspoonful, t. i. d.

Report, Sept. 9, 1893: Patient still gaining in weight; sleeps better than ever before; no night sweats; appetite good; very little cough; continued syrup of soda hypophosphites, 20 drops, t. i. d.

Report, Oct. 3, 1893: Patient is doing nicely; still gaining in weight; total gain since the beginning of treatment, twenty-five pounds; no cough nor expectoration; discontinued the syrup soda hypophosphite.

Report, Dec. 12, 1893: Patient at office again; intends to go West to accept work; as a matter of precaution he wants to take a bottle of medicine along, but as he has felt so well since October he thinks he will not have use for it.

Remarks: I have not seen the patient since the date of last report, but from patients whom he has sent I have heard that he came back from the West and is living in East St. Louis again, in good health. The last indirect report I received about him was in 1894, the exact date I have not recorded.

Cases Nos. 2 to 9, inclusive, were so similar in their general characteristics and history that I have not considered it necessary to give a detailed account of them. They were all in their general features duplicates of Case No. 1. The tubercle bacillus was found in every case, at the beginning of treatment, by microscopic examination; indeed I do not diagnose a case of consumption until I find the bacillus present.

Case 10.—Miss A. L. B., age 21 years; date of consultation, June 5, 1894.

History: Since February, this year, patient has been suffering with amenorrhea; lost rapidly in weight, six pounds in as many weeks; all last winter patient suffered with cough, dry at the beginning; now there is expectoration with little cough effort; expectorates small lumps, as she expresses it.

Examination of lungs: Left and right supra-clavicular region affected; on both sides, expiration blowing (bottle sound); inspiration rough, rolling, with moist rales; right and left infra-clavicular regions show dullness on percussion; inspiration in those regions rough, with dry rales (but very fine). Microscopic examination of sputum showed tubercle bacillus.

Treatment, June 7, 1894: Syrup hypophosphite of soda (Gardner), half teaspoonful, t. i. d., after meals.

Report, June 18, 1894: Expectoration slightly increased; thinks she feels somewhat stronger but not much; decreased the dose of syrup hypophosphite of soda to 20 drops, t. i. d.

Report, June 28, 1894: Patient feels stronger; sleeps well; appetite is increasing; coughs very little; the expectoration is brought up with very little effort; she no longer notices lumps in the expectoration; same treatment continued.

Report, July 15, 1894: Has gained one pound in weight; feels strong; appetite good; hardly any cough; expectoration just as I want it; continued syrup hypophosphite of soda, 20 drops, t. i. d.

Report, Aug. 7, 1894: Patient looks well; has gained another pound since the last visit; there is a little lassitude; discontinued syrup hypophosphite of soda on account of this.

Report, Aug. 27, 1894: The lassitude has not left her; close examination shows that she had a chill about a week ago; fever followed the chill; some sweat after the fever had left.

her; since then she felt chilly and feverish, off and on; headache; sleepy during the day; loss of energy; slight cough again; diagnosis, malaria; gave quinin solution.

Report, Sept. 5, 1894: Feels better; has not been feverish in last few days; feels no longer sleepy during the day; no headache; continued quinia in smaller doses and added Fowler's solution.

Report, Sept. 15, 1894: There are no longer symptoms of malaria; coughs very seldom; hardly any expectoration; discontinued all medication; gave order to report again in two or three weeks.

Report, Oct. 8, 1894: Expectoration a little tight; appetite fair; no symptoms of malaria have reappeared; continued syrup soda hypophosphites, 20 drop doses, t. i. d.

Report, Oct. 20, 1894: Expectoration no longer tight; appetite fair; no symptoms of malaria have reappeared; continued syrup hypophosphite of soda, same dose; gave order to discontinue the medicine for a week if expectoration should get too free.

Report, Nov. 25, 1894: Patient has regulated the medicine according to the condition of the expectoration; there is now neither cough nor expectoration; has gained four pounds since the last time she was weighed; syrup hypophosphite of soda, 6 fluid ounce bottle, dose 20 drops, t. i. d. Gave order to commence with the medicine in about a week from now; take it for one week, every day; then every other day.

Report, Feb. 23, 1895: Patient has not taken any medicine for about two months; has some of it on hand yet; no cough nor expectoration; feels better than for years.

Remarks: Patient is married. I treated her husband in the latter part of November, 1895, for indigestion, etc. Says that his wife has not been sick since she saw me last. "If he only had her stomach he would not suffer with indigestion," was one of his remarks. I have not heard of the family since then.

Cases Nos. 11 to 22 inclusive, are all similar to case 1, and are not reported in detail. The tubercle bacillus was found by microscopic examination in every one of these cases, at the commencement of the treatment. The examination for the bacillus was not regularly made at the close of the treatment, as it would involve some expense to the patient, and it seemed unnecessary, as they were feeling well. One of the cases where the bacillus was plentiful at the beginning of the treatment, showed a very few bacilli after some months' treatment.

Case 23.—Mr. J. B. W. History: Patient has had a cough for about two years, dry and hacking in the beginning; later it commenced to get loose, and patient coughed up lumps of a greenish, yellow color; soon commenced to lose flesh. For the last six months, severe night sweats; shortness of breath for about a year; feels very weak; coughed up blood, off and on, within the last year; had a severe hemorrhage eight months ago; the last hemorrhage, fourteen days ago. Cough very troublesome during the night; no appetite; fever in the evening. Examination of the lungs: Both apices affected. On left side, infra-clavicular region, a large cavity; blowing hollow sound on in- and expiration; cracked-pot sound on percussion, very distinct. The tubercular process has extended to the pleura, and the result is a very painful "tubercular pleurisy." Microscopic examination of sputum showed tubercle bacilli. Treatment, June 5, 1894: Syrup hypophosphite soda (Gardner), half-teaspoonful doses, t. i. d., after meals.

Report, June 15, 1894: Patient's appetite a good deal better; feels stronger and better all around; sleeps better too; has coughed no blood; those severe and painful pleuritic pains have disappeared entirely, and that is the reason, as patient thinks, that he sleeps so nicely now; expectoration amounts to about a half-pint, during twenty-four hours. Gave this time, syrup hypophosphite of lime (Gardner), half-teaspoonful, t. i. d., after meals.

Report, June 25, 1894: Feels twice as strong as he did at the last call; appetite very good; sleeps well; expectoration reduced from a half a pint, to about two tablespoonsful in twenty-four hours; patient is certain that it is not more; those pleuritic pains have not reappeared, which patient seems to appreciate more than all the other improvements. Same treatment continued.

Report, July 5, 1894: Patient has been taking medicine just thirty days; feels well and strong; sleeps well and appetite is fine; has gained three pounds since he came under treatment; expectoration gets a little too dry, therefore, changed the

medicine. Syrup hypophosphite soda, dose 20 drops, t. i. d., after meals.

Report, August 15, 1894: Has been without medicine for four weeks. Felt well and strong all that time; in fact, he felt so well that he considered wood-sawing in his yard the best thing to kill time. A slight hemorrhage followed ten minutes' work; expectoration about four tablespoonsfuls again; changed medicine immediately. Syrup hypophosphite lime (Gardner), dose 20 drops, t. i. d., after meals.

Report, August 25, 1894: Expectoration amounts to about two tablespoonsfuls during twenty-four hours. Same treatment continued.

Report, Sept. 15, 1894: Patient has gained four pounds in addition to the three pounds gained up to July 30. Expectoration about one and a half tablespoonsfuls during twenty-four hours. Syrup hypophosphite lime, 20 drops, three times every other day.

Report, Sept. 30, 1894: Patient doing nicely. Same treatment continued.

Reports up to June, 1895, a year after commencement of treatment, are so monotonous, that I leave them out.

Report, July 15, 1895: Patient at office again; will leave for Colorado in a few days, and wants two large bottles of the medicine; gave him syrup of hypophosphite of soda, 12 ounce bottle, and syrup hypophosphite of lime, 12 ounce bottle. Being under treatment so long, he knows exactly when to take each, according to the amount of expectoration.

Received a letter about a month later. Therein patient states that he felt fine, and has the greater part of the medicine on hand. Through his uncle, I heard that he got careless, on account of feeling so strong and well, and exposed himself to unnecessary risks, and had, in the beginning of 1896, a relapse. He did not come under my treatment again; why, I do not know. He died a few months after the relapse.

Cases Nos. 24 and 25 are so similar to others given, that they are omitted.

Case 26.—Miss W. J. A., age 27; date of consultation, July 15, 1894. History: For four years patient has suffered with cough, which was dry and hacking during the first year; had severe night sweats last winter; lost in weight, especially within the last few months; had also a hemorrhage last fall; feels very tired, weak and worn out; fever in the afternoon, and toward evening; headache quite frequently; glands of the neck enlarged; shortness of breath; weight 110 pounds.

Examination of the lungs: On left side, infra-clavicular region, a circumscribed catarrhal area; on right side, infra-clavicular region, a large cavity. Microscopic examination of sputum showed tubercle bacilli, in great numbers. Treatment, July 16, 1894: Syrup of hypophosphite soda (Gardner) dose one-half teaspoonful, t. i. d., after meals.

Report, July 23, 1894: Patient looks better; on some days she felt really "good"; there is fever every evening, without chill preceding. But about two, and sometimes three times a week, she gets a severe chill, and a higher fever than usual follows. There is no doubt that we have to do with two kinds of fever, one a "hectic fever," and the other a "malarial fever." She feels also an aching in the joints, bones and muscles, before the malarial fever appears. Gave quinia in solution; discontinued syrup hypophosphite soda.

Report, July 26, 1894: Patient feels a great deal better, after taking the quinin mixture. Continued quinia mixture, to be taken every other day. On the days between, continued syrup hypophosphite soda, half-teaspoonful doses, t. i. d., after meals.

Report, August 7, 1894: Feels well and stronger than before; long walks no longer exhaust her; during the last few days, the cough is more frequent, and somewhat dry. Increased the dose of syrup hypophosphite soda, to 40 drops, t. i. d., after meals.

Report, August 14, 1894: Patient feels stronger than at the last visit; cough is still very troublesome; expectoration amounts to about four tablespoonsfuls during twenty-four hours. Changed to syrup hypophosphite lime (Gardner), 20 drops, t. i. d., after meals.

Report, Sept. 1, 1894: Patient has been without medicine for ten days. During all that time she felt well; cough and expectoration diminished; her strength is not quite as good as when she is under the influence of the medicine but nevertheless she feels 10 per cent. stronger than eight weeks ago. Syrup hypophosphite soda (Gardner), half teaspoonful, t. i. d., after meals.

Report, Sept. 10, 1894: Feels stronger since she has taken the medicine; cough very moderate, and not troublesome. Same treatment continued.

Report, Sept. 22, 1894: Patient feels well; expectorates very little during the day; only in the morning, and that does not

amount to much; gained five and a quarter pounds since the beginning of treatment; present weight, 115 $\frac{1}{4}$ pounds.

Patient lost weight during the first few weeks; my books give no record of this, but I remember the case well. Gave syrup hypophosphite soda, half teaspoonful, t. i. d., after meals.

Report, Oct. 14, 1894: Has been doing nicely all that time; during the last few days she complains of pleuritic pains; hardly any cough; has gained two pounds more; present weight, 117 $\frac{1}{4}$ pounds. Syrup hypophosphite soda, same dose and mustard plaster to the chest.

It would make the report too lengthy to continue the record. Patient took the hypophosphites steadily up to August, 1895, that is, a little over a year, counting from the day of first consultation. From August, 1895, she took the hypophosphites only occasionally. During the year 1896, she called several times at my office feeling generally well, and working every day. The least little cough, or loss of strength, was always promptly attacked with a bottle of syrup hypophosphite, and the battle ground was ours in a day or two.

It was a hopeless case of four years' standing, with a large cavity already formed, as it came under my observation. As I saw her last, I could not help thinking about "then and now."

The cases Nos. 27 to 45 inclusive, were similar in their general features to case No. 1. It would be tiresome to give the histories of them in detail. The cases I have outlined are fairly typical of the others, and my favorable experience in the past, is now continually being repeated, as new cases come under my care; all progressing well, and may form the subject of another contribution in the future. There can be no uncertainty concerning the diagnosis; every case was established beyond a doubt by the detection of the tubercle bacillus.

A BRIEF REPORT OF THE RESULTS OF A BACTERIOLOGIC INVESTIGATION OF THE NASAL MUCUS IN ONE HUNDRED CASES OF CHRONIC NASAL DISCHARGE.

WITH SPECIAL REFERENCE TO THE PRESENCE OF THE KLEBS-LÖFFLER BACILLUS.

Read before the Philadelphia County Medical Society, Jan. 27, 1897.

BY EUGENE LARUE VANSANT, M.D.

Professor of Diseases of the Throat and Nose, Philadelphia Polyclinic; Laryngologist and Aurist to the Howard Hospital, etc.
PHILADELPHIA, PA.

Although a full report of the following investigations will be published later, still it may perhaps be of interest to those who are present this evening to hear a brief report of the results obtained. The patients included in the investigation all had one thing in common, namely, a chronic nasal catarrh; none of them were subject to any acute febrile affection, but were simply the walking cases that I see daily in my office and at my service in the Polyclinic and Howard Hospitals. Great care was exercised in their examination to exclude all those showing any of the well known clinical signs of diphtheria. The bacteriologic examinations were made by Dr. W. J. Gillespie, and in the more important cases afterward reviewed by myself. The examinations embraced 113 cultures of specimens taken from 100 different patients. Of these patients, twenty-five suffered with chronic atrophic rhinitis, thirty-one with chronic hypertrophic rhinitis, fourteen with chronic rhinitis, sixteen with chronic purulent rhinitis, seven with nasal syphilis, two with disease of the accessory sinuses, four with acute rhinitis, one with fibrinous rhinitis.

The bacteriologic examination shows the presence of diphtheria bacilli in no less than thirty of the cultures examined, these cultures representing the dis-

charges found in twenty-six different patients. In four additional cultures (obtained from three patients) organisms strongly resembling diphtheria bacilli were present. In fifty-eight cultures, staphylococci were found. Of these, seven were recognized as staphylococcus aureus, five as staphylococcus albus, one as staphylococcus citreus. The great majority of the cultures contained many diverse forms of organisms, such as bacilli, cocci, diplococci, etc. Leptothrix was found in four, bacillus subtilis in six and yeast cells in two of the cultures.

Of the twenty-six patients with diphtheria bacilli in their nasal secretions, eleven were cases of chronic atrophic rhinitis, three were cases of chronic purulent rhinitis, five were cases of chronic rhinitis, three were cases of nasal syphilis, one was acute rhinitis and three were cases of hypertrophic rhinitis. For each disease examined the proportion of cases with diphtheria bacilli was as follows: Eleven in twenty-five cases of atrophic rhinitis, three in sixteen cases of chronic purulent rhinitis, five in fourteen cases of rhinitis, three in seven cases of nasal syphilis, one in four cases of acute rhinitis, three in thirty-one cases of hypertrophic rhinitis, none in two cases of accessory sinuses, none in one case of fibrinous rhinitis.

The following clinical histories were obtained in some of the cases where diphtheria bacilli were present:

John McM., age 16, occupation store boy, consulted me in November, 1896, complaining of nasal obstruction and of muco-purulent catarrh with post-nasal dropping. He stated that the duration of the catarrhal symptoms had been about six months, but although his general health had been below his usual standard, still at no time had there been fever or symptoms of any acute disease. Upon examination of the nose it was seen that the cartilaginous septum was deflected to the right, producing stenosis with marked obstruction, while on the left side the lower turbinal was hypertrophied. Both nasal chambers contained considerable muco-purulent secretion. He also had a chronic granular pharyngitis and some slight enlargement of the tonsils. Cultures were made from the nasal secretion and the bacteriologic report was that it was almost a pure culture of diphtheria bacilli. Upon investigation it was found that a younger sister of the patient had had diphtheria four months previously, and furthermore that different members of the family (which comprised ten children whose ages ranged from a few months to 19 years) had all suffered more or less from nasal catarrh and sore throat during the summer and autumn. This led me to decide to make further examinations. Six members of the family were examined and cultures taken from their nasal chambers, with the following results: One, a school girl of 8, was found to have chronic purulent rhinitis with muco-purulent secretion. Bacteriologic examination showed "a few diphtheria bacilli in involution forms." Another, a girl aged 9, was found to have chronic purulent rhinitis with muco purulent nasal secretion. Bacteriologic examination showed "staphylococci, numerous leptothrix and numerous small bacilli." Another, age 11, also a school girl, was found to have chronic purulent rhinitis with beginning atrophy and muco-purulent nasal secretions. The bacteriologic report was "staphylococci and long slender bacilli." A fourth member of this family, age 6, a school boy, had purulent rhinitis with beginning atrophy and muco-purulent nasal secretion, also subacute follicular tonsillitis. Bacteriologic report, "large, heavily stained bacilli, resembling diphtheria in form." The mother, age 40, showed fibrinous rhinitis with a thick white membrane clinging to both sides of the septum, with muco-purulent nasal secretion; the mucus membrane of the pharynx reddened and congested (no pseudo-membrane on pharynx). Bacteriologic report, "staphylococci and small, irregularly stained bacilli." The mother stated that all the children had been in good health previous to last July, but since then had been continually suffering from a catarrhal condition of the nose and throat. All of the children examined were weakly, listless and anemic, but at no time during the past six months had any of them suffered from an acute illness.

Lizzie C., age 33, mill-worker, sought relief for chronic nasal catarrh, complaining of formation of crusts with thick muco-

purulent nasal secretion, the duration of the symptoms extending back many years. Examination showed an advanced atrophic rhinitis, the lower turbinals had completely disappeared. The middle turbinals were enlarged, congested and polypoid. The pharynx was dry and glazed; mucous membrane atrophied; no membranous deposit seen anywhere. Bacteriologic report, "typical culture of diphtheria bacilli." Questioning and investigation revealed no source of the infection. The patient had no symptoms of any acute condition, and all the members of the family were well. This patient was kept under treatment for some months. Cultures were taken from the nasal mucus at different intervals and with the exception of a time when certain local treatments were being applied the diphtheria bacilli persisted. Each bacteriologic examination gave the same positive results.

Mr. P., age 35, occupation grocer, consulted me six years ago, suffering from constitutional and nasal syphilis. The lower and middle right turbinal bones had been exfoliated. The left nostril was normal. The patient's health at that time was very poor, having lost forty pounds in weight. Appropriate treatment, however, soon restored him to his normal weight; his general health improved and he discontinued his visits, except at long intervals. Last September he returned, complaining of poor health with pain in the region of the frontal and ethmoidal sinuses and reported a loss of fifteen pounds in weight. Examination showed the right nasal chamber filled with crusts and muco-purulent secretion. The lower and middle turbinal bones, as before stated, had been exfoliated. The chamber was very large and some uncovered bone could be detected in the region of ethmoidal cells. Cultures were taken from the nasal chambers, and the bacteriologic report was "a typical culture of diphtheria bacilli." Inquiry revealed no source of the diphtheritic infection. The patient was placed on active syphilitic treatment and again rapidly regained health. Cultures were made from time to time from the nasal mucus and diphtheria bacilli repeatedly found.

Many of the other patients with diphtheria bacilli in their nasal secretions, gave somewhat similar histories to those just cited.

REMARKS.

It is not the intention of the author to discuss in this paper the specific virulence or non-virulence of the diphtheria bacilli found in such a large number of these cases. Some experiments with cultures from several of the patients are about to be made upon animals and may throw some light upon this point. Many interesting points, however, occur to one's mind upon contemplating the results already obtained by this investigation, and some of these may be said to be positively demonstrated. Thus, it would seem proven that in a large percentage of chronic nasal catarrh the secretions are infected with diphtheria bacilli, staphylococci and other bacteria.

The importance of this fact in surgical procedures upon the nose, throat and adjacent parts, particularly the eye, is evident. Certainly the surgeon should precede such operations by a clinical and bacteriologic examination of the nasal chambers, and when necessary institute treatment to remove the nasal infection. Such treatment should include very strict disinfection of the nasal chambers, and the author would state that in most cases he had no difficulty in quickly effecting this purpose, although for a permanent removal of the germs, treatment must be continued for some time, for in a number of cases after stopping the local treatment, the diphtheria bacilli were found to return and were recognized in the cultures.

Again, the diphtheria bacilli were chiefly found in cases of atrophic rhinitis, chronic purulent rhinitis and nasal syphilis. In other words, where a pathologic condition of the nasal chambers with altered and morbid mucous secretions continues for a considerable length of time, thus offering a suitable soil for infection, not only by the diphtheria bacilli but

by many other germs, as was ascertained by the bacteriologic investigation. Now, it is well known to us that in such cases we frequently find several members of the same family afflicted with the same disease, and although certain inherited and acquired constitutional dyscrasias frequently underly such conditions, yet we are impressed with the great importance not only of disinfection but also of avoidance of infection to others.

From this point of view, the common use of a handkerchief among the children of a family, such infected children sleeping with healthy ones, or the indiscriminate kissing of children, may be mentioned only to be unreservedly condemned. Again, in all the cases where the diphtheria bacilli were present, the patients were observed to be in ill health, being listless, pale and anemic. It was also observed, that after treatment was instituted, not only the local condition but also the general health greatly improved. It may therefore be possible that in such cases there is a slight chronic toxemia caused by the nasal condition.

Again, it is quite probable that in such diphtheria, infected nasal secretions may account for the present wide spread of diphtheria, indeed, several instructive instances have come under my notice; it is to be hoped, therefore, that the proposed investigation upon animals to determine the virulence of the bacilli will aid us in forming some positive decision.

In conclusion, it gives me great pleasure to acknowledge my indebtedness to Dr. W. J. Gillespie, whose careful and painstaking laboratory work alone enabled me to collect the material for this report.

1929 Chestnut Street.

ACUTE OTITIS MEDIA.

BY B. MERRILL HOPKINSON, M.D.

Member of the Medical and Chirurgical Faculty of Maryland and the AMERICAN MEDICAL ASSOCIATION.

BALTIMORE, MD.

After a very careful and interested study of the paper upon the above affection by Dr. Norval H. Pierce, and the discussion by some of his colleagues, members of the Chicago Academy of Medicine in the JOURNAL of Dec. 19, 1896, I have felt impelled to report a case, in which the treatment followed was very dissimilar to that advocated by the essayist and his confrères.

The case I shall herein report occurred in my own person, and is but a description of many others occurring in the practice of my very able and accomplished medical attendant, as well as in that of his students, and I am proud to number myself among the latter.

I fully endorse what was said by Dr. Wm. L. Balingier in the discussion of the paper, viz.: "Dr. Pierce is to be congratulated upon the pathologic and bacteriologic portions of his thesis;" and I take pleasure in adding, that his clear exposition of the etiology of this most distressing affection, also calls for hearty praise and commendation.

It is only along the lines of treatment that I must and do take issue; and in order that my position may be made plain, and as well for the sake of brevity, I will detail as concisely as possible the history of my case, calling attention in passing to certain modifications in treatment, as compared with that advocated by Dr. Pierce.

On Wednesday, Feb. 5, 1896, I used in a Birmingham douche, a 50 per cent. solution of glyco-thymolin

for the relief of a mild attack of post nasal catarrh, and upon subsequently blowing my nose rather too vigorously, became conscious of having forced some fluid into the Eustachian tube, thereby infecting the tube and middle ear and enabling me to clearly demonstrate the etiology of the following inflammation.

On Thursday night after a day of some uneasiness I attended a performance of an oratorio, noticed a beginning of confusion of sounds, and commencement of pain and upon reaching home instilled into the external ear a warm solution of cocain and atropin, hoping for a subsidence of symptoms, or, perhaps I ought to say, hoping that I was not to be afflicted by otitis media.

I did not succeed in wooing the goddess of sleep, save for brief intervals, and early Friday morning I called upon my friend and teacher, Dr. Julian J. Chisolm, who made a diagnosis of acute otitis media, and prescribed as follows: Frequent applications, ten or twelve times daily of an antiseptic solution by means of an ordinary ear syringe, the injections to be made as hot as could be borne with comfort, and an abundant quantity of the solution to be used at each application. The solution used by me was mercuric chlorid, 1 to 1000.

The relief derived from following this advice, must be felt in order to be realized, and just here let me say from experience, not alone upon others, but from the best of all, upon myself, that I should never advise cold applications, until I have fully demonstrated that heat was of no avail.

The inflammation increased in violence during the day and night, and the frightful pain I experienced for the following five days, paroxysmal in character, has, I am sure, increased the volume as well as the quality of my compassion for other sufferers for all time. In addition to the hot antiseptic injections, Dr. Chisolm ordered me to keep the drum membrane well inflated by using a modified Politzeration, viz., by grasping the nose and blowing steadily many times daily. This afforded me some little relief from pain each time it was performed, and I had recourse to the action times without number. I was advised to use morphin in suitable doses to procure sleep, if I so desired, but I had sufficient courage, thanks to my athletic training, to refrain.

I desire now to call attention to the use of a drug ordered by Dr. Chisolm and not mentioned by Dr. Pierce or his colleagues; and I regard its use as beneficial in the highest degree in the treatment of the affection under consideration. I refer to pilocarpin muriate and I am sure that in my case, and in many others, middle ear inflammations have been terminated without suppuration by the combined use of this drug and the treatment outlined above.

He ordered one $\frac{1}{4}$ gr. dose upon retiring and also another during the day, if I remained at home, but as I did not abandon my work at any time, I only took the dose at night. The effect of the pilocarpin about thirty minutes after its exhibition was simply delightful. There was complete muscular relaxation and capillary dilatation, and I was simply dripping with perspiration from every pore in my skin. The sialagogue effect was also well marked in my case, but this is not constant.

After the excessive effects of the drug somewhat subsided, I was enabled to secure a few hours' quiet sleep, and I am sure if I had remained at home and used the second daily dose, my troubles would have ended much sooner than they did.

I reported daily to Dr. Chisolm or his son, Dr. Frank M. Chisolm, and they were daily surprised upon examination to find an intact drum head, a history of continued violent pain, and no discharge. Just at this point I think there should be a distinct emphasis laid upon the injunction to all physicians, never to perform paracentesis unless there be distinct bulging outward of the membrana tympana, demonstrating the presence of fluid in the cavity of the middle ear. Upon the eighth day the inflammation subsided rapidly, and while musical sounds produced a most distressing jargon for some days longer, daily improvement was observed, and by the 16th I was able to attend to my duties with some degree of comfort to myself.

During the height of the inflammation the watch could not be heard upon close contact; afterward it could be heard at a rather abnormal distance, farther by several inches than the unaffected ear, giving a most happy result to a most unhappy affliction.

I will not speak upon the subject of paracentesis, for the necessary removal of pus, and the subsequent treatment in such cases, as my object is simply to report my own case, and the treatment followed, in order to demonstrate that resolution may follow even so violent a case under the treatment as related.

In conclusion, allow me to say that I do not charge the Birmingham douche or the solution used as being the causative factors of my trouble in any way.

I should have known better, as a physician, than to have blown my nose after the use of spray or douche, save in the gentlest manner possible, and here let me sound a note of warning to physicians, even to specialists, who prescribe douche or spray, that they warn their patients of the danger of using violence in blowing the nose immediately after the use of such means to relieve catarrhal troubles, for by so doing many cases of middle ear disease will be avoided.

THE DYING FADS OF PROSTATIC THERAPY.

Read before the St. Louis Medical Society, Jan. 15, 1897.

BY G. WILEY BROOME, M.D.

ST. LOUIS, MO.

In order that I may be clearly understood I will here state: That unless we attribute to the words of a speaker or writer the same ideas which he intends to convey by them, we can never arrive at his conclusion. It will therefore be necessary that the ideas which I intend to convey by the title or heading of this paper should be explicitly understood, so as to prevent the misunderstanding or misconstruction of the remarks which are to follow: The words fad and faddist as used here are intended to convey the ideas expressed in the following sentences, viz.: A fancy adopted and pursued for a time with irrational zeal. An important matter imperfectly understood, taken up and urged with more zeal than judgment or discrimination. In connection with this explanation I wish to emphasize a statement to the effect, that no reflection whatever is intended upon those who originated and developed by painstaking and conscientious research new methods of prostatic therapy, which may be, and are, contemplated in the light of fads at the present time. I would not for a moment allow the impression that it was anything but the most commendable spirit that moved the deservedly celebrated medical gentlemen who first introduced and advocated prostatectomy

by various methods, castration, tying the vas deferens or the massage of the prostate through the rectum for the relief of chronic prostatic obstruction. And yet I wish at this time to emphasize just as strongly my condemnation of the practice with many physicians of alluring these unfortunates on to an untimely death with the enticing promises held out by the manufacturers of many proprietary medicines advertised and certified to as possessing great curative powers, when in reality the only benefit derived from their use is to increase cash in the pockets of the manufacturers themselves, and who in most cases never examined the prostate gland when diseased, or are capable of comprehending it in a physiologic or pathologic light.

It would seem both fair and proper for me at this stage of the consideration of the subject and before the various methods of treatment which are to be condemned and relegated to the domain of faddery, that I consider briefly and in plain language the following questions relating to the prostate gland.

1. How does it differ when hypertrophied and in this condition?

2. What complications are entailed? Lastly

3. What would appear to prove the most rational thing to do to relieve the patient without incurring any mutilation, increasing the suffering or adding to the dangers of a fatal termination.

1. Then how does the prostate differ when hypertrophied? I have two specimens for exhibition to show the macroscopic difference between a normal prostate and anabolic prostate; I might talk for a week and not make the difference so clear as it will appear by the objective instruction, and as to the macroscopic difference in the structures of the two prostates. Dr. Fisch will make the demonstration with the microscope and from the explanation you will see that the structure formed in any of these chronic enlargements consists of a multiplication of almost all of the normal tissue elements and an augmentation of the entire gland. The histologic structures are not necessarily however in the same relative proportions, nor arranged in the manner of the normal prostate; for in the majority of cases the connective tissue of the gland is the part most concerned in the hypertrophy, the glandular and muscular elements taking little or no share. In a few instances there is a general hypertrophy of all the tissues of the organ: Glandular, muscular and stromal, and very rarely the glandular element is in excess. The gland attains the greatest size when the enlargement is chiefly due to connective tissue hypertrophy.

Now as to the 2d question: What complications are entailed? I have a specimen here showing the early stage of infective inflammation of the inner wall of the bladder, which of course is a complication resulting from the enlarged prostate, the earlier complications come on rather insidiously, micturition becomes more and more frequent especially at night and is not followed by a sense of relief but of unrest and uneasiness in the bladder, eventually expulsive efforts are futile and retention becomes complete. Decomposition in the urine soon takes place and besides an offensive odor it becomes turbid, the reaction changes to neutral, then alkaline and ammoniacal and acute cystitis is set up, and the patient's distress is at its height, added to this condition vesical calculi may form and complicate and aggravate the prostatic symptoms, later the ureters and renal pelvis become dilated and secondary changes occur in them due to infection from the inflamed bladder, *pari passu*, with the renal

changes, the general health suffers, rigors and attacks of fever occur, and uremic poisoning or septic infection and coma bring about a fatal termination.

And now as the last question: What would appear to prove the most rational thing to do, to relieve the patient without incurring any mutilation, increasing the suffering or adding to the dangers of a fatal termination? If I were asked to answer this question in one word I should say without any hesitation whatever, and in the most earnest and emphatic manner possible—*rest*. I have never forgotten for a moment the impressive teaching of Professor Gross, when upon the subject of the surgical treatment of inflamed parts. He himself was clearly cognizant of the great importance and value of rest in the alleviation of pain and in the restoration of an inflamed part long before Hilton wrote his small but valuable book on Rest and Pain. I recollect so well when Professor Gross lecturing on this subject, he would suddenly stop when he came to the latter end of his lecture to begin the treatment after deliberating for a minute and casting his eyes from one student to another, apparently to satisfy himself that he had the absolute attention of every listener, he would say: "The first requisite, gentlemen, in the treatment of an inflamed part is rest." Then after a pause, during which he would again sweep the amphitheater with his eyes, *rest*. Then rising to his full magnificent height and folding his arms he would bend majestically forward and in the most earnest and forceful manner possible repeat, "In the name of God, *rest*."

To give the inflamed bladders of these poor unfortunate old men rest, appears to me to be the most rational thing to do to relieve the patients. Simple rest, nothing else! For it is the want of rest that kills them. They die because they can get no rest from the distress of the bladder, and no rest for the mind or the body, and thus their agonies increase until death mercifully closes the scene. How may rest be secured to patients in this condition, may be asked, without incurring any mutilation, increasing the suffering or adding to the dangers of a fatal termination? I answer that in my judgment, based upon extensive practical experience and clinical observations, there is but one plan of treatment yet devised that will afford the patient anything like prompt relief and the hope of a restoration to health or the rest that he is praying for without entailing any mutilation whatever; and that is by easy, complete and permanent suprapubic drainage together with occasional disinfecting irrigation. No other method of treatment in my opinion possesses rationality or is free from effects essentially calculated to intensify the patient's present suffering and unrest. The specimens I exhibit here, ought to satisfy any one that at least in some cases a prostatectomy attempted for the purpose of establishing a low level channel in order to enable the bladder to void its contents and for other reasons of great importance is beyond the limits of honest legitimate surgical procedures, whether the enlarged prostate is attacked through either of the three routes, viz.: Perineal, urethral or suprapubic or the operations attempted by means of the finger-nail, knife snare, gouge, scissors, chainsaw, or thermo, galvanic, or actual cautery. These operations in these cases must be relegated to the domains of antiquity and faddery.

It is not within the scope or intention of the writer of this paper to even introduce a discussion relative to certain tumor formations in the prostate, in which sur-

gical interference may be clearly indicated and warranted, notwithstanding obstructive and other symptoms are marked in the case. For here, as is present everywhere, the benign tumors are encapsulated and all encapsulated growths are amenable to successful surgical enucleation, when the tumor mass is situated so as to be at all accessible. I furthermore wish to say as was intimated at the outset of this hurriedly written paper, that I have nothing but words intending to convey the most profound respect and veneration for the names of Mercier who first practiced urethral prostatectomy, and Bottini who first advocated galvano-caustic prostatectomy, and Harrison who was first to carry out the operation of perineal prostatectomy, and also for Mr. McGill who first devised and practised suprapubic prostatectomy. These methods of treatment were results of calm conscientious and honest deliberation, but should be no longer cultivated, and when we come to contemplate the Raumm-White operation of bilateral castration for the cure of chronic enlargement of the prostate a feeling of the greatest misgiving and doubt comes upon us at once. It is difficult to understand how any one can conscientiously believe when he undertakes the operation how the distress and the diminution of the cystitis and cystopyelitis is to be alleviated and the patient, already in the greatest agony, be relieved by this mutilating operation. A similar onslaught was inaugurated a few years ago on the normal ovaries, and women were spayed for a cause and sometimes for no cause at all, only a consideration, and the male is being emasculated to cure his enlarged prostate, but as has turned out in some instances where the operator exercised more zeal than judgment, instead of an enlarged prostate a stone was found, or a simple specific cystitis existed. But the fad will go on to reap its harvest for the pocket of the operator and for the grave its victims for a while; just as the fad of castrating women flourished for a time, men will be castrated for stone in the bladder, chronic cystitis, malignant and tubercular diseases. For it is not always easy or possible to make a positive differential diagnosis between hypertrophy of the prostate and some of the conditions which simulate it closely. Castration is such an easy operation that every tyro in surgery has attempted to perform it upon willing subjects, suffering from obscure affections of the bladder complicating hypertrophy of the prostate gland. But I trust that the day is very near at hand when the removal of any normal organ for any purpose will not be countenanced for a single moment.

THE TREATMENT OF ALCOHOLISM BY SUGGESTION.

BY F. A. BURRALL, M.D.
NEW YORK.

In the *Tribune Médicale* of Jan. 13, 1897, is a notice of an article by M. Tokarsky (*Wratch*, 1896, No. 31), on the "Treatment of Alcoholism by Suggestion," and which seems to me as likely to interest both the general practitioner and the specialist in nervous diseases.

The profession and the public have come to regard the victim of chronic alcoholism as a neurotic, under the influence of a nerve degeneracy, which implicates most readily that condition of nerve tissue of which instability is the prominent feature. These terms are perhaps somewhat vague, yet they are sufficiently definite to convey the idea. It is not the self-contained, vig-

orous constitution with strong power of resistance and obstinate vitality, which yields readily to the baleful influence of alcoholic excess, but the sensitive and the neurasthenic; such material as goes to the formation of the "nervous" part of society. Since this view has become more generally adopted and alcoholism has been treated as a disease, my experience has been that more cures have been effected. It is not strange that this should be the case, and the result also indicates how much the continuance or cure of alcoholism depends on the improvement of the mental or "nervous" condition. A man who is regarded as a brute by his neighbors, and who is scoffed at for not using his "will power" and throwing off a disgusting habit, is in a deplorable and crushing condition. He is often refined and cultivated when not under the influence of alcohol, yet soon transformed into an impersonation of all the lower traits of humanity by the taking of a few glasses of an alcoholic stimulant.

The habit may have been formed by the protracted use of alcohol which has been prescribed by a physician; he may have inherited a predisposition to its use; at all events the will power has been overcome, and he feels that society does him a great injustice by treating him as a criminal when he knows that he would give anything to rid himself of the bands which seem stronger than adamant.

Now, for such an one to feel that he is not a criminal any more than the patient who when under ether, before the operation, fights in delirium, is a great aid in the restoration of self-respect and hope. If he is a sick man he can look for sympathy and medical treatment. In fact, society has often dealt with the inebriate most unjustly. It has placed all kinds of temptation in his weak path, and then punished and degraded him for having walked into them.

Since the view that alcoholism is a neurosis has been adopted, various plans of treatment have been brought forward and used in many cases with complete success. In estimating the value of these different methods, we come in contact with the same difficulty which encounters us in the study of most nervines, in fact of most medicines which are given in neurasthenia. Where does the medicine *per se* show its effects, and where does what is popularly called "mind cure," exert its action? Often, discrimination is impossible. I have known the use of strychnin, atropin and chlorid of gold and sodium in very minute doses, repeated at short intervals, to be followed by cessation of the liquor habit in several cases of alcoholic habitués. We may regard, as combining to produce this effect, the "suggestion" accompanying each dose, the substitution of one habit for another, the cumulative effect of long continued dosage and the *personal* influence of the physician. We see how difficult it is to say surely where the curative influence exists. To turn from a digression which was naturally suggested by the subject, the following extract is subjoined.

"The treatment is as follows: The patient is hypnotized (*endormi*), preferably when he has drunk nothing during the day. For chronic alcoholics the treatment is begun during a period of abstinence. From the first *séance* the "suggestion" is made to the patient that he should drink no more. Two days afterward the same experience is repeated. Usually after two sessions there is an improvement, and the third treatment can be deferred two or three days

¹ The patients were not restricted in their drinking, but soon lost their taste for it.

later. Gradually, the intervals between the visits are lengthened, until they are made every two, three or four months. The treatment can not be considered as complete under a year, since this length of time is considered necessary to observe all the variations to which the nervous system is subject. In favorable cases, patients stop drinking from the commencement of treatment. If they continue after the third *séance* or commence during treatment, it is regarded as a proof that good results are not to be expected and that 'suggestion' is unavailable as a remedy."

With suggestion M. Tokarsky employs strychnin in combination with opium. The strychnin is given in doses of 3 milligrams, gradually reduced to 1 milligram, which is continued for six months. After strychnin arsenic is used, or iron, etc. While the strychnin is used the watery extract of opium is advised in one dose of 15 milligrams.

In some cases of what he terms alcoholic neurasthenia, good results may be obtained by hydrotherapy. Still, all these therapeutic agents do not exert a satisfactory effect if unaccompanied by suggestion.

We believe, however, that there is an influence akin to suggestion, which is often exerted by the physician upon his un hypnotized patient, and which is very useful in the treatment of inebriety.

It is a question whether the use of opium in cases like those referred to in the above article is not attended with the danger of forming a new habit. It should certainly be used with care.

The subject of inebriety is one of such deep interest that it is at present engaging an unusual amount of study. It is of universal importance and intimately connected with human happiness and misery.

A COUNTRY DOCTOR.

BY THOMAS H. SHASTID, A.B., M.D.

GALESBURG, ILL.

For more than thirty years it has been my good fortune to possess the acquaintance of a certain country doctor—a man unknown to the world at large, but yet, like many another of his class, a man that the world would honor itself in honoring.

Even in my youngest days I knew him. His tall form, his lean but kindly countenance, his thin hair and tuft of chin beard, were among the earliest images of my childhood. Often I played in his yard. Often he would call me into his office where he sat at study, there to read to me from his books, or to demonstrate to me the bones of a skeleton, or, if the day were clear, to show me in his microscope the structure of the kidney or lung. Often, too, I went with him on his rounds; many a long summer day we rode, from farmhouse to farmhouse, uphill and downhill and along prairie, until at last, as the darkness settled about us, I clung close to his side and fell asleep beneath his arm. I naturally did not much understand in those days the various excellences of the doctor's character; but I recall how kind and gentle he always seemed to me, and I remember especially the keen sense of childish pity with which, when I happened to awake one stormy night, I heard him drive from the stable and down street in the cold wind and rain.

In my youth and early manhood it was my pleasant lot to pursue the study of medicine under this doctor, and then I ever found him both a skillful physician and a man of most interesting and amiable

personality. His dominant passion, I think, was his love of children. I have never seen another man in whose affections children held so large a place. He used to shout at the children as we passed along the road, and if sickness were not urgent he would stop his horse, call them to the side of his buggy, and teach them to count in Latin and Greek. How many a bright toy did he not take to sick children of the poor! How many a word of endearment did he not speak to them! And how many a night, when only he was up, did he not study, hour by hour, to relieve the sufferings of children the more especially!

A hundred instances occur to me of the doctor's intense devotion to children. What a night was that when Joe Shepard, worthless fellow, came in at 10 o'clock, dripping from top to toe with rain! The lightning flashed incessantly and roar after roar of thunder burst about our very ears. Joe took up his position next the stove; the night was chill. The doctor was abed, where indeed he had been for three days, sick of a fever. Would the doctor come to see his folks? No; it was out of the question, he was sick himself. "It's mainly the little feller, Doc." "What! Not the one I gave the jumping-jack to?" "Yes, him," said Joe. "All right," said the doctor, "I'll go." And go he did, though I had to help him dress.

The doctor had once in his care a child to whom he had taken a great fancy—a child of poor and shiftless parents who lived far out in country, "on the back of another man's farm." There was not the slightest prospect of pay in the case, and the house was so situated as to require much time and trouble to reach it. Yet the doctor visited the child regularly and gave it his most earnest thought and devoted attention. Day after day we went to the cottage and day after day the doctor's face grew more clouded and anxious. At last there came a change. Yes; the child was certainly better, though the disease was treacherous. Then, one day, the doctor took with him a toy book—a brilliantly colored affair—and he showed it to me on the way, and said how cheap and poor a thing it takes to make a child happy, and how much more intense, besides, the happiness of childhood is than the happiness of older life. I stayed in the buggy that day and waited for the doctor. As he entered the doorway I saw the toy book sticking from his pocket. He was not long gone, and when he came out his head was bowed and he had his handkerchief to his nose, blowing vigorously, and from his pocket still projected the toy book.

And the children appreciated the kind doctor. They used always to answer his shout as we passed along the road; and now and then some urchin more enthusiastic than the rest would come tearing down to the gate, mount it, and shout after us his "*Unus*, one; *duo*, two," until we were out of sight. Many of them used to call him "*My doctor*." And I have seldom seen anything more touching than once when a sick, indeed almost a dying, child spread its thin, blue lips into a smile and murmured "*My doctor*," as the doctor approached its bed.

Next to the doctor's love of children came his love of nature. When, on our rounds we left a farmhouse the first thing was, as a matter of course, to discuss the case. That over, he invariably talked of the pleasant sights and sounds around us. It mattered not what the day was—sunny day or cloudy, colored day of autumn, white day of winter, budding green

day of spring—all days alike were to him beautiful and pleasant. Even days of storm he found not wholly unacceptable. He used to say that a man listening to the rain on his buggy-top and his horse's hoofs in the pools would, if normal, possess a sense of shelter and snugness never felt elsewhere.

But his favorite days were those of early summer. Then it was that he fairly grew ecstatic. Then it was that he talked by the hour of a meadow lark that sang from a rail-tip; of a field of wheat where a red and yellow reaper clicked and clacked round a square of standing grain; of the blue-vaulted sky and its infinite distances and its massive piled-up clouds that sailed along like chains of floating mountains. The clouds, indeed, which were the doctor's greatest delight of all, sometimes inspired him so much that he broke into verse. His lines were always somewhat stilted and bombastic, but no one could have known it better than he did himself, for he always overcharged them purposely as he neared their end, and then laughed at them heartily. Then, too, the clouds always suggested Italy. Italy—that was his theme. Italy—the land of Cæsar and Cicero, of Virgil and Horace—for the doctor was a classical scholar—but, better still, the land where cloud and sky are more than elsewhere on earth of divine and inexpressible beauty. "I shall certainly go to Italy some day," he would always say, "when I get money enough ahead."

There was one side of the doctor's character which, upon first acquaintance, you might not have suspected—his humor. Shy and even timid among strangers, he became, at times, among his older families and when we two were alone together in the buggy, the most jovial and jocular of men. Many a moment in the sickroom he rendered lighter with his merriment, and many a convalescent, leaning on elbow and listening to his happy talk and clear ringing laugh, must have thought that even sunshine could have been no better. In the buggy he sometimes stooped to nonsense. I can hear him now singing:

"Oh, a green peach pudding and a blackberry pie,
A black cat kicked out a yellow cat's eye."

But his funny moods never lasted long. He was essentially a grave and serious man, full of cares and full of tenderness and pity for the sick.

Indeed these qualities of tenderness and pity serve to explain, I think, in some measure, his intense devotion to his studies. Medical works were to him not mere dry treatises on science. They were storehouses of facts that were to be of service to suffering humanity. Whenever he read of a disease he seemed to see some person that had it. Whenever he read of a remedy, he seemed to see some pallid countenance looking up imploringly for relief. Every new book, every new number of a journal, he read with the utmost avidity, as one whose brother was condemned to die might read some legal document in which he expected to find a word of reprieve or pardon.

Even in his experiments, to which, for some years at least, he was greatly given, you could trace the influence of his kindness and sympathy. In his little one-room office—an apartment of his house—he would not infrequently sit up half the night pouring this thing into that and triturating something else with the other; and the commonest object of his search was—to find some way of rendering nauseous medicines pleasant and palatable. Agreeable pharmacy, you see, we did not have in those days. None

of his experiments, I believe, ever came to anything. He lacked the necessary apparatus, and more than that he lacked the necessary leisure. But some of the ideas he worked on in those days have since been taken up by large manufacturing houses and have made them rich and famous.

As might be supposed from his great sympathy, the doctor almost never refused a call. Whether he was summoned in the daytime or in the early evening, or in the later evening when only he was up sitting at his books, or in the far dead of night, he was always ready for duty. Suns were never glaring enough, nights were never dark enough, roads rough enough or muddy enough, rains pouring enough, frosts cold enough, snows deep enough, winds loud or chill enough to keep him from the sick. And "rich or poor" made no difference. The only question was, did some one need him?

I remember that one morning after the doctor had been out all of a black and stormy night, we were very much startled by seeing his horse come tearing down street to the gate, without driver, without buggy, and with only a few pieces of harness clinging to his back. A messenger arrived shortly afterward to say that the doctor had been run away with, and had been thrown from his buggy, but that he had not been much hurt, and hence had got another horse and buggy, and would make another call or two before returning home. He was really in a sad and sorry plight, as we found when he got back. His clothing was torn and covered with mud, his face was scratched and bloody, and his arms and shoulders were so badly bruised that we wondered they had not been broken. He was sick, too, for several days. We scolded him not a little because he had not come back as soon as he was hurt. But what could he do, he said. There was a poor old sick woman a few miles further down the road, and a few miles further still a sick child, both of whom needed assistance badly; and as for himself, why *he* could wait.

I know of nothing more suggestive of the hardships of the doctor's life than a collection which he used to keep in a drawer of his office of the various buggy lanterns which at one time or another he had used in his practice. Why he kept them I never knew. All of them were useless. Most of them were eaten out by rust; some of them—curious, patented things—had never been of service; others were mashed and twisted from runaways and wrecks. But they told a story of many a bad night.

A man who once saw those lanterns said to me that at a time when he was sick for several weeks he used as he lay of a night to watch for the light of the doctor's lantern as it first appeared at the turn in the road. One night he became much worse. And, as he was a poor man and the night was so dark and stormy, he feared that the doctor would not come in time. And, lying there in agony, he took one of those strange fancies that sick men not infrequently take. He said to himself that if the doctor's light appeared by 1 o'clock, the usual time, he would live; if not, he would die. And he lay and waited. And a little before 1 the doctor's light appeared. It seemed to him, he said, the brightest star that ever dawned. I have often thought that in the many years of the doctor's practice ten thousand other eyes must have watched no less eagerly for the light of his lantern as it came shining down the country road, bearing its messages of life and health and happiness and joy.

Into the sickroom this doctor must have come like

hope. You could tell by the compression of his lips that he meant to save; and you could tell by the calm of his eye that his sympathy had not perverted his judgment. He had a way, when he began to examine a patient, of whistling softly to himself. Then he went slowly and cautiously from symptom to symptom. Nothing escaped him. There was no hurry. No matter how sickly the time or how sleepy and aching his head, everything must be gone over systematically, carefully, critically. Some one thing might make all the difference. I can see him now rubbing his spectacles to make sure he has read his thermometer with the utmost accuracy. Then, when he took up his "pill-bags" and placed them with the band across his knees and spread out the powder-papers on the band and took up the bottles and dosed the medicine on the papers, and then took up the papers one by one and folded them, you saw in every step the same great precision, the same thoughtful care. What a void he must have left in the sick-room when, at last, the round of instructions gone over for the second and even the third time, he shouldered his "pill-bags" and departed! Surely no money could ever pay such a doctor, and surely, had he not had a family of his own, scarcely a thought of money had ever entered his head.

I must relate an incident that illustrates the doctor's intense and bulldog-like pertinacity in a hand-to-hand encounter with death. A man who had taken an overdose of morphin was given up by his other physicians to die. Nothing, they said, could now be of any service to him. Anything further done to keep him awake would be mere unnecessary pain and torture to him. But *this* doctor did not give him up. He stayed with him day and night. When the lungs threatened to breathe no more he started them with electricity or with burning paper to the nape of the neck and the spine, or with artificial respiration. The neighbors came about, as neighbors sometimes will, and said it was a sin and a shame, that it ought to be stopped, that the misguided doctor was simply mutilating a corpse. But the doctor did not heed them. He turned his other cases to the other doctors and kept on. He tried everything of which he had read or heard or dreamed. The hours of the night wore slowly away. The hours of the next day wore slowly away. And then those of the next night. Finally, at sunrise on the second day, the last of the effects of the morphin had gone and the man stood up and looked upon the earth and lived. His neck and back were somewhat blistered and sore, but he lived. And he lives today.

Well—even in these later years my acquaintance with this country doctor does not cease. He is still in active practice, and on my visits to my native town I always meet him and always ride with him in the country. Our rides have not much changed. Again he discusses the cases, again he shouts at the children, again he talks of the beauty of field and sky, again he says he means to visit Italy some day when he gets money enough ahead.

I am inexpressibly pained, on some of these visits, to observe that the furrows in his face are growing deeper; that his form, once erect and elastic, is getting stiff and stooped, and that his clear, almost ringing, voice is beginning to show, though happily at long intervals, the tremors and quavers of age. Yet his kindly face and his old-time figure still make, I ween, no less pleasant a picture as they enter the sick man's doorway, and his cheery voice still makes to

the sick man's ear no less pleasant and hope-inspiring music. Still he goes about his duties, still he goes on his mission of health-giving and hope-giving, still he responds to the calls of rich and poor alike, by night and by day, in sunshine and in storm. Sometimes I think that he has done enough, that forty and odd years of practice on those hills should constitute sufficient of duties performed for any one man. And yet I know that did he cease to practice he would be unhappy, and that many a sick child would miss "my doctor," and that many a sick man or woman, looking out at window, would long in vain to see the old white-headed physician come once more, "pill-bags" in hand, along the path.

Such, gentle reader, is my weak and inadequate description of the character of my father. Being my father, he naturally occupies in my estimation a higher place than could possibly there be given to any other man. And yet, if I err not, there are practicing in the length and breadth of this country many hundreds, nay, possibly even thousands, of country doctors who, in skill and in judgment, in geniality and kindness, and tenderness and sympathy, and ready response to calls, and dogged and never-ending pertinacity in the fight with our old and common enemy—disease—are *almost* the equals of my father. What more could I say for them?

THE MENDACITY AND FILTH OF QUACK ADVERTISING.

BY JOHN MADDEN, M.D.

MILWAUKEE, WIS.

"O Lord! Lord! how this world is given to lying."

In a conversation, a short time ago, with a gentleman who is the business manager of a great and influential newspaper, the subject of what doctors could or should do in the way of making themselves known through the columns of the lay press, was discussed at some length.

The journal which this gentleman serves is unusually clean, and he assured me that in a single year he had rejected "medical" advertisements which would have brought his paper an income of fifteen thousand dollars at least. These rejections were made upon the grounds that the matter rejected had a direct tendency to corrupt public morals; that it was filthy, obscene, and often a direct invitation to the public to become accessory to the crime of manslaughter. He mentioned one instance, coming to his own observation, in which the innocent boys and girls of a morally clean neighborhood were defiled by the filthy literature sent out by a local quack in answer to a letter written by a bright young lad who wanted to find out what the advertisement meant. This paper however continues to publish the gray-headed frauds which have grown fat on printer's ink and divers new frauds improved by the terminology of modern medicine.

Now this gentleman is a good business man and he very naturally regards this matter from a business standpoint. He sees no reason why an honest physician or surgeon, or all honest practitioners of medicine, in fact, should not be willing to modestly announce their names and location in his journal. He thinks, and justly too, from his standpoint, that having purged his columns of everything objectionable in medical advertising excepting the ordinary mendacity which attaches to all kinds of advertising, honorable medical

men would not be in bad company and his paper would receive some merited compensation for that which he rejected.

In reply to this pleading and answering for myself alone, I wish to point out what seems to me to be the objections to medical advertising.

If a man is known by the company he keeps it would be well for the physician to examine the character of the medical advertisements which appear in the newspapers before he decides to be one of the advertisers. He may easily find them for they are everywhere in print, and their pretensions are great and numerous. For the purpose of determining their character, let us make an examination of those cut from one issue each of five newspapers, four of them published in Milwaukee and one in Chicago. These yield a total of 131 advertisements. Revising this count by cutting out all but one of the advertisements appearing in two or more of the papers, there are still more than one hundred; about one hundred and fifteen. Nothing is gained by separating them into advertising doctors and remedies advertised; so it appears better to examine them from the standpoint of public policy and its relation to moral ethics. Accordingly these advertisements fall naturally into three classes: Those that are false, those that are false and filthy, and those that are false and filthy, and criminal.

By far the greater number of "medical advertisements" (I wish here to apologize to the medical profession every time I use the word medical in this connection) belong to the first class. They represent to the public that they can cure certain diseases, that as a matter of fact they have cured thousands of such cases, "in their worst form," after they had been given "up by the doctors," and that no patient treated by them had ever died of the disease. You may say that nobody believes such lying as this; but it is a peculiar psychologic fact that thousands do believe them.

If the patient be not seriously ill and would recover speedily had he taken no medicine at all, makes the diagnosis of Bright's disease of the kidney (Had he not read the symptoms in his almanac?) and forthwith takes Dr. Quack's medicine or consults Dr. Quack himself, is he not, after a speedy recovery, as ready to give Dr. Quack any number of testimonials as he was to fill Dr. Quack's pockets with money?

As to chronic cases, I wish here to raise the question as to whether patients ill with long continued diseases should not have guardians appointed to keep them out of the hands of this as well as every other kind of shark. Can one be of sound mind when his brain cells have been for months saturated with the ptomains of a disease like tuberculosis? That, however, is another story.

Here then are the objections to this class of medical advertisement. The patient makes his diagnosis while he is as ignorant of human anatomy and the symptoms of disease as he is of the duties of the Grand Llama. No matter how trifling his ailment he believes he is a "pretty sick man." If this quack doctor makes the diagnosis he is sure to be very sick. In either case he is imposed upon and in all cases, and he swallows stuff that he were better without and is always fleeced of his money. It may be objected that all advertisers set forth their claim upon public patronage with small regard for the truth.

It may be said with truth that the merchant who says he is selling his goods below what they cost him or that his goods are far superior to those of his neighbor yet he is selling them for less money, is saying what he knows is not true; but the public has its safeguard in the fact that only ordinary judgment is necessary to disprove the claims of this kind of advertiser, while years of study and investigation are necessary to deal properly with the falsehood of the medical advertiser. If the merchant sells a garment which he advertises to be "all wool," the purchaser has only to burn in a gas flame a few threads pulled from the material to prove or disprove the statement; but a careful chemic analysis is necessary to determine the character of the advertised nostrums.

Thousands of cases come yearly to the notice of the medical profession in which some poor victim has been robbed of his money or his health or both by the representations of the advertising mountebank. Two prominent cases of this kind were brought to the notice of the writer. The first patient had contracted syphilis and immediately went to the "Hot Springs," the Mecca of syphilids and there he met one of the fraudulent "doctors" which curse the place, and from this man he bought twenty pills "warranted to contain no mercury and to cure the disease inside of two weeks!" For these pills the young man was to pay \$160, \$60 at the time the pills were purchased and the balance when a cure was effected. After paying the \$60 he had just enough money left to bring him home, and immediately upon his return he presented himself at my office with a mercurial sore mouth. The most remarkable thing about his case was the pertinacity with which he believed the statement of the rascal who robbed him of this \$60.

He was fully convinced, however, when a simple chemic process yielded a large globule of metallic mercury from three of the pills. He knew what metallic mercury looked like. Another case was a victim of too much "catarrh snuff." He was a catarrh snuff "inebriate," in fact. Physicians know what this means, but the laity must be told that the principal ingredient of this snuff is cocaine, the most seductive and most ruinous of all stimulating narcotics. He became a "cocain fiend" and is today, if he is not dead, wrecked beyond hopes of recovery, and the amount of money he has paid for Dr. Fraud's "catarrh snuff" must have made that rascal considerably richer. How many more victims this deadly snuff can claim is unknown, but the number can not be inconsiderable. The writer has met this Dr. Fraud. He wears the garb of a gentleman, is suave in manner, and his shirt front is decorated with conspicuously large and brilliant diamonds. Last year his business brought him a profit of more than 50 per cent. on a "capital stock" of \$100,000. The man who sells intoxicants over the bar calls things by their right names and pays the State and city a large license for the privilege. Let the temperance reformers not forget that there may be worse things than the liquor traffic.

It is not contended that all the nostrums advertised are harmful as those above. Many are only inert or unnecessary, and are purchased largely by poor people who can not spare the money thus spent, for the price of nostrums is high. Some are amazingly bombastic, some refreshingly foolish, some setting forth ideas so gray with age that their author might have been a medical student with Hippocrates, talking as

they do, of the humors and "what humor is the worst of all humors." Here is a fellow who wants to convince us that we are sick or well according to the condition of our "inside nerves," and that his "inside nerve tonic" is just the thing our inside nerves have long suffered for. Everything is fish that comes to their nets and they or their medicines are the "only divinely appointed" for the regeneration of humanity. There is, indeed, not a passion nor a prejudice which is not played upon by the gentlemen of the quack profession. Here is an amiable old divinity whose eccentric methods in Germany have been transplanted in America. He is not a doctor of medicine, but came of his ideas by some sort of ecclesiastical introspection. He is a fad, and milady loves a fad. She will rise early in the morning to trot around in the wet grass barefooted, give up corsets, eat plain food, and go to bed early, all because it is delightfully unconventional. Her family physician has a hundred times warned her against late hours, the eating of indigestible food and the taking of too little exercise; but the family physician, you know, is a dry old chap, given to considering medicine as an exact science, and the entire absence of frills about him makes him something of a stick. It is different with dear old divines who practice medicine; but, some day milady will adopt a new fad.

In the same paper from which the above advertisement was cut, a religious paper, by the way, are found others in clerical garb. Here is one with a nice little chapel in the foreground saying that Brother Jones' tea is good for the liver, kidneys, stomach and blood; for salt rheum, pimples, blotches, coughs and colds. Here is another reverend gentleman who has a medicine that cures about twenty-five serious diseases, beside "increasing the flow and power of nerve fluid." He owes an explanation to the medical profession. Here is another one for the cure "of dropsy" (is it possible that intelligent men still call dropsy a disease?) and here is another which says, "your doctor will tell you this is true." Now this is a rather large story for a religious paper to publish. There are others. One of them, a testimonial from a Methodist minister out in Iowa. It is perhaps a sign of the times when a Methodist minister's letter is published in a paper whose religion is not Methodist.

When I was a student in college I had a good but mischievous chum, who used to annoy me by reading quack medical advertisements to me. He is a lawyer now, and I trust he does not carry any of that kind of humor in the court room with him. If you gentlemen are tired of this, I beg your indulgence a few moments to a class of medical advertisements which are as mendacious as those just described, but filthy beside, and still another which are a stain upon our civilization.

The most prominent of the second class of advertisements mentioned above are those which call the attention of young men all over the country to a physiologic process that almost invariably comes with puberty, is as natural at that time as is breathing to the newborn infant, and is an evidence of health and not of disease. A new life is opened to the boy; he has different thoughts, different feelings, and his nervous system has grown wonderfully sensitive. All this is played upon by the rascally quack, and if the poor boy is unfortunate enough to get possession of one of this fiend's pamphlets he suffers untold misery and is often made at least temporarily insane. Speaking

of cases of this kind, an eminent French writer in the *Journal de Médecine de Paris* says: "In the United States such cases are innumerable, and such hallucinations are fostered by the public press, that venal and unscrupulous in the extreme as to money-making by fraudulent advertisements, prints horrible faces of men before and after treatment. The only wonder is that medical men of that country do not rise up and demand the suppression of such vile newspaper ads. Advertisements that send scores of American young men to the asylums and drive many more youths to suicide. No civilized nation in the world except America would tolerate such 'journalism.'" If this French doctor should come to America he would see how little our reputable medical men have to do, as yet, with shaping medical legislation. But that can not be dwelt upon here. It is another story. If this gentleman came to Milwaukee and picked up one of our afternoon papers he would find half a dozen or more of such advertisements which he so justly condemns. Should he cut all the quack advertisements out of this same paper, he would not have much of the paper left.

One shrinks from mentioning all the nastiness which meets his eye in the daily newspapers, in the shape of medical advertising. They are the luring traps set for the foolish boy or young man, to lure him into a den of thieves with promises it is impossible to fulfill, rob him of his money and kick him into the street worse than when he entered.

The last and greatest offense against public decency, the law and good morals, of which I wish to speak, is that class which advertises a willingness to commit a crime which our statutes have defined as manslaughter. It is astounding that these so thinly disguised advertisements are allowed in the public press. Here is one, verbatim, with the name left out. It appears daily in at least two of our city papers: "Ladies needing confidential treatment may consult —, specialist in female complaints; cures all female irregularities, skillful and scientific." What does this mean? Ask any physician the cause of at least nine-tenths of all female irregularities, and how they are cured by such advertisers, and you will have a key to the situation. Positive proof as to what this class of treatment means is not lacking. About a year ago a woman bearing the same name as that signed to the above in the newspapers, and, undoubtedly the same person, was tried in a court in this State for the very crime which she now advertises to commit. A physician well known to the writer, gave testimony as to the possibility of committing the crime in the way described by the State's witnesses, which was at once affirmed. She was quickly found guilty by the jury, and the trial judge, with apparent reluctance, gave here the shortest possible sentence, namely, four years in the State prison at Waupun. After serving eighteen months, the trial judge signed her application for a pardon, and our late pardoning Governor set her free. She now announces that she is apparently ready to commit the same crime "skillful and scientific." But Milwaukee papers are not the greatest offenders. I hold in my hand nine advertisements of the same import, expressed in surprisingly plain language, taken from one column of a Sunday issue of a Chicago daily. Truly, good Sunday reading. Perhaps it will be argued that Chicago is not a moral city, that only in Constantinople is it so easy to get rid of undesirable citizens. There is this dif-

ference, however: Representatives of the great European powers are watching the wrongdoings of the Mussulman and the people of all civilization are looking toward the slaughter; but America heeds not nor cares not for the slaughter of thousands of citizens unborn and unprotected; and the murderers may safely advertise openly in the Sunday papers their disgusting criminal "business."

On January 29 last, speaking before the New York Academy of Medicine, President Cleveland said of this class of criminals: "Within the limits of your professional power and influence you seek to restrain any reproach to criminal malpractice, yet newspapers disgustingly, though covertly, advertise in the way of such crimes and startle their readers with sensational tales of death and misery to which they are directly accessory. I need not suggest such evils are allowed to exist by reason of the insufficiency of our laws or a laxity in their execution. I have intimated that for this condition you are not responsible in a professional sense, but are you sure you are doing all in your power as citizens to remedy the situation."

Today we find this shamelessly hypocritical statement in an editorial of a Chicago journal, which publishes on another page several of the very class of advertisements which Mr. Cleveland has characterized as "disgusting" and criminal: "The President urged upon his hearers the public duties that peculiarly devolved upon them as professional men and as citizens. The warfare against charlatan-ism, miraculous cures, all sorts of pretenders who prey upon the sick and the afflicted, not to speak of the ever-increasing cases of criminal malpractice, should not only be unceasing but it must largely be directed by the medical profession." "If," said the President, "enactments already in force are neglected or badly executed, you should not forget that it is your privilege and duty to insist upon their vigorous and honest enforcement. If members of your profession were oftener found in our National and State legislative assemblies, ready to advocate reformatory measures you have demonstrated to be necessary and to defend your brotherhood against flippant and sneering charges of impracticability, the prospect of your bestowal upon your fellow-men of the ripened results of your professional labor would be brighter and nearer."

This is undoubtedly truth, and yet it demands large exceptions. Medicine, no less than law, is a jealous mistress and exacts from those upon whom she would confer her highest favors the most undivided affection and submission. It is an arduous profession, but there should be a stage in the doctor's career where he could give up some of his private duties and devote more time to the demands of high citizenship. Congress and the State Legislatures would be greatly bettered by representatives from the medical profession. But whether in office or out he ought still to remember his ordinary obligations to the community in which he lives by attending primaries, conventions and elections and thus do all in his power to advance the cause of honest government.

The editorial closes with the Pecksniffian statement that, "this is what the President chiefly meant and his words may well be pondered by the profession everywhere." Do you see through the thin veil which is meant to hide this man's hypocrisy? Another "great" Chicago daily of the same date notices the President's speech in an editorial three-fourths of a

column in length; but not a word does it say about that part of the speech which says, "Yet newspapers disgustingly, though covertly, advertise in the way of such crimes." This is too vigorous a criticism of an important and, no doubt, highly profitable department of this journal's advertising. Anyone who would take the trouble to examine its columns for a few days will find that it freely lends its aid to its dishonest brethren not only in the form of advertisement and news, but in its editorials also. No doubt it does this for money, but is the secular journal which does this a whit better than the blatant rascal and his remedies which it advertises and commends to its subscribers?

It is not possible to read without a thrill of joy the first recognition of this abominable crime by a layman of Mr. Cleveland's influence, but the heart shrinks from a task compared to which the cleansing of the Augean stables was a school boy's morning task. Is it possible that the medical profession can do nothing in this matter?

Then there are the infallible "pennyroyal" and "oil of tansy" medicine for the purpose of criminally interrupting the function of gestation. From taking the latter with unlawful intent the writer has seen one death and one case of violent poisoning in which the escape from death was very narrow.

In writing the above I am aware that I have only touched the border of the kingdom of quackery. There is the faith curist, the divine healer, the therapist and pathist of every kind and condition. There is the woman who will make you beautiful by plastering certain abominable mixtures upon your face, and the one who would make your bust at least six inches larger. This reminds us of the story of an advertising charlatan in London who declared to the public that he could make long men shorter and short men longer. It was surprising to see the number of long and short clients he accumulated in a short time. Soon, however, after gathering up a good many of Her Majesty's coin of the realm, he suddenly disappeared, leaving a large and sorrowing clientage. A wag hearing of the circumstances, remarked that the mountebank had fulfilled at least half of his contract, for were not the long shorter, a good deal shorter, while, of course the short were shorter than they were before? As to a woman making a bust larger there seem to the writer, for physiologic reasons, to be insurmountable obstacles.

Such, then, is the character of the company to which the honorable medical man is introduced, no matter how modest his announcement, if he allows his name to appear in a newspaper. Surely, it is a company from which he must shrink with loathing and disgust. Beside, what chance would the physician's modest card have to attract the attention of the public in the midst of all this florid mendacity, this filth and criminality, this portraiture, and all the other trappings which aid the professional fraud to catch the dollars of the trusting public?

There are still other reasons why the physician may not advertise as the term is understood by the laity. Suppose he should say to the public that he has spent so many years in a certain university, where he received the foundation for a medical education, that he afterward took his medical degree in its department of medicine and surgery, then, after practicing general medicine ten or twelve years, he went to some large city, where he was a student of Professor Jones,

the world's greatest specialist in a certain class of diseases, and that he was a resident here to practice Professor Jones' specialty? Now, all this would be unobjectionable if it did not appear as an advertisement in the foul company of the secular newspaper medical advertisers; but what good would it do the advertiser? The public never heard of Professor Jones, his name nor portrait never appeared in the papers, therefore his student must be a poor stick. Beside, have they not their own great specialists at their very doors, with a column of testimonials, headed by the rascal's portrait? The attitude of the public toward the medical profession and all things relating to cures is an anomaly.

They seem to have kept pace with all forms of learning except in medicine. Here the grotesque painted and befeathered medicine man is still with us. Here only are miracles worked, and the newspapers give us so many each week that the spirits of the patriarchs of old must blush with envy (if spirits ever blush). In all other departments of human activity the miracle is conspicuous by its absence. No thirsting Moses has in modern times struck the pinnacled rocks of the Bad Lands and caused a stream of pure water to flow therefrom, nor has any modern Jonah taken a summer vacation trip to Europe in the stomach of an accommodating whale, nor does anyone now turn water into wine, though the knight of the white apron has been suspected of turning wine into half water.

How long before the public will learn that the laws of health and disease are as inexorable as those which regulate the seasons and day and night. If your friend and brother, O public! is all but destroyed by the tubercle bacillus, and your family physician, who has been like a father to you, tells you that the grim reaper is near at hand, will you take him to the advertising miracle-working quack who has "never lost a case of consumption," and have his days made uncomfortable by the foolish bombastic rant of this fellow who wants only your money and then have him insult you by telling you that your friend and brother was "not brought to me soon enough."

Why does not the lawyer advertise? He might say, for instance, that he never lost a case in which he had defended a murderer, although he has had hundreds of such cases. How long would a judge permit such a lawyer to practice in his court? Would the public give heed to a lawyer of this kind, except to spit upon and spurn him? Yet the statement is not as absurd as that of the medical quack who advertises to the same purpose, and yet the learned judge is willing to give a signed testimonial, mayhap with his portrait, which Dr. Fraud proudly displays in his next advertisement.

What, O learned and incorruptible judge! has the noisy rascal whose nostrums you thus commend ever done for the cause of humanity? Do you know that he has invariably stolen a common instrument of the medical profession, dressed it in the garb of ancient mysticism, put the mask of miracle upon its face and sent it forth to rob under the pretense of doing good? Be lenient with the man who comes before you charged with getting money under false pretense, for you are accessory to the crime.

Why do not ministers of the gospel advertise? Using the language of the fraudulent medical advertiser they might tell of new and improved ways of saving the soul, discovered by some pious man in cen-

tral Africa or the Fiji Islands. These reverend gentlemen might say that thousands and thousands of happy souls are in paradise today, which were all saved by their methods, and that they can give treatment by mail at \$3 a week. I have before me an advertisement which contains the following, signed by a gentleman who writes "Reverend" as a part of his name. He declares that: "When I entered Dr. Fraud's Institute I had catarrh of the head, throat, stomach and bowels. Under Dr. Fraud's incomparable treatment I got entirely well. I was not only cured of my infirmities, including deafness, but completely reestablished my health." Suppose now that the Rev. Jones used the same methods to get "trade" as Dr. Fraud uses and suppose (which requires some imagination) that the Rev. Jones had converted by a "new method" Dr. Fraud, and made him an honest Christian gentleman. It would be only proper and reciprocal for Dr. Fraud to give the following testimonials: "When I met the Rev. Jones I was a very bad man, I suffered with dry rot of the soul, lack of conscience and the difference between truth and falsehood was not known to me. Indeed, so bad was my case that I had no remembrance of ever having known truth or honor. After remaining in the Rev. Jones' Hallelujah Institute and taking his salvation incantations and regenerating rubbings, I became again a good man and promise to give back as far as possible all that I have got by fraud. I shall advise all persons similarly afflicted to go to Rev. Jones' Institute." If the Rev. Jones is shocked because things sacred to him are thus treated flippantly, let him be told that there are no things in our lives more sacred than truth, honor and charity. How much of any of these virtues is possessed by the fraud whom he is helping to continue in this shameless imposition upon the people.

The above, then, are my reasons for not putting any kind of advertisements in the newspapers, and I think they are also the reasons of my professional associates. When will our lawmakers compel those debased men and women who so lightly trifle with valuable human lives, to give satisfactory proof of the truth of their claims or to be at once suppressed? Honorable members of the medical profession are every day doing deeds, which, when compared to the silly gabble of the blatant fraud, shine as the electric arc light to the penny rush. They are forming ties which bind them to beautiful, intelligent and loving households, who give to them the priceless honor of gratitude and confidence which no other man receives, and in no other profession or calling does a member receive the ungrudging honor of his fellows for meritorious deeds more than in the medical profession.

MISCARRIAGE PRODUCED BY GUNSHOT WOUND PENETRATING THE UTERUS.

BY J. A. BAUGHMAN, M.D.

NEOGA, ILL.

Mrs. J. M., living near this place, seven months advanced in pregnancy, while descending a flight of steps holding a child in one arm and a loaded rifle in the opposite hand, dropped the weapon in such a manner as to discharge it, the ball entering her right thigh back of and a little below the trochanter major. It ranged upward through the obturator foramen, through the broad ligament into the uterus and amniotic sac, liberating the fluid contents thereof

through the os uteri. I was hastily summoned, and went prepared to make an abdominal incision if necessary.

Although American born, she belonged to the race of the great unwashed, and my first act was to borrow from a kind neighbor some linen, of the sort akin to godliness, enough to dress the patient and her bed, after I had administered a prescription of *sapo domesticus* and *aqua communis* applied externally.

I examined the vagina and bladder carefully for injuries, but found none. I then delivered the dead fetus and the placenta in the course of an hour, and controlled a postpartum hemorrhage of considerable severity. With my hand in the uterus I could feel the point of entrance of the bullet, but could find no exit, in fact I do not know what became of the ball. I ordered a vaginal douche and kept myself in readiness to do a laparotomy should troublesome symptoms arise. Her recovery was very rapid and uneventful, for in fifteen days the patient was again delving in her household duties, renouncing the doctrine of immersion, happy in having forestalled Malthus' precept of not marrying without a fair prospect of supporting a family.

If some of our city gentry who are engaged in checking over-population are on the *qui vive* for something new I advise them to try a gun.

A SIMPLE METHOD OF ATTACHING THE CALVARIUM AFTER POSTMORTEM.

BY H. A. SIFTON, M.D.
MILWAUKEE, WIS.

Every one who has done any number of autopsies has been annoyed by the displacement of the skull cap after the work is finished. To remedy this a number of methods have been devised to retain it in place, such as cutting the bone at an angle, sewing the temporal fascia, but none, so far as I know, has proven satisfactory.

This led me to devise the following :

Just before ready to remove the calvarium, mark the skull with the saw on each side at right angles to the circular incision. When ready to replace the skull cap incise it to the depth of half an inch at the point marked, then incise the skull (on the proximal side) at the point marked to the same depth. When the calvarium is replaced this makes a slit the width of the saw half on each side of the circular incision. Now insert into this slit a small piece of sheet copper with one end turned over for a head. If the wedge of copper is thickened on the edges by a few strokes of the hammer, it will hold so much the better. The copper of the wedge should be about as thick as the saw plate, and can be cut with a scissors. It holds the skull cap in perfect position and can be applied in half a minute.

SURGERY ONE HUNDRED YEARS AGO. AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

CHAPTER I.—DOCTOR AND BARBER.

(Continued from page 362.)

Barbers practiced side by side with physicians. A characteristic, in the broadest sense of the word, of the eighteenth century may be expressed: Medicine and surgery were sharply separated and German surgery lay almost entirely in the hands of the barbers. A cursory glance into the past of German surgery shows that in spite of the great fondness of Germans for war and the chase in the twelfth and thirteenth centuries, it was little valued and, at times, even left to the butchers (carnifices), who opened the corpses of the great and embalmed them. If one of the nobility had been harmed by a surgeon when bleeding him, the surgeon was sentenced to a fine of 160 scudi, and in the case of death the law gave him into the hands of the relatives of the deceased, who could do with him as they pleased. The contempt shown for every phase of surgical work was particularly due to the papal Councils, which with the pretext, "*ecclesia abhorret a sanguine*," forbade the monks in the monasteries to perform surgical operations, although they had hitherto practiced surgery. Servants and tonsors were employed for these operations and the result was that they gradually became independent surgeons, and began to travel through Germany as itinerant rupture-surgeons and lithotomists. After the church convention in Rouen (1092) the monks were not permitted to wear a beard. Five hundred years afterward, Sigismund, Archbishop of Magdeburg, made regular trips *contra barbam*, and one time, when he gave an elaborate banquet in Mansfield, in 1564, he ordered all the beards, except the mustaches, of those present to be cut off; similar orders he gave in Braunschweig, Wolfenbüttel and Halle. After the accession of the youthful kings of France, Louis XIII. and Louis XIV., a beardless chin was considered an especial ornament. Consequently someone was needed to dress and shave the beards, which had their fashion, just as the cut of the clothes and the shape of the hats. Thus originated the barber. Gradually he, being a good follower of the church, was permitted to have a barber shop, journeymen and apprentices, and to practice surgery on a small scale, that is, bleeding, bandaging wounds and ulcers, etc. His calling was thought a very inferior one, for he, like the bath-keeper, was not recognized as a craftsman, and, like the shepherds and hangmen, was not considered of good repute. In the certificates of birth of the mechanics it was very explicitly stated that "bearer is born in wedlock of honest parents, not descended from serfs nor related to barbers or bath-keepers, not vandals, but of true German nationality."

The cause of this contempt lay in the fact that guilds and fraternities guarded their privileges very strictly, and barbers, and more especially bath-keepers, were not considered eligible to membership. This disbarment, resting upon groundless prejudice, could only be removed by law. The Emperor Wenzel took the first step in this direction in the year 1406, when he was rescued from captivity in Prague by the daughter of a bath-keeper and out of gratitude made her his mistress, declared that bath-keepers and bar-

bers were respectable. But Wenzel was an ex-Emperor, consequently his charter could carry no rights. As early as 1538, in the March of Brandenburg, the bath-keepers, after a required examination, were permitted to bandage and cure the wounds, and the barbers, that is, "those careful masters of the barber and surgical trade," were promised protection from the quack doctors; but it was not until 1548 that the imperial diet (Reichstag) in Augsburg declared them both eligible to the guilds. Their masterpiece (meisterstück) was the shapening of knives and scissors. Now the children of linen weavers, shepherds, barbers and so-forth, if they were legitimately born and had lived honestly, were received by all artisans without question. In the March of Brandenburg special guilds were formed for barbers and bath-keepers, having their own constitutions. In 1686, Emperor Leopold I. declared their profession an art, and placed it above the apothecary's in rank and authority, and changed the masterpiece (meisterstück) to the making of salves and plasters. As the beard gave rise to the barbers, so for her bath-keepers and her hospitals Germany has to thank the Crusades in the eleventh century and the leprosy which they introduced. The pilgrimage to the holy sepulcher gave occasion for the establishment of hospitals for the care of the sick pilgrims, and it is said that the first one was erected about the end of the fourth century. During the crusades several brotherhoods were founded which assumed the care and protection of pilgrims and attended the sick soldiers. Among the most noted of these was the Order of the Knights of St. John, the Knight Templars and the German Order. On their return home various princes brought with them certain members of these orders and commissioned them to erect inñrmaries in their own states. Thus, in 1159, Albert I. brought some of the Knights of St. John to his margraviate of Brandenburg, where they established hospitals for the care of the lepers, who, after the return of the crusaders, became very numerous in Europe (in France in 1225 there were 2,000 hospitals for lepers, "Leproséries"), each one of which was endowed with 100 sols by Louis VIII. His son, Louis the Good, founded in 1260 a special hospital for the Egyptian blind. Soon the number of hospitals and cloisters was insufficient for the lepers and bath-houses were built, and the necessary bath-keepers were engaged, in order to prevent the spread of that disgusting skin disease through the general neglect of cleanliness among the upper and lower classes. The greater part of surgery gradually fell into the hands of barbers, but operations were generally left to the itinerant mountebanks. The charter of the bath-keeper extended only to bathing and cupping; later on, where he also undertook bleeding, the treatment must be done in their own homes, for they were generally not allowed to enter the houses of the patients. Subsequently bathing was much neglected and finally discontinued entirely and the bath-keepers took to practicing surgery, but much later than the barbers, not until the middle of the eighteenth century. They were permitted to do so publicly in several countries after having passed the examination required of the barbers. In Prussia, however, they were not allowed to undertake any surgical cases, except the treatment of wounds and chronic diseases.

In order to see what was expected of an honorable and educated barber and bather of the 18th century, read the writings of "the faithful Eckardt, the daring

surgeon" of 1698. After many years of apprenticeship, they must visit large hospitals and journey to noted surgeons, then serve as field or ship's surgeons. A knowledge of Latin and modern languages as well as botany was important. Before all he must study anatomy, for "without it surgery is nothing," and he must make himself known to industrious scholars, 'not drain the beer glass.'" The lack of cadavers was supplied by the carcasses of animals, since if doctors did not shrink from studying them, then "an impudent barber's or bather's apt journeymen would not consider it beneath his dignity to follow them." For surgery, the books of Fabrız von Hilden, Paré, Würtz and Scultet were recommended. Among the sixteen different virtues of a barber, which the faithful Eckardt enumerates, the fear of God stands first. "He should be careful, prudent, temperate and ready to use both hands with equal dexterity, prodigal in nothing since foresight is one of the most beautiful adornments of a surgeon. No idler can accomplish anything, for the science of surgery demands the whole of a man. . . . By discreet encouragement he will awaken confidence in those disheartened. . . . A conscientious barber will not bleed a patient in order to get two or three groschen, unconcerned as to whether it is advisable or not. But many are such desperately bad knaves, that, if they are not paid promptly they will do the patient great injury so that they must serve him still further. . . . He should not boast of his cures at the beer rooms. He must not handle his patient roughly as a pig handles a beggar's sock, nor tyrannically abuse him when ill-tempered. He must discriminate between the gentler and coarser natures; he must ingratiate himself with men as he would with a dog. . . . He should not be so hard on his patients, that they would prefer to see the hangman rather than the barber. . . . He must consult the physicians and obediently follow their instructions. . . . His apparel is not to be adorned with ribbons, cords and laces, because cuffs and ruching are a great hindrance in bleeding. . . . He is not to ask twelve thalers, if he has earned but two. . . . Arrogance seems most prevalent among barbers, as a common saying would imply: 'Barbers are proud animals.' It is astonishing to see what an amount of conceit is fostered by the master and his journeyman, making themselves very conspicuous on the streets and by-ways, the master with his projecting punch and solemn step as if the world were too narrow for him. . . . He must not cast envious glances at a successful co-worker, not take away a patient from another, but faithfully assist him when attending serious cases. I am surprised to see the great hatred and envy which the barbers entertain for the bath-keeper, and even the dirty-faced apprentices show among each other the beginnings of this developing hatred. . . . Not blindly is he to operate; my good friend, remember it is human flesh, not oxen or swine, and the skin is of priceless value. In serious cases he is to consult physicians and other masters. He, who has only learned shaving and yet wishes to be a surgeon, is startled as if plunged into hot water when called upon to attend a case; another stands as if he were fastened to the spot." Thus writes Eckardt.

The German surgeon of the 18th century or more strickly speaking the barber, for the path to practical surgery lay almost without exception through the barber shop, was in general exceedingly ignorant and unskilled. Nor is this so surprising, when his unhappy

education was no different from that of any workman. If there was a boy among the lower classes, destined to become a barber, he was apprenticed to a barber-surgeon when he had scarcely learned to read and write German in the public schools and had been confirmed. The parents pay a fee of 50 thalers to a demonstrator: 75 thalers yearly for board and lodging. Sometimes the district physician examined him to ascertain if he could write legibly and read Latin; if he could not he was refused. The Archbishop of Würzburg demanded that the young applicants be well behaved, with adequate intellectual faculties and bodily strength, with gentle heart, that they could read and write, be well instructed in Latin, and possess enough means for the purchase of books and instruments (1787). The apprentice learned to shave and then went from house to house, the whole day; the little time remaining to him, he had to sharpen his knives, spread plasters and pick lint, besides take care of the children and use the same light as the maid, for it would have been disrespectful to make use of the light of his principal's wife. He attended to all menial labor inside and out, and was in general the servant of the master and his journeymen. An advertisement gives the following description of his exterior appearance:

"Last Friday morning, the 7th of January, Christian Heinrich Springer, an apprentice of the surgeon and bath-keeper Mr. Bufe living in Jurusalem Street, secretly ran away, out of spite; he is 17 years old, fairly good looking, has a pointed nose, light brown hair, wears a bran new pearl-colored piquesche, with dark yellow buttons, a blue coat with red lining, blue vest, Manchester trousers and has on a new pair of boots; he who can furnish any information of the whereabouts of the rascal, will be rewarded." (*Sperersche Zeitung*, January 11th, 1774). After a time, the apprentice was taken to visit a patient and then the arts of bleeding, cupping, of giving an enema, of applying leeches, and sometimes of extracting teeth, were practically taught him. Since the master himself, as a rule, understood nothing of the subjects, he either gave no instruction at all in anatomy, physiology or surgery, although pledged to do so, or else his teachings were nonsense. The law passed in Prussia in 1734 required three years' apprenticeship for barbers, which time having been served he presented his master with the usual set of silver instruments; had then to be thankful, "that such a poor creation of God had even learned to shave a beard à la mode or spread a plaster." Before the apprenticeship was ended, however, an examination was necessary, but often the whole guild was too stupid, or too lazy to prepare one. Whoever the presiding principal of the establishment was, a miller, tailor or any other workman, signed the indenture of the apprentice, whereupon the apprentice became a journeyman. Now he went on his travels, once more going through the whole course of shaving. The journeyman lived at the home of his master and was not allowed to marry. When he had served some sixty or more customers, and now and then bled some one or banded a patient's wounds for his master, he received as wages his dinners and six or at the most eight good groschen a week. This paltry sum scarcely sufficed for even his most immediate wants; therefore he began to dabble in his own account and frequently developed into a careless braggart. Study was out of the question, because attendance at the lectures in the larger cities was not possible after their fatiguing day's

work, the want of books for the purchase of which money was lacking, and with the disquiet prevailing in the house, and if a few of them very diligently began to study, they did themselves more harm than good because of their deficient education. Much of that which they studied they misunderstood; they crammed their brain with disconnected ideas and they became intolerable, arrogant gossips. After six or seven years a journeyman could be become a master. To attain this position he had to apply to a district physician, collegium medicum or a faculty, present his indenture and his certificate of time served as journeyman, and then pass an examination. The Prussian regency preferred an application from a city man to that of a peasant; then if a surgeon wished to settle in a large city, he must pass an examination in anatomy at the anatomical amphitheater of Berlin and take a course in operations. If he established himself in a village, no course of study was required, only an examination before the physician of the district.

The barbers and bath-keepers of Prussia, the first country to recognize the importance of regulating the practice of medicine, were under the control of the Collegium Medicum. This was founded Nov. 12, 1685, by the great Kurprince Frederick William, who, at the same time introduced the first medical code in Germany. The Collegium Medicum had the jurisdiction over all the health officers.

In 1724, under Frederick William's successor, the Kurprince Frederick III., the college attained its greatest activity and was made the Ober. Colleg. Med. (chief college), there being one such in each province. Its faculty consisted of a Minister of State, who was the principal, the body and court physicians, the district physician and the older practitioners in Berlin, the body surgeon and surgeon general, the court apothecary and three surgeons and two apothecaries. Beside this chief college and the provincial colleges, there had been since 1719 a so-called Collegium Sanitatis, founded on account of the plague that had broken out in Hungary, which was at first called pest collegium, because it was obliged to devise measures for protection against the plague, contagious diseases and cattle plague. In 1762, there was such a sanitary college in every province.

The greatest progress in the German medical system was due to the famous edict of Sept. 27, 1725, a memorial of King Frederick William I., perfected by Eller and Stahl, which decreed everything possible at that time and contained very appropriate precepts, which did not undergo a radical revision until a hundred years afterward. Similar medical institutions soon sprang up in various German cities, in Braunschweig in 1747, in Dresden in 1768 and in Hildesheim in 1783. The above-mentioned edict provided that the barber and bath-keeper "should lead a righteous, temperate, retired and sober life, in order to be at their best when their services are required, be ever ready in the day time or at night to assist their neighbors intelligently with their skill and scientific knowledge . . . and during the time of a plague and death, to be ever ready to respond when called to the hospitals." Similar in substance was the ordinance by Marie Theresa (1770): "Surgeons and bath-keepers must live in a moderate, honorable and God-fearing way, exercise as much diligence and precaution as possible, be indefatigable day or night and must willingly enter the hospitals in time of plague and death.

For their pains they are to receive a reasonable recompense, etc.”

The masters attended to the mechanical part of their work and prepared all external remedies themselves when they were not obliged to procure them from an apothecary. Beside this they dabbled in medicine without permission, knowing nothing at all of the science. Those who were caught in such dishonorable business were fined twenty thalers or received corporal punishment, and if they led a dissolute life, or in case of drunkenness, their concession could be taken away from them. In case the barber's trade was not lucrative, he endeavored to fill other positions beside; for instance, it is said that Henckel's father was surgeon, municipal judge and postmaster at the same time. Barbers were so envious of each other, that one of them would begrudge a piece of bread in the hands of another, as the following saying of the time verifies: "A potter is hostile toward a potter, a singer to every singer." Purmann said in his "Lorbeerkranz" (paper) that in order to obtain the patrons of some of their colleagues they practice foul means and tricks along with their trade.

The bath-keepers, however, did not rank with the barbers in Prussia, where the former were subject to a heavy penalty for calling themselves surgeons and where they were not allowed to use more than four basins; not until the year 1779 were the bath-keepers united with the surgeons and at the same time the bath-keeper's guild was incorporated with the that of the barbers.

That young men of ability were not desirous of entering a class of such inferior rank as the barber-surgeons, was not surprising. As late as 1790, good surgeons were rare in Germany. The ratio was everywhere one skilful surgeon to ten who were barbers, skilled only in shaving and cupping. Before the masses they tried to cover their gross ignorance, but the poor unfortunates who fell victims to them were made more miserable than they had been. Once Siebold was called upon to examine the country surgeons of a prominent state in practical surgery and was not a little astonished to find that there was scarcely one of fifty who knew the first principles for the cure of wounds. The mechanical part of the work was the remunerative one, therefore the most important; the scientific was only incidental. Surgeons were compelled to do shaving, which in reality belonged to the duties of the hair-dresser; for aside from the few privileges granted to body and court surgeons, also to the surgeons of the royal hospitals by the order of the cabinet, no surgeon, however skilled in his art, was allowed to practice the same unless he was the head of a barber shop and bath-house, kept assistants and apprentices and belonged to the barber-guild. In case of the demise of a surgeon in Austria, his widow had to procure a registered pharmacist within six months, or she had to marry one in order to preserve the license for her apothecary (1773). Intelligent men complained, at the beginning of the century as well as at the end, of the melancholy fact that German surgeons were educated in the barber shops, lamenting bitterly that surgery should be associated with the barber trade. However, the union remained; no one wished to stir up a wasp's nest. One needs only to read the counsels by Plenck how to educate useful surgeons for the state, to see that mere talking could not better the condition of affairs; for instance, it was said that the apprentice

was to be 16 years old, must possess genius and understand Latin, and above all things study anatomy and physiology; but for the latter, only diligence and a good memory are necessary and little genius, and can be acquired by even a dunce. In the eighteenth century there was no one to undertake a thorough revision and nothing to hope from the Reichstag under the political conditions then existing. Among the conditions was the fact that the social position of surgeons was necessarily on the lowest round of the ladder. In the middle of the century, the practice of surgery was not considered a business for an honorable man, and barbers' and apothecaries' journeymen were not permitted to carry a sword. A surgeon was not admitted into good society nor tolerated in a circle of physicians. If his treatment resulted unfavorably, he was pursued by hatred and animosity.

C. C. von Siebold bitterly deplored the position of surgeons. He was very enthusiastic when he began practicing, had had considerable experience in surgery during the Seven Years War and in France, but nevertheless had to contend with great difficulties before he could enter society, with his profession. His good will and his high intentions were scorned and frustrated. Beside this the peasantry were greatly prejudiced against operations. Siebold relates that the operation for cancer of the lip was so frightful to the ordinary man that he refused to submit to it, and another man with hydrocele endured two punctures every year for twenty-eight years, rather than permit an operation for a radical cure. Soon after extirpating a cancer from the breast of a woman, Siebold discovered that a new one had formed in the armpit, necessitating another operation; so to avoid a sensation, and that the public might not smirch his reputation, he removed his patient to another town, where he successfully performed the operation. The physician boasted of his own education and disdainfully looked down upon the surgeon and surgery in general, a very natural consequence. Even Zimmermann considered the relation of surgery to medicine the same as that of geometry to higher physics. There certainly were good reasons for watching the barber, considering the great dangers to which the public were exposed when, after years of wandering about plying his razor, he suddenly as a master undertakes to treat fractures, luxations, herniæ and maternity cases! Therefore the district physician had to look after the books and instruments used by the surgeon, and had to see that the pupils were properly instructed by him, and not detained from their studies by agricultural labor or domestic duties. In this control there was one evil so great that every contention of rank between physicians and surgeons appears ridiculous and absurd; the physician understood little or nothing of surgery. While at the university the physician was obliged to content himself with theoretic lectures, and he seldom or never saw surgical patients and never laid a hand on one. The very famous physician, G. E. Stahl, wrote an Introduction to Surgery which is not read today, for in it, among other things, he thought little of the difficulties connected with trephining and bronchotomy, but was more concerned about the healing of a wound in the trachea, and agreed with the surgeons as to castration for rupture. Even at the end of the century there were comparatively few physicians in Europe who could correctly diagnose important surgical cases. The dentists of Germany were just as poorly off. A. G. Richter said:

“Dentist is a despicable name in most German ears, and dentistry with us is a profession which demands nothing more than the skill to draw a tooth; one is almost ashamed to concern himself with it, and he the more willingly leaves it to the unskilful and ignorant, the more generally people neglect the proper care for the preservation of the teeth.”

Now, imagine a consultation between physician and surgeon. Under penalty of losing his practice, the state ordered the latter to call in a physician in all complicated surgical cases. In some towns, they were obliged to notify the authorities when assuming charge of a serious case, so that they could caution the patient to seek advice from greater men. In a consultation the physician demanded the control of the case in question and reserved for himself the right to judge of it and prescribe the surgical remedies required. As a Doctor of Medicine he claimed a higher rank, and he did not even consider a surgeon who had obtained his doctorate as his equal. His dignity would have been lowered had a surgeon had the last word; in general, he would not consult with the surgeon but simply expected his own directions to be followed. Many obeyed the physician in order not to offend him. A qualified surgeon finally acted as his judgment dictated, and if called in first to a serious case, revenged himself by not summoning a physician until he had applied the bandages. The many disputes resulted in disagreeable scenes, and if neither party gave up, the matter ended in a lawsuit.

An essay by Stahl on “The Duties of a Physician when Attending Surgical Cases,” strengthened the physicians in their determination to oppress the surgeon as much as possible. If so noted a man did not encourage the surgeon, but subjected him almost completely to the commands of the physicians, the difficulties with which surgeons had to wrestle to raise their standing can well be imagined. The treatment of internal diseases was allowed the licensed physician, while the surgeon was permitted to practice surgery and obstetrics, which in Prussia were connected with each other till 1791. If a physician wished to practice surgery or any part of it, as, for instance, couching for a cataract, he must get a permit from the collegium medicum. In the country, on account of the scarcity of physicians, a separation of the two sciences could not be very strictly maintained; there bath-keepers and barbers treated everything that came their way. When no physician had settled in a village or town, the surgeon also treated internal diseases, but with the restriction that he was to prescribe no strong purgatives or emetics, opiates or narcotics, etc.; in syphilis he was not to employ a salivating treatment, and in high fevers not to do any bleeding. Every district had its special surgeon, to whom several villages were assigned, where he alone had the right to keep journeymen and apprentices, and to do the shaving and cupping. These official surgeons were expected to possess sufficient skill to attend to all operations, as tracheotomy, trephining, herniotomy, when they could not be postponed. The restriction of freedom in the trades was also extended to the Prussian capitals, where only twenty German and six French surgeons were allowed to practice (1725), beside the court and private surgeons. In lawsuits, surgeons were also summoned. The six city surgeons of Berlin, under the direction of the city physician, had to examine the prostitutes, treat the poor, and in case of sudden casualties to render immediate assis-

tance; at first, without any recompense, but later, in 1780, for a salary of 100 thalers.

Until the year 1800 every German surgeon carried on a medico-legal business, but after surgery was separated from medical law, had to undergo a special examination. On account of the different degrees of education among the surgeons they were divided into classes, wherein every petty state being distinguished, exercised a sovereign right different from its neighbor. The Bishop of Hildesheim had three divisions of surgeons: 1. Those who practiced all branches of surgery, called official surgeons (Amtschirurgen). 2. Those who treated only fractures, luxations, wounds, swellings, inflammations and so forth. 3. Those who shaved, cupped and bled. The promotion into a higher class depended upon a new examination (1782). The earldom of Lippe possessed: 1. The medical surgeons, who were permitted the entire practice of surgery, with the condition that in important operations a physician must be summoned; they could also offer immediate help for internal diseases. 2. The licensed surgeons or barbers, who attended only to the surgical diseases, for which they had been especially examined. The examination was conducted by the city physician, who should “examine so critically, with a gentle manner, not forbidding nor peevish” (1789). In Austria in 1805 the surgeons were classified into: 1. Doctors of surgery—an Austrian creation to which we will refer later—they were required to show knowledge of general medicine, just as the doctors of medicine were required to have a knowledge of general surgery. They had the same rights and the same duties. 2. Medico-surgeons, who could practice surgery in all its phases and were permitted a restricted practice of medicine, but obliged to summon a physician when performing important operations. 3. The bath-keepers for inferior surgery. Klysterizing, except in surgical cases, was expressly forbidden the Austrian surgeon and was the business of the apothecaries. In order to break up the dispute between barbers and the bath-keepers, both were usually called surgeons since the year 1773 and all indentures were worded the same way. With the physicians and apothecaries they were placed at the assemblies in the first class for their yearly requisitions, but were put on the fourth class list for their payment of war taxes, which in their case amounted to 12 guilders out of the 100 guilders. Considering their inferior social position, the income of surgeons was very good, if we compare the surgical tax of that time with that of eighty years afterward, for the Prussian tax of the year 1815 was still in force with the exception of a few changes in the 1876 tax.

The following are some of the fees allowed (Mgr.= about 23 cents U. S.; Thlr.=about 70 cents U. S.):

	Lippe, 1780.		Prussia, 1815.	
	mgr.	thlr.	mgr.	thlr.
For treating a plain wound one week (1 bandage)	12-18		1/2-2/3	
For treating a complicated wound one week (1 bandage)	21 mgr.-	1 thlr.	1/2-1	“
Trepanning	2	“	8	-12 “
Setting of a dislocation of the upper part of the arm	4	“	3	-6 “
Setting of a dislocated thigh	8	“	10	-20 “
Treatment of a plain fracture of the arm or foot of a young person (setting)	4	“	1	-3 “
Treatment of a plain fracture of the arm or foot of an old person	5	“	1	-3 “
Operation of a cataract	8	“	8	-15 “
Operation of a cataract on each eye	12	“	12	-22 1/2 “
Operating a fistula on lachrymal gland	6-10	“	6	-10 “
Operating and treating cancer of the breast	10	“	8	-15 “
Operation and treatment of an ulcer on the seat	4-10	“	5	-10 “
Operating a polyp in the nose	4-6	“	6	-10 “
Operation and treatment of a cancer of testicle	8	“	10	-20 “
Operating and treating of aneurysm	8	“	6	-12 “

Amputating the thigh and treating the same (upper part of arm and upper of thigh) . . .	Lippe. 15 Thlr.	Prussia. 8 -15 Thlr.
Amputating the arm and treating the same (forearm and lower part of thigh) . . .	10 "	10 -20 "
Amputation of fingers and toes with treatment . . .	1 "	2 - 4 "
Lithotomy of adults . . .	15 "	20 -50 "
Lithotomy of children . . .	8 "	20 -50 "
Herniotomy of adults . . .	6 "	10 -20 "
Herniotomy of children . . .	4 "	10 -20 "
Price for a cramped fracture . . .	1-3 "	3 - 5 "
Operating and treating paracentesis of the chest . . .	4 "	5 -10 "
Operation of phimosis . . .	24 mgr.	2 - 4 "
Tracheotomy . . .	5 thlr.	6 -12 "
Scutaceum . . .	1 "	1/2 - 1 "
Euema . . .	6 mgr.	1/2 - 1 "
Tobacco euema . . .	12 "	2/3 - 1 "
Catheterismus (douche) for men . . .	24 "	1 - 2 "
Catheterismus (douche) for women . . .	18 "	1/2 - 1 "
Extracting a tooth . . .	3 mgr.	1/2 - 2/3 thlr.
Bleeding . . .	4 "	1/2 - 1 "
Putting on leeches (which are thrown in) . . .	2 "	1 - 2 "
Putting on leeches (which are paid for) . . .	1 "	1 - 2 "

As a further illustration, a comparison of prices of the necessaries of life of that time (during the war years of 1740-65) and today will serve, which stand at a ratio of 1 to 4 (One kreuzer equals 1-10 cent United States, florin equals 25 cents United States):

	1740-65.		1872.	
1 pound beef . . .	4 kr.	19 kr.		
1 pound carp . . .	7 "	22 "		
1 pound codfish . . .	5 "	14 "		
1 sheep . . .	1 fl. 40 "	8 fl. 40 "		
1 calf . . .	1 " 30 "	10 " 30 "		
1 pound of rice . . .	5 "	10 "		
1 pound of raisins . . .	7 "	28 "		
A quantity of barley . . .	5 " 0 "	14 " 0 "		
1 glassful of brandy . . .	" 20 "	" 40 "		
Total . . .	8 " 58 "	35 " 28 "		

Nothing worked more injury to the art of healing, or laid a greater obstacle in the way of the development of German science, than the separation of surgery from medicine. This was unknown to the Greeks and Romans, and if the ancients did divide the science of medicine into dietetics, medicine and surgery, they had no such separation in mind. One person carried on the three. The separation existed since the time of the council, which, as has been said heretofore, forbade the clergy to perform any bloody operations. Various causes helped to maintain the separation. Among them were the continued oppression of the Roman hierarchy, the papal decrees, which in consequence of the contempt for surgical work, formerly separated medicine and surgery. For example, the University of Paris refused to admit a student who had not foresworn the study of surgery; and, furthermore, the denunciation of the study of anatomy by the church retarded the progress of surgery. Each profession was considered so difficult that but a few could at the same time master and practice the two, and many of the city physicians thought the study of surgery too burdensome and disgusting. But the main reason was that the physicians had no desire to be associated with the surgeons, whose station in life was so little respected. So it very seldom happened in Germany that a physician was also a surgeon, and it was an extremely difficult matter to eradicate the deep-seated customs. The physicians watched with Argus eyes all the efforts made in that direction.

When Mederer, in 1774, was appointed professor of surgery in Freiburg im Breisgau, he delivered an initial address on the necessity of combining medicine and surgery. In consequence he was persecuted by the public; the physicians stirred up the medical students and surgeons against him; they threatened to assault his house and to abuse him during the lectures. He nevertheless clung to his assertion and did all that he could to uproot this prejudice. When, in 1796,

twenty-two years later, he took his departure from his pupils, he referred to the above incident in his last lecture. The students serenaded him at night and sent a deputation to beg pardon for the affair. Mederer thanked them and once more assured them that the time would come when both sciences would be united. He himself would not see the day, but would die unconcerned, in as much as the new Constitution of France contained the fundamental principle to combine medicine and surgery, and the Royal Sanitary Commission of Vienna unanimously resolved in favor of their union. The subject once opened became the burning question of the day and prominent men urged the connection.

The association of the two sciences was indeed close and their boundaries entirely undefined. History showed that the healing art, when separated, always suffered a decline and all classical scholars of earlier times were arrayed in favor of the union. It was desired that no other difference except the practice of his special profession might exist between the physician and higher surgeon, and that the former ought to know surgery theoretically and the latter the principles of medicine. Indeed, in country practice and in war it was not possible to maintain such a separation. A. G. Richter repeatedly remarked that no one could be a good surgeon who was not a physician at the same time.

As time passed on, this prejudice among the physicians began to wane, because men like Richter, Siebold, Mursinna, Loder and others in person set an example, showing the possibility of the combination. In 1797 the Electoral Academy of Erfurt called for a prize essay on the subject: "Is it necessary and possible to combine medicine and surgery theoretically as well as practically?" Of the fourteen papers submitted twelve decided in favor of the union, one against it and one was doubtful. But the wise men of Erfurt were still so set in their prejudices that they awarded the prize of twenty ducats to the only one who had spoken against the question. This one was the district physician of Hanover, J. H. Jugler, whose reasons for the most part would scarcely stand a test, and a portion of them were truly absurd. He deemed it slavery if men like Werlhoff, Frank Zimmermann and Wichmann were to perform bleeding, apply leeches and to apply a seton; not even the country doctor had time to attend to these when an epidemic raged. It would be cruel to take the bread of the bath-keeper, and quite unheard of to demand that all resident surgeons should first study medicine and the physicians should learn humble surgery. Moreover, he maintained that there was a great lack of institutions where young men could be practically trained in both departments, and other like arguments.

The suggestions that were made to elevate surgery were of little use, because they forgot to uproot the evil. The request was made that apprentices be excused from playing nurse and doing the work of a common laborer, and that the journeymen should receive stipends to further their scientific education, yet the instruction imparted would be of little avail, as they had had no school training and no education, and many scarcely understood their mother tongue. It was demanded that even the shops of barbers who died should be bought by the prince and he in turn should sell or rent it to a hairdresser who had proven his ability to shave a beard.

The great step toward improvement lay in the abolishment of the guilds and fraternities, wherein Vienna, in 1783, set the good example. There they abolished the fraternity of the surgeons and declared that shaving was the business of the hairdresser. The journeymen continued for a while to live from the customers of their masters, but attended the surgical lectures until they received a position as surgeon. Not until the beginning of the nineteenth century did the rest of Germany catch the spirit of this new movement. They now demanded that a person be both physician and surgeon. In Bavaria the corporations of the bath-keeper and surgeon were abolished in 1804 and no one was permitted to practice surgery without having studied medicine (1808). In Prussia the rules established in 1786 regarding the settlement of physicians and surgeons were annulled in 1808, so that they could establish themselves wherever they pleased and so enjoy their freedom of trade. In the year 1811 the barber license was no longer essential for the practice of surgery; shaving of the head was entirely separated from the practice of surgery and open to everybody; the privileges of the barber were abolished and to pursue the barber trade only a license was needed.

(*To be continued.*)

INFANT MORTALITY DURING LABOR, AND ITS PREVENTION.

BY Z. LINCOLN WHITMIRE, M.L., M.D.
URBANA, ILL.

(*Concluded from page 357.*)

Cord around some part of the child.—When such a case occurs the hand should be placed in the uterus and the loops of the cord drawn down and slipped over the part encircled. When this is done delivery may proceed normally.

Knots in the cord.—This is of rare occurrence. The knots are made early in gestation, as a rule, the fetus then being small enough to pass through the loops of the cord. In such cases the child is usually dead before the end of gestation, and the first indication that trouble exists is the occurrence of premature labor. If the knots occur later and are not tight enough to retard circulation, an early diagnosis is almost impossible. As soon as the uterus begins to expel the child the knots tighten, circulation is checked and a stillbirth is inevitable. If the physician can detect by the color of the presenting part that the circulation is being interfered with he may (in very rare instances) be able to deliver with sufficient promptness to save the child.

Prolapse of the cord occurs fully as often as any other complication that involves the cord. It is usually the result of a relaxed condition of the uterine walls, heavy cord and an unusual amount of motion on the part of the child, and after the membrane ruptures it is very easily diagnosed. Before the membrane ruptures it may be detected between pains. When such a state of affairs is present the child's life may be lost by the cord being compressed between the presenting part and the walls of the passage, which it is the duty of the physician to prevent. A case of prolapse of the cord may be handled in one of the following ways: 1. The cord may be pushed back and held there, if necessary, while labor progresses normally. 2. The child may be delivered as rapidly as possible, paying little attention to the cord. If the first

plan is adopted it will be found possible in some cases to replace the cord so that it will remain throughout the delivery, though this is rare. It is the rule that the easier the cord is replaced, the less likely it is to remain there. Sometimes it can be held there with the fingers, but the best plan is to tie it to a catheter and push it back to its proper place, where it may be held till delivery is complete. However, even that will be found to be impossible in some cases and the second plan will have to be adopted. My experience has been that the greater number of living children may be secured in these cases by delivering as rapidly as possible, using forceps if necessary, and paying no attention to the cord except to use it as an index to the pulse of the child.

Placenta previa is a complication that fortunately is very seldom met with, for it is fully as dangerous to the mother as to the child. The child's life is endangered if the placenta is torn from the uterus before the child is in a position to use its lungs, because it then dies from asphyxia, while the mother is apt to die from loss of blood.

When a case of placenta previa is present it is usually recognized early by the severe hemorrhages, which begin about the sixth or seventh month. They are frequently so excessive as to bring on premature labor or to oblige the physician to do so. Hence few cases of placenta previa reach full term, but when one is found at full term it is to be handled as follows:

Introduce two fingers within the os and detach the placenta from the walls of the uterus for a distance of two or three inches all around, and if necessary, push the placenta to one side.

Rupture the membrane, and if there is an unfavorable presentation turn the child so as to make the breech engage in the os, or if there is a head in the first instance that presents, the forceps may be used if a speedy delivery is indicated, which is usually the case.

A partial detachment of the placenta may sometimes check the hemorrhage. The strength of the woman is the main thing to care for and that may be done by the usual means.

After waiting in vain a reasonable time for the uterus to expel the child the physician may deliver by art.

It will sometimes be found necessary to dilate the os, and this may be done with the dilating instruments, though in most instances the fingers will prove not only to be sufficient but to be the very best for the purpose. Watch carefully for post-partum hemorrhage, for it is apt to follow a case of placenta previa.

This brings us to the third and last general class of complications, viz.: Those located in the child itself. This class has three divisions, the first being:

Large head.—By this is meant a head that is too large to be delivered naturally. Such cases are not of uncommon occurrence. They may be easily recognized by the manner in which they progress. As far as their effect upon the child is concerned and as to the manner of treating them, they are very similar to cases (above cited) of deformed pelvis and cases of obstructed passage. That is to say, the child's life is endangered by uterine contractions, and in order to deliver the child successfully the obstruction must be removed or circumvented. Since the child's head is the obstruction (owing to its size) we may not remove it, but we may remove the size of the head by compressing the skull with forceps. When this can not be done and a living child is to be secured, symphyseotomy or Cæsarean section must be performed.

A large body offers the same dangers and is to be treated in the same manner as a large head, except that forceps can not very well be used to advantage. It is claimed, however, that when the breech presents the forceps may be used with good effect; but that is also disputed by equally good authority, and with reason, because the breech can not be compressed like the skull. It has also been advocated that blunt hooks should be used in the axillæ of a large-bodied child, after the head had been delivered, but experience will soon teach one that artificial hooks of all kinds should be avoided and if it is necessary to use a hook the fingers will be found to be all that is needed.

Face presentation.—In a face presentation the head is thrown back so that the occipital bone rests on the base of the neck, while the chin is thrown forward. This presents the longest diameter, and with a medium-sized head in this position an uninterrupted delivery is impossible. Before delivery can be effected the head must be righted so that the crown presents. This may be done by pushing the body back so that the head can be moved to the proper position. Sometimes it may be accomplished by allowing the woman to assume the knee-chest position, when the head may be moved after the body has gravitated toward the abdominal cavity, while at rare intervals the body will slip back between pains and the head come down of its own accord. When the proper position of the head has been acquired the delivery may proceed according to existing circumstances.

Breech presentation is an abnormal position that is quite common. It is easy to diagnose even before the membrane ruptures, and after that it is almost impossible to mistake it. In a case of this kind there is no danger of the child's life till after the body is born and head and cord are passing together over the perineum, when the danger becomes quite imminent. While in this position the cord is compressed so that circulation through it is completely stopped. Even when labor progresses with normal speed through this danger point the child sometimes dies, and when anything interferes with its progress at this point the child is sure to be killed unless something is done to prevent or to lessen the danger. Hence it is the duty of the physician to see that the labor proceeds through this stage rapidly and without pause, and before it reaches this stage he should see that everything that is necessary to be used in resuscitating the child is placed close at hand.

Breech presentations are slower than head presentations, on account of the soft and yielding character of the breech not being so well adapted to the work of dilating the os nor to holding the ground that has been gained.

This slowness of labor and the prolongation of the pain and suffering through which the woman has to pass are great causes of weakening her resisting powers, so that when the body is born, and the parts contract down around the neck, the relief experienced is so great that it is almost impossible to secure another pain. Hence a very possible result at this period is the occurrence of uterine inertia, and it could not occur at a time when it would be more apt to prove fatal than just then. When the body and legs are born they will serve as an excellent register of the child's enduring powers, and for this purpose they should be kept constantly under the eyes of the physician.

It is always best to wait a short time for the uterus

to act, and it is also a very good plan to administer to the woman some warm drink or a teaspoonful of brandy, but the moment the child begins to lose its healthy pink color the physician should begin to deliver the head. Seldom will he have time to apply the forceps; but even if he has time, it is far better in these cases to use the forceps nature has given him—his hands—for they are far superior to any that man has contrived when cases of this character are to be handled. Allow the body of the child to rest upon one hand while the other is placed so that the fingers, which are along the sides of the child's nose or in its mouth, may have a good hold. Then by pulling the chin well down upon the breast and guiding the direction of the traction by moving the body with the other hand, the child may be rapidly and easily delivered. If it is not already dead, measures may be taken to resuscitate it.

Next to the danger from the pressure on the cord is that of an arm being pushed down along by the side of the head. In a case where a small child is being delivered by the breech this might serve as a protection to the cord, but it is not usually safe to allow it to remain in this position. It must be replaced. The physician who allows such cases to continue without replacing the arm is sure to see a great majority of those children born with a crushed arm or skull, or a crushed or dislocated shoulder.

Twin labor is generally not a dangerous case, though it is always more or less exciting. One or both of the children are usually small enough to render the delivery an easy operation, and when any trouble comes it is because they become head-locked or get wedged in the passage. When both attempt to enter the passage at once they may become wedged. This may also occur when one has reached the outlet and the other tries to enter it. When one child is born by the breech its chin may catch under the chin of the other child, which condition forms what is known as the head-lock. In either of the above positions they check the progress of labor till something is done to remove them from their locked position, and if they are left alone too long death will follow from uterine pressure. To avoid this, the physician must do as follows: Push one child up, if possible, and allow the other to pass. Should this be impossible, one child should be sacrificed to save the other. This question may arise: Why not perform symphysectomy and save both children? It is easily answered. Twin labor is not the natural labor of the human race, and since it is an abnormal condition it is probably responsible for the fact that one of the twins usually dies, and sometimes both. Hence, inasmuch as it is the rule for one of them to die, it is not good logic to advise the mother to subject herself to the dangers of an operation that, after all, is apt to result in the loss of one of the children, when by sacrificing one of them in the first instance she will be free from those dangers.

This completes the nineteen main causes of infant mortality during labor and the discussion of their respective merits, and after a careful reading of the whole it can be seen that the causes of death and the remedies for each complication may be expressed in a very few words. Most of the dangers to the child's life are from uterine pressure, and the remedy for all of them is a prompt and rapid delivery. The exceptions to the causes are as follows:

1. Uterine inertia.—With this the child dies, be-

cause its head is left too long on the contracted condition necessary in passing over the perineum, or, in a breech presentation, from pressure on the cord at the same period in the case.

2. Short cord.—Here the contractions of the uterus are indirectly responsible for the trouble and produce the main cause of death, which is the rupture of the cord (asphyxiating the child before it is able to use its lungs). The tension of the cord may also stop the circulation through it in cases where it is shortened by knots or being wound around some part of the child.

3. Placenta previa.—In this the child dies from asphyxia, caused by an insufficient connection between the placenta and the uterus.

As mentioned before, the remedy in each case is a prompt delivery. That does not mean that the forceps are to be used regardless of circumstances. They are to be used only when absolutely necessary. Remember that forceps are to be used to save life and not merely to save time. Make it a rule, if you can, that your labor cases must be placed under your exclusive care before the eighth month of gestation.

Let every examination be thorough. Do not examine your patient too often, but at the same time do not allow such a caution to prevent you from being thoroughly informed as to the progress and condition of the case.

Through the whole of the confinement you should be cool, without being frigid; gentle, without being timid, and rapid, without being hasty. In short, if there is one case more than another in the whole field of medicine and surgery that every attribute of the true physician is needed to treat properly, it is that case where he is at the bedside of a woman who is about to become a mother.

By bearing these thoughts in mind and having a thorough knowledge of the subjects herein mentioned, with the ability to make a practical application of that knowledge, there is no doubt that any intelligent physician can meet and successfully handle any case of labor, be it ever so complicated.

Fourteenth Biennial Report of the Board of State Commissioners of Public Charities for the Years 1895 and 1896.

ARTHUR R. REYNOLDS, M.D., PRESIDENT.

(Concluded from page 366.)

At the last session of the legislature a law was enacted authorizing county judges to take children having no parents out of poorhouses and to place them in homes, without cost to the county. It was believed by some that this law would remove the children from the almshouses, but it has failed to do so, and can not touch the class of cases above referred to, in which vicious and irresponsible parents compel county officials to maintain their children in the almshouse year after year. In preparing this report, the Board sent a letter to every county judge in the State, as follows:

"1. Will you please state how many, if any, children you have released from almshouse and placed in homes under the statute approved June 21, 1895?"

"2. Will you please make any suggestions you can as to needed changes in the law regarding destitute, neglected or dependent children?"

"A reply at your earliest convenience will be a favor to the State Board of Charities. Kindly answer upon this sheet, if practicable, and forward in enclosed envelope."

Replies were received from fifty-five judges. In fifty-four cases no use had been made of this statute. In one case one child had been committed under this act.

In a few cases suggestions were made by county judges. We quote as follows:

Hon. Chas. H. Donnelly, McHenry County:

"I would suggest that more power and authority be given to the county judge in regard to the control of dependent boys, and some of the power which is now vested in the trustees of training schools be taken away. In my opinion, the County Court ought to be vested with full power to release from such institution any child whenever, upon a proper showing, in his opinion such child should be released."

Hon. Rufus C. Bailey, Winnebago County:

"I would suggest a change giving authority to the Court or some proper tribunal, for instance the Judge and Chairman of the County Board or a committee appointed by the County Board, to place such children in private families, and when necessary to pay for their care in such families for a reasonable time and charge the county with the same."

Hon. Orrin N. Carter, Cook County:

"I believe the law regarding dependent children should be changed in such a manner that the authorities managing industrial and training schools should report to the County Court of each county once every six months, the disposition made during the six months last past before such report, of the children committed to the school from such county."

"I think I should also be in favor of an amendment to the law, forbidding the keeping of children in an industrial or training school longer than, say, one year, without an order of the Court which committed the child to the school, permitting on proper showing such child to be kept a longer period of time."

Hon. Colostin D. Myers, McLean County:

"I think it were well if the law relating to homes or schools for dependent children was amended to allow the court in which the proceedings for commitment are had to retain jurisdiction of the case with power to discharge or vacate the order of commitment upon proper showing."

"Also that provision be made that the court may by summary process compel a parent to contribute to the support of the child and the expense while it remains an inmate."

"In more than one instance I have known that parents were unfit and do not care to control their children, but have means whereby they could and should be compelled to support them. While the salvation of the children should be of first concern, yet it is an imposition upon the public to relieve the parents of their natural and proper burden if they have means."

Hon. Robert H. Lovett, Peoria County:

"The law with reference to dependent children should be changed so that girls past the age of 13 taken from houses of ill-fame should not be sent to the same industrial school with virtuous children. *Virtuous* children should not be compelled to associate with *lewd* ones. I will not send them there. I refused yesterday to send a wayward girl (16 years of age) to our Industrial School. The trustees of these schools should be *compelled* to find homes for children in a certain number of years. They get children *in* and never get them *out*. This means a great expense to the county."

"The Home should be under the direct control of the Board of Public Charities and the Board of Supervisors."

Hon. Carl E. Epler, Adams County:

"Dependent boys, and boys under 10 years of age, stealing and not liable as under age to commit crime, need attention. The law provides for their being sent to industrial schools, but provides no schools, leaving that to private enterprise. Lack of room for such boys and lack of proper attention and care will impose them on the State as paupers and criminals if not cared for by the State."

Hon. Isaac Hudson, Moultrie County:

"I have had but one such case called to my attention under the new law and the law did not apply to it because the father of the children is living. The circumstances in that case were such that I believe some amendment is needed to make the law fit such conditions."

"The children were taken to the poor farm and left by their father. I think if possible the law should be amended so as to fit cases of abandonment, and in case a parent on account of worthlessness or dissolute habits fails to provide for his or her children, it should be regarded an abandonment. Such children are frequently in a worse condition than if they had no parents living, and the future welfare of themselves and the community requires that they should be provided with better surroundings."

INDUSTRIAL SCHOOLS.

The laws under which the industrial schools of the State exist, were enacted because of a profoundly humane and generous feeling. They are a recognition of the fact that the child of neglect must be cared for in new surroundings, if he is to become a useful citizen and not a menace to the community. So rapid has been the growth of the State, and unfortunately

so correspondingly rapid has been the growth of a class of dependent and neglected children, that the great industrial schools, especially those for boys, are eadly over-crowded, and their proper and legitimate work rendered difficult by the failure of our present law to provide the judge with authority to dispose of the child in any way save by sending it to an industrial school.

The schools have an absolute power of discharge, which is necessary in certain cases, but which is liable to abuse, since the child who may be discharged from the school for a good and sufficient reason is not remanded to the court under the law. but is left in the same situation as before he was declared dependent. A case was recently brought to the notice of this Board, supported by sworn statement, in which the County Court, after a full hearing, adjudged dependent a boy of 6 or 7, directing the father to pay the board of the child at school. The father was known to be irresponsible financially. Both parents had been proven in court to be improper persons to have the custody of the child, yet the mother applied to the officer of the school for the child and he was given back to her. Thus upon the same day upon which the court had determined that the mother was an unfit person to have the child, and as compelled under the law had confided the child to the guardianship of the school during his minority, the school abandoned the guardianship to this same parent. While we trust that such instances are rare, we submit that the possibility of their occurrence shows the wisdom of the county judges above quoted in advising that the powers of the county court be extended.

We believe that such legislation as we have advised above is entirely in the interest of the proper management of industrial schools. The existence of the industrial schools in Illinois renders unnecessary the establishment of the State School which might be necessary if the industrial schools did not exist or could not be utilized for temporary care in cases demanding it. The legislation advised will protect the industrial schools in their legitimate work and tend to prevent the over-crowding now so prejudicial to their usefulness.

Quarterly reports under the headings shown below for the schools for boys and girls respectively are now filed with this Board.

St. Mary's School at Feehanville now cares for nearly 400 boys. The economy and efficiency of its administration is most admirable. It needs, in our opinion, enlarged buildings, so arranged as to afford better opportunity for separating different classes of boys. It also needs some improvements in the plumbing and bathing arrangements, especially good and sufficient bath rooms. The location of this school upon the Des-plaines river is ideal.

The school at Glenwood has about 250 boys. It has the advantage of a system of separate cottages, which permit somewhat more personal supervision and separation of inmates. The location here, too, is excellent.

Chicago Industrial School for Girls, on 49th and Prairie Avenue, is an admirable well ordered institution. It cares for an average number of about 163. The school teaching is above the average found in such institutions, and there is a careful use of the text-books used in the public schools, which we specially commend. The industrial work is good and practical, and the children seem well cared for.

The Illinois Industrial Training School for Girls at South Evanston has much improved its grounds and has erected a handsome addition to its buildings since our last report.

The Industrial School for Girls at Peoria has an average of about 36 inmates.

It is the opinion of the Board that all of the schools which endeavor to place girls out in country homes, should also make a point of teaching them dairy work, the care of poultry and gardeniog, and should endeavor to interest them and make them proficient in those occupations which pertain to country life. And for this reason we consider that such schools should be situated in the country. We append below statements of the industrial schools above named.

EDUCATION AT THE SOLDIERS' ORPHANS' HOME.

During the last year a building for manual training has been erected at this institution. We would recommend that manual training be made a part of the educational plan for the children under 14, and that a head teacher or superintendent for the school be appointed, who shall under the superintendent of the Home have sole charge and direction of all the educational work of the institution. It is particularly necessary that this school should be brought to the highest possible efficiency. There are inherent difficulties in educating large numbers of children thus gathered together and deprived of that intimate association with their parents and elders which forms so large a part of natural education. These children too are cut

off from the education and stimulus of the street which is by no means all bad. These difficulties are not realized at first, but they exist and can only be met by great effort to make the school practical, interesting and stimulating. The Board trusts that it may be made a manual training school of the best type and a model to the State.

In pursuance of the same principle which has influenced the Board in recommending the placing out of children in homes, the Board would advise that these children be placed in homes on reaching the age of 14 years or before if possible, and that when necessary to their proper schooling or training until they reach 16 a sum shall be paid for their living and teaching, not exceeding the cost of maintenance in the institution, but that the period of their retention in the Home be limited to the present age 14 years.

COOK COUNTY.

The charitable work demanded of Cook County is so vast as compared with that demanded in any other county of the State that here the county almshouse has been differentiated into a county hospital with an average of 1,000 beds, a detention hospital for the insane, an infirmary and an insane asylum.

Following is the report of Cook County Hospital for 1895:

Patients on hand Jan. 1, 1895	794
Number of patients admitted to Hospital	14,861
Total number cared for	15,655
Number of patients discharged	13,629
Number of patients	1,194 14,823
Total number remaining in Hospital Jan. 1, 1896	832
Average number of beds, 1,000.	

MATERNITY WARD.

Births	395
Deaths (infants, includes still-born)	64

HOSPITAL.

As regards the Cook County Hospital the Board renews its former suggestion that medical students be allowed upon the wards. During the last year there have been repeated assurances of gross misconduct and neglect of patients upon the part of certain doctors, and there is at all times a laxity of attendance upon the part of staff physicians, from which the patients suffer, being left as they are to the care of internes. This great free hospital contains a destitute population as evidenced by their presence here. Their sickness and helplessness certainly compel sympathy, and we have no doubt that it was with a view to protection of the patients as well as to put an end to a quarrel among the schools that the old practice of bedside teaching was discontinued in this Hospital.

Free hospitals are found in all great cities of the civilized world and they are everywhere open to bedside teaching, and in consequence enjoy the services of the most distinguished physicians and teachers of medicine in their respective cities. It seems plain that the theory that the free patient in return for the benefit received in the hospital shall give opportunity to students of medicine and thus repay society, results in the patients obtaining the services of the most eminent men in the medical profession. While the other plan now followed by Cook County leaves the wards closed to students and therefore deserted by their teachers, and the patients abandoned to the mercy of untrained fledglings in the medical profession, or to physicians whose appointment is due to some other cause than fitness. In situation, equipment, buildings and nursing force this hospital is all that can be reasonably demanded.

In the opinion of this Board the usefulness and efficiency of the Cook County Hospital would be greatly enhanced if it were superintended by a competent medical man. Medical skill is required in the housing, feeding and clothing of patients just as much as in the prescribing of drugs. Private pay hospitals are in their every detail managed by medical men and public opinion demands not less in the care of the poor whom the public assume to treat when ill. It is not a fair charge to make against the profession of medicine whose members embrace those well known to be the most humane and gentle of men, that the admission of students upon wards of a hospital would result in unkindness or maltreatment of patients, for their lives are devoted not only to relieving and healing the ills of the race but to the prevention of disease as well.

This Board unqualifiedly believes that the admission of students to the wards in small groups in company with the attending physician or surgeon would be of benefit to the patients and submit that the medical man is the best judge of how and when such visits should be made.

We renew our suggestion that some provision for convalescents other than Dunning be afforded. It is our belief that many a self-respecting man or woman is turned into a pauper by being sent from the County Hospital to Dunning for convalescence.

INFIRMARY AND INSANE ASYLUM.

The population of the Infirmary and Insane Asylum is fully discussed in the Appendix. The insane are overcrowded and the Infirmary inmates on the men's wards as well. In the opinion of the Board the Infirmary population should be entirely removed from Dunning.

It is too near the city limits for an almshouse. The line of city saloons across the street from the grounds are a source of constant disorder and mischief and form a strong argument for the withdrawal of the Infirmary, since there is no power to compel the withdrawal of the saloon.

The Board would urge that the records of the Infirmary, be more carefully kept, especially that the very large duplication be noted. This is further discussed in Appendix II.

Whether the insane of Cook County are cared for by the State or by the county, they should not be removed farther than their present location from their friends and relatives, who can now reach them at a trifling cost. The present location is wholesome and adequate for an insane hospital if the entire plant could be used and the buildings remodelled, but it is not enough for Infirmary and insane asylum too.

At present the Cook County Insane Asylum receives many curable and recent cases owing to the crowded state of the Eastern and Northern hospitals. Its vital lack in an administrative sense is a competent medical superintendent to have sole responsibility for the care of the patients.

A reorganization of the patients themselves under medical supervision should be made so as to keep more of them employed in various ways. The idleness and dulness of these wards is oppressive to the observer even in contrast with other similar institutions.

DETENTION HOSPITAL.

Patients are brought to this hospital for security pending a legal inquiry as to their mental condition. They are often in a state of acute mania, a condition demanding medical care and good nursing. While the Board believe that the conduct of this hospital has somewhat improved, it can not be considered as adequate.

The detention hospital should be under practically the same nursing charge as in Cook County Hospital. It should be under the medical charge of physicians who are specialists in mental disease, and should be visited daily in turn by at least two such physicians. If this were done it would render natural and easy the change from jury trials to inquiries by commission in Cook County, and that, too, without consuming more time than the present plan. The County Judge has the right under the law to appoint as commissioners in lunacy two qualified physicians in regular and active practice, when no jury trial is demanded or appears to the judge to be necessary. By appointing as such commissioners doctors who should serve for a period of ninety days, more or less, visiting the hospital daily during their term, and thus seeing each patient repeatedly, a medical decision in each case could be secured which would be of real value, and if presented to the judge would certainly facilitate rather than retard the proper disposition of these cases. Such medical attendance combined with the nursing of a sick ward would doubtless result in the cure of some acute cases without recourse to a State Hospital.

SOCIETY PROCEEDINGS.

Chicago Pathological Society.

Regular meeting was held December 14, 1896.

Dr. ARTHUR R. EDWARDS, Vice-President, in the Chair.

Dr. HENRY F. LEWIS read a paper entitled "Iniencephalus, with demonstrations." (See page 388.)

Dr. EDWIN KLEBS—In reference to the very interesting subject discussed by Dr. Lewis I have only a few remarks to make, as I have not specially studied the subject.

1. I would say that I do not like the name of iniencephalus, as the foremost alteration is in the spine, showing the highest degree of spina bifida or rachiochysis. As the whole fetus with well-formed head and extremities shows a high degree of retardation of growth, it may deserve the name of a dwarf-growth. The head is retracted by the shortness of the spine; the upper and lower extremities approach one another. In comparison with the well known cases of microcephalia and micromelia (diminished growth of head and limbs) one would give to this monster the name of microrhachia.

2. As to the development of the spina bifida, I have shown in a case of dwarf fetus, no longer than 16 m. in the fourth month of development, that the alteration begins at the time of the formation of the chorda dorsalis, probably by adhesion of the flat embryo to the egg membranes, hindering the occlusion of the opened spinal canal and the development of the spinal marrow.

3. In this case it seems to be remarkable that notwithstanding the general arrest of development the formation of head and limbs shows normal forms. As the intervertebral ganglia in such cases are developed the normal formation of the extremities is regular. Other cases of rachiochysis and amelia can not depend upon the destruction of the spinal marrow. It seems that in micromelia the development of the limbs is retarded by mechanical obstacles, probably the shortness of the amnion. In this case the amnion was normally developed, and no obstacle formed to prevent the development of the limbs. That the place of the first adhesion of the fetus to the egg membrane can not be detected is explained by the high power of regeneration in the egg and fetus.

4. It may be remarked that the abnormal conditions in this case of iniencephalus, as in so many other cases of malformation, are caused by the presence of another well-developed fetus.

EXHIBITION OF SPECIMENS.

Dr. E. R. LE COUNT showed a *cyst of the urachus*. The patient from whom this specimen was obtained was admitted to the Cook County Hospital Feb. 27, 1895. He was a man 52 years of age, white and single. He was admitted for an illness which began four weeks previously with frequent micturition and pain in the region of the kidneys. Examination revealed an enlarged prostate. Symptoms of cystitis with retention of urine, hydronephrosis and uremia prevailed, and death occurred April 9.

Bladder and cyst of the urachus, greatly reduced in size.

Autopsy abstract: The bladder is large with markedly thickened walls. Each lateral lobe of the prostate is the size of an English walnut. At the summit of the bladder and separated from the bladder cavity by a thin membrane, is a cyst the size of an average orange, which contains a thick, turbid, viscid, brownish fluid. The lining of this cyst presents an irregular surface, but there are no distinct rugæ. The irregularities of the cyst lining are present upon the upper surface of the intervening septum between it and the bladder cavity, and the rugæ of the bladder are continued upon its inferior surface. The ureters are dilated, as are also the pelves of both kidneys. Careful dissection failed to reveal further urachus remains in the abdominal wall or about the navel. Microscopic examination of the septum between cyst and bladder cavities disclosed the fact that the muscular coats of the bladder wall were not continued into the septum. This fact, taken in conjunction with the position of the cyst and the fact that the peritoneum of the abdominal wall was reflected upon the back of the cyst and from thence upon the back of the bladder, leaves no doubt

but that the cyst represents the unobliterated and dilated lower end of the urachus.

Dr. F. E. WALLACE presented a case of *suppurative pancreatitis*.

Mrs. F., aged 26 years, Irish nationality; mother of two children. She was admitted to St. Elizabeth Hospital Oct. 26, 1896. Family history negative.

In the past two years she has had four or five attacks of pain in the region of the gall bladder with slight icterus. She has also had one miscarriage. Her present illness dates back five weeks, when she had attacks of pain in the epigastric region with nausea, vomiting and thirst. These symptoms persisted for three weeks and then abated under treatment. Five days ago vomiting began and persisted up to the day of her entrance into the hospital. She was admitted for an operation, a probable diagnosis of gallstones having been made.

On admission her condition was as follows: Temperature 100.4 degrees, pulse 114, strong and wiry, hurried respirations; face highly flushed; nausea and vomiting; pain in epigastric region; great thirst; bowels confined, and passing small quantities of urine.

Urinalysis showed one-fifth by bulk of albumin and large quantities of biliary coloring matter. The operation was postponed. Sp. gr. 1.015 and an acid reaction.

Alcohol sweats were given and following the use of this treatment the albumin diminished one-half.

Oct. 27—Thirty-two ounces of urine passed in the previous twenty-four hours. The symptoms of nausea, vomiting and thirst continue.

Oct. 28—Patient passed but 16 ounces of urine in the last twenty-four hours.

Oct. 29—Heart seems growing weaker and is passing but little urine; the feces and urine being voided at the same time. During the last three days the temperature has been one to three degrees above normal and the pulse above 100.

In the evening of October 29 she passed into a deep coma and died at 11 p. m., the treatment having been symptomatic.

The autopsy was made by Dr. E. R. LeCount. A synopsis of the postmortem findings follows:

Body and tail of pancreas consisted of shreds of necrotic tissue extending across and lying free in a cavity formed by the stomach, the retro-peritoneal and perirenal adipose tissue, the transverse mesentery, the duodenum and the tissue of the lesser omental cavity, as well as some loops of the small intestines and colon. The walls of this cavity were necrotic, dark gray and slaty in color. The cavity contained fecal matter from perforations of the colon and stomach. The head of the pancreas was the least involved.

There were many small gallstones and the gall bladder was contracted and small from connective tissue bands in the walls.

Disseminated in the omentum, mesentery and abdominal fatty tissue generally were small grayish areas such as are seen in fat necrosis. Acute parenchymatous nephritis was present. The spleen was small. The heart and lungs appeared normal.

Dr. ARTHUR R. EDWARDS presented:

1. *Urethral stricture with extravasation of urine.*

These specimens are from a case of urethral stricture in which the patient had been treated on a previous occasion for stricture and retention of urine (as a sequence of the stricture) successfully by dilatation of the urethra with sounds. The patient left the hospital after this dilatation had been effected. The history of the interval between his discharge and return to the hospital is somewhat meager, except that he stated he suffered again from retention of urine and was unsuccessfully treated by sounds by a physician. The sounds were passed many times, consisted of various calibers and shapes, and the patient had had a considerable quantity of blood escape from the urethra, but the passage into the bladder was not reached. The patient

entered the hospital in a delirious condition, and the true state of affairs was not appreciated, as the history was obtained only after his death. He had been in the hospital some little time with retention of urine when periurethral abscess pointing in the perineum, which was incised and which shows in the specimen. There was afterward infiltration of urine, not so much into the perineum, the scrotum and the soft tissues of the external genitalia as upward into the abdominal muscles, especially into the recti.

At the necropsy the findings in the rest of the body were practically negative, except there were in the lungs, which are unfortunately not here, one or two small metastatic abscesses in the right lower lobe. In some of the larger veins outside and back of the bladder there was a suppurative thrombo-plebitic process. The specimen itself distinctly shows the stricture, and proximal dilatation of the urethra, the stricture being about two inches from the external meatus. Further up is the point where the incision had been made from the back of the urethral abscess into the urethra itself. Just above the point of division of the urethra where the tissues are disorganized we found a peri-urethral abscess. The cut which you notice about the neck of the bladder was made at the opposite direction to see if there was a deeper process in the prostate. There was very intense cystitis, para- and peri-cystitis. The recti muscles on each side of the pubes were greatly disintegrated, and the foul decomposition had extended to a lesser degree over quite a distance in the abdominal walls.

The pathologic process did not extend to the ureters or to the kidney.

2. *Carcinoma of the cervix uteri.*

The second specimen is an ordinary carcinoma of the cervix uteri in which a history was given of the disease lasting for about twelve months before the patient entered the hospital. She was in the hospital only a comparatively short time before she died. Three or four months prior to her admission there was a very offensive discharge, which was present when the patient was admitted.

An examination showed the pelvis to be extensively infiltrated with the neoplastic masses. The abdomen was somewhat rigid and contained palpable masses.

The subphrenic organs are shown here, although they are of little interest beyond the invasion of the liver by the tumor and, what is more interesting, the invasion of the diaphragm, which shows distinctly. In the hilus of each lung the secondary deposits were lacking; yet on the upper surface of the diaphragm the lungs were adherent to it and the subpleural lymphatics are involved.

PRACTICAL NOTES.

Argentamin in Ophthalmics.—Hoor has recommended argentamin as a substitute for silver nitrate in eye affections where the latter is indicated. Argentamin is chemically ethylenediamin-silver-phosphate. Unlike silver nitrate, which when crystallin is acid in reaction, and when fused neutral in reaction. Argentamin is alkaline, and this accounts for the fact that its application caused only slight and transient local reaction, a point much in its favor. It never gives rise to a deposit on the abraded or ulcerated cornea, which nitrate of silver sometimes does, nor to staining of the conjunctiva, nor to the disagreeable metallic taste associated with the use of the latter. It may be used in 3 or 5 per cent. watery solution, once or twice a day, or oftener if required. It seems to have all the advantages and none of the disadvantages of silver nitrate.—*British Medical Journal*, October 17.

Successful Treatment of Whooping Cough with Inhalations of Mentholized Formic Aldehyde.—According to the experience of P. Rosenberg, the inhalation of the vapors disengaged by a solu-

tion of 60 per cent. formic aldehyde in methyl alcohol to which menthol has been added, produce a peculiar effect on the mucous membrane of the respiratory passages, which can be utilized in cases of phthisis and especially of whooping cough. He has demonstrated that inhalation commenced with the first appearance of whooping cough, have succeeded in arresting it in the course of a few days. Commenced later, they are equally useful in diminishing the number of the paroxysms and abbreviating considerably the duration of the disease. The windows and doors of the room are closed air tight and 5 to 10 c.c. of the methyl solution of formol, with the menthol, are evaporated in a saucer by means of a "very feeble source of heat."—*Bulletin de la Soc. de Pharm. de Bordeaux*, December.

Salol in the Treatment of Non-Diphtherial Throat Affections of Children.—In the *Journal des Practiciens* for December 5, M. de la Carrière remarks that the internal employment of salol in angina has given excellent results, and that he has prescribed it in cases of amygdalitis, acute angina, and non-diphtheritic cases, whatever might be their cause. It is a general antiseptic and analgesic, with an elective action on the pharynx. It quiets the pain and the dysphagia almost immediately, it brings about a rapid relaxation in the physical symptoms, it prevents the formation of abscesses, and it always shortens the duration of the disease, especially if administered in the beginning. The daily amount for an adult is sixty grains. For children the adjustment of the dose is easy, as salol is always well borne, for trouble with the kidneys, which is the only contraindication, is exceptional in them. The amounts to be taken daily are as follows: For children a year old, eight grains; for children two years old, fifteen grains; for children three years old, twenty-three grains; for children four years old, thirty grains; and for children eight years old, forty-five grains. This amount is sufficient until the age of fifteen, when it may be increased to sixty grains without inconvenience, if necessary.

With regard to the mode of administration, de la Carrière recommends the following formula:

R. Salol	30 grains
Sweet almond oil	60 grains
Syrup	450 grains
Distilled water	2.5 ounces.

Peppermint, orange-flower water, vanilla, or cherry-laurel water may be added to make it aromatic.

This quantity is sufficient for three doses during the day. Salol may be given at mealtime, as it does not disturb the digestion. The employment of this drug should be suspended if the urine appears of a dark color.

Treatment of Tuberculous Epididymitis.—Dr. W. L. Rodman, in the *American Practitioner and News*, January 9, states that his experience leads him to say that in the vast majority of cases the disease is primarily in the epididymis. [This is also the view held by Monod and Terillon.—ED.] He has examined many specimens removed by himself and others and has never yet seen a case where it was not demonstrated that the disease began in the epididymis. He has seen many cases in which the disease is limited to the epididymis and others in which the body of the testicle became involved later. A patient may have considerable disease of the epididymis for years without any other part of the genito-urinary tract becoming involved. If the disease is bilateral more conservatism should be observed than if it is unilateral. If it is clearly unilateral it is best to sacrifice the testicle. "My belief is that a man is about as well off with one testicle as with two. A patient whom I exhibited to this society about two years ago, after a unilateral castration, has since become the father of a child and tells me there is no difference in his condition sexually. In view of the fact that I have been in the habit of practicing partial operation in benign tumors I can understand how this same

plan of treatment can be pursued in tubercular disease of the testicle. But it must be remembered that here we are dealing with something in the nature of a malignant disease and we must be more radical. I would not castrate if the prostate was involved also. How many cases of tubercular disease of the epididymis of the testicle get well? I can not recall a single case where I have practiced castration that has come back to me with involvement of other parts of the genito-urinary tract. There may have been recurrences, but they have not come to me; as such cases follow one, I take it none have occurred."

Dr. Howard Kelly's Operation in Ectopic Pregnancy.—In the *Johns Hopkins Hospital Bulletin* for December, Dr. Kelly has a paper on the treatment of extra-uterine pregnancy by vaginal puncture. He has now the records of ten cases treated with good results in this way since 1882. There has been no mortality, and relatively little suppuration. He describes the operation as follows: I do not consider it necessary any more to make the abdominal incision. After an accurate diagnosis of the case, outlining the sac and its relations by abdominal and rectal palpation, and after careful vaginal palpation to determine the proximity of the sac to the upper vaginal wall, a point is located behind the cervix in the vaginal fornix close to the sac, and a pair of sharp scissors is plunged upward in the direction of the axis of the pelvis. The scissors are then opened and some of the fluid blood usually trickles out at once. Larger scissors are then introduced, if need be, and the opening widened by withdrawing them with blades open. It is important to have a large opening, both for the purpose of getting two fingers in to clean out the sac and for good drainage afterward. The torn edges of the wound never bleed excessively. The sac must be delicately cleaned out, and everything brought away down to the shell of the sac and surrounding adhesions. In one of these cases I brought out a well-defined Fallopian tube cast, due to hemorrhage in the tube. The cleaning out is followed by irrigation, after which the sac is plugged with gauze, which is left in for several days, and sometimes longer, and then the wound is washed out daily until it closes. I know of no instances of more than moderate suppuration following this plan of treatment.

Eclampsia Caused by Leucomains.—By means of venous fistulas on animals (Eck's method), Massen has established the extreme importance of the functions of the liver in the processes of oxidization occurring in the animal organism, and the toxic action of the amin-carbonic acid generated by the incomplete oxidization of the nitrogenized substances. This acid produces in animals an intoxication resembling in every respect the picture of eclampsia. He has also studied with the microscope the lesions of the viscera in eclampsia. The parenchyma of the liver shows profound alterations, and the other organs a general and severe intoxication. By a series of parallel researches he has become convinced that eclampsia is caused on the one hand by a disturbance of the processes of oxidization in the pregnant woman, and on the other, by a subsequent intoxication from the products of the incomplete oxidization, among which amin-carbonic acid plays the principal role, although analysis of the urine in eclampsia does not disclose an excessive amount of this acid. The urine, however, always contains a large quantity of leucomains; before an attack of eclampsia the quantity of leucomains in the urine is always two and one half to three times the normal, rapidly diminishing after the attack. He announces therefore that eclampsia is in fact a leucomainemia. Leucomains are found normally in much greater abundance in the pregnant woman than in the non-pregnant, but as they circulate in the organism they do not produce any disturbance unless the balance of the nervous system is destroyed by extreme pain or some other excitation of the nervous system.—*Presse Méd.* from *Cbl. f. Gyn.*, 1896.

Alterations in the Cremasteric and Bulbo-cavernosus Reflexes in Neurasthenia.—It is unnecessary to dwell upon the value of a sign that would enable the diagnosis of neurasthenia to be made with certainty, without depending upon the statements of the patient, whose reliability is frequently questionable. Critzman calls attention to the absence of certain reflexes which he has invariably found wanting in well defined cases of neurasthenia in the male, and suggests that their absence may prove an important aid in the diagnosis. The cremasteric reflex is entirely absent and the other is profoundly modified. This is contrary to the usual ideas in regard to neurasthenia, according to which the reflexes are exaggerated. There are two methods of exciting the cremasteric reflex, one when the patient is in the decubitus dorsal and the other when he is standing. The latter is the most reliable. The patient should stand erect, facing the physician, and raise and hold his shirt himself. The slight effort this requires draws his attention away from the physician's maneuvers. It is best not to inform him of what is sought, but keep the conversation on indifferent subjects. The skin of the upper inner part of the thigh is then irritated with the nail of the right forefinger or the wire brush of the electric apparatus, *always from above downward*. As this is done the testicle on this side is at once drawn up toward the external inguinal ring. This always occurs in normal health and in children, Critzman states, and with equal energy on both sides, perhaps a trifle stronger on the left. It can also be excited by strong pressure with the thumb on a level with the ring of the third adductor or on a level with the internal condyle of the femur at the point where the internal saphenous nerve is in the groove separating the sartorius from the vastus internus. It fails to present itself in cases of varicocele of the spermatic cord, with relaxation of the scrotum, and in bilateral orchitis, in ataxia and hemiplegia, but it persists otherwise, even in cases of impotence not due to any organic lesion. In his nine cases in which it was conspicuously absent, the general health was good; the patients looked flourishing; there was no varicocele to be discovered nor relaxation of the scrotum, and they had never had double epididymitis. But they were all subject to hereditary neurasthenia, which manifested itself in the most various ways, as he describes at length in the *Presse Méd.* of December 12. He invites discussion of the subject and further confirmation of his assumption of the connection between neurasthenia and the absence of the cremasteric reflex. The bulbo-cavernosus reflex is produced by placing the left forefinger on the bulb of the urethra, while with the right hand the dorsal surface of the gland is irritated with the edge of a piece of paper, or by lightly pinching the mucosa, when the left finger perceives a more or less energetic shock due to the contraction of the ischium and the bulbo-cavernosus. This reflex does not show such decided modification as the cremasteric, but in the neurasthenic subjects examined it was either absent or very weak, or very slow in appearing.

Improved Suppositories.—The ideal suppository can not be made of glycerin, as this irritates the tissues more or less, while it is impossible to sterilize it satisfactorily. It often contains also products prejudicial to the tissues. Cocoa butter also fails, as it seems to be impossible to blend the medicaments with it in regular proportions throughout, some containing more than the required amount and some less, while it may be entirely absent from parts of the suppository. A new material has been found admirably adapted for the purpose, agar, used to such an extent in bacteriologic investigations. One part of the finely pulverized agar, heated in the water bath with 29 parts water for a few minutes, produces a gelatinous mass that pours out easily and hardens soon into a smooth, slippery, tenacious, resistant substance, which dissolves readily when used as a suppository. As it has an acid reaction, it is neutralized by the addition of 0.1 gram natrium bicarbonicum to

10 grams of pulverized agar. The medicine (which must be soluble in water) for the desired number of suppositories is put in a bottle with 1 part neutral pulverized agar and 29 parts by weight of water and the whole energetically shaken. The cork is then tied on tight and the bottle placed for five to ten minutes in boiling water. Paraffin paper has been found the best material for the molds. Small pieces of the paper, 4 cm. square, are rolled up in a cornucopia, the points turned up and the cornucopias set up in a frame made of light thin wood with two or three concentric plates, 5 to 9 centimeters in diameter, in which holes have been bored to receive the molds (about 3 mm.). The frame is placed in the scales and the hot agar mixture is poured into the molds. The suppositories are left in the paper molds until used. Some medicines that are not soluble must be rubbed into the pulverized agar first and then finished as above. Others, like tannin, are prepared without heat (tannin 1 part, mixed with pulverized agar 2 parts and kneaded into the suppository form with 7 parts water). Medicinal pencils and vaginal balls are made in the same way. Ten per cent. iodoform bougies are made by mixing 1 gram neutralized agar with 3 grams iodoform in a bottle and adding 29 parts water as directed above, pouring the hot mixture into suitably prepared paper mold in corresponding holes in the frame. Balls are made by pounding parchment or wax paper with a suitable stamp into round holes in a block of wood, and the hot mass is then poured into the paper cups thus made. (L. Lewin and Eschbaum, in the *Deutsche med. Woch.* of January 7.) Suppositories for the ears could also be made in the same way.

A Case of Cretinism Treated by Thyroid Extract.—Mr. Rushton Parker reports in the *British Medical Journal* the case of M. K., aged 8 years. This child's mother had congenital defects of cleft palate and hare-lip and underwent severe shock a short time prior to the birth of the daughter. In no other respect was there anything noteworthy in the family history—no goitre, no consanguinity, and the four grandparents living to a good age. During infancy it was noticed that she differed from other children in being always very still and quiet, in sleeping inordinately, and in never crying. Up to 6½ years of age she remained very stunted in growth, propped up all day on a chair, being unable to sit up or stand, usually very stolid, sleeping indefinitely, breathing very noisily and unable to recognize people or to speak. She was very cold, liking to be near the fire. Her actions were very slow, so that she would take a full minute to raise her arm when asked to shake hands. Her face was swollen, so that her eyes were often scarcely visible; her lips were swollen and livid; her tongue was swollen and livid and commonly protruding; the teeth were black and stumpy; the mouth seemed always full of phlegm; the bridge of the nose was sunken and the tip flat; the neck was thick, the thyroid gland quite imperceptible; there were soft swellings above the collar bones and similar masses outside the nipples; the limbs were short and stumpy, the belly was swollen and an umbilical hernia protruded to the size of a walnut. The hair of the head was not noticeably scanty or coarse. A five-grain thyroid tabloid was given every week-day in one dose for the succeeding six months, during which time the swelling gradually vanished from the tongue, then from the face, then from the body and limbs, so that in a few months her mother thought she felt quite a stone lighter, although she had grown some inches in height. On November 28, after twelve months' treatment, she had very much the appearance of any healthy child from 2 to 3 years of age, but being unable to talk, with the exception of saying a few simple words, and having several healthy permanent incisors, most of the old, black, stumpy teeth having vanished. The thyroid treatment caused no unpleasant symptoms whatever, so that it was never discontinued or the dose reduced; but the impression throughout has been that the child was taking just about as much as she could tolerate, being occasionally on the verge of diarrhea and feverishness.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the Association living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, FEBRUARY 27, 1897.

COMPARATIVE PATHOLOGY.

The fact that Chairs of Comparative Pathology have been established in Harvard University and in the University of Buffalo shows that more interest is being taken in this country in this subject, which is bound to throw much light on human pathology. It is the purpose of this article to point out some of the analogies between pathologic processes in man and those in the lower animals.

We find some affections occur only in animals, a small number are peculiar to man and some are rare in man though common in animals. "No matter," says QUATREFAGES, "which kingdom (animal or vegetal) they belong to, races have their pathologic characteristics as well as their external or anatomic ones; man is not exempt." Domestication and captivity are potent factors in the determination of disease processes. Thus wild animals are rarely attacked by the infections or intoxications, yet domesticated or wild animals in captivity are subject to nearly the same pathogenic factors as man. In the case of wild animals contracted space for exercise and inappropriate diet are responsible, in the case of the domesticated animals insufficient or inappropriated food and cramped quarters. For instance in the Faroe and Shetland islands the cattle and ponies are given dried stock fish when the supply of hay runs short. It is interesting to note that the more cultivated or "finer" the breed of domestic animals, the more liable it is to disease.

Beginning with the intoxications, animals in the

vicinity of chemical works may be poisoned by arsenic, lead or zinc, either from grazing on leaves or grass on which these fumes have settled, from drinking out of water courses contaminated by the discharges from the works, or possibly by inhaling the fumes themselves. The ox resists mercury less than the dog, and this animal less than the horse. The horse and dog on the contrary are more easily intoxicated by lead than the ox. Plumbism in the horse is attended by many of the symptoms noticed in man—gingivitis, nephritis, paralysis (CADIOT: "Traité de Pathogénie Générale," I, p. 103). On the other hand many animals are capable of resisting substances poisonous to man. Thus the herbivora may eat belladonna for some time without producing any evil effects, and rabbits may eat it until their flesh is so tainted as to be actually dangerous to man, yet show no signs of poisoning. So too, goats frequently eat stramonium, and ROBERT has shown that the hedgehog can take large doses of cyclamin, which is intensely toxic to man, without any untoward results.

As regards infections and parasites we find that the bacillus coli communis is found in the intestinal canal of nearly all mammals, and FLINT (JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Feb. 29, 1896) has shown that it occurs in some of the lower vertebrates, also, snake, frog, turtle. It frequently causes fatal diarrhea in rabbits when this microbe alone is found in the stools. Avian diphtheria seems to differ from the human variety by the absence of the KLEBS-LOEFFLER bacillus. Typhoid does not seem capable of transmission, though the bubonic plague is, and nearly all the accounts speak of the immense mortality among rats. Of bacterial diseases capable of transmission from animals to man or *vice versa* we find anthrax, hydrophobia, glanders and tuberculosis. While the first three of these are decreasing the last is increasing among men. Animals vary in their susceptibility to the tubercle bacillus; thus while it is frequent in the ox, and especially common in grain-eating birds, it is not frequent in the horse and pig, but somewhat more so in the sheep and goat. As regards monkeys it is now believed that its supposed frequency has been somewhat exaggerated. It has even been found in snakes on two occasions. This seems incredible, as these animals have their blood lower than the temperature necessary for the growth of the bacillus tuberculosis. BLAND SUTTON, who reports one of the cases, attributes it to the increased heat during the breeding season while the eggs are being incubated.

DANILEWSKY, some four years after LAVERAN'S discovery of the plasmodium, found similar organisms in the blood of birds, and GRASSI and FELETTI confirmed his observations, though among the domesticated species they were only able to find them in pigeon's blood. Recent researches of DANILEWSKY led him to

conclude that malarial infection both in animals and man is produced by a parasite of the blood, that it can be discovered in blood drawn from the vessels, and that these cytozoa give rise to the formation of melanin, which may be detected in the spleen, liver, bone marrow, etc. With regard to the larger parasites, whose name is legion, space forbids any detailed synopsis. Suffice it to say that tapeworms, round worms, flukes and hematozoa are all found in lower animals. No human parasite seems to inhabit animals, and but one of the animal parasites, *tænia cucumerina*, is at all frequent in man.

Malformations and monstrosities are also common; some varieties, as diprosopus, are more frequent in animals. According to ST. HILAIRE at least three-quarters of the known monstrosities belong to mammals, the other quarter to birds. Teratomata are common in fish, snakes and batrachians; even tapeworms have two heads, and various other monstrosities. VIRCHOW mentions an interesting malformation met with occasionally in Polish hens, which have large topknots. The roof of the skull under this topknot is sometimes wanting, and a sort of meningocele is formed. AS BLAND SUTTON points out, we have a condition here somewhat similar to *spina bifida occulta*, the feathery topknot corresponding to the tuft of hair found overlying the *spina bifida*.

Of degenerations it will be sufficient to mention the mucous, which may be called a physiologic process in fish, producing the slime covering their bodies more or less. In the group of myxinoids this is seen in an extreme degree; a species of *bdellostoma* of our Pacific coast with a slender body about twenty inches long, if placed in a pail of water, will quickly convert it into slime from the mucous glands on the sides of the body. Attention may also be directed to the fatty infiltration of the liver of "Strasburg" geese.

Nor are instances of hypertrophy and atrophy wanting. Good examples of the former may be found in the foot-pads of animals kept in dirty cages, or the hoofs of cows and horses in damp pastures or dirty stables, or again in the warts on the noses of animals grazing in stubble fields. A good example of the process of atrophy may be seen in the right ovary and oviduct of female birds; the chick has two at first, but the right atrophies.

The formation of tumors is frequently observed. According to CADRIOT (op. cit.), the dog is most often affected with neoplasms, then the horse, cat, ox, pig; they are somewhat frequent in birds, but in this group they exhibit special histologic characteristics. As in man, benign tumors are found in the young animal, sarcomas in the adult, carcinomas in the aged. Lipomas and myomas are rare, osteomata somewhat common, especially in fish. Odontomes are very common; typical specimens are often met with in gnawing ani-

mals and in elephants. Sarcomas are very common also and are met with throughout the mammals, also in fish and snakes. The melanotic variety is frequent, and many persons have probably noticed them in gray or white horses, where they form large masses around the anus. Cancer seems to be almost unknown in wild animals, but it is not infrequent in the domesticated species. FIELD has reported two cases in cats (JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Dec. 29, 1894.)

We now come to the general diseases. During the smallpox epidemic of 1894 in Chicago Dr. WARREN noticed the transmission of this disease to the horse and cat, including the formation of papules, vesicles and pustules (Report Dept. Health, 1894). A few weeks ago an epidemic of spinal meningitis was reported among the horses at Phoenixville, Pa., which was attended with a large mortality (*Medical Record*, Jan. 30, 1897). Rickets is common in dogs and carnivora in menageries from eating flesh with little or no bone in it. Gout is met with in birds and sometimes in reptiles. Osteo-arthritis is widely distributed. It seems to be the most frequent bone disease in animals. Rheumatism is met with in horses; animals imported into Japan from China and Corea are said by the *Sei I Kwai* to be invariably attacked and crippled by this disease. HARRISON narrates a case of chronic rheumatism in a giraffe.

Concerning special diseases those of the circulatory apparatus present the same lesions as in man. Race horses are often subject to cardiac hypertrophy and it is not rare to read of them dropping dead during races. A case of septic endocarditis, with vegetations at all the orifices, is reported in a calf five weeks old (Trans. Path. Soc., London, 1893). Pericarditis, with or without obliteration, is found even in birds, and HARRISON mentions purulent pericarditis in a young lion.

In the *Bristol Med. Chir. Journal* for December 1894 is an extremely interesting paper by Dr. A. J. HARRISON, in which he gives details of numerous necropsies on the wild animals dying in the Bristol zoologic gardens. Speaking of pulmonary diseases he states that monkeys are very susceptible to chest affections, and that he was struck by the very small ratio of lung tissue. "The lungs of monkeys seem to correspond very much with what we see about their antics, a succession of little movements, quick and often; a leap; a scramble, then a rest; a period of quick breathing and then a pause." This author also states that the large cats are very prone to inflammation of the lungs, and almost every postmortem examination shows evidence of recent or remote disease. Pneumonia in the domesticated animals seems to be of two varieties, one of which is contagious and is due to a microorganism isolated by SCHUETZ.

Lesions of the intestinal tract are numerous and

varied. Intussusceptions are common in dogs. HARRISON mentions a case of stricture of the colon and invagination in a brown bear. Hernia may be considered here; this is somewhat common in monkeys, sheep, horses and dogs. As BLAND SUTTON points out, it seems strange that it is not commoner in animals, for the funicular process remains patent in many of them.

Among diseases of the genito-urinary system may be mentioned nephritis, common in dogs, and paroxysmal hemaglobinuria in horses. Rupture of the uterus and difficult labor are also met with in the inhabitants of menageries. Many of the cases are undoubtedly due to contracted pelvis following rickets. Even venereal diseases are found; horses in France are sometimes affected with *dourine* or *mal de coït*, which is propagated by sexual intercourse and is very contagious. It seems to be but slightly analogous to syphilis. HARRISON mentions a case of rupture of an enlarged spleen in a lion following coitus, and LARCHER states that birds frequently have cerebral hemorrhage under such circumstances.

Nervous affections are more common in domestic animals and especially the "finer" bred dogs and race horses. Epilepsy in the goat was first noted by HIPPOCRATES; it is found besides in the horse, ox, pig, dog, cat, and in birds. Rabbits and roosters may be thrown into a cataleptic state by holding them steady for a few moments and drawing a line with chalk in front of their nose; frogs by holding them in the same position. Cretins are found among calves and dogs; the latter animals are also subject to dementia and chorea, and horses to acute mania. The Polish hens before alluded to, according to SUTTON, are given to performing circular movements and walking sideways if excited. Birds bear anesthetics very badly. HARRISON mentions a cockatoo which died under chloroform, and the writer has seen two similar cases in a canary and parrot.

The lower animals are not without their vices; for example, many monkeys are addicted to masturbation, also dogs. It is also seen in stallions and bulls, and cock turkeys are said to make use of round stones for this purpose.

We learn from this array of facts that the same rules governing disease processes in man govern those in the lower animals also.

THE PROBLEM OF POPULATION.

The "depopulation" of France, as it has been called, has brought out within the last two or three years a considerable amount of social theorizing in the secular press, and this has to some extent invaded the current medical literature, which as a rule leaves economic questions alone. The subject of population, however, which is one of the most important social questions, has also its medical bearings, and can be treated

more freely and fearlessly in some respects from a medical than from a purely economic standpoint. As regards France, the problem is a simple one; there is no question as to the fertility of the Gallic people, the evidence of the conditions in Canada is sufficient to prove their virility. In France the lowered birth rate is without much doubt the natural result of the saving and thrifty tendencies of the mass of the French people. If France had not the largest public debt in the world, and if this was not held by its own people in minute subdivisions, and further, if instead of the general heirship of all the children, some law of primogeniture or other expedient of inequality was the rule, it might again reach its old birth rate and the fears of its statesmen be allayed. The present difficulty in France is a direct result of economic conditions, their civilization has reached a static phase as regards population, and this is due in this special case to the general well-to-do condition of its people. They are, with of course lower ideals of comfort and standards of living, more generally than any other people, in the creditor class, and, as in that class in other lands, their birth rate decreases.

The prevalent militarism at the present time, the law of universal service, with its results in the way of delayed marriages, the extension of sterilizing venereal diseases, etc., though it undoubtedly has its part, can not be properly credited with the reduction of the death rate to any great extent, for it notoriously has no such effect in other European countries where the same conditions prevail in this regard. In Germany there is no marked decrease of births, and the population increases in spite of emigration; nor are any such complaints as those from France, heard from other quarters in Europe. Her ailment seems to be peculiar to herself and it is believed that the reasons given are the correct ones to account for it.

It is more than probable that the methods by which the result is brought about directly are not all such as can receive medical approval. Of course there is no such state of affairs as prevails in some Oriental countries where the courtesan is an honored member of society and infanticide is legitimized; but there must be a certain social demoralization that is more or less disastrous to society, altogether apart from the national enfeeblement in fighting material, if population is repressed by general practices of any kind that interfere with the order of nature. The present state of affairs in France, and it may be to some extent locally elsewhere, is certainly not a satisfactory one, and so far as it may be due to a moral dry-rot, and a spread of any kind or form of sexual vice, is most unsatisfactory.

The present tendency in civilization to the growth of great cities is bound to have a deleterious effect upon the population. It has been said that "Paris is France," and this may suggest a theory of French decadence.

The same causes however exist elsewhere and it is not impossible that the same evils may follow them.

The medical bearings of the subject are sufficiently obvious, and it is probable that the remedy, if there be one, will have to be administered largely by the aid of the medical profession in educating the public, encouraging correct notions upon certain matters of sexual morality, and generally pointing out the proper ways of conduct and living. The idea of marriage is, or should be, connected with that of the family and where they are separated one of the greatest stimuli to progress is done away with, and when a nation or a people, as a whole, shirks the struggle for existence in this particular, when fatherhood or motherhood is not looked forward to as the most desirable result of sexual union, then that people may expect sooner or later to yield to some more virile race in the struggle for national prominence or national life. It is unfortunate for France that economic conditions have so apparently hastened or temporarily produced this symptom of decadent or senile civilization.

PHTHISIS WARDS IN ITALIAN HOSPITALS SIX DECADES AGO.

The contagious nature of phthisis was an accepted doctrine with the Irish Royal College of Surgeons and the Scotch and continental schools with which it was in affiliation, nearly two centuries ago. The opinion as to the contagious nature of phthisis lasted longest in Italy and Spain. In Naples no one could conceal phthisis under penalty of three years at the galleys for common people and three years imprisonment and a fine of 300 ducats for the nobility. A physician who failed to report phthisis was liable to a fine of 300 ducats for the first offense and a banishment of ten years for the second. To aid a consumptive in the invasion of quarantine was punishable by fine and six months imprisonment. In Spain and Italy consumption was literally a "terror" to the community. In 1839 GEORGE SAND traveled in Spain with CHOPIN, the musician, then affected with the phthisis, to which he succumbed a decade later. On installing themselves at Majorca, SAND writes:

"At the end of a month poor CHOPIN had called in a physician, two physicians, and even a third, each a greater ass than his colleagues, if such a thing be possible. Each went away spreading the news throughout the island that the stranger was a consumptive in the very last stage. And what a commotion it caused! Phthisis is very rare here and is generally considered contagious. We were regarded literally as pestiferous, all the more as we did not attend mass. The proprietor of the little house that we had rented, brutally put us out of it and brought a process against us to force us to rehabilitate the reputation of his house contaminated by our presence. The indigenous magistracy pluck us as though we were chickens."

At Barcelona new trials and tribulations awaited them. On leaving the hotel, CHOPIN had to pay for the bed and bedding he had occupied, which were

seized and burned by the police. In a letter (dated at Rome, Nov. 6, 1802) in which CHATEAUBRIAND announced to FONTANES the death of Madame DE BEAUMONT, the following passage occurs:

"For the balance I am very much embarrassed. I had hoped to save a couple of thousand crowns from the sale of my carriages, but by law dating back to the time of the Goths, phthisis is declared a contagious malady here in Rome, and as Madame DE BEAUMONT had ridden in them a few times (twice or three times only) nobody will purchase them."

The room in which poor KEATS died was treated in like fashion.

The Italian hospitals had isolation wards for phthisis. Of them, Dr. A. L. PIERSON wrote six decades ago (*Medical Magazine*, April, 1834).

"The patients with tubercular phthisis are separated from the rest by being placed in a separate ward, in a building having a small court-yard to separate it from the principal edifice. The belief in the contagiousness of the disease is as predominant at Naples as at Rome. In both cities it is customary to sacrifice the clothes and furniture used about the sick, and even to scrape the walls and tear down the woodwork of the chambers in which they have been sick. But if consumption be contagious, how perfectly inadequate is this protection by separation. For multitudes who occupy beds in other parts of the hospital on account of other diseases are tuberculous, and consequently must be poisoning the air with phthisical emanations. I was indeed astonished at the number of consumptive patients which this hospital contained. Nearly one hundred beds were occupied by cases of confirmed phthisis. One can hardly realize that so much has been said and written to recommend this city as a residence for consumptives, when some of the best informed Neapolitan physicians estimate the deaths by consumption among the residents at one-fourth of the whole mortality. A separate ward for consumptives is terrifying enough to those who enter it and might well bear the inscription: 'Let him who enters here leave hope behind.'"

THE PLAGUE AND FAMINE OF INDIA.

The varied correspondence from Bombay agrees upon the proportions of the visitation, with the telling commentary that the sanitary conditions are not improving. From Bombay the report comes that "the natives employed in the shops were the first victims. In one large German establishment three natives only out of eighteen remain. The rest are dead; and the Europeans are already beginning to drop off. The plague advances."

In that city the death rate has become quadrupled over the ordinary, when the population counted up to 800,000; now also the panic has become of the wildest. "Several native quarters in the city are absolutely deserted. The cotton mills, that employed thousands of hands, are closed. Merchants and business men have all disappeared, and both importation and exportation have completely stopped. From morning till evening," continues the account, "there is a procession of funerals; and in the evening the sky is reddened with the fires that consumes the bodies. An absolutely terrifying spectacle is presented at the Queen's Road Square, where the Hin-

doors burn their dead. For a considerable distance we can see the huge columns of smoke and hear the wails of the relatives, the lugubrious sound of the cymbals, and the crackling of the blazing wood."

As regards the famine, the same drama of horrors, with the more or less spectral details, possesses the stage. The famine belt is roughly computed to be 1,300 miles long and 400 miles wide, while a fresh food supply is impossible until September. Add to this as evidence of almost incredible vitality that individual adults not infrequently descend in weight to less than fifty-six pounds. "Mere skin-covered skeletons," is the graphic phrase employed.

CORRESPONDENCE.

The Object of the Berlin Leprosy Conference.

NEW YORK, Feb. 16, 1897.

To the Editor:—In a correspondence with Dr. Goldschmidt, December, 1895, a plan was devised by the writer for the formation of an International World's Committee, composed of delegates of all governments. This plan was submitted to Dr. Hansen, who approved of it, and submitted it to the Norwegian government through his chief, Dr. Holmbos. The answer came back that before Norway issued the invitation, it was necessary to obtain a general opinion of the leading leprologists. Dr. Hansen said that his government would probably ask a credit of parliament for the expenses of the Congress.

The Provisional Committee was formed of Goldschmidt, Hansen and Ashmead. The plan was explained to the public in medical newspapers, and was brought to the attention of the leprologists through private correspondence. It seemed to be generally approved. It remained to determine the seat of the Congress. Here there was a divergence of opinion. Some were for Bergen, others for London. Moscow was proposed also, especially as there was to be there a general medical Congress.

When we had brought the matter so far, suddenly Dr. Ehlers started a committee of his own. It seems that before we had thought of a Congress he had, perhaps two years before us, revolved in his head, "while investigating leprosy in Iceland," a plan for some kind of palaver, or learned talk, between *renowned* leprologists who, giving their opinions either in German, or English, or another language, would by their eloquence destroy the scourge of leprosy. Anyone will admit that there was not much originality in the idea.

He succeeded in forming a committee in Berlin, and persuaded Dr. Hansen to go with him. They issued an invitation to a debate.

Our idea was, and always has been, that the only way to combat and eventually destroy the dreadful scourge, was the isolation of lepers, enforced by law. In one generation, leprosy not being hereditary, the victory would be complete. Remedy for the disease there is none. Experimentation with the bacillus for twenty-five years has resulted in nothing. The disease is certainly contagious, and spreads only by contagion, directly or indirectly. Therefore isolation alone can conquer, and no learned talk, no amusing communications of experiences, are of any use. Any man who really, as a physician and a philanthropist, wants truly to fight the dreadful enemy, must stand for isolation. Salaries may be gained, high positions may be occupied, commissionships may be enjoyed, the honor of being sent as delegates to conferences, or other palavers, may be obtained, and, though a number of *renowned* leprologists, whose works are *known*, will become still more

renowned and their works still better *known*, yet leprosy will continue to gnaw at the vitals of the race.

Dr. Ehlers speaks of the "capacity of discussing a good cause." This is, in his opinion, all that is wanted in Berlin. As if that good cause had not been discussed by men even greater than Dr. Ehlers himself for 2,000 years!

We wanted to *do something*; they come together to talk.

Dr. Ehlers says that the governments are only invited to send delegates, but that these delegates will have no special function in the Berlin Conference.

That is, every active means against the disease must be avoided like poison, and nothing but talk is to take place, absolutely nothing but talk. It is a conference to amuse us fellows, us leprologists, not at all to destroy the most horrible punishment that ever nature has put upon mankind.

Dr. Ehlers says that he has "no use for governments," because they have always neglected the holy name of hygiene. But we wanted only that, and did not think, and do not think now, that anything can be done except by "stirring up the governments." Does Dr. Ehlers really believe that talking is better than "stirring up the governments?" Can the disease be stopped in Iceland in any other way than by the operation of the Danish government? Will they stop it by the talk and reciprocal compliments in Berlin? The doctor himself in his *known* works, says that in no other way can leprosy be conquered in Iceland except by isolation. But these things seem to be expected to happen, only a hundred years after the Berlin Conference has met, and the great talking has come to an end.

Until our great grandsons see that happy ending, let us talk and discuss, and enjoy the company of all the *renowned* leprologists, and praise their celebrated works. Talk is the order of the day.

To put our opinion in a few words: We want to have official delegates from every government, to meet at stated intervals, who will form a permanent committee.

We declare at once that we are contagionists, and that we do not believe that anything but absolute isolation can destroy a disease which afflicts nearly a million of human beings. Such a committee can not but be for isolation. In this respect, we are intolerant. We are also intolerant in this: We condemn every effort that is made against vaccination. We are for vaccination as we are for isolation. We confess to be entirely intolerant in this respect.

There is to isolation but one great opponent today, it is England. The maintenance of her 200,000 Hindu lepers, not to speak of her West Indian and other lepers, would be an enormous expense. England is opposed to isolation from utilitarian considerations. Recently, as Mr. Jonathan Hutchinson tells me, measures for the isolation of lepers in India were withdrawn from Parliament because of the opposition which he led against them. His opposition was certainly not of a scientific, and still less of a philanthropic character.

The Berlin Conference will meet, the Berlin Conference will go. It will have been very interesting; it will be, as Prince-Bismarck said to the Battenberger, "a pleasant thing to remember afterward," but there will be at least (probably much more than) 200,000 lepers in India, 100,000 in China, 100,000 in Japan, 27,000 in Colombia, 5,000 in Russia, 3,000 in Brazil, 500 in Cuba, 500 in the United States and 159 in Iceland, the place where Dr. Ehlers has had his only experience of leprosy, and where he prepared himself for the palaver which is to take place in Berlin, October, 1897. There the world will be told by several *renowned* leprologists how the leper problem can be solved without isolation; but if the numbers quoted above are not increased at the time when all that science becomes public, I shall be very much astonished.

Very interesting theories will no doubt be expounded. If Dr. Wernich were living, he would, if he had not changed his

mind since he wrote on leprosy in Japan, explain how the disease arises from a depravity of digestion, caused by the excessive absorption of rice. He, I suppose, is one of the *renowned* leprologists whose works are *known* to Dr. Ehlers, and it is to be hoped, for the amusement of all the scientists who will meet in Berlin, that there are still other men living who possess no less imagination than Dr. Wernich.

We do not care very much about the greater or less renown of a leprologist; this is absolutely of no account in our business. We might say that Dr. Hansen is the greatest of leprologists, because he chanced to light on the bacillus. Yet the discovery of the bacillus has not saved one human being, has not diminished the sufferings of a human creature. If a thousand leprologists, as great as Hansen, meet, they will not do more than Hansen himself has been able to do. Not any of the *known* works of the learned gentlemen can do more than the discoverer of the bacillus has been able to do. All that the greatest of leprologists has been able to do, was done by isolation, imposed by his own government, and independently of the bacillus, and *without palaver*.

ALBERT S. ASHMEAD, M.D.

P. S. In a letter dated Nov. 16, 1896, to Dr. Goldschmidt of Paris, Dr. Ehlers, the Secretary of the Berlin Leprosy Conference Committee, said "that he could assure him that Dr. Hansen had never approved the project of Dr. Ashmead, and that the latter acted without any kind of authority from the Norwegian government, and even without the formal authorization of Dr. Hansen."

In a letter to me dated Sept. 4, 1896, Dr. Hansen says: "I should best like if you and Dr. Goldschmidt alone took the task of convoking the Congress on your shoulders; but should you think it very desirable to have my name, you may use it, but on the condition that the Congress is only regarded as arranged by us. If the Congress then will meet in Bergen, I hope still that the Norwegian government will pay the business matters; the best would be, if the participating governments each paid their tribute.

"If the Congress shall not be secured without its help, the government will probably ask a credit to furnish the Congress with a secretary, local (place), for the meetings, and other matters of business."

This shows conclusively, I think, that Dr. Hansen permitted the use of his name on our provisional committee, and gave us warrant to use the name of his government.

ALBERT S. ASHMEAD, M.D.

"Independent Medical College" Mill.

TECUMSEH, MICH., Jan. 8, 1897.

To the Editor:—I inclose you what purports to be a medical journal. It certainly is the rankest thing I ever saw. Is it not likely that it is the child of the Wisconsin Eclectic Medical College? You will notice that the editor is J. Armstrong of Chicago. I have looked him up in Polk's Medical and Surgical Register of the United States, 1896, and find that he lives at 683 W. Van Buren St., but following his name is the little star that refers to the following note at the bottom of the page: "No report received in answer to inquiry regarding graduation." J. H. Randall, Ph.D., M.D., is given as associate editor, but his name does not appear at all in Polk's Register and I mistrust he is a myth. I am lead to this belief by comparing the name, with those given on page 14 in the article, "Report of Proceedings of the United States Medical Liberty League." It is stated that several persons met to organize the league in response to invitations of the faculty of the Independent Medical College, and in the proceedings the names of five M.Ds., are given, namely: J. Armstrong, Mary E. Sellen, C. K. Drumheller, A. J. Clausen, J. H. Randall. The first two are given in Polk's Register. Mary E. Sellen is or was a resident of Columbus, Ohio, and her school of practice is given as "Sci.," if any one knows what that is. The names of the other three organizers of the United States Medical Liberty League can not be found in Polk's Register anywhere in the United States.

I have no doubt that J. Armstrong and Mary E. Sellen are the prime movers and that they are the officers and members of the league. On the last page of cover is an advertisement of the Independent Medical College, which announces that "This school advocates a new and successful method of acquiring a medical education." The names of the members of the faculty are not given if there are any, but as the announcement is the baldest possible bid for the sale of diplomas without college attendance, and as the journal is avowedly opposed to all medical legislation, it is almost certain that J. Armstrong and Mary E. Sellen are "the journal," the league and the college, all in *two*. On page 16 are the opinions of doctors who have read No. 1 of the *Medical Liberty News* (this copy is No. 2) and have words of commendation for it. There are just six of them, and three of them have the suspicious and tell-tale star following their names in Polk's Register, and the names of the other three do not appear at all. The object of the "Liberty league" seems to be to organize and raise funds to oppose all medical legislation and in case any member of the league is prosecuted for illegal practice to help him with funds and prestige. On page — occurs this fine statement: "We also declare persistent and uncompromising warfare against the practice of *vivisectioning live animals*."

I send the pamphlet to you in the hope that you will put it into the hands of the proper officials and that they can by legal means shut up the "diploma mill" at least. Their journal and the "league" are beyond the reach of the law, I fear.

I am very respectfully yours, L. G. NORTH.

Massage.

CHICAGO, ILL., Feb. 15, 1897.

To the Editor:—In the JOURNAL, issue of Jan. 9, 1897, there appeared a part of a serial article on "Massage," written by myself, which was "to be continued." As the continuation did not appear, I wrote to you about February 12 inquiring the reason thereof and received from you the following reply:

"Dear Doctor:—I have your letter of February and have to say that after publishing the first part of your article we had a protest from Dr. Douglas Graham, in which he claimed that a large portion of the history of massage was taken from his book, a charge which seems to be sustained, etc."

1. Now, as a matter of fact, I did quote Dr. Douglas Graham some and wherever I did I think I gave him credit for it. I did not put his name at the end of each line, but at the end of certain articles. If I should have neglected to do this in any instance it was an oversight and I beg pardon of Dr. Graham.

2. I challenge Dr. Graham to prove that the "Ancient History of Massage" as I have written it is *entirely original with him*, and I will prove to him that there are a score of books on the subject by other authors who use language similar or like it in part. Dr. Graham can not quote ancient history and call it his own.

3. Get a number of books on any subject (medical), as surgery, for instance, and does not one author quote the other or a dozen others?

4. I do not know as I quoted Dr. Graham any more than other authors; if I did, then he ought to be proud of it.

Since when is medical literature private property?

Respectfully yours, JOHN KERCHER, M.D.

Embryonic Specimens Wanted.

BALTIMORE, MD., Feb. 20, 1897.

To the Editor:—During the last ten years I have appealed to physicians from time to time to send me the human embryos which fell into their hands, and have in this way procured some very valuable specimens. These specimens have been cut into sections, and are now being modeled and studied very carefully. Yet a number of important stages are still wanting, and I therefore ask through your columns that physicians send me any material which they may obtain.

The best method to preserve human ova is to place the unopened ovum, without handling, and as soon as possible, in strong alcohol. By this method the embryo within is well hardened for future microscopic study.

It is very injurious to wrap these delicate specimens in cotton before sending them by mail or express. A perfect method is to place the preserved specimen in a bottle filled completely with alcohol, thus imitating the condition of a *fetus in utero*. If there be no air or cotton in the bottle, it is almost impossible to injure the embryo by shaking it. Very sincerely yours,

FRANKLIN P. MALL,
Professor of Anatomy, Johns Hopkins University.

Spitting in School Rooms.

PHILADELPHIA, PA., Feb. 4, 1897.

To the Editor:—If the numerous articles that are being published throughout the United States in the leading newspapers are true; that is, that tuberculosis is an infectious disease, and one of the most dangerous ways of spreading the disease is through the spittle, do you not think the placing of steam or hot-water pipes, coils or radiators in a school room where fifty or sixty pupils are congregated for hours, is highly unsatisfactory? The spitting upon the floor in a school room by teachers or pupils whose antecedents were infected with tuberculosis seems to us would dry, become finely powdered and, as all of the air in a room must go to the radiating surface to be reheated, would be the means of thoroughly distributing the germs of that disease. Possibly this is true of other diseases, such as diphtheria, scarlet fever, smallpox, etc. What is your opinion on the subject? Respectfully yours,

THE SMEAD & WILLS WARMING AND VENTILATING CO.

The "Surfeit."

ATLANTA, GA., Feb. 14, 1897.

To the Editor:—Will the erudite editor of the JOURNAL kindly inform me what is meant by the term "surfeit," as applied to the affection to which the death of medieval monarchs was commonly ascribed? We read that Henry VIII died of "a surfeit"; was this his malady, or is it a vaguely facetious reference to his uxoriousness?

BERNARD WOLFF, M.D.

ANSWER:—Crapula (or *cræpula*). It is also *κραίπαλη*, a surfeit. A disorder from something taken into the stomach, and occasionally a sickness or at least a loathing of the offending matter. It sometimes signifies a plethora from indulgence and full but improper feeding, in which case perspiration is checked and eruptions formed on the skin. It is sometimes called the *cholera accidentalis*.—Bartholomew Parr's "London Medical Dictionary," 1819.

The Various Quoted Stanza Again.

To the Editor:—Many years ago I picked up in London an old volume of medical rhymes published in the last century, and in this "God and the doctor" ran thus:

"God and the doctor we alike adore,
Only when in danger, not before,
The danger o'er both are alike requited,
God is forgotten and the doctor slighted."

This is certainly another verse than any quotation so far given in the JOURNAL.

W. S. CALDWELL, M.D.

PUBLIC HEALTH.

Vaccination in Afghanistan.—The *Gaz. d. Osp. e d. Clin.*, January 5, states that Miss Lilius Hamilton, special physician to the Emir of Afghanistan, has succeeded in impressing upon her royal client the importance of preventive vaccination. He has ordered the necessary steps to be taken to introduce it into his domains, with Miss Hamilton in charge of the service. More than a fifth of the children there die every spring from smallpox, and the country will owe a large debt of gratitude to "Jenner's valorous proselyte," when such ravages cease.

Epidemic Icterus.—G. Mori publishes a study of an epidemic of thirty cases of icterus at Chiusi, in the *Gaz. d. Osp. e d. Clin.*, of January 10. His conclusions are that it was caused by some infective agent belonging to the same category as the microbe of malaria, and that this agent entered by the mouth and produced a duodenal gastro-enteritis. The toxic products of this infection then affected the main biliary passages, from the portal vessels to the hepatic cells, resulting in icterus.

Is Consumption Disappearing?—Dr. Arthur Raneoms, of Manchester, England, thinks that "if phthisis were to continue to diminish in prevalence at the same increasing rate of decline for another thirty years it would then have entirely disappeared. The first great drop in its rate took place in the decade 1840 to 1850, about the time that serious attention began to be given to sanitary reform and especially to land drainage. It then remained scarcely reduced for about seventeen years; but from 1867 to 1894 it has been steadily on the decline. It is in this period that most of the great sanitary work has been carried out in this country." Surely here is an indication in what direction an effort should be made toward stamping out a disease which is said to carry off one-seventh of the human race. One would think insurance companies would be the first to promote a reform of this character, but they will not. Their method of covering a risk is to charge an extra rate. There is no extra rate against death from consumption.—*Medical Examiner*.

The Anti-Cholera Serum of Kitasato.—The *British Medical Journal* has an annotation regarding Kitasato's work in regard to cholera prevention, from his assistant bacteriologist, Dr. Nakagawa. The latter reports the results of the serum in one hundred and ninety-three cases. The former rate of mortality (among Japanese) has been about 70 per cent. In these cases the percentage was lowered about 20. The subsidiary results are similar to those of diphtheria antitoxin: 1. Urticaria, very common. 2. Arthralgia, observed in only eighteen cases. 3. Myalgia in six cases. The difference in prognosis, according to the time which had elapsed before coming under observation, is shown as follows: Less than eight hours, no deaths; eight to twelve, 22.2; twelve to twenty-four, 32.1; twenty-four to forty-eight, 39.7; forty-eight to seventy-two, 38.7; over seventy-two, 31.1 per cent. mortality. Three cases were observed in children under two years of age.

Cholera in England.—A note of alarm has been struck by the news that a transport with cholera on board had arrived at Plymouth Sound. It is questionable how the infection got on board, but most probably it was conveyed from Port Said by the fruit purchased there. Probably in any other country but Britain the disease would have been landed and gained ground, but here Dr. Williams, with Surgeon-Major-General Hamilton set to work and took immediate and perfect precautions. The excellence of our medical officers of health can not be overestimated. Our readers may remember that in 1892, although thirty-five cases of cholera reached these shores, it did not spread in one single instance. We do not think England will ever be again visited by such terrible epidemics as those of sixty or less years ago; the medical inspection arrangements are so perfect and our system so excellent, despite the silly people (some of them members of the medical profession) who "rush in where angels fear to tread" and advertise their stupidity by trying to create panics. Our present arrangements are not merely for infected parts, but they provide for careful watching over possible far away centers of infection. They are in every way practical and far above the extraordinary mystical performances (called "hygienic") of continental countries.—*Medical Times* (London), January 23.

The Death Rate of London in 1896.—The total number of deaths in London in 1896 was 81,721, with a rate of mortality of 18.2 per 1,000 living; the population was estimated on July 1, of

that year, at 4,421,955. The deaths of infants under one year were in the proportion of 160 in each 1,000 registered births. The death rate in London was lower in 1894, at 17.4 per 1,000; and in 1893 and 1895 at 20.9 and 19.4, respectively. Measles cost 3,692 lives, diphtheria with croup, 2,663, whooping cough 2,931, scarlet fever only 940, enteric fever 564, typhus 5, diarrheal diseases 3,192. The mortality by measles, diphtheria and whooping cough was in excess of the average of the ten years last past; that by variola and scarlet fever was lower. The death rate from all causes, at 19.4 per 1,000, with only two exceptions, is the lowest on record for that city and was 1.6 per 1,000 lower than the ten years' average. Of reportable diseases, smallpox had 225 cases with 9 deaths, scarlet fever 25,647 cases, diphtheria 13,808 cases, measles and whooping cough sickness cases are not registered, membranous croup had 446 reported cases that are included in the total for diphtheria, enteric fever 3,190 cases, erysipelas 6,436 cases, puerperal fever 277 cases. Total report cases 49,705. Work done by the medical profession, in the way of report making, not much under 131,426 cases, and certificates of death, not a small item.

Bovine Tuberculosis in New York.—The action taken by the Health Department of New York City regarding tuberculous cattle and the milk supply is of considerable importance to that community. It has been found that 15 per cent. of the 1,500 cows within the limits of this municipality were diseased and killed by order of the Board. The herds in the great dairy districts of the State are doubtless, equally with these, purveyors of the bacilli of tuberculosis to the people of that city and of all the other cities and towns of the State. In the face of these facts the Legislature has failed thus far to appropriate money for the protection of the people against this great menace to the health of this and future generations. The State Board of Health stands ready to co-operate with local boards in this matter, but can do nothing without funds for the employment of experts and the compensation of cattle owners whose animals it is found necessary to destroy. The time has come when the people should demand that this preventable disease should be stamped out, and whenever such demand shall be made we believe it will be heeded.—*Medical Review*, January.

New Instructions for English Vaccinating Officers.—New instructions have been issued by the Local Government Board, relating to public vaccinators, the following paragraphs being substituted for those similarly numbered in the schedule of the previous order: (5) "Endeavor to maintain in your district such succession of cases as will enable you to vaccinate with lymph directly from arm to arm at each of your contract attendances. When stored lymph, whether humanized lymph or calf lymph, is used, it should be preserved either dry on ivory points thickly charged and constantly well protected from damp; or liquid in tubes hermetically sealed at both extremities. With all stored lymph caution is necessary, lest in time it have become inert, or otherwise unfit for use." (6) "Consider yourself strictly responsible for the quality of whatever lymph you use or furnish for vaccination. In storing lymph, be careful to keep separate the charges obtained from different subjects and to affix to each set of charges the name, or the number in your register, of the subject from whom the lymph was derived. Keep such note of all supplies of lymph, whether humanized lymph or calf lymph, which you use or furnish, as will always enable you to identify the origin of the lymph. Do not employ lymph supplied by any person who does not keep exact record of its source."

Antisepsis in the Treatment of Infantile Diarrhea.—The part played by bacteria in the production of the diarrhea of infants was suspected and practically admitted by many long before the researches of Escherich and others had established this theory of its origin upon a scientific basis. According to the

observer just mentioned, the two forms of germ life most active in the diarrhea are the production of bacterium coli and the bacterium lactis. The influence of the latter will suffice to explain why it happens that a large number of cases of infantile diarrhea—we might almost have said all such—become amenable to treatment when the usual milk dietary is reduced, or even for a short time discontinued, in favor of one consisting of fresh raw meat juice. The bacterial hypothesis explains also the success which has in a number of cases attended the temporary discontinuance of all nourishment and the substitution in its stead of boiled and subsequently cooled water given frequently in small quantities. This method, which has recently attracted some attention in France (*Journal de Clinique et de Thérapeutique Infantile*, January 14), is not altogether novel. Its *modus operandi* in cleansing and procuring rest for an overwrought bowel while maintaining blood pressure by its ready absorption calls for little explanation. Something also remains to be said in favor of the procedure, often successfully employed in the case of dysentery, which obeys the same teaching, and by combining a sedative with an excitant of the liver aims at producing by means of the bile the moderate action of an antiseptic force which is resident in the body itself.—*London Lancet*, January 30.

Lack of Consistency of the Royal Commission on Vaccination in Great Britain.—At the last council meeting of the Epidemiological Society, held on Jan. 15, 1897, it was resolved to submit a resolution, in reference to the recent report of the Royal Commission on Vaccination, to the next ordinary meeting for adoption, in tenor somewhat as follows: That this society while noting with satisfaction the pronouncement of the Royal Commission as to the value of primary vaccination, and the necessity for maintaining it, regret that, although the report also brings forward conclusive evidence as to the value of revaccination, the Commissioners have not had the courage of their conviction and recommended legislation which would place it on the same basis as primary vaccination. The Epidemiological Society in former years took an active part in the question of vaccination, and its carefully prepared report on the subject was of material assistance to the Legislature in framing the Vaccination Acts. Doubtless the increasing proof of the need of revaccination as a protective which the experience of later times has brought may have weighed with its council in submitting the above resolution to the society. If it does nothing more it will at any rate show that those who have the best opportunities of judging the question are persuaded of the importance to the community of securing a system of revaccination comparable to that to which Germany owes her immunity from smallpox.—*London Lancet*, February 6.

Model Buildings for the Tenement House Class.—The City and Suburban Homes Company of New York, incorporated in July last with a capital stock of \$1,000,000, which is said to have been more than fully subscribed, is founded for the purpose of supplying improved dwelling places to wage-earners. The first block is to be on a plot of ground between Tenth and Eleventh Avenues and Sixty-eighth and Sixty-ninth Streets. Each building is to be 100 feet square, and of the 10,000 square feet 3,000 are to be given up for light and ventilation; each is to have an interior courtway 30 feet square, and in a block 200 by 400 feet an east and west courtway 20 feet wide runs through the entire block. Each building is to be divided into four compartments by walls from cellar to roof; the construction is to be slow-burning, and the stairways are to be fireproof and brick inclosed. The *Independent* says: "The tenement does not merely repress, it destroys. Transfer to it the most intellectual and refined family in America and in the course of a few generations—provided the usual condition of complete helplessness were added to poverty—the process of degeneration

would be completed. The sole real reform of the tenement is its abolition; there is no middle stage. The architect of the first block of improved dwellings expects to be able to show that the construction of separate dwellings upon the usual city lot is a senseless waste of ground-area in walls, and makes proper lighting and ventilation impossible; while by building in common upon such lots the waste in walls can be minimized, more space for light and air can be had, no rooms need be dark and interior open spaces can also be had. A reach beyond improved tenements is also intended; suburban homes in the shape of detached and semi-detached cottages are proposed along rapid transit lines. The purchaser is to pay down 10 per cent. of the price, having ten to twenty years for the remainder; an interesting feature is that the company will insist on insuring the purchaser's life, at its own expense, as a guarantee to his family. It would be insincere and idle to pretend that decent dwellings are as profitable to the owner, in money, as the abominable tenement has been or could be; it is for the law to say and see that the latter profit shall cease to be. But decent dwellings can be reasonably profitable; happily, there is no room for doubt about that. They are a fair investment and capital need not fear to take counsel of philanthropy."

NECROLOGY.

ABRAM VAN NEST BALDWIN, M.D., College of Physicians and Surgeons, New York, 1882, died from pneumonia at his home in New Brunswick, N. J., February 14. He was a son of Dr. Henry R. Baldwin and was born Nov. 16, 1858. Among the positions held by him were the Secretaryship of the Health Board, of which he was also a Sanitary Inspector, and held a membership in the Board of Education, his second term of service. He was a man of much industry and promise.

RALPH ERSKINE SWINBURNE, M.D., Bellevue, New York, 1877, died of acute atrophy of the liver, at his home in New York city, February 14. He was born at Rouse's Point, New York, Dec. 27, 1853 and came to New York in 1874, beginning general practice in Fordham, when it was a far distant suburb. In 1879 he came to Harlem (N. Y. city), and devoted himself to diseases of the eye, ear, throat and nose, believing that they were more satisfactorily treated in groups, than by the current methods. In 1881 he founded the Harlem Eye, Ear and Throat Infirmary, of which he became chief surgeon. He was also consulting ophthalmologist of the J. Hood Wright, formerly the Manhattan, Hospital. He was a member of the Academy of Medicine, of the County Medical Society, and of the Harlem Medical Association. He was a nephew of the late Dr. John Swinburne of Albany, N. Y., after whom the artificial quarantine island was named, and who for some years was Health officer of the port of New York. A daughter by his first wife, a son and second daughter born six hours previous to his death, together with the mother are his survivors. His mother is also still living.

SATURNINO M. JIMENEZ, M.D., Jefferson Medical College, 1878, was a son of Antonio Jimenez, a planter of Mantanzas, Cuba, where he was born in 1851. After a distasteful trial of the shipping business in this country he began the study of medicine, and after his graduation went to Paris. After a year spent in that city he returned to Philadelphia to enjoy the benefits of the hospitals there but finally came to New York to manage the practice of a friend who was compelled to go to Europe for his health. He was a member of the Marti Relief Association and was well known in the Cuban colony. The date of his death was February 17.

S. GRATZ MOSES, M.D., Medical Department University Penn., 1835, died in St. Louis, Mo., Feb. 22, in his 85th year. He was a Pennsylvanian by birth and before going to St. Louis was physician to Joseph Bonaparte, the elder brother of

Napoleon. As a member of the AMERICAN MEDICAL ASSOCIATION he was well known, particularly in its earlier history. He has the credit of having established the first dispensary in St. Louis.

HENRY A. CREAMER, M.D., Bellevue Hospital Medical College, New York, 1892, died in Brooklyn, N. Y., aged 25 years, on February 20. He was the youngest son of the late Dr. Joseph Creamer of that city.

Dr. LEVI W. BALLARD, a graduate of Cleveland Medical College, 1848, at Auburn, Washington, January 30, age 81 years.

—Dr. J. J. ARMSTRONG, at Caldwell, Idaho, January 14, 1897.
Dr. F. FROMAN, at Caldwell, Idaho, Jan. 7, 1897, aged 73 years.

SOCIETY NEWS.

New York Academy of Medicine.—At the annual meeting in January (see JOURNAL, February 6), the President reported the following officers for the ensuing year: President, E. G. Janeway; vice-president, Everett Herrick; trustees, Joseph D. Bryant, Clement Cleveland; committee on library, C. H. Knight; on admissions, Thomas E. Satterthwaite. The scientific business of the meeting was introduced by a paper by Dr. H. D. Chapin upon the prevention of the spread of contagious diseases, in which the author emphasizes the view that the public schools were the most potent factor in such spread. Especially is this true of the schools in the poorer sections of the city. All the elements favoring the spread of disease are found there. The ventilation is poor and the cubic air space insufficient, being much less than the board of health requires for lodging houses. Great stress was laid upon the unsuitableness of the wardrobes and places for hanging clothing. Damp clothing should not be hung in the school room nor should it be placed in close unventilated wardrobes, so favorable to the development of pathogenic germs. Dry, well-ventilated rooms should be provided for this purpose. In the discussion following this paper, Dr. George B. Fowler, health commissioner, called attention to the work which is being done by the board of health of the city. He stated that the city has been divided into thirty-five districts, with an inspector for each district, whose duty it is to report all cases of contagious diseases to the department, and that by this system it was expected to reduce the rate of contagious diseases in this city by at least 5 per cent. Dr. Fowler presented statistics showing the difference between the years 1888 and 1896 in the death rate by contagious diseases. 1, the percentage by population; 2, the percentage by cases; 3, the total number of deaths, showing a marked decrease in 1896 over 1888. He stated that much of this decrease was due to the system of inspection established by the board of health, and that he was perfectly satisfied that the death rate can be still further diminished. He believed that this would be the better accomplished if the board of health had thorough control of these cases, and emphasized the fact that at the same time the profession at large would not be interfered with in the least.

Milwaukee Medical Society.—At a meeting of the Milwaukee Medical Society held on the evening of Jan. 26, 1897, action was taken regarding the antivivisection bill, No. 1552, recently favorably reported to the United States Senate. A committee of three was appointed by the president of the Society to draft resolutions expressing the sense of the Society upon this matter, to report to the Society at the next regular meeting. This committee met in accordance with instructions and reported the following:

MR. PRESIDENT: Your committee to whom was referred the matter of framing resolutions to express the sense of this Society in regard to the bill to prevent vivisection in the District of Columbia, have the following report to make:

WHEREAS, The United States Senate Committee on the District of Columbia has reported to the Senate a bill No. 1552, to suppress vivisection in the District of Columbia, recommending it for passage, and,

WHEREAS, The Milwaukee Medical Society believes that the favorable report thus returned to the Senate is the result of

misrepresentations to the committee by certain fanatics who have no proper knowledge of vivisection and its relations to modern medicine and surgery; and that this Senate committee have heard practically no evidence from those who by their knowledge of this matter are capable of properly representing it; and,

WHEREAS, The passage of this bill would entirely suppress modern and progressive methods of medical investigation in the District of Columbia, therefore, be it

Resolved, That the Milwaukee Medical Society most heartily disapprove of this pernicious bill and beg of Wisconsin's Senators and members of the lower house to do all they can honorably do to prevent its passage, at least until they have heard from the teachers of physiology and biology of our leading medical colleges. Be it further

Resolved, That a copy of these resolutions be sent to each of our United States Senators and Representatives as soon as it may seem expedient to the Society to do so.

J. M. MADDEN, M.D.
U. O. B. WINGATE, M.D.
SAMUEL H. FRIEND, M.D.
Committee.

At a meeting of the Society held on the evening of Feb. 9, 1897, a motion was made to amend by adding that copies of these resolutions be sent to each medical association of Wisconsin, sufficient for their endorsement, one to be sent to each of the United States Senators and one to the Congressmen in whose district the societies meet.

This amendment was amended by including, for the same purpose, all higher institutions of learning in the State, the university, colleges and normal schools.

American Laryngological, Rhinological and Otolological Society.—The meeting of the Southern Section of this Society will be held in New Orleans, La., Wednesday, March 3, 1897, at the new St. Charles Hotel.

Address of welcome by Dr. Jno. B. Elliott, Chairman of Reception Committee. Opening address by Dr. W. Scheppe-grell, President of the Section, "The Progress of Laryngology." Address by Judge A. G. Brice, Chairman Auxiliary Reception Committee, "The Division of Labor and the Development of Specialism."

Papers will be read by Drs. E. B. Dench, New York, N. Y.; A. W. Calhoun, Atlanta, Ga.; Robt. C. Myles, New York, N. Y.; Arthur G. Hobbs, Atlanta, Ga.; Augustus McShane, New Orleans, La.; T. C. Evans, Louisville, Ky.; Norval H. Pierce, Chicago, Ill.; D. Ziem, Dantzig, Germany; J. A. Stucky, Louisville, Ky.; Louis J. Lautenbach, Philadelphia, Pa.; Edward F. Parker, Charleston, S. C.; J. Aloysius Mullen, Houston, Texas, and W. Scheppe-grell, New Orleans, La. Members of the medical profession are cordially invited to attend.

Officers of the American Laryngological, Rhinological and Otolological Society: Frank Hyatt, president, Washinton, D. C.; Robt. C. Myles, secretary and treasurer, New York, N. Y.; vice-presidents, Frederick L. Jack, chairman eastern section, Boston, Mass.; John S. Mabon, chairman, middle section, Alleghany, Pa.; W. Scheppe-grell, chairman southern section, New Orleans, La.; James E. Logan, chairman western section, Kansas City, Mo.

Southern section: W. Scheppe-grell, president.

Reception committee: J. B. Elliott, chairman; W. S. Bickham, J. D. Bloom, W. E. Brickell, Chas. Chassignac, F. Formento, C. A. Gaudet, Joseph Holt, A. McShane, B. A. Pope, E. T. Shepard.

Schuylkill (Pa.) County Medical Society at its last annual meeting elected the following officers: A. F. Bronson, M.D., president; H. C. Bowman, M.D., vice-president; J. W. Coble, M.D., secretary.

MISCELLANY.

Appointment.—Dr. R. G. Black of Castle Rock, Wash., has been appointed superintendent of the St. James Hospital at Vancouver, Wash.

The Journal of Cutaneous and Genito-urinary Disease has changed its management and is now published at 115 West 84th Street, New York. It is edited by James C. Johnston, M.D., and George K. Swinburne, M.D.

Calculus in Wharton's Duct.—A tumor in the mouth was about to be extirpated when it opened spontaneously and discharged a calculus, which Lavoine assumes had originated in Wharton's duct.—*Nord Méd.*, January 15.

Five Months' Retention of Fetus.—Nearly six months elapsed before the fetus was finally expelled from the uterus. It was mummified, and the placenta was distinctly albuminous.—*Lyon Méd.*, No. 51, 1896.

Kobert's Resignation.—Dr. E. R. Kobert, professor of pharmacology, dietetics and the history of medicine at the University of Dorpat, Russia, has resigned his chair and left Russia to assume the management of the Brehmer Sanatorium. His name is familiar in connection with various preparations.

Dispensaries in Private Residences in Havana.—The bishop and a physician named Penichet have each established a free dispensary for children in the ground floor of their homes and in the former the children also receive an allowance of milk. The children in the orphan asylum have been transferred to a convent and the asylum turned into a military hospital.—*Archivos de la Policlinica*, January.

The "Ophthalmic Record," now in its sixth year has been enlarged and improved and its editorial and publishing offices removed to Chicago. It is edited by the well-known ophthalmologists, George E. de Schweinitz, G. C. Savage, Casey A. Wood, John E. Weeks, F. C. Hotz, H. V. Würdemann, W. E. Hopkins, Harold Gifford. T. A. Woodbury is editorial secretary. Published at 214 South Clark Street.

Bequests to Hospitals.—Mrs. Mary L. Wood of Bridgeport, Conn., has left by will a bequest of \$15,000 in cash and other property of value. Of this amount \$10,000 is set aside to establish two free beds. Mrs. Wood some time ago donated \$20,000 to the same institution for the purpose of building a suitable surgical ward. The Bridgeport Orphan Asylum, the Protestant Widows' Home and the Charitable Society will also get about \$20,000 each.

Insurance Fees Forty Years Ago.—The *Boston Medical and Surgical Journal* (Vol. 1x) some forty years ago expressed the following views anent life insurance companies, singularly like those pretty generally held by the profession today:

"Of all corporations they seem to be the most soul-less. An institution which pays a medical man one dollar (when it pays him anything) for an opinion which no lawyer would give under fifty dollars, is not likely to listen to any proposition about reducing its charges, however probable it seems that its earnings would thereby be greatly increased."

In Memoriam of Professor Huxley.—A memorial very fittingly conceived and carried out by some of the friends of the late Professor Huxley will henceforward be a mark which English travelers in Switzerland will strive to attain. On the shores of Sils Lake at Maloja, in the Engadine, a spot which was to Huxley what Asolo was to Browning, a huge block of granite has been engraved with the following inscription: "In memory of Thomas Henry Huxley, the illustrious English writer and naturalist, who passed many summers at the Kursaal Hotel, Maloja. Erected 1896."—*American Practitioner and News*, January 9.

Professor Koch's Plans.—Professor Koch has so nearly concluded his work in South Africa that he will soon return to Berlin. He will take with him his newly discovered serum, which promises to become an immunizing treatment for the rinderpest. He is unable to state whether or not he will be able to prevent all domestic animals from being infected with the disease. He has demonstrated that sheep and horned cattle are the most liable of all animals to contract the disease. Dogs, monkeys and rodents enjoy complete immunity from it. Dr. Koch, it is said, does not purpose to go to Bombay to study the bubonic plague, despite the fact that he has been asked to head the commission which is to be sent to Bombay for that purpose.

Cilium Within Anterior Chamber Causing Tumor.—At the December meeting of the Liverpool Medical Institution, Mr. R. Williams showed a drawing of a tumor of the iris due to the presence of a cilium in the anterior chamber. The patient, a stonemason aged 22 years, had received an injury to the left eye two years previously. As evidence of this there was a linear scar on the cornea opposite the tumor. The cilium lay across the upper part of the anterior chamber with its root apparently embedded in the tumor. The tumor was rounded and supposed to be a cyst; when the anterior chamber was opened and the cilium removed the tumor was found to be devoid of cyst wall, and was probably composed of proliferated epithelium from the root sheath of the hair.—*British Medical Journal*.

Large Gifts to Charities.—In December, 1896, Miss Thurston, the last member of a wealthy and generous Brooklyn family, died and by her will just admitted to probate, a fortune has been distributed among various charities and institutions. About \$25,000 was given outside the city of her home, but her benefactions to the charities in Brooklyn were equally large: Brooklyn Home for Consumptives, or Garfield Memorial Home, \$3,000; Faith Home for Incurables, \$2,000; Brooklyn Howard Colored Orphan Asylum, \$2,000; Brooklyn Bureau of Charities, \$3,000; and four other charities \$20,000 among them. During her lifetime Miss Thurston had given much more than remained to be distributed by the will, and it is said that she was personally known to but few of her beneficiaries. "She lived very simply that she might have the more to spend on others," has been aptly and truthfully said of her.

Washington's Medical Nephew.—It is not generally known that a nephew of the first President of the United States was a member of the medical profession. Dr. Bailey Washington entered the United States Navy as a surgeon in 1810. He died Aug. 5, 1854, at the age of 72. He was the surgeon of the *Enterprise* when she captured the *Boxer* during the war of 1812. He afterward acted with great efficiency on Lake Ontario under Commodore Chauncey and was selected by him as fleet surgeon, although a junior officer in the service. He was afterward fleet surgeon under Commodores Rogers, Elliot and Patterson in the Mediterranean, and closed his active sea service during the Mexican War. At the time of his death he was consulting and visiting surgeon of the navy yard and marine barracks in Washington.

An American Physician at the Persian Court.—Dr. William S. Vanneman, born in New Jersey, educated at Princeton and the University of Pennsylvania (class of 1888), is court physician to the Shah of Persia, having under his care the half-thousand wives and servants of that newly crowned potentate. Dr. Vanneman was born thirty-three years ago, on a farm near Salem, N. J. He went to Persia as a missionary under the direction of the Presbyterian Board of Missions. When the cholera raged in Persia Dr. Vanneman rendered heroic and valuable service, which brought him under the notice of the highest officials in the Persian Kingdom. During the summer time, the court officials and their harems pass their time at Tabriz. Here in 1895 Dr. Vanneman made the acquaintance of the late Shah's youngest son, and on several occasions attended the Prince and the members of his harem. His skill quickly made the Prince his friend, and when the latter's father was murdered by a fanatic last May, Dr. Vanneman was one of the first to extend his sympathy. Not long after, when the Prince was named to succeed his father as Shah, the new ruler sent for the American and offered him the position of court physician. In August last, Dr. Vanneman and his wife set out from Tabriz accompanying the Shah's harem to Teheran. The caravan consisted of twenty carriages—about all there were to be had in the land—and 500 horses laden with men, women, children and baggage. The journey was expected to take three weeks, the caravan traveling from twenty-five to

thirty miles daily. Dr. Vanneman and his wife occupied one of the carriages, and they had three tents for camping at night.—*New York Press*.

The Earliest Human Ovum.—At the recent meeting of the Naturforscher-Versammlung at Frankfort-on-Main, Professor Leopold exhibited microscopic sections of the youngest human ovum ever detected. The uterus of a woman, aged 30, was removed for cancer of the cervix. The interior was carefully examined. An undoubted ovum as big as a lentil was seen, making a prominence on the surface of the uterine mucous membrane, which was hypertrophied in its neighborhood. The periphery of the ovum was bounded by a deep groove devoid of mucous membrane. After careful inquiries it was concluded that the ovum had reached the eighth day after conception. Great pains were taken when accurate drawings had been made of the undisturbed ovum to procure successful sections. The highest expectations were fulfilled. The arrangement of the villi, and the opening of the arterioles of the endometrium into the intervillous spaces came out very clearly. A full report of this remarkable case, well illustrated, will, we understand, be published. Dr. Kanthack has added to the museum of St. Bartholomew's an instructive specimen of a very early human ovum in its membranes. Histologic study of the human embryo and its envelopes during the first few weeks of development is much needed. We must not rely too far on homologous structures in the lower mammals, where the anatomy and physiology of the genital tract differ in important details from the same in our species.—*British Medical Journal*.

The Tendency to Specialism and to Surgery which distinguishes these closing days of the nineteenth century, is manifested in every branch of science. One of the latest evidences is the recent announcement of the *Gazette Méd. de Paris* that henceforth it is to be devoted exclusively to surgery. The name will remain the same, but its scope will be limited to this department of the healing art. It states that the demands of the day necessitate the separation of the theoretical from the practical, and that the various scientific periodicals will have to devote themselves to certain specialties, as none can contain them all—the long studies, the practical notes, the miscellaneous news in every branch of science, and the records of experimental work. Such remarks seem strange to the readers of the *JOURNAL*, which publishes in a week as much as the *Gazette* in months, and leads them to rejoice anew in the wonderful capacity of these columns in which each specialist finds the news, the progress and the technical instruction in which he is most interested, brought to him every week from all over the globe and indexed for his ready convenience in each issue. The *Gazette*, and similar publications, with their limit of twelve pages of large type per week are of course forced to restrict themselves to some specialty, of which the readers of the *JOURNAL* also get the benefit, as their contents are reviewed each mail in these columns.

The Surgical Corps of the Cuban Army.—While accurate details regarding Cuba in general are extremely difficult to obtain, yet the reports which have reached us indicate that a great deal of excellent work is now being done by the surgical staff, whose members have displayed a degree of skill and conscientiousness which is somewhat surprising. They number about ninety men and are assigned to the six army corps of the insurgents. When we consider the organization of this army, which is without a basis of supplies, is constantly on the move and waging a sort of guerilla warfare, the difficulties attending the proper care and management of the wounded can be readily appreciated. Yet in spite of all this, the principles of modern surgery are carried out to the fullest extent permissible. The surgeons are well supplied with instruments and a fair supply of antiseptics, which the climatic and other conditions render absolutely essential to good work. It may

be said that the surgical corps is far superior in every way to that of the Spanish army, whose hospitals, even in the city of Havana, are filthy and overcrowded and in no degree provided with the essentials of surgical care. While the executive officers are inefficient and often uneducated, the reverse prevails among the ranks of the insurgents. The surgeon general is a graduate of one of our colleges and has had a military training, while no small number of the corps is composed of Americans and Cubans who are regular practitioners of medicine. Nearly all are well qualified and skilful. Under the circumstances, therefore, it is not surprising that they have acquitted themselves with honor if not with glory.—*New England Medical Monthly*.

Washington.

FAVORABLY REPORTED.—The House Committee has made a favorable report on Mr. McCormick's bill to regulate the sale of poisons in the District of Columbia.

THE X-RAYS IN COURT.—The X-rays were recently used in a case before the police court to determine the existence of a fracture of the forearm, claimed to have been produced during a recent arrest.

THE PURE FOOD BILL.—House bill 9842, relating to the adulteration of foods and drugs in the District, introduced at the instance of the Medical Society, has been reported upon favorably by the Commissioners, as amended by the Health Officer. This measure provides that adulterated foods or drugs shall not be sold or exchanged in the District, and that the courts shall construe the provisions against all forms of adulteration liberally, so as to prevent the mischief intended to be guarded against. The term "drug," as used in the act, includes "all medicines for external or internal use, antiseptics, disinfectants and cosmetics." The term "food" includes confectionery, condiments, and "all articles used for food or drink by man."

THE WASHINGTON DIRECTORY FOR NURSES.—The annual meeting of the joint committee of the Washington Training School for Nurses and the Medical Society, was held on the 8th instant. The report of the superintendent and the secretary showed the directory to be in a flourishing condition, and giving entire satisfaction to the public and the physicians. The number of independent directories in the city tend to scatter the nurses and their official records, hence to obviate this objection and centralize the supervision of the nursing community and raise the standard, a special committee, consisting of Drs. H. L. E. Johnson and S. S. Adams, was appointed to cooperate with the different directories and medical societies in securing concentration of nurse registration and supply, in one headquarter or clearing-house. If this cooperation and centralizing is accomplished it will be of the greatest advantage to the nurses, the schools, the public and the physicians.

COMMITTEE ON PUBLIC HEALTH.—At the meeting of the committee on public health of the Board of Trade, held on the 9th instant, it was agreed to urge an appropriation from Congress to secure the reclamation of the Anocostia flats after the plan proposed by the engineer corps of the army. At present there is no greater disease-producing element in any city in the country. The Army, Navy, Interior Departments, and the Health Department have repeatedly urged the abating of this nuisance, and demonstrated its influence in disease production. The petition should receive prompt consideration and action by Congress.

A RESOLUTION AFFECTING QUARANTINE.—Senator Elkins, of West Virginia, has introduced the following joint resolution:

"WHEREAS, in view of the alarming nature and spread of the bubonic plague, now prevailing in India and adjacent countries, and in view of the danger of this scourge being brought to the United States;

"Resolved, That at any port or place in the United States where the Secretary of the Treasury shall deem it necessary for the prevention of the introduction of contagion or infectious diseases that incoming vessels, vehicles or persons should be inspected by a national quarantine officer; such officer shall be designated or appointed by the Secretary of the Treasury, on recommendation of the Surgeon-General of the Marine Hospital Service, and at any such port or place no vessel, vehicle or person shall be admitted to entry without the cer-

tificate of said officer that the United States quarantine regulations have been complied with."

MEDICAL SOCIETY.—At the meeting of the Society held on the 10th instant, Dr. Norton read a paper on Infantile Scurvy and Rachitis; Dr. Shands reported a case of Hare-lip; Dr. Perry, a case of Necrosis of the Tibia; Dr. Prentiss, a case of Erythromelalgia, and presented the patient; Dr. Burnett, cases and specimens of old wound (gunshot) of orbit and temporal bone, bullet exhibited; large penetrating wound of cornea and iris.

WASHINGTON OBSTETRICAL AND GYNECOLOGICAL SOCIETY.—At the 257th meeting of the Society held on the 5th instant Dr. H. L. E. Johnson read the paper of the evening, on A tresia of the Uterine Canal after the Menopause. He referred to his original article on that subject published in the JOURNAL on Dec. 7, 1895.

THE PUBLIC SERVICES.

Army Changes. Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from Feb. 13 to Feb. 19, 1897.

Capt. Philip G. Wales, Asst. Surgeon, is granted leave of absence for four months, to take effect upon his relief from duty at Ft. McPherson, Ga.

Major Robert M. O'Reilly, Surgeon, will be relieved from duty as attending surgeon in this city (Washington, D. C.) by Major William R. Hall, Surgeon, and upon expiration of his present leave of absence will proceed to Ft. Wayne, Mich., for station, relieving Lieut. Col. J. M. Brown, Deputy Surgeon-General. Lieut. Col. Brown, on being thus relieved, will proceed to New York City, and upon the retirement of Col. Charles T. Alexander, Asst. Surgeon-General, May 3, 1897, will take charge of the medical supply depot in that city.

PROMOTION.

Capt. John M. Banister, Asst. Surgeon, to be Surgeon with the rank of Major, Jan. 26, 1897.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending Feb. 20, 1897.

Surgeon R. Whiting, placed on retired list Feb. 15.
Asst. Surgeon J. C. Rosenbleuth, detached from the "Raleigh" Feb. 20 and ordered to the "Massachusetts."

Change of Address.

Cook, J. E., from 128 Franklin Ave. to 258 Pearl St., Cleveland, Ohio.
Coffman, G. L., from 1654 California Ave. to 1521 S. Compton Ave., St. Louis, Mo.

Getzlaff, Bruno, from Fitzgerald, Ga., to St. Peter, Fayette County, Ill.
Holmes, H. R., from Portland to Salem, Ore.

Kent, J. L., from Dublin, Va. to 101 East 25th St., New York, N. Y.
Read, Flora A., from 520 to 502 Main St. Fond-du-Lac, Wis.

Roach, J. F., from 3308 Lucas Ave. to 4349 Forest Park Blvd., St. Louis, Mo.

Ross, G. M., from Masonic Temple to 2139 Wabash Ave., Chicago.
Seaman, Gilbert E., from 225 Grand Ave., to 315 Goldsmith Bldg., Milwaukee, Wis.

Waterman, Oscar M., from Milwaukee, Wis., to 59 Washington Market, Milwaukee, Wis.

Younger, Wm. J., from San Francisco, Cal., to Auditorium Hotel, Chicago.

ORIGINAL ARTICLES.

THE CARE OF THE INSANE IN PRIVATE PRACTICE.

Read before the Portland Medical Society, Portland, Ore., Dec. 15, 1896.

BY HENRY W. COE, M.D.

PORTLAND, ORE.

One needs but to examine the literature and to see who writes upon the topic, to ascertain beyond question that the subject of insanity receives but little attention from the general practitioner.

After looking over the reports of the last five sessions of the Oregon State Medical Society, and calling to mind the work of the Portland Medical Society during the same period, it seems safe to say that no paper upon this subject has been presented by a physician of this State at any of these meetings during such time. Papers upon almost all medical topics have been presented before these societies by physicians of this State, but the great field of psychiatry has been during this period ignored. The history of medicine in Oregon in this particular is, to a great extent, the history of medicine everywhere, and it teaches us that the general practitioner is leaving the subject of insanity, to a very great degree, to those who make of it a specialty.

Personal replies to letters of inquiry addressed to the various medical superintendents, and the last annual reports which are accessible for the State insane institutions of this region, give us the following information of the work of the preceding year:

Asylums.	Admitted.	Discharged.	Recovered.	Died.	On Hand.
Agnews, Cal. 1	390	155	97	95	902

In addition to those noted as "recovered," the reports also show that others have been "much improved," "improved," etc., and the Idaho report does not specify the number "recovered."

The reports above mentioned also show that there were 10 per cent. more patients confined in these asylums at the end of the fiscal year, than at its commencement.

Insanity is increasing. Dr. Forbes Winslow,¹² in his address at the Medico-Legal Congress in New York, September, 1895, said that the increase in England is now about 2,000 cases per year; the proportion being in 1895, 30 per 10,000 population, while it was but 28.12 in 1886.

In the United States in 1880, we had 50,155,783 inhabitants, and an insane population estimated at

56,205. The census nine years later gave a total population of 62,622,250, and the number of insane in private and public institutions was 97,535, indicating, as pointed out by Dr. John Punton,¹⁴ an enormous increase of our insane in this brief time of over 73 per cent.! This increase, however, was more apparent than actual, the statistics being much more reliable and complete at the latter date. The per cent. of increase is actually small, but that there is an increase is quite certain.

Dr. John Punton,¹⁴ in speaking of the relation of the profession to the great subject of insanity, also remarked: "It is surprising as well as humiliating to notice how many members of the profession admit both by their words and actions, that they have given this subject little or no study, and in this way excuse themselves from their lawful and responsible duties."

The foregoing statements showing the frequency of insanity, and the local dearth of literature upon the subject, are presented to this Society as an excuse for the present paper. Oregon has many physicians of large experience, and ample knowledge of the science of psychiatry, and in the absence of any recent medical paper from these gentlemen, I have thought it permissible to discuss one phase of this great and growing subject.

The disposition of the general practitioner to shift his own responsibility as to insane cases to the shoulders of a State officer, is in many cases entirely wrong, and this paper will attempt to show why he had in the interest of his patient, rather to employ private than public care, wherever the former course is possible.

The physician upon whose professional advice a human being is committed for the first time to a public institution for the insane, is not only treading upon solemn ground but, in participating in an act which takes the right of liberty from another, is in that act assuming a most responsible position. The judge who issues that mandate from which shall come the confinement of a fellow citizen in an insane asylum for the first time, and that will affix a stigma to the individual which can not thereafter as long as life shall last be removed, is performing an act most serious and solemn. "The matter of committing a patient to a hospital for the insane is one of grave importance. No man can safely say that he will never come under its scope. It affects all conditions of life."¹⁵—Semple.

Alienists tell us that a considerable proportion of the insane of our race comes from those known as defectives. Homeless, penniless and friendless, with a mind diseased and life's prospects a blank, we may readily make ourselves believe that the only hope for such an individual lies in the kindly hands of skilled officers of a State insane asylum. While this class of our insane may thus seem to be at their best when promptly handed over to the authorities of an insane

asylum, I am constrained to express the view, that in the initial outburst of insanity they, more than any other because more helpless and needful of aid, and more readily impressed by psychic influences, should be given the benefit of scientific, patient, careful, separate treatment.

Many of this class will either die early, or develop chronic insanity; but none the less, those who are passing through an initial and uncertain stage which might early give place to sanity, should have the right to go through life without the consciousness in self or the knowledge on the part of the public that they have been inmates of an insane asylum.

The man whose mental balance was but off the narrow line of sanity, but who in hurried haste was consigned to an asylum, will ever feel cause for harassing shame day and night, while he who may have been a frantic maniac, yet treated in a private home, when again clothed in his own mind will have an image of his former misfortune more shadowy from day to day, which will ultimately pass away. The largest proportion of our insane are poor, but the poverty of one of these is not a reason for a careless or hurried commitment. The cost for the public care of our insane almost exceeds that of any other branch of the government. Why should not the municipality or county divert a portion of its funds to the private care of the insane poor?

We have State penitentiaries and county jails. One is for the confinement of the confirmed or grosser criminal, and the other for the milder cases of crime. While the penitentiary and jail are for the vicious, and the insane asylum is for the unfortunate, and while in one sense comparison might appear harsh, yet in the matter of expense and benefit to these charges of the public, much may be learned in regard to one class, by studying the methods and results of the care of the other. We see that there is a disposition on the part of the commonwealth to show consideration for criminality in its initial state; a desire to save from the greater ignominy of a State penal institution those new in crime; a sympathy not given to that more unfortunate class, the insane.

I believe that these poorer classes of the insane deserve our deepest sympathy, and should, where there is a likelihood of recovery, have careful treatment in private or county hospitals before confinement and contact with other insane shall be made in a State asylum. Under our present system I recognize the fact that this is practically impossible. Proper treatment would necessitate a quiet, homelike place, a skilled nurse in constant attendance, and that more than ordinary thought and care should be given by the physician in charge.

Such cases at the present time would come under the regular county physician, and he is not expected, nor has he the facilities, or is he paid to look after these cases. They would in the larger cities require that a special physician should be detailed by the municipality to care for them. Until the public can better understand the subject and shall realize what is to be gained by the separate treatment method, the slightly increased expense necessary in private separate care, will not be readily undertaken by the public authorities.

If the method which I advocate is the best one, it will devolve upon the medical profession to first educate the public up to the facts, and to follow this by an effort for proper laws providing for the private

treatment of the insane poor. Under the present laws of this State, an insane case in private practice is restrained under the same liabilities to the physician having the same in charge, as are present in the restraint of a fever patient with delirium or any similar condition; such liability being therefore much more personal than that exacted of the authorities of a public insane asylum. It should be so, to guard against abuses in private treatment, but laws should be passed providing for the private care of the pauper poor. Private institutions for the insane should be subject to close inspection by State officials. The private treatment of the poor would not include the care of the incurable or chronic, but the conservation of the private interests of the individual, always of prime importance to the State, should make it desirable that every case in its initial stage should, in my opinion, have the benefit of private treatment.

Our public asylums are made as pleasant as circumstances will permit. They are always crowded with those unable to enjoy private treatment. They are officered by the choicest students of psychiatry in the profession, and ministered to by medical men with kind hearts and broad minds, yet there is, and always will be, a sense of dread and horror when contemplating the medley of mental wrecks under treatment at a public hospital for the insane; and if a case of insanity can recover outside of the atmosphere of such an institution, he can scarcely fail to have gained by such an advantage. To awaken to sanity and witness and live even for a brief time in a neighborhood of lunatics, with the feeling that the individual himself has just escaped such thralldom, will leave a never-ceasing impression upon the invalid which will not only cloud his life, but may affect generations yet unborn.

There is another phase to this subject, and that is the question of State expense. At present many persons of the families of the well-to-do accept the service of the State insane asylum. The poor of every class are entitled to public charity, but the insane rich should no more accept support from the State, than should the wealthy sane expect an appropriation from the poorhouse fund to relieve his daily wants.

In the language of Dr. H. C. Willison:¹⁶ "The pecuniary cost of maintaining so great a number of non-producers in our State asylums at the public expense, must necessarily engage the serious consideration of the statesman and political economist." We should therefore consider the private resources of the patient, and especially in the early stage of initial insanity, and decline to be a party to an act which will make a public charge of one otherwise readily and properly provided for.

"The average length of life in the chronic insane is estimated at twelve years. Of the number admitted, less than one in three recovers, making an average of eight years' treatment for each person admitted to the hospitals. At \$16 per month their cost of maintenance would be over \$1,500 each, and the per capita cost of buildings required for their shelter at least \$500 more."—Semple.¹⁷

Most States provide by law for the care at public expense of the poor only, but that local authorities and insane boards seem to be willing to make of all insane cases public charges, is illustrated by a statement made by the board of trustees of the Agnews Asylum of California.¹⁶ They say: "We believe that there would be more pay patients if the county courts or officers of the courts, would diligently investigate

every patient at the time of commitment, as to his ability to pay the cost of their maintenance."

"State asylums are supposed to be for the indigent, but they are not always so. Upon investigation we have obtained information to our satisfaction that there are a number of patients in the asylum committed as indigents, who, as a matter of fact, own property in their own right or are heirs to estates now being probated, or have relatives amply able to meet the expense of their care and maintenance, but we fail to find any provision of law by which we can do otherwise than maintain them as wards of the State."—Pike.¹⁹

Our asylums are also much crowded. The reports of the various superintendents, when discussing this subject are much in the same strain. Dr. Asa Clark²⁰ says: "The number of patients in the asylum has not lessened during the past eight years, although other State asylums have been opened, but still maintains its uncomfortable magnitude."

There is a large number of those who become insane that comes from the better walks in life. People of good birth, noble ancestry and taintless blood, whose families are fortunately situated so that they can meet whatever expense may be deemed necessary to restore to health or to give a chance for such restoration, the mental faculties of the invalid friend or relative. In this class are to be included many who are victims of injury, of poison, septic, intestinal and otherwise, of sickness, of grief or prolonged mental strain, or of other extraordinary influences. The friends of these patients shrink from the idea of public asylum treatment, and an association with the public insane of the criminal and lower classes, and desire that private care shall be employed. These are therefore the cases which today are amenable to private treatment. From the position which such patients occupy in the social, professional or mercantile world, there is still greater reason that the odium of asylum life shall not attach to them. From financial advantages possessed by these people there comes, as always to those financially strong, a certain special responsibility to the community. Their means should be made of advantage through wise action or proper laws to those less fortunate. A demonstration of the benefits to be derived from private treatment should be gained through the methods and results obtained in their cases.

The insane case will fare best when under the care of a practitioner who has pursued his studies among the insane in public and private institutions, and acquired such a groundwork of knowledge that when cases do present he shall have little difficulty in renewing his knowledge by a review of the literature on the subject. Yet, without such experience the average practitioner can usually handle these cases if he is willing to take time to study up the matter and possesses the facilities therefor.

The insane mind is of subtle composition, and by the early recognition of the initial aberrations, we may be able to put a stop to mental changes then going on, which, if unrestrained, might lead to the grosser mental states of unsoundness. We often require too much to convince us that the patient is beginning to show signs of mental change and needs mental treatment. It would be better to insist upon an early treatment of the malady under the name of nervousness, than to await acute symptoms which all may be able to denominate as insanity.

Williams²¹ says: "Those who are not acquainted with the progress or nature of insanity, seek to ignore its presence unless it is accompanied by positive evidence of material derangement. Regarding disease as an active agent whose exposition necessitates physical change, they demand further proofs of its existence than such as are derivable from actions admitting, as they assert, of conflicting explanations."

"That the insane are sick people who are entitled to the kindest consideration and management, and treatment by the best medical skill attainable, is a fundamental principle that should guide us as in all matters concerning them," says Dr. William Francis Dreary.²² What kind of treatment, what manner of consideration for a mentally sick person is it to crowd him into jail among criminals, to a court for examination, and from thence to hurry him off to a place of confinement along with hundreds of others like unfortunate?

There is a larger proportion of recoveries from acute insanity than from many other acute diseases, and many insane are not half so violent and troublesome as a typhoid fever patient. Why is not the unfortunate who is mentally sick entitled to as much consideration as the patient whose intestinal glands are in a state of specific fermentation? Dr. A. S. Watson, quoted by Dr. Mary B. Atwater,²³ has this to say: "Fully 80 per cent. of all insane cases may be cured if treated early and properly."

The association so often necessary in asylums of those who are pure-minded, yet demented, with the criminal insane, is a matter of no small consequence. Upon this subject Dr. G. H. Thomas³ has this to say: "Eminent alienists depreciate the association of this class of patients (criminal insane) with those who are innocent of crime, but whose confinement through sickness or misfortune is made necessary. It is not only a question of association, but this class of insane are usually violent, and for safe keeping must be kept in restraint; the effect of this on the better class of inmates, who frequently realize the character of such violent associates, is not conducive to good order or to their recovery.

Many cases of insanity even of a rather violent type, will soon recover if tact and patience are employed in the care of such cases. I have in mind a patient which Dr. E. W. Tape of this city asked me to see with him on two occasions in February last, where the friends were somewhat determined to have the invalid, who was wildly delirious, sent to the State asylum. In view of the fact that this patient had formerly been insane, it was not unreasonable for the friends to believe a commitment advisable; but with the recovery from a concurrent malady, and after close and wearisome care upon the part of the physician, Dr. Tape had the satisfaction of seeing his patient within a short time fully recovered from his mental distress.

Not every case will recover, but if not, the family and friends can not fail to be much better satisfied after a course of private treatment has been entered into and thoroughly carried out; even should the case eventually become chronic and public care thereupon be invoked. Dr. H. C. Hoffman of this city asked me to see a case in April, 1896, which is in point. The greatest reluctance was felt by the friends to a public commitment and private treatment was instituted. Although this case passed out of the professional observation of Dr. Hoffman and myself many months

ago, yet I have learned that some degree of private care and treatment was administered up to the time of commitment, which was but a few days ago, and I feel certain that not only were the rights of the patient conserved by the opportunity for private treatment which was given, but that the friends are much more resigned to the results than they otherwise would have been.

The Oregon report²⁴ shows that there were sixteen patients committed to the asylum under 15 years of age during the year. It is a sad sight to see patients so young committed to an insane asylum. Dr. Sarah B. Welt, in a series of tables on this subject,²⁵ speaks of the rarity of insanity in the young, although admitting its presence and seriousness. The hospital reports indicate that it is frequent.

Sachs says:²⁶ "It is well to emphasize the fact that mental derangement in childhood is recovered from more frequently than is the case with insanity of later years. But a child that has ever been insane is a tender plant that needs special care." Forbes Winslow²⁷ points out that children are liable to transient mental disorders, which pass away without leading to after-results.

"Many young people who are just entering manhood and womanhood have been so raised that a special amount of moral perversion, bordering so close upon insanity, has ensued, that their parents in desperation are inclined to have them committed as cases of moral insanity. These cases are not insane but need restraint, and in firmer hands than formerly accustomed to at home, will often become useful citizens."—McCassy.²⁸

Dr. W. A. Hammond²⁹ emphasizes the fact that the insanity of children is most often marked by fixed delusions and a malignancy toward relatives, a special reason for separation of such cases from their own homes. A case came under my treatment last August from Dr. J. J. Leavitt of Mollalla, Oregon, which illustrates the youthfulness of some patients, also the brevity of the attack in many cases. This patient was a sufferer from melancholia with delusions of persecutions. She was but 16 years of age, of a good family, and had been in excellent health until attacked by a severe and prolonged course of inflammatory rheumatism in the course of which cerebral meningitis was present. After a tedious recovery melancholia had ensued. She was placed under treatment and at the end of six weeks returned to her home entirely recovered.

The mental state in this case, while pronounced, was of a mild and transient character. Within a year she will hardly remember her trip to Portland in connection with any mental difficulty, and her friends will scarcely take notice of that event, now or hereafter. If she had been sent to a lunatic asylum the associations of such an event would never have passed from her mind, and the odium of such confinement would have remained with her until the end of her life, no matter how remote that event may be.

We need but give a casual examination of the insane hospital's report to ascertain, if we did not know it before, that the largest proportion of "recoveries" occur shortly after admission into these institutions. From the Oregon Report²⁴ we learn that 163 patients were discharged as recovered; of these 118 were in the asylum less than six months, and one-half of these recoveries occurred in less than three months from the time of first confinement, while there were only 25 recoveries occurring over one year after reception at the asylum. The moral of this is that but a com-

paratively brief course of private treatment will be required to determine as to the question of recovery in most cases and, too, such figures emphasize the statement which has been made, that the asylum stigma should not be permitted, except after at least a few months of private treatment.

Another class of cases which should, where possible, be given the benefit of private treatment, are those individuals on the border line between the regions of sanity and insanity, who have become addicted to alcohol or other drugs to such an extent as to require that some restraint should be employed while the poison which has been taken is being withdrawn. These cases are often sent to asylums to their everlasting discomfort and chagrin, although the hospital officials may even decline to receive them. In fact, as pointed out by Dr. W. H. Anderson,³⁰ in some States, as in Washington, the law forbids the commitment of cases of "inebriety, harmless chronic mental unsoundness and acute mania potu."

"Alcoholic excesses are directly the cause of at least 10 or 12 per cent. of insanity, and probably a somewhat larger percentage."—Vaughop.³¹

"It is now well established that the unrestricted use of narcotics and stimulants, or those agents which unduly and directly dull or excite the mind organs, are the most powerful exciting causes of insanity. These are well-established biologic facts, and it now remains for philanthropists, sociologists and legislators, in their respective spheres, as well as the individual, to take these facts and use them for the prevention of a great part of this awful affliction—insanity."—Givens.⁶

No one is more competent to discuss the subject of commitment than Dr. Landon Carter Gray,³² who says: "The question of committal of a case of melancholia, is often one that involves a great responsibility. My rule is, never to commit a patient who can be treated at home, for I am no believer in asylum treatment of curable cases of insanity. In melancholia, as well as in many other forms of mental disease, the preceptions and the memory are frequently unimpaired, or but slightly affected, and the patient either has a full realization of the fact that he or she is in an asylum, or will in time awaken to such realization.

"The nurses of a lunatic asylum are never as efficient as the trained nurses which we are now fortunate in possessing in such numbers, nor are they of as high a class in point of refinement and education.

"Beside the convalescence of patients in a lunatic asylum simply brings them face to face with what is generally regarded, whether justly or not, as one of the most distressing things in life, namely, a lunatic asylum. Then too, however slight their mental affections may have been, the fact that they have been committed to a lunatic asylum clings to them through life. Like Lady Macbeth's 'damned spot' that would not out, it too frequently blasts their career, while a severe attack of mental disease treated at home is lightly regarded by the laity under some soothing euphuism, as brain fever. Nor do I believe that the stage of convalescence can fail to be retarded by the constant contact with lunatics. For all these reasons I never commit a patient to an asylum, as I have said, if he or she can be treated at home. The question whether the latter can be done will be determined by the degree of insanity, the probable duration of it, the environment of the patient and his or her circumstances."

In a considerable number of drug habitués, including alcoholics, morphin and cocain users which have been under my care, several have been upon the borderland of sanity, and in at least two cases actual insanity was present. The relief from the drug habit has restored the normal mental condition, and the patients who were supposed to be under treatment for other complaints, have returned to their friends without the stigma of having been inmates of an insane asylum.

Regarding the confinement of the pauper drunkard, Dr. T. D. Crothers³³ says: "That he should be sent to the inebriate reforming hospital or workshop, for the institution should include both these features. We are dealing with a diseased person not a criminal, but as a pauper inebriate without friends, or if he has friends without means. For the wealthy inebriate there are abundant provisions, as private asylums are numerous and the appointments are very complete for his treatment, both here and abroad."

Dr. L. L. Rowland³⁴ in his report for the Salem asylum, refers to the number of alcohol, morphin and cocain habitués that are sent to that institution and points out the undesirability of the same from every point of view. Nothing, it seems to me, is worse for a drug-taker, than to be compelled to associate with the insane. I believe that alcoholism and other drug-habit conditions are largely diseases, and should be treated as such. That there is an insane phase to many of them seems probable, while actual insanity in many cases is prominent and unmistakable.

I might refer to a cocain-morphin-chloral patient, referred to me by Dr. H. D. Fenton of Portland some months ago. This habitué was and had been insane for some time before he came under my care. The treatment of the case included not only the treatment of the drug habit, but also the insanity from which he suffered, yet within two months his drug habit had been broken and his proper mental state recovered. Asylum treatment could not, I believe, have done as well for this patient. His friends and neighbors do not know he had a drug habit and they have already ceased to, if in fact, they ever did, comment upon his visit to Portland, whereas, if he had been sent to an insane asylum he would have secured notoriety which would have scarcely ever passed from him.

A paper of considerable length would be required to discuss the details of the treatment of the insane, which is not now attempted, and therefore only a glance can be cast at this phase of the subject. New methods are being adopted and the plans of treatment are changing, and while the general practitioner can scarcely be expected to remain fortified with knowledge upon this subject so that he may be ever ready for such occasional case as may come under his care, yet when it does appear he needs to thoroughly canvass the field of psychiatry in quest of the latest methods of treatment.

The insane should rarely ever be treated in their own homes. A patient is best environed when placed among strangers. The family should be excluded from the sick room. "Visitors to insane patients often do much harm unintentionally. Friends and relatives exert an irritating effect upon the insane in unexpected ways, and calmness has frequently been succeeded by weeks of disturbance after a visit of the well-meaning relative. There are times, which the physicians are prompt to recognize, when the patient is made better by seeing his friends, and they are usually notified at once upon such occasions."—Clevenger.³⁴

The returning mentality of the insane needs to be nurtured like the growing mind of a child. It must be led step by step. The benefit of the promises of reward and the good results experienced in exceptional cases is illustrated by a patient now convalescing under my care at Mindsease Sanitarium, which was referred to me by Dr. H. S. Pernot of Corvallis, Oregon. The mental discipline and the cheerfulness resulting from the promise of the visit of a loved relative kept prominently before the patient for many days, broke into a markedly melancholic state with gratifying results.

On the subject of environment, Dr. Punton³⁵ has this to say: "It seems beyond the comprehension of many persons that insanity deranges rather than destroys the mind in its incipient stage. Much therefore depends upon the selection of a responsible nurse to carry out the treatment. Another important step is the isolation of the patient, whether treated at home or elsewhere. It is often with difficulty that the friends and relatives can be made to realize the necessity and importance of this measure. But those of us who have devoted time and attention to this study, know too well that the probability of recovery is much increased when the patient is committed to the care of strangers."

"In many pronounced cases of melancholia in which the family relations are a source of worry and anxiety, I positively refuse to treat the patient unless isolation can be obtained."—Landon Carter Gray.³²

"In the beginning, at least, our object must often be to remove the patient from the action of those daily irritants which are often exercised upon him in his business in the care of self-support, in the irrational conduct of his relatives and often in violent reproaches. In recent cases it is then always better for a time to break off all communication with the family in order to avoid emotional excitement."—Kirchoff.³⁵

"In mental diseases, as in all other derangements of the organism, a duly regulated measure of repose and activity is among the most important means of treatment; for the most part this can only be obtained by entirely removing him from his usual neighborhood and by exposing him to the influence of new and perfectly different impressions."—Grisinger.³⁶ Even if taken but across the street, the patient is benefited by the removal from home and surroundings.

"Perhaps the most important factor of family care, so-called, is the nurse. Persons fitted to the care of the insane are born and not trained. Isolation, either in a well-equipped hospital or a private house other than his own, is imperative."—Riggs.³⁷

There is no more prolific source of insanity than auto-infection, and to meet this condition, Bouchard³⁸ calls attention to the necessity of a carefully selected diet and the free operation of all the emunctories. Salines he especially recommends, and I can testify as to their value. Intestinal antiseptics should be a feature in nearly every case, and the agent employed for this purpose should be such as shall not interfere with normal digestion and yet be powerful enough to destroy the microorganisms which are doing the mischief and to neutralize the ptomaines already present in the tract. My own experience accords with that of Dr. John Aulde³⁹ and Dr. G. M. Blech,⁴⁰ that hydrogen dioxid is a most satisfactory agent for intestinal disinfection. Dr. Aulde uses a 3 per cent. and Dr. Blech a 2 per cent. solution of hydrozone in water, from two to eight ounces of this mixture being employed a half

hour before meals. I have made use of this method with pleasant results, and in cases where there has been much gastric fermentation I have employed an additional ozonized solution, glycozone, a teaspoonful immediately following meals. The glycerin which is the menstruum in this latter solution, acts as a mild stimulant to the intestinal glands, thereby accelerating the excretory functions of the tract. I have wondered if a little of the good effects from the use of a powerful static machine, which I have noticed in several cases of mental trouble in my practice, has not been due to the general effect from the inhalation of liberal quantities of ozone from the atmosphere in which the patient has been enveloped during the use of the breeze. Dr. Riggs and many other writers are enthusiastic over the use of the static current in the treatment of insanity. Dr. Gray³² believes that the ozone from the static breeze accounts for much of its benefits in hysteria, and why not also in insanity?

Tonics are indicated and iron is often the best. Gray mentions ferratin, which I have myself employed with excellent results, and as it is easily assimilated and does not interfere with the stomach it is a favorite with me. Hypnotics should be employed with caution, although at times they are indispensable. A lengthy paper would be required to discuss them and we can only say in passing that they often do more harm than good. The sleep produced by a hypnotic is often followed by a more pronounced attack of excitation. Hypnotics should always be given cautiously, pushed vigorously if needed, but avoided when possible. Trional is one of the best hypnotics for the insane, although the large dose required, 20 to 40 grs., makes it rather expensive.

Surroundings should be such, so far as possible, as to produce quiet sleep. Sleep, that blessed restorer of faded mentality; sleep should be perfect, however. Macfarlane, speaking of the relation of wakefulness to insanity, and the states of restless sleep, says:⁴¹ "It is highly probable that the very portions of the brain which most need a state of rest are, even during sleeping quiescence of other portions, more wastefully engaged in the activity of their functions than they can be in a waking state." "Want of refreshing sleep we believe to be the frequent origin of insanity."—Buchnill and Tuke.⁴²

Gynecology has suffered much in the past by the methods of many of her operators, who have sought to cure nervous and mental diseases by operations upon the female pelvic organs, and the directness of the criticisms of the neuro-alienists during the past have been of much benefit to humanity and to the real science of gynecology, as well as of neurology. Fortunately at the present time this bitterness of the past has nearly passed away, and as a result the alienist is ready to ask that the pelvic disorders of his female patients shall receive medical or surgical relief from the gynecologist, and the gynecologist no longer assumes to cure diseases of the nervous system and brain by the removal of healthy ovaries, etc.

"The clinical fact is that⁴³ many women require both the conservative gynecologist and the most skilled of neuro-alienists to successfully conduct their cases. A rational gynecologist that recognizes women as being possessed of other than a uterine system to account for some of her ailments is henceforth to prevail."—*Alienist and Neurologist*.

"It is gratifying to know that at last gynecology and neurology are in accord, and that henceforth

women are to be treated in a rational way for their nervousness."—Macfarlane.⁴⁴

Many cases of mental diseases are induced or exaggerated by disorders of the pelvic organs, and a relief of such disorders by surgical or other means, will often be of material benefit in restoring the mental equilibrium. In evidence upon this point I might refer to two cases of insanity seen in consultation. One had been operated upon at the time I first saw her and was convalescing, but was sent to me for a short course of static electrical treatment to round out her recovery. In the other case I advised that an operation should be done with hopes for favorable results to the mental state, which, in fact, within a month and by the time she was up after the operation, had restored the patient to nearly a normal condition.

These two cases seen last summer with Dr. H. R. Holmes and Dr. E. F. Tucker of this city, had pelvic lesions of long standing, the constant nervous irritation of which had finally ended in functional disease of the brain, but which readily gave way when normal physiologic pelvic relations were reestablished, and appropriate general treatment had been employed.

Dr. Roswell Park⁴⁵ has said that cases of insanity which are otherwise appropriated for commitment to a lunatic asylum should have the benefits of an examination for gross surgical brain lesions such as tumors, etc., and that when deemed permissible the benefits of operative treatment should be sought.

Dr. M. Allen Starr⁴⁶ has said that a few insanity cases can be traced to traumatism, and in selected ones an operation should be done to relieve brain pressure or irritation.

In the private care of an insane patient, the responsibility is not light nor the work and worry small, but with patience, firmness, gentleness and tact, and with fair facilities for the care of such a case the result obtained is often very satisfactory.

CHRONIC CATARRHAL GASTRITIS.

A Clinical lecture delivered in Rush Medical College.

BY HENRY M. LYMAN, A.M., M.D.

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE.
 CHICAGO, ILL.

I desire to call your attention, this morning, to a number of patients who belong to a large class that will confront you during the whole of your active career as medical practitioners.

The first one is a young woman, 25 years of age, who had typhoid fever about a year ago. She had been employed as a shop girl for seven years previous to her illness, but had considered herself in good health till a month before the attack. She says that she was very ill for a period of five weeks and "took a lot of strong medicine." Instead of recovering her normal vigor she has remained thin and feeble. Her heart, lungs, kidneys, spleen, liver and reproductive organs appear to be healthy, but she complains of lack of appetite, epigastric distension, frequent eructation for several hours after eating and constipation of the bowels. She is listless, depressed in spirits, slightly dizzy when walking and easily put out of breath. There is anemia with a reduction of hemoglobin to 70 per cent. The pulse is small and rapid, 95 to 100 per minute. Pressure below the xiphoid cartilage is painful, and often there are transient pains between the ribs and under the left scapula. The contents of the stomach, removed with the gastric syphon about four hours after an ordinary meal, exhibit numerous traces of undigested flesh fiber; there is present a large quantity of glairy mucus, and the chemic examination indicates an excess of lactic and butyric acids, with scarcely a trace of free hydrochloric acid.

The next patient is a man, 36 years of age, thin and sharp featured. For years he has smoked and chewed excessively, but has not used alcoholic beverages. For several months he has been troubled with frequent eructations and sometimes with vomiting. The fluid that is thus evacuated is very copious in amount, and is as frothy as beer. Microscopic examination reveals the presence of *sarcina ventriculi* in large quantity, to say nothing of yeast fungi and numerous other microbes that are frequently present in the mouth and stomach.

The next patient is a veteran bartender. Fat and coarse-looking; his rubicund visage and blooming nose testify to the depth and vigor of his potations. His breath carries the offensive odor of chronic alcoholism; his tongue is thickly covered with a yellowish-brown coating; he is troubled with a frequent, dry, spasmodic cough. In the morning his head aches, he coughs and retches until he can expel a few mouthfuls of thick, ropy mucus mixed with saliva that was swallowed during the night. Appetite is gone; whatever is eaten becomes an excitant of pain in the epi-

gastrium; the liver is somewhat prominent below the short ribs and is tender on pressure. The intestines are distended with gas and are alternately affected with diarrhea and constipation; the urine is scanty, high-colored and loaded with urates. Examination of the gastric juice indicates serious reduction in all the special constituents of a healthy secretion, so that in this case it consists chiefly of mucus, saliva and water.

One more patient will suffice to illustrate the principal characteristics of the disease. He is a book-keeper, about 48 years of age; tall, thin and anxious-looking. He formerly smoked excessively and kept late hours, but for the last three years he has been the victim of painful digestion and hypochondriac depression. He suffers after eating with flushing of the face, throbbing in the temples and a sensation as if something were loose and rolling around within the cranium. He is frequently so dizzy that he can not walk without a great effort. He is confident that his case is not understood by the physicians to whom he has applied for relief and that he is the victim of an incurable disease of the brain. The heart beats irregularly and sometimes violently. Many of his worst symptoms are relieved temporarily by eructation of gas or by the passage of flatus from the bowels, which, by the way, are obstinately constipated. He is often somnolent after eating, but is correspondingly wakeful at night. In cold weather he suffers much with neuralgia in the abdominal and thoracic walls, and almost every spring and fall he is inconvenienced for several weeks by an attack of hemorrhoids. These are sometimes replaced or preceded by a severe outbreak of urticaria, covering the whole body. Latterly there have been patches of eczema in the flexures of the knees and upon the lateral surfaces of the fingers. Last summer he had a severe attack of bronchitis with asthma, which continued until October, when it disappeared during the course of a hemorrhoidal bleeding.

Such, then, are some of the cases about which you will be frequently consulted. They all possess the common characteristic of chronic gastric catarrh. This disease often follows as the sequel of an imperfectly cured acute inflammation of the stomach. It is a common consequence of the various infective diseases; it is excited by errors of diet, hearty eating, imperfect mastication, excessive indulgence in alcoholic drinks, consumption of coarse and indigestible food and the habitual use of iced water, strong tea and coffee. It accompanies local diseases of the stomach, such as round ulcer and carcinoma; it is necessarily produced by all the disorders of circulation that are occasioned by obstruction in the portal vein, liver, heart, lungs and pleural cavities.

Could we look into the stomachs of these patients we should discover a variety of pathologic changes. The pyloric extremity of the organ is the seat of the principal disorder. There the mucosa is of a gray or brownish color, which in very chronic cases is sometimes of a dark slate color. Hemorrhagic extravasations are not uncommon in the connective tissue between the glandular organs. The distinction between the different kinds of cells in the glands themselves is often destroyed and the secreting cells are swelled with cloudy contents, or have undergone atrophy from pressure and imperfect nutrition. In some of the older cases, where the patient is anemic, there is general glandular atrophy, accompanied by the development of the symptoms of pernicious ane-

nia. The deep brown or gray or slaty discoloration of the tissue is due to the accumulation of pigment deposited by the excessive extravasations and stagnations of blood in the capillary network that envelops the gastric glands. The submucous connective tissue and the muscular coat of the stomach also participate in the inflammatory process, so that their cellular elements multiply and increase the thickness of the gastric wall. The interstitial spaces are frequently loaded with small round cells and leucocytes, as if actual purulent formation were about to occur. By the increased thickening and swelling of the tissues thus produced, there is sometimes effected an actual stricture of the pylorus, leading finally to dilatation of the stomach. Occasionally, the external serous investment of the organ shares in the general disposition to inflammatory thickening, and sometimes the entire wall of the stomach becomes symmetrically hypertrophied, so as to reduce the cavity of the viscus, and to suggest the idea of a malignant change in the substance of the tissues, requiring the aid of the microscope to distinguish this chronic inflammatory hyperplasia from the growths of carcinoma. In many of the older cases of catarrh the mucous lining of the stomach presents a roughened, warty appearance that is caused by irregular development and contraction of the submucous connective tissue. In certain rare cases small cysts are formed by the occlusion of isolated glands, ducts and the accumulation of their imprisoned contents. By a sort of reversal of this process the interglandular elements occasionally multiply and protrude into the gastric cavity, forming mucous polypi, which are only important when large enough and sufficiently near to fall into the pyloric orifice of the stomach, more or less completely hindering the passage of food into the duodenum.

The recognition of a catarrhal inflammation of the stomach is seldom attended with difficulty, but it is not always easy to decide whether it is an uncomplicated affection or whether it is dependent upon some other grave disease in the thoracic viscera, in the kidneys or in the gastric wall itself. The discovery of cardiac, pulmonary, hepatic or renal disease will render it highly probable that the disorder is secondary to those causes of perverted circulation and nutrition. The existence of general hyperplastic thickening of the gastric wall may be suspected when the gastric tumor feels smooth, firm and devoid of irregularities in its shape. But in the absence of tumefaction and resistance to pressure in the epigastric region, the question will resolve itself into a threefold query: Are we dealing with a carcinoma, an ulcer, or merely a chronic catarrh of the stomach? If the patient be in early or middle life the probability of cancer is less than in advanced years. The absence of cachexia and discoloration of the skin, long duration of the malady and freedom from bloody vomit favor the diagnosis of chronic catarrh. Enlargement of the lymphatic glands in the left groin and supraclavicular space sometimes accompanies malignant disease of the stomach, but is not a constant symptom. The absence of free hydrochloric acid from the gastric juice is a very trustworthy, though not invariable, symptom in carcinoma. The presence of minute, coffee-ground particles of altered blood-clot in the gastric contents is a weighty indication in favor of cancer rather than atrophic catarrh of the stomach. In many instances it is impossible to

discover before death the presence of a gastric tumor, but, in such cases, the absence of free hydrochloric acid, the existence of cachexia, lymphatic enlargement in the left groin and supraclavicular space, and, in the later stages of the disease, the occurrence of edema in the extremities—all these symptoms concurring in an elderly person would suffice to warrant the diagnosis of a latent gastric cancer. In a large proportion of the deaths occurring among old people, without definite symptoms beyond gradual wasting and exhaustion, the cause will be discovered in a latent carcinoma developed within the abdominal cavity.

The existence of an ulcer in the stomach should be inferred when the pain is more severe and narrowly circumscribed than in simple catarrh, especially if it be aggravated by eating. The disease is usually encountered among chlorotic and anemic young people, and when vomiting of blood takes place the hemorrhage is considerable, and large clots are thrown up instead of the "coffee-ground" sediment that appears in cases of cancerous bleeding.

No disease demands for its treatment more careful adaptation of means to individual necessities than chronic gastric catarrh. The daily life of the patient must be studied and all errors of hygiene, clothing, occupation and diet must be corrected. If the teeth are defective the aid of a dentist must be invoked, and the patient should be taught how to chew his food, for without thorough mastication easy digestion of the food is impossible. The food itself must be selected with a view to ease of solution in the stomach. For this reason it should resemble the food that is provided for a newly weaned infant. It must, therefore, consist chiefly of articles derived from the animal kingdom. The nursing child is a carnivorous animal by nature, and the convalescent invalid is in these respects on a level with an infant. The principal article of food should be milk—not boiled, but heated to the temperature of 160 degrees F., and drunk before it is cooled, so as to secure the stimulant effect of a hot liquid. In fact, no cold drinks should be allowed, because the muscular coat of the stomach is usually, in these cases, relaxed and atonic. This lack of tone is aggravated by the introduction of cold liquids, which must, therefore, be forbidden. Occasionally you will meet with patients who do not like milk or who think that it renders them constipated. You must reassure such people by telling them, what is true, that if they will begin with a tablespoonful of milk at each meal, and will gradually increase the quantity to a pint, or more, their constipation will be cured. Only once have I failed in this way to overcome the repugnance of the patient, and that was a case of peculiar intolerance, in which the use of milk was always followed by an eruption of erythema.

The prescription of a milk diet may be supplemented with broths and soups that have been strained, cooled, skimmed free of fat and then heated again.

Ordinary vegetable food and fruits should be forbidden until recovery is complete. Rice may be allowed as a substitute for vegetables, but it must be steamed or boiled in a water-bath, so as to avoid the necessity of stirring while being cooked. In this way it can be furnished with every grain whole, separate from its fellow, yet thoroughly soft and perfectly well done. It should be eaten with salt and hot milk.

The craving for bread that is usually experienced by persons who have been placed on a restricted diet,

should be satisfied with bread that has been sliced and dried in the oven before it is toasted. It should be eaten with a little butter, hot from the toasting-fork.

The animal food should be, at first, of the tenderest possible description. Calves' brains, sweetbreads, stewed tripe, tenderloin steak, lamb chops, chicken, game birds, the soft portion of the oyster, soft-boiled eggs, boiled ham, roast beef. These must be thoroughly masticated, or, if that be difficult, reduced to a pulp or mincemeat before they are taken into the mouth.

Many patients exhibit a desire for spices, mustard and vinegar, but this is a morbid craving which should not be gratified. Alcoholic beverages are forbidden because of the local irritation and the hindrance of digestion that follows the contact of alcohol with the inflamed mucosa.

Having thus regulated the diet of the patient, in many cases it is only necessary to await the favorable result. You must not be impatient at the delay which often attends recovery. Months and months of favorable conditions are frequently needful to effect a cure. Not infrequently, however, it will be desirable to have recourse to other methods beside hygiene and diet. You should then follow the indications derived from a chemical analysis of the gastric juice. I will not delay you with a review of the tests by which you may ascertain the presence, or the absence, of free acids in the stomach, for you have already become familiar with the use of the gastric syphon; and the significance of the change in color of congo paper dipped into the filtered liquid thus obtained from the stomach is something of which I need not remind you. You have often seen the behavior of the phloroglucin-vanillin reagent when heated with gastric juice; and you are well-informed regarding these simple qualitative tests. A quantitative analysis requires more time and labor; but, fortunately, it is seldom necessary outside of the laboratory of a professional chemist or physiologist. Few busy physicians can afford the time for such an examination, and in our large cities, whenever occasion requires, an exact analysis can be easily obtained from such sources. For all clinical purposes the character of the qualitative reactions is usually sufficient as a guide to treatment.

If, then, you find that the filtered juice turns red congo paper blue, you may know that it contains free acid. If now, on heating the same juice with a few drops of the phloroglucin-vanillin reagent upon a white dish, no carmin color appear, you will have learned that free hydrochloric acid is absent and that the acidity of the liquid is due to the presence of lactic, acetic, or butyric acids, for which the appropriate tests may be employed. With a little practice you will be able to draw tolerably accurate inference regarding the relative quantity of free hydrochloric acid; but if absolute accuracy is desired you must resort to the laboratory method of qualitative analysis, as described in your handbooks of physiologic chemistry.

In cases that are marked by the absence or deficiency of free hydrochloric acid, you may administer dilute hydrochloric acid. This should be given in doses of ten drops in half a glass of water with each meal. Many physicians prescribe it in larger doses, but a little reflection will show that it is not to be regarded as a substitute for the normal gastric acid. Were such the fact, it should be given in a dose of

one hundred drops, diluted with nearly a quart of water. Nor should the fact that it is often grateful to the patient betray one into the advocacy of large doses, for such patients generally experience a craving for acids and spices to an extent that is positively injurious. It is probably through its local antiseptic action, and by its diuretic effect upon the kidneys, that the medicinal acid is useful. Since the peptic ferments are usually reduced in quantity along with the free hydrochloric acid, it is well to add ten grains of pepsin to the acid draught.

When the patient complains of gaseous distention of the stomach, and of eructations indicative of fermentation, you should administer remedies to prevent such decomposition of the food. Half an hour before meals, when the organ is nearly, if not quite empty, give ten grains of salol, or the same quantity of pure salicylic acid, or a grain and a half of resorcin. The efficiency of these agents is somewhat increased by giving them in peppermint water, or in capsules with a drop or two of the oil of peppermint. When the eructations are acid from the presence of lactic, butyric or acetic acid, sodium bicarbonate in scruple doses may be associated with the other antiseptic remedies. If the bowels be constipated also, ten grains of calcined magnesia should be given with the sodium powder.

But if the stomach be dilated these measures will not suffice. It then becomes necessary to wash out the stomach every morning with the aid of the gastric syphon. Water of the temperature of 90 to 100 degrees F., to which has been added sodium bicarbonate (one or two drachms to the pint) should be run through the tube, in and out of the stomach, until it returns clear and sweet. The disinfectant remedies above mentioned may be then administered before the patient takes his first meal.

In such cases, and the majority of chronic sufferers fall into this class, there is considerable relaxation of the muscular tone of the gastric wall. The process of irrigation and disinfection of the stomach should be, therefore, followed by the administration of bitter tonics, which arouse the contractility of the muscular fibers. Sulphate of strychnia, in doses of one-twentieth of a grain, may be given after each meal. Ten drops of tincture of nux vomica, or a half drachm of tincture of gentian, a half drachm of the fluid extract of condurango, a wineglass of the infusion of quassia, a teacupful of the infusion of camomile flowers, or the same quantity of the infusion of eupatorium perfoliatum, are useful tonic bitters. The compound tincture of cinchona and the various elixirs of calisaya bark are often prescribed with good effect; but, as a general rule all preparations that contain alcohol should be avoided, on account of the narcotic effect of alcohol upon the secreting glands of the mucous membrane—an effect that favors the occurrence and persistence of mucous inflammation.

For the invigoration of the general nervous apparatus of the body, electricity may be employed with great advantage. General electrization with the aid of the static machine for fifteen minutes every day is useful. Or the faradic current may be applied for the same length of time daily, with one electrode upon the back of the neck, while the other is moved slowly in every direction over the epigastrium and abdominal surface. Massage given daily is another useful method for patients who are confined to the house. Daily sponge baths with cold water are indispensable

for the confirmation of nervous vigor. You must carefully instruct your patients with regard to these methods, together with exercise in the open air, for without such aid it is useless to expect a cure in chronic cases of exhaustion arising from gastric catarrh. It is also very important to procure for the patient a complete change of scene and occupation, for such people are usually much depressed and hypochondriacal. Hence the great benefit that may be derived from travel or from almost any new and interesting mode of bodily exercise.

When pain in the epigastric region is an important symptom, it sometimes becomes necessary to have recourse to various narcotics. Of these the most popular is alcohol, but, though it gives temporary relief, it always aggravates the inflammatory condition of the mucous membrane. A similar objection lies against the use of nitrate of silver, compound tincture of iodine, salts of bismuth, etc.; they must be administered with great caution and in small doses, lest they do more harm than good. Cocain, in doses of one-tenth of a grain, often affords relief, but it is a dangerous drug and the cocain habit may be thus easily acquired. Sometimes it is actually necessary to prescribe an opiate, and in such cases it is well to exhibit small doses of Dover's powder, since the ipecacuanha which it contains is a valuable stimulant to the glands of the digestive mucosa, and does in some measure obviate the tendency to constipation that is occasioned by opiates alone. For the same reason small doses of belladonna are often useful, either alone or associated with opium or morphin, but if there is constipation codein should be given the preference, since it interferes less than other opiates with intestinal peristalsis. Chloral hydrate may be given with advantage, in doses of five to ten grains, whenever required by a recurrence of pain, if there be any objection to opiated anodynes. The bowels should never be permitted to remain constipated. As laxatives, may be recommended the popular pills containing aloin, belladonna and strychnin, or the compound liquorice powder of the German pharmacopeia, or calcined magnesia, or the elixir of rhubarb and magnesia, or cascara cordial. If the stools exhibit a deficiency of bile, podophyllin may be given in small doses (one-tenth to one-fourth gr.) after meals, in connection with the alkaline laxatives that neutralize gastric hyperacidity.

Arthritic patients are often benefited by laxatives that contain sulphur, such as Squair's Compound Sulphur Tablets, or Garrod's Tablets, or the old-fashioned mixture of sulphur and cream of tartar. So great is the number of elegant laxative preparations that everyone can have his own favorite, and it may suffice to point out the importance of giving the preference to those drugs which stimulate secretion and aid gastro-enteric peristalsis—in other words, the gently stimulating laxatives rather than the drastic purgatives. When constipation is chronic and the liver is engorged with blood and bile, a course of mineral waters is often beneficial. They should be drunk in quantity sufficient to produce gentle catharsis, and may be taken preferably from half an hour to an hour before breakfast. As a general rule, hot mineral waters are better than those that are cold. When the natural spring water is cold, or when bottled waters are used, the morning draught should be followed by a cup of hot water, to raise the temperature of the stomach before eating. It is always best to drink the waters at their native source, in order to experience

the good effects of rest, change of environment, etc., which are associated with a vacation at the springs; but when such advantages are impossible, much good can be obtained from the bottled waters that can be drunk at home. In cases of simple gastric catarrh, the waters that contain a predominating quantity of magnesian salts, or chlorid of sodium, or of carbonate of sodium, are sufficient. When the tongue is thickly coated and yellow, indicating hepatic disorder, the waters that are richly charged with sulphate of sodium are most efficacious. The waters of Saratoga, of the deep artesian wells in eastern Michigan, when largely diluted, and the hot saline springs in Colorado and the other mountainous regions of the continent are all valuable. Of the ordinary bottled waters the Saratoga, Hunyadi Janos, Friedrichshall, Racoczy and Rubinat waters are extensively used. For arthritic subjects the sulphurous waters may be recommended. Of these the springs at Richfield or among the Alleghany mountains and in Kentucky and Tennessee, are among the most noted. The hot springs of Arkansas possess little or no value beyond the quality of heat which they derive from the rocks through which they flow.

When prescribing the use of mineral waters or their artificial substitutes—solutions of magnesian and sodic salts—care should be taken to caution the patient against their too persistent use. Few can drink the stronger waters longer than five or six weeks without exciting an inflammation of the gastrointestinal mucosa that may be very difficult to heal. It is better to use them for a month or six weeks at the springs and then to abstain for a number of weeks, or to have recourse, if needed, to the mild vegetable laxatives. It is always important in this, as in all other protracted courses of medication, to provide for occasional intermissions, in order to prevent both local irritation and the establishment of tolerance of the drug that is employed.

ANTITOXIN AND DIPHTHERIA.

Read before the Harrisburg Academy of Medicine, Dec. 29, 1896.

BY W. H. SEIBERT, M.D.

STEELTON, PA.

At a meeting held here about a year ago I read a paper entitled "Diphtheria," in which the subject was treated in its entirety and some reference was made to the use of antitoxin serum.

The paper which I present tonight deals chiefly with antitoxin and some reference is made to diphtheria as seems to be proper or relevant to the subject.

Careful observations were made during this year in the treatment of all cases occurring in my practice, and the results will be presented briefly, together with statistics of our town so far as applies to results in the treatment with and without the serum. In addition, there will be presented statistics of many of the largest cities of the United States relating to frequency of the disease, comparative mortality, mortality rates of the pre-antitoxin years as compared with the mortality of the present year.

In referring to the history of diphtheria it may be said that it comprises three main periods, the first of which dates from the earliest times of medical history to the sixteenth century. In this period various descriptions are given of the different epidemics of the disease by Hippocrates, Aretæus, Galen and various other writers. The second period extends from

the sixteenth century to the latter part of the present century, and in this is observed a more definite and scientific description as to details and results as well as a marked advancement in the clinical observations of the disease. An excellent description is given by Baillou, a noted French physician of the time, and after him Brettoneau distinguished himself by his studies and gave the disease a distinctive place in the nomenclature of diseases. Later Trousseau and numerous writers of various countries add to the researches and history of the disease, but little to the prophylaxis and treatment. In the latter part of this period it was believed by some writers that a particular germ was the cause of the disease and various theories were advanced to explain its action. This was the semi-scientific period and led up to the third or present period, which may aptly be called the scientific or bacteriologic period of diphtheria. Here we have after Pasteur's brilliant discoveries the magnificent researches and experiments of Koch and his followers, arriving at conclusions which definitely identify the cause of diphtheria. The bacillus being now discovered and identified, the field of discovery was further advanced by Behring, who, by long and patient investigation and experiment, finally reported his discovery of antitoxic serum about April, 1893. From this time on, various reports were made of its use and value, and within two years it was used in many places in this country, and several laboratories or manufactories produced a serum on the same principle and of the same value as that produced in Germany.

The method of manufacturing the serum is as follows: A colony of the bacilli derived from a virulent culture is transferred into bouillon which is placed in a favorable surrounding until numerous bacilli are grown or developed, by which a large quantity of toxin is produced, after which the bacilli are destroyed by the addition of a chemical. The bacilli are then removed by a process of filtration. This fluid or serum is of unknown strength, and in order to establish its strength or toxicity experiments are made by injections into guineapigs and in this manner is determined its relative strength to quantity, or the basis of antitoxin unit to cubic centimeter. The establishing of the unit is after Behring's method and I believe all manufacturers follow it. An antitoxin unit signifies one cubic centimeter of the quantity of the fluid or serum which is necessary to protect a guineapig from ten times the least lethal quantity on injection. A small quantity, about a cubic centimeter, of the above fluid is injected into the animal—the horse being preferred on account of tractability and capacity—and at repeated intervals increasing quantities are injected until the animal is thoroughly immunized, requiring about three months. The animal is now bled, the serum removed and properly preserved by the addition of a chemical, then tested to adapt its strength and finally bottled and labeled. The label explains the number of c.c. and the number of antitoxin units, and as the serum comes in different strengths, it is always preferable to speak of and designate it by the number of antitoxin units instead of the c.c. It is desirable to use the more concentrated preparations, as they are more readily injected, more quickly absorbed, cause less pain and likely contain less chemical as preservative. The serum is administered hypodermatically in a place where the skin is loose, as on the side of the chest, back, arm or leg. Antiseptic precautions must be observed

and the syringe must be thoroughly sterilized before and after every injection. The time to administer the serum in any given case is at the earliest possible time after the clinical diagnosis, and doubtful cases should also be injected, whether or not an epidemic exists. The quantity of serum to be used depends somewhat upon the age and weight of the patient and on the type or form and stage of the disease. In a mild case under 2 years of age, if seen within the twenty-fourth hour of the disease, 500 antitoxin units should be injected at once and the same should be repeated every twelve to twenty-four hours until improvement results. If the case is very severe or when seen late, or of the laryngeal type, urgency demands 1,000 to 1,500 units at once and to be repeated in twenty-four or even twelve hours, if no improvement is manifested. In children over 2 years of age, when the case is severe or advanced, 1,000 to 1,500 units should be injected at once and followed every twelve to twenty-four hours until the progress of the disease is arrested. I saw a child of 7 years in the seventy-second hour of the disease, being a most severe laryngeal case—one of membranous croup—in which there seemed absolutely no hope of recovery until 4,000 units were injected within thirty hours, after which the membrane of the larynx and bronchi became softened, loosened and came away in large sections, and recovery except for paralysis which was persistent, was uninterrupted. Experience and urgency demand that double the usual quantity be given in laryngeal cases. For immunizing or protecting against an attack of the disease from one-fourth to one-half the ordinary quantity is recommended. To avoid pain during injection a 5 per cent. solution of carbolic acid rubbed briskly on the skin is useful. I have found the chlorid of ethyl spray quite satisfactory and efficient. The pain, however, is usually slight and it is only in exceptional cases that a local anesthetic is required. In a few cases I observed a diffuse redness around and beyond the site of injection and also in one case an urticaria that might be attributed to the injection, but these disappeared within twenty-four hours without treatment. As to the danger from injections of the serum, I have seen no untoward or harmful effects, and when it is considered that now about a million injections have been made, with only a few fatal results, all of which are indefinitely accounted for, and in view of the good accomplished, it is scarcely worth while to hesitate on this account. As to the method of cure it may be said that the serum acts by arresting the growth of the bacilli, or that it counteracts the progress of the disease. As to its clinical effect, I observed that its immediate action was, in over 75 per cent. of my cases, to lower the temperature one to two degrees in twenty-four hours and the pulse rate in the same proportion, and the progress of the disease seemed arrested. In a few of the cases the temperature and pulse rose higher immediately after the injection but within the next twenty-four hours they gradually receded toward the normal. Now as to the practical value of the serum, there seem to be but few persons who have made a fair and thorough trial of it but what they are ready to testify in its favor. From all sections, in private practice, hospitals, cities all over the United States, Europe, Asia and Africa, comes the most favorable testimony. Indeed, it would seem but necessary to call our attention to the reluctance with which we formerly gave our hopeless opinions

in the laryngeal or so-called membranous croup cases, and yet today we approach these cases quite hopefully.

During the present year, 1896, Steelton, with a population of 10,000, was invaded by an epidemic of diphtheria, mainly confined to a section four squares wide and same length, this being drained by large sewers for surface drainage only. Statistics have been accurately kept by the board of health. During the year thirty-two cases came under my treatment. The local treatment of these cases consisted in using cleansing and antiseptic applications of hydrogen dioxid followed with a lotion of mercuric chlorid 0.2 to 0.1 per cent. in equal parts of tincture ferri chlorid and listerin, applied on cotton to the affected parts in the pharynx. Hydrogen dioxid and listerin were injected freely into the nasal passages and in some a one-fiftieth per cent. solution of mercuric chlorid in glycerin and water was injected thoroughly. Atomization and inhalation of same remedies were employed for nasal and laryngeal cases. These remedies were applied every two to four hours, and in addition, where possible, gargles were used frequently. The constitutional treatment consisted of tincture ferri chlorid, mercuric chlorid or both combined, calomel 1 to 2 centigrams hourly as to age, being preferred in the laryngeal cases, as it was deemed more stimulating to the local secretions. Quinin was given early and frequently throughout the attacks and later through convalescence strychnin was used. Proper attention was given to hygiene, and free ventilation was insisted on and persistent nourishment was enforced from the beginning of every case. Of these thirty-two cases twelve were treated without antitoxin serum and twenty were treated with the serum, and in all other respects they were treated alike, so that the antitoxin treatment was supplementary. Of these cases the former or those in which antitoxin was not used were deemed the milder and it was thought possible to cure them without its use. Of these twelve cases three died, two of extreme weakness and one suddenly of cardiac paralysis when it was presumably convalescent. The average active treatment of these cases lasted twelve days and the mortality was 25 per cent. Of the twenty cases treated with antitoxin, one died, and this within six hours of its use, being a hopeless case as it was also in the fortieth hour of the attack when first seen and toxemia was extreme. The average active treatment of the cases treated with the antitoxin was seven days. Of these twenty cases five were laryngeal and two of these as severe cases of laryngeal stenosis or so-called membranous croup as I ever encountered, all of which recovered. Albumin appeared less frequently in the serum cases than in those treated without it, and paralysis followed somewhat less also. Altogether there were 115 cases in Steelton in the year, being a proportion of 1,150 cases per 100,000 population, and the number of deaths was 16, being 160 per 100,000. Of these cases twenty-three were treated without serum, of which ten died, being a mortality of 43 per cent. Ninety-two cases were treated with the serum and six died, being a mortality of about 7 per cent. or a gain over the other series of over 80 per cent. In addition to the above I cite from the report of the American Pediatric Society, which has a report of 1,256 laryngeal or membranous croup cases treated with antitoxin. In over half of these recovery resulted without operation and of the 533 cases operated on the mortality was 26 per cent., or only about one-half of former mortality. I have also reports from many of

the largest cities in the United States arranged in tables showing: 1. The relative number of cases per 100,000 of population. 2. The relative mortality per 100,000. 3. The mortality rate for 1891 to 1896. 4. The mortality for 1896. The source of this information is from the local boards of health and it is gratifying that statistics are now so generally kept and available, though in a number of important cities the statistics are too incomplete to be fairly tabulated and for this reason had to be omitted. The method of calculation is by taking the populations of 1890 and end of 1896 and averaging by the number of years and the number of cases, and the results are obtained alike and fairly in all. The percentages are stated in whole numbers.

Cities.	The average number of cases per 100,000 for the years 1891-1896.	The average number of deaths per 100,000 for the years 1891-1896.	Average mortality per cent. for the years 1891-1896.	Mortality per cent. for the year 1896.

The average number of persons affected yearly per 100,000 in all these cities of ten million population for the years 1891-1896 is 242 and the average yearly number of deaths is 61. The average yearly case mortality for the years 1891-95 is 28 per cent., and for the year 1896 is 19 per cent., being a gain of 32 per cent over the average of the previous five years, and a gain representing nearly 2,000 lives. Now if the entire population of the United States were affected in the same ratio and the mortality the same, it would equal the saving of 14,000 lives annually. These comparisons could be extended, but so far, I think the main object is accomplished; that of demonstrating from widely extended, disinterested and impartial statistics—the local health boards—that during the present year in which the antitoxic serum has been pretty generally used, the mortality rate is 32 per cent. less than the yearly average of the preceding

five years. These results are fairly attributable to the improved treatment by the efficient and more general use of antitoxin. There are many useful statistics at hand by various authors, but I preferred this comparison by the larger cities of the United States, and if the cities from year to year will keep accurate statistics or complete records what a useful field would here exist for exact observation of the results of this or any other method of treatment.

In the use of antitoxin it should be remembered that it is not a panacea or a specific in the sense that no other remedies need be used, but that it is to be used with the usual other remedies or treatment. Beside, a number of the cases are mixed or multiple infections, that is, the streptococcus and staphylococcus germs are also present, and the diphtheria antitoxic serum has no effect on these germs. In addition to the serum and general treatment efficient local treatment no doubt limits the infecting or septic area and since we recognize that diphtheria is caused by a specific germ or bacillus which is lodged or implanted on the mucous membrane of the nose, pharynx or larynx and that it produces an erosion from which is absorbed its toxin, and even the bacilli are absorbed and enter the blood and the various organs of the body. Again, when we recall the quite large area of the nasal tract and also that in autopsies the bacilli have been found in the frontal, ethmoidal and sphenoidal sinuses as well as in the antrum, it seems but reasonable that local treatment is in most cases, if not in all, indispensable. So that the best results are to be expected by using the serum combined with local and constitutional treatment. It is confidently urged that the profession adopt its use universally and the mortality rate will be materially decreased from year to year, and as a result the yearly number of cases must decrease instead of increase as has been the case in most cities. Promptness in using the serum early is a very important factor and it is suggested that it is not necessary to wait on a bacteriologic diagnosis, but to act promptly in all cases on a clinical diagnosis and thus much valuable time is gained both in treatment and prophylaxis.

Much might be said of the utility of bacteriologic work and of the propriety of stations throughout the commonwealth from which rapid and free examinations should be made by the State. Such a system would be of incalculable benefit in the management of diphtheria and the various other germ diseases which are now so rapidly claiming our attention as to this new and apparently successful method of serum therapy. The utility of bacteriologic work seems to be greatest in determining the sporadic and doubtful cases which occur at the beginning of an epidemic and in isolated districts so as to prevent by quarantine and prompt treatment the spread of the disease, for it is apparent the more cases the more bacilli and hence the greater the danger of the spread of the disease. The prophylaxis of diphtheria and other contagious diseases could be materially advanced if communities were properly informed and protected by laws forbidding or limiting expectoration in public places or where people gather or come in contact as well as the disinfection of vessels used for expectoration. And if all cases of diphtheria were strictly isolated and treated with the serum it is reasonable to hope that diphtheria will be eradicated or at least limited to a small per cent. of the cases which now annually occur in all cities and in all countries.

THE USE OF ANTITOXIN IN THE TREATMENT OF DIPHTHERIA.

Read before the Detroit Academy of Medicine, Jan. 12, 1897.

BY GEORGE DUFFIELD, M.D.

ATTENDING PHYSICIAN AT HARPER HOSPITAL AND PROFESSOR OF CLINICAL MEDICINE IN THE DETROIT COLLEGE OF MEDICINE.

DETROIT, MICH.

The fear and misgiving which attended the administration of the anti-diphtheritic serum at the outset is no longer justified. From every part of the world come numerous clinical reports attesting the value of the new treatment. Its untoward symptoms have been promptly and carefully studied, so that with proper care it is a safe and efficient remedy for the treatment of diphtheria.

In September, 1894, I treated my first case of diphtheria with anti-diphtheritic serum, a bottle of which I had obtained from Aronson's laboratory in Berlin. The case had been a severe one; the serum was used after secondary infection had developed and the case seemed hopeless. The membrane had extended where it would and could not be checked. The temperature stood at 103 degrees and pulse at 120.

The serum was injected with all due precaution. The temperature continued to rise for several hours, showing that diphtheritic intoxication was not materially checked, but about six hours after the injection the fever began to fall; in twenty-four hours after the injection the temperature stood at 98.5 degrees, the membrane had grown white and the edges were loosening, and by thirty-six hours after the injection all of the membrane had been expectorated. The disease was not only controlled, but enough anti-diphtheritic serum had been introduced to counteract the toxic effects of the existing diphtheria, and the result seemed almost miraculous.

Since then, my faith in this new therapeutic agent has increased greatly. In the fall of 1895 I had from thirty-six to forty cases, and during the last three months of 1896, eighty cases were treated with only two deaths.

It should be the duty of every practitioner to place the antitoxin at the head of all therapeutic measures that he may know of for the cure of diphtheria, for it proves its efficacy whenever it is administered early, and in sufficient quantities to neutralize the poison which it is to antagonize.

An early diagnosis can not always be made from the clinical symptoms; frequently a tonsil may be covered with spots like a follicular tonsillitis, and one of the spots be true diphtheria and the case treated for an ordinary tonsillitis, when in reality a true case of diphtheria is developing in a medium that will prove a regular hot-bed for the development of the Klebs-Löffler bacilli.

All cases suffering from sore throat should receive the benefit of the doubt as to whether the case be one of simple or diphtheritic sore throat by a bacteriologic examination and the earlier such an examination is made, the greater the chance of saving our patient.

Our Detroit Board of Health has furnished test tubes for the making of cultures from suspected sore throats, and I believe that if they were used more often, the epidemics in our city would be reduced.

The dose to be administered at first is a question of importance. I think it is best to overdose at first, than to give a lesser curative serum. The bulk is the same, whether 500, 1000, 1500 or 2000 units are used,

and as the inserting of the needle is always painful, it is better to give a full dose early, rather than to have to repeat the injection.

The amount to be used depends upon the length of time the patient has been sick, the extent over which the membrane has spread and the thickness of the membrane.

As to the antitoxin to use, having tried five or six different makes in the past two years, I have found that which has been manufactured by Parke, Davis & Co., most efficacious. Apart from the potency of this brand, I must commend the ingenious manner in which it is marketed, viz., in hermetically sealed glass bulbs, which exclude the air and keep the serum strictly aseptic.

From the charts I exhibit, you will see that when a dose was given of sufficient strength, the action on the toxin producing the constitutional symptoms, namely, fever, high pulse and great prostration, was prompt and effective; the fever being reduced rapidly. Laryngeal cases recovered slowly, but showed marked improvement after each injection.

Strange as it may seem, the serum varies in strength, different manufacturers furnishing the same number of units in various bulks, and many brands containing a less number of curative units than claimed.¹ Such brands are to be avoided. The most concentrated serum is, I think, the best to use, as there are rarely any bad results from its injection. It has been noted in several cases that an erythema or urticaria develops around the point of injection. None of the severe symptoms as noted by some have been noticed by me, though several hundred injections have been given under my direction. Several have had rheumatic pains, but no other symptoms showed themselves, not even an abscess, and their absence was probably due to the great care used in the manufacture of the serum administered.

During the past year there have been 111 cases of diphtheria in Harper Hospital, five of which died. Three of these entered moribund, and one man had been sick six days before entering the hospital and the action of the toxins upon his heart centers was so great that he died from heart failure, the result of the diphtheritic poison. Some cases where large doses of antitoxin were used close together showed subnormal temperature for several days. There have been six tracheotomies and twelve intubations. There have been many laryngeal cases that were treated successfully with merely antitoxin and inhalations. The youngest case was a child of five weeks, bottle-fed. During the months of October, November and December there were over seventy cases in the hospital under my care, and six in private practice.

The nurses who were on duty were at first immunized with 250 units, later with 500 units, and still later with 1,000 units, as the prophylactic effect was better. The nurses were constantly, except when off duty, exposed in an atmosphere saturated with diphtheria. Two nurses took the disease after having been immunized, and one took diphtheria after nursing a man who started with a "follicular tonsillitis," but which later turned to a true diphtheria. All the nurses recovered. When the disease was taken by those who had been immunized the attacks were mild.

Too much praise can not be given to the corps of nurses who cared for the patients day and night, with promptness, cheerfulness and efficient vigilance.

Had it not been for their splendid work, many of the patients would have succumbed to the disease.

In all the hospital cases the patients had been sick from two to three days before entering, hence it was necessary to use the strongest antitoxin serum early and repeat the dose in six, twelve or twenty-four hours, if the growth of the membrane was not checked or stenosis promptly relieved.

We have several standing orders that patients receive as soon as they reach the hospital, for we believe in using some medicines that proved useful before the discovery of the antitoxin.

An examination of throat is made to see the extent and location of the membrane.

1. A hypodermic of antitoxin 1500 or 1000 units.
2. A liberal dose of calomel if tongue was coated and bowels constipated.
3. An ice collar, worn until all glandular enlargement disappears.
4. A gargle every two hours of

Hydrogen peroxid	2 parts.
Euthymol	2 parts.
Lime water	4 parts.

5. Membrane to be touched for 10 or 15 seconds with Loeffler solution, every three hours. This is composed of:

Menthol	10 gm.
Toluene q. s. ad	36 c.c.
Creolin	2 c.c.
Iron chlorid sol	4 c.c.
Alcohol q. s. ad	100 c.c.

This dissolves the membrane and destroys the Loeffler bacilli *in situ*.

Should the patient be needing a stimulant, the calomel was omitted and whisky or strychnin administered. Other symptoms were met by appropriate means as soon as they arose.

Cases of laryngeal diphtheria were treated with steam inhalations after being injected. Children with pneumonia complicating diphtheria were put in the oil silk jackets and kept in an atmosphere of comp. tr. benzoin and other non-irritant inhalations.

The frequency of dose of the antitoxin depends upon the spreading of the membrane and the condition of the temperature.

How soon is a patient to be discharged as cured?—I have had a culture taken from throats each day for three or four days until all Klebs-Loeffler bacilli disappear before I pronounce the cases well enough to mingle with others, for it has been known that the Klebs-Loeffler bacilli may be carried in the throat of a person without danger to himself, and yet be the source of great danger to others.

As a rule the cultures taken after all membrane has disappeared from diphtheritic throats prove negative after three or four days.

Just how dangerous the diphtheritic bacilli are after the use of the antitoxin, remains for the bacteriologist to determine. Where antitoxin has not been used, I have known reinfection to occur ten or fourteen days after primary attack.

Diphtheritic paralysis developed only slightly in two cases, but more severely in another case where all the vital centers had suffered from previous disease. Albuminuria was noted in a few cases, but as the disease predisposes to renal disease the antitoxin could not be held responsible; all these cases cleared up as soon as the poison was neutralized. No secondary infections occurred after the disease was once under control.

¹ Medical News Report.

ASTHENOPIA NOT DUE TO REFRACTIVE ERRORS.

Read at the Meeting of the Chicago Ophthalmological and Otological Society, Jan. 12, 1897.

BY HENRY GRADLE, M.D.
CHICAGO.

The inability to use apparently healthy eyes for near work, without increasing discomfort or pain, is usually caused by refractive errors, or insufficiency of accommodation. In a series of 500 patients with asthenopic complaints taken consecutively from my records, the symptoms were caused by hypermetropia, astigmatism or presbyopia in 75 to 80 per cent. In 20 to 25 per cent. the asthenopia could not be accounted for in this manner, for either the optic conditions were perfect or, if not, their correction gave no relief.

Some of the factors which lead to asthenopia, in the instances not dependent upon optic faults, are suggested by a study of the refractive cases, if we consider them as patients and not merely as the possessors of optically imperfect eyes.

The importance of refractive errors varies according to whether we study them either in the patients of our office practice or in the population at large, that is to say, in school and military examinations, or in people whom we treat for other than refractive anomalies. Instructive, too, is the study of presbyopes. From such material it can be learned that many people can pass through life up to middle age without being annoyed by an existing hypermetropia or astigmatism of 1, or perhaps even 1.5 dioptics, and that when the error exceeds this amount, or the accommodation begins to decline with age, the normal and typical annoyance upon using the eyes is a feeling of strain or fatigue bordering on pain. In office practice, on the other hand, we see patients annoyed by errors far below this limit and complaining often, not merely of fatigue, but of various forms of pain, headache and even distant nervous symptoms. In a previous discussion of this subject ("The Neurological Aspect of Asthenopia," *New York Medical Record*, Dec. 7, 1895) I have tried to emphasize these differences, by terming *normal* asthenopia that amount of fatigue and discomfort which is inevitably produced by a refractive error of sufficient degree, while I called *exaggerated* asthenopia the excessive eye annoyance which asthenopia leads to only in certain patients.

Observation shows that on the whole, those persons who complain only of normal asthenopia or who tolerate low errors without disturbance, represent the healthier part of the community. On the other hand, persons who suffer great annoyance in consequence of an unproportionately low degree of asthenopia, show often in many other ways that their nervous system is not in perfect condition. In some we get a decided history of inherited nervous instability. In others the past history, or perhaps only the subsequent observation, reveals other functional neuroses. Sometimes enfeebling infectious diseases have undermined the resisting power. Anemia or impaired digestion are also not uncommon precedents in exaggerated asthenopia. Finally faulty habits, improper hygiene, and especially insufficient muscular work, are very often factors which lead to an excessive reaction from eye-strain. The rôle of these various pernicious influences is all the more striking in those instances in which a moderate refractive error had been borne without inconvenience until a breakdown occurs on

account of such additional factors, while when these influences can be eliminated the patient may again be able to dispense with his correcting glasses. It is true there are cases, too, in which we can not elicit any other reason why a low error should cause such disproportionate discomfort, or why the eye strain should lead to other nervous symptoms. But is it not most logical to admit that there must be some reason why that patient's nervous system reacts so much more than that of average healthy persons, even if we can not detect it? In other words, I hold that normal asthenopia is the natural discomfort associated with a refractive anomaly, while the man with exaggerated asthenopia is indeed a patient who has, beside his optic defect, a deficient nervous system. It is, however, self-evident that no sharp line can be drawn between normal and exaggerated asthenopia.

The same reasoning holds good for asthenopia dependent upon other causes beside optic defects. In about 3 per cent. of asthenopic patients I find the ocular anomaly to be slight chronic inflammation of the conjunctiva or the edge of the lid. It is self-evident that a patient with pronounced conjunctivitis can not use his eyes without increasing discomfort, and it would be illogical and superfluous to describe his condition as asthenopia. If, however, decided asthenopic symptoms are complained of and we find merely a squamous blepharitis, or a minimal degree of chronic conjunctivitis so slight as to escape any but expert observation, and furthermore, if the annoyance ceases after the cure of the inflammatory condition, we can not but call it a case of exaggerated asthenopia. That is to say, the individual, on account of some peculiarity of his nervous system, reacts with asthenopia to an irritation which most persons can tolerate with scarcely any discomfort.

The symptoms of asthenopia dependent upon conjunctival irritation differ in many instances from the characteristic fatigue and ache due to ametropia. The annoyance is usually described as burning or watering, which may lead to headache in neurotic persons.

Occasionally asthenopia has a multiple origin. It may depend upon low ametropia in conjunction with blepharitis or chronic conjunctivitis and will in such instances require attention to both factors.

As another ocular lesion which bears some relation to asthenopia, I wish to refer to a certain anomaly of the retinal pigment epithelium. I do so with some reserve because I probably stand isolated in the interpretation and because the interpretation of such clinical facts is extremely difficult or uncertain. I refer now to certain slight changes in the appearance of the fundus which I have often met with in cases of exaggerated asthenopia. I can not give exact statistics because I have only paid attention to the subject in the last five years, while the statistics I quoted were partly from the time previously and partly from my records of last year. I should say, however, that I have observed this condition at least fifty to seventy-five times.

The normal fundus is, as you know, homogeneous in appearance. In some subjects, however, we find a condition which may be described as graining, or salt and pepper appearance. With it there may be in addition partial atrophy of the pigment epithelium exposing the choroidal vessels. The special lesion to which I refer seems to depend upon irregular distribution of the pigment epithelium, and we see an appearance which would be produced by the mixing

of fine black and white powders with grains so minute that the eye can not discern the separate grains. Sometimes a few of the grains are coarse and discernible and white and black specks may be recognized with the ophthalmoscope. This condition is clearly more than a structural peculiarity. I judge so for the reason that when I encountered it in adults it was in connection with actual lesions of the fundus as, for instance, in conjunction with localized foci of choroiditis and particularly during the retrogressive stage of neuritis. Otherwise I have hardly met with it in people over 25 years of age, but only in children and young people. This appearance is usually most pronounced in the lower nasal quadrant of the retina, but it may extend over the entire periphery and may even reach the macular area. I know of no reference to it in literature except the occasional use by writers of the term "woolly fundus," or "stripping." (*Archives of Ophthalmology*.) It is not identical with Gould's ametropic choroiditis.

With few exceptions the children in whom I found this appearance of the fundus were asthenopic. In some instances the asthenopia depended entirely upon refractive errors and was corrected definitely and permanently by glasses, but even in those cases it was always the exaggerated form of asthenopia. There was great complaint in proportion to the degree of error actually found. In other instances, however, there was no refractive error measurable, or if present its correction gave no benefit. These individuals were markedly neurotic and the neurasthenic condition might be taken to account as a predisposing cause for the asthenopia, but still the coincidence of this peculiar irregular distribution of the pigment epithelium in connection with such exaggerated asthenopic complaints is worthy of note and I would like to call the attention of the members to it. We can not influence the fundus condition directly by treatment, and hence can not prove absolutely its significance. It was generally accompanied in my cases by slightly lowered vision, about two-thirds or one-half, which could not be fully raised by glasses. It never led to any greater disturbance of vision, but it gave, in many cases, marked discomfort in the form of burning or smarting, often leading to headaches. There was commonly some sensitiveness to light, and the symptoms were most marked in the morning on rising. Although it was asthenopia in the sense that the discomfort increased on using the eyes, still the discomfort was ordinarily not quite absent and generally most pronounced on rising.

The only therapeutic measures that gave me any satisfaction whatsoever were absolute rest of the eyes and dark glasses. Personally, I have seen very little benefit from the dark glasses in other forms of asthenopia. But in this form the use of dark glasses has proven the most satisfactory of any of the measures employed.

This finishes all I can say about ocular causes of asthenopia, except that I might refer to the subject of muscular anomalies. That subject I trust, however, will be taken up by other members this evening who have had more experience than I have, for I have not seen much to convince me of the importance of muscular anomalies as a cause of asthenopia. My own impression has been that the number of cases in which muscular anomalies are associated with asthenopia is not large, if we analyze the cases properly, and that in the majority of instances the muscular anomalies

are not dependent upon anatomic peculiarities of the muscles, but are of neurotic origin, rather associated with the asthenopia than the cause of it. However, I do not wish to deny there are cases of muscular asthenopia, only I have never happened to see many of them in my own experience.

If we seek for other disturbances in the system which may provoke asthenopia I know of two organs which play a considerable role in its production. These are the mucous membrane of the upper respiratory organs and the stomach. Various German rhinologists (Gruenwald) have referred to the existence of asthenopia in connection with suppuration of the different accessory sinuses. Some of these observations are suggestive rather than convincing. Personally, I have not had any definite experience in this connection. The cases of suppuration of the accessory sinuses seen by me which had ocular symptoms, were more in the nature of a steady discomfort than a distinct asthenopic complaint. I have, however, seen quite a number of instances, and my records place them at about 3 per cent. of all my observations upon asthenopia in which the nose played a greater or lesser role in the production of ordinary asthenopic symptoms. Most of the cases were of the nature of a chronic catarrhal rhinitis, with secondary hypertrophies, or, with stenosis due to deviations of or excrescences upon the septum. In placing the figure at 3 per cent. I must admit that it is not based entirely upon my therapeutic records. Not all of my patients were willing to undergo the tedious treatment that nasal stenosis would require, while others were not observed long enough. But in accepting that figure for my statistics I did so on the basis of the therapeutic successes in a smaller number of cases in which the probability of relationship was raised to certainty by the results of the treatment. At any rate, I can refer to a reasonable number of instances where there was heaviness and discomfort in the eyes, burning or a dull feeling upon using the eyes, and where the removal of the spurs from the septum or the evulsion of mucous membrane of the turbinals led to permanent cessation of the symptoms. In some cases glasses had been prescribed either by myself or others. But in the convincing observations these glasses which had only been of moderate benefit could be discarded after the nasal treatment. In none did the glasses give entire satisfaction before the nasal treatment.

Another naso-pharyngeal condition to which I would attribute an occasional influence in the production of asthenopia is enlargement of the pharyngeal tonsil, the condition usually termed adenoid vegetations. I have seen at least twelve to fifteen cases in which children complained of decided asthenopia, where they could not use the eyes without discomfort, and where glasses given by myself or others did not prove wholly satisfactory, although the correction of the ametropia was not entirely useless. In these cases the removal of the adenoids gave definite results, namely, complete relief from the previous asthenopic symptoms. In all these instances, however, we can not exclude more or less instability of the nervous system. Indeed, I am not ready to admit that *exaggerated* asthenopia of any kind, or from any cause, can occur in a person whose nervous system is perfectly up to par. There are all possible degrees between normal asthenopia and the exaggerated form, because under the present conditions of our civiliza-

tion there are only relatively few persons whose nervous system is trained from youth and reared by proper inheritance to the strictly normal physiologic condition.

As regards the influence of the stomach upon asthenopia I can not quote any statistics. My records are not detailed enough in all instances. Moreover, I am not sure that stomach disturbances alone would ever account entirely for asthenopic complaints. But I have observed quite a fair number of instances in which asthenopia associated with refractive errors, or without any measurable error of refraction, could not be relieved by any means whatsoever until the patient's stomach was cured of the condition in which had been, presumably a chronic gastritis. These individuals showed a coated or furred tongue, complained decidedly of distress of the stomach, had gaseous eructations, bloating, or general discomfort after meals, or, at least, after any indiscretion of diet. It is in these cases, as a rule, that we can not get relief until we place the patient upon rational diet, and prescribe sufficient outdoor exercise. On the other hand, by advising such measures a fair number of dyspeptics can get rid entirely of their asthenopic symptoms and may be able to dispense with glasses, which previously had been a necessity, although without ever having obtained full satisfaction from the glasses alone. This perhaps is as much as I can say definitely upon the subject of asthenopia not dependent upon refractive errors from the basis of my own experience.

Unfortunately, our therapeutic influence upon the nervous system which is at fault in such cases, is at the best a slow and often imperfect one. We can not correct hereditary influences. The patients are not always able to change their faulty habits. The pernicious after-effects of infectious diseases, like typhoid fever or measles, as a rule, are not amenable to treatment, only to time. But the condition of anemia which underlies this trouble can quite often be benefited by the administration of iron, and iron is a valuable adjuvant in the treatment of asthenopia if anemia be present at the time.

I might add a few words about the relation of some of the vague forms of asthenopia to hysteria. I was led to these views by observing the relatively acute onset of asthenopia in some instances. We all know that, as a rule, asthenopic patients can not state exactly when their annoyance began. In a small minority of instances, however, a time can be fixed and it coincides with some pernicious influence active at the time, for instance, the sickness of a child necessitating long waking hours of the mother, or overwork in the preparation for examination by students. Again, in other cases a change of boarding house with poor diet may have led to dyspepsia, while in a few of my observations the occurrence of acute coryza preceded the ocular disturbance. In such cases of asthenopia not dependent upon refractive anomalies *with relatively acute onset* I have had good results, provided they had not lasted long, by removing these pernicious factors, insisting upon proper hygiene, proper muscular exercise and absolute rest, if possible, for the eyes. By strictly carrying out this treatment many of these patients were cured within a number of weeks. On the other hand, if we get these cases after they have persisted for months, if they have been insufficiently treated, or have not sought medical advice at the proper time, we all know how very

persistent such asthenopic complaints may be, even though the original cause has ceased to act. The persistence of the asthenopia when the starting cause is a matter of the past, might be logically attributed to hysteria. After all, perhaps, as good a definition as we can give of hysteria is "functional neuroses which are dependent upon psychic influence." Asthenopia in the cases mentioned does not start from cerebral influence in the first place. It may start from some tangible cause as coryza, dyspepsia, persistent overwork, etc. After these causes have ceased to act, the persistence of asthenopia in some cases is purely psychical. At least, we can find in some instances no somatic anomaly whatsoever which would account for the persistent asthenopic annoyance, and close analysis renders it probable that the patient retains the remembrance of his former suffering and suffers still when using his eyes, simply because he expects the discomfort.

About the only mode of therapeutic influence which I have found of benefit in these cases was to get the patient to forget the trouble gradually. If circumstances permitted I advised to drop work entirely. It is by change of surroundings in these slow cases, especially by a vacation and traveling; it is by oblivion of the annoyance attending previous eye work and by the suggestive influence of promised relief that I have attained moderately satisfactory results in these cases where no somatic condition remained to which the asthenopia could be attributed.

DISCUSSION.

Dr. CASEY A. WOOD—There are two causes of asthenopia, unconnected with the refractive state, that are common enough and to which I would draw the attention of the Society. First of all are those minute choroidal changes which one, now and then, observes about the macular region. In Moorfield's we were accustomed to give certain phases of these the name of Tay's choroiditis. They occur, in my experience, mostly in young adults, and although they are confined entirely to the choroid, I have a suspicion that in many instances (and I believe that I have been able to show it) that there is a slight lowering of central vision, which corresponds to ill defined relative scotomata. Exactly what these changes are and what they are due to I do not know, but I am certain that in many instances they produce asthenopic symptoms, because after correcting all refractive errors and after disposing of the various muscular anomalies that commonly produce eye strain no relief is obtained.

The treatment of such cases has with me been extremely unsatisfactory. I have never succeeded in doing very much for these patients except to give them temporary relief under atropin for long periods and to prescribe tinted lenses. After the effects of the atropin had worn off I endeavored to keep them from tiring their eyes, especially by prohibiting all near work. I recall very distinctly a case which I had that had been examined and treated by quite a number of ophthalmologists, by most of whom these changes had been recognized. After this patient had been under my care for months, during which time I treated her *secundum artem*, I urged her to take about two years' holidays from the work she was trying to do, but at the end of that time I do not think she was able to do more than a quarter or a half hour's near work at a time. In other words, I have come to regard such cases as practically incurable, at least while the choroidal process is active. Central vision was excellent in this case, *i. e.*, distant vision was almost normal and very fine print could be made out.

A careful examination with the perimeter shows, in most instances, doubtful central scotomata for red and green, not

always confined to the fixation point, but sometimes a little to one side of it, and not so well defined as one sees in toxic amblyopia and in similar diseases:

I hesitate to speak about the other source of asthenopia, although I have referred to it in print before, because it is usually only a manifestation of the so-called neurasthenia. I refer to insomnia. In a scientific society like this it is hardly fair to speak of a mere symptom as productive of asthenopic symptoms, but, be that as it may, I think I am correct in asserting that in the presence of decided insomnia, not associated with organic disease, but which seems to be a part of a general neurosis, the treatment of cases of asthenopia is far from satisfactory. The correction of the refractive error, looking after the eye muscles, etc., do not produce the usual results. Whatever be the cause of the insomnia, I consider it my duty to tell the patient that unless it can be relieved in some way or other I shall not be able to do very much for him or her, as the case may be.

Dr. F. C. HOLTZ—I shall speak of only those local conditions which produce asthenopia, and among these I wish again to refer to what Dr. Gradle has already touched upon, to blepharitis as one of the common sources of asthenopic symptoms not referable to refractive errors, and I lay more stress on this condition than did Dr. Gradle, and I do not agree with him that in those cases where there is a slight or hardly perceptible blepharitis, the inflammation produces asthenopia only because the patient is in an abnormal nervous condition; for I find whether the blepharitis is slight or well marked the eyes show a particularly marked sensitiveness to any irritating cause, such as exposure to light, to wind, and consequently the exertion of the eyes in near work produces congestive conditions in the lids, and the result is a feeling of heaviness due to the congestion, and expressed by the patient as fatigue, burning, smarting and pain leading to headaches.

We know that some time ago errors of refraction were charged as causing blepharitis, and it has become a habit with many oculists to prescribe glasses and nothing else in cases of blepharitis. I still insist that the relief is more prompt by paying attention to the local treatment of the inflammatory condition of the lid than to the refraction, and I know many cases in which glasses have been worn for years and no relief of the asthenopia was obtained, when under proper local treatment the patient was relieved and could use his eyes with perfect comfort, whether he had the glasses on or off.

We find a similar condition in the conjunctiva. Very often the inflammation is so slight that it is not shown over the tarsal portion of the conjunctiva, which on eversion of the lid looks perfectly well. There is often only a slight congestion of the retro-tarsal folds, a congestion which is aggravated by near work and leads to a succulent condition of the retro-tarsal folds, which causes a feeling of fatigue to the patient. These slightly succulent or congested folds are usually not exposed when we turn the lid in the ordinary way, but they can be very easily brought into view when the eyeball is pushed back into the orbit by slipping the lower lid over it and pressing upon the lower lid, pushing it back into the socket, while the everted upper lid is held against the supra-orbital margin. This makes the retro-tarsal fold spring forward and in many cases where the conjunctiva looks perfectly normal when the lid is everted in the usual way, you will be surprised to find a diseased condition of the fold which fully accounts for the complaints of the patient.

A third local condition has also been touched upon, viz., slight changes in the choroid. I would mention as quite frequent an excessively saturated redness of the fundus, a slight indistinctness, or blurring of the outlines of the papilla, and changes in the pigmentation. Very minute white dots scattered over the fundus have also been observed by me and I had reasonable grounds to regard them as the local condition for

the asthenopic complaints. In some of these cases I discovered little choroidal patches in the periphery of the fundus, so that I am inclined to think that in many cases which are considered as choroidal hyperemia there is an actual peripheric choroiditis which under the strain of near work produces painful eyes and the symptoms of asthenopia. Old people during the development of cataract often complain of a dull recurring pain in the eye, and Dr. Risley has called our attention to the fact that in a good many of these eyes there are changes in the periphery of the choroid.

Dr. CHAS. M. ROBERTSON, Davenport, Iowa—Not as much has been said about the nasal causes as I think there should be. Dr. Gradle hinted at the subject in saying that stenosis of the nasal cavity might be the cause, either from enchondroses, an excrescence, a deviated septum, or from chronic rhinitis. The only form of rhinitis that is exempt, according to American authorities, is the atrophic, although Schwartz, and some others than he in Europe, state that they have seen cases originating in atrophic rhinitis. My experience has taught me that we are more liable to have reflexes from vaso-motor paresis than from chronic rhinitis and true hypertrophic rhinitis, although the great majority of cases of hypertrophic rhinitis are the result of a parietic condition. Some authors believe that an enchondrosis on the septum acts by producing a vaso-motor paresis behind the occlusion thus formed and not from the enchondrosis *per se*. A spur may act primarily by producing pressure irritation to the turbinated body opposite.

I have had several cases in which the removal of the spur was followed by complete relief. A great many cases of conjunctival irritation or blepharitis may be due to obstruction by pressure of the inferior turbinated body on the lachrymal duct opening. I have had one case of such where cauterization of the inferior turbinate relieved the condition which produced the asthenopic symptoms.

Dr. W. F. COLEMAN—We all recognize the fact that probably 90 per cent. of all cases of asthenopia are due to refractive errors. Of the remaining 10 per cent. I agree with Dr. Gradle that perhaps only 3 to 5 per cent. are due to muscular condition; not that muscular insufficiencies are uncommon, because in non-asthenopic eyes they are extremely common, but that relieving these muscular conditions does not cure the symptoms in an asthenopic patient. Tenotomies in my limited experience have not been successful. Of those having satisfactory results the ones dealing with vertical insufficiencies have been most satisfactory.

Dr. Coleman then reported several cases showing that in spite of every effort to correct refraction and muscular insufficiency the symptoms remained.

Dr. WM. H. WILDER—Dr. Gradle has covered the subject very thoroughly. I would like to speak particularly of the peculiar "pepper and salt" appearance of the retina. In Moorfield's it was Mr. Nettleship's habit to call attention to this condition, especially in young adults and children. It may be that this peculiar arrangement of the pigment epithelium is sufficient to cause hypersensitiveness of the part.

Dr. HUGH T. PATRICK—There were one or two points brought out in the discussion that I might speak of. Dr. Wood spoke of asthenopia due to insomnia, and I wish most emphatically to dissent from any such way of stating the interrelation of symptoms. Insomnia is simply a symptom of disease, and I do not believe that any case of asthenopia can be cured by treating the insomnia *per se*, because it must in the nature of things be treated by treating the underlying nervous or other conditions. Many of these cases of asthenopia are nothing but excessively nervous subjects. It is to be expected that a person who is nervously exhausted, who is in the true sense of the word a neurasthenic, who is suffering from nervous prostration, should suffer from asthenopia. He gets tired if he walks too far, and gets tired if he follows a train of thought. Such a person

would not be expected to read as he ordinarily does. We should expect him to become weary and the print to blur.

There is another class of neurasthenics that suffer from asthenopia, and they are the neurotics *par excellence*; the patients who show the classical symptoms of neurasthenia from insufficient cause. Such is the laborer who, after overlifting, shows the typical symptoms of neurasthenia coming on one by one, and with them asthenopia. Or a woman who undergoes a trivial gynecologic operation, where there is no material loss of blood, no shock, no infection, but anxiety, apprehension, or other abnormal psychic condition, and who after the operation develops one after another, generally slowly, the typical symptoms of neurasthenia and asthenopia. The asthenopia of these cases arises not from overwork and nervous strain, but from psychic causes. To treat such cases by treating any anomaly of the eye alone is very short-sighted. It would also be short-sighted to treat only the nervous system without treating the ocular abnormality. In many of these cases the ocular symptoms may be the most pronounced, and so largely mask the other manifestations.

I wish to impress from the standpoint of the neurologist, that in these cases neither rest, over-feeding, or anything but psychic treatment will do any good, if any good can be done.

Dr. C. W. HAWLEY—I would like to state that I find more and more the influence of general conditions on asthenopic patients. I no longer confine myself in many cases to the exclusive treatment of the eyes, but often have cause to congratulate myself for treating general conditions, and in this way relieving the asthenopia.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

CHAPTER II.—THE QUACK.

Family quackery, old women, shepherds and others; The charlatan at the annual fair; Secret remedies; Hernia curers, castrators; Cataract-couchers, Hilmer, John Taylor; Stone cutters; Frère Jacques, Rau; Hangmen, torture, guillotine; Quacks in foreign lands; Remedy against quackery; Our time.

Quackery is an evil innate in human nature, and enters the sick room with every old woman. Who is there that visits a patient and does not feel impelled to pass judgment on his ailment, to display wisdom as to diet and temperature, or to recommend with the utmost eloquence a remedy which has at some time helped this and that acquaintance? With this misguided condolence, which is not peculiar to the feminine sex, there sometimes lies behind the impulse to play the doctor, only indiscreet sympathy, but very often it is largely arrogance and self-conceit. The traditional blundering of mothers and aunts, even to this day, makes the life of the practising physician so bitter that he often leaves the sick room feeling that medicine is indeed a sublime science but a miserable business. This well meant quackery is only a little twig of that rankly luxuriant quackery of the 18th century which like a poisonous vine shot up out of the superstition and prejudice of the German people. However much custom, habits, laws and forms might change, the prejudices as to medicine remained fixed as they had been for centuries and were handed down from one generation to another. The stupidity of the public promised rich plunder.

The people were wholly ignorant in medical matters. They had no opportunity to instruct themselves

concerning life and health, and were incapable of distinguishing the true physician from the quack. Of public hygiene, the physicians themselves knew little and whenever they ventured to interfere were strenuously opposed by the lawyers, who had always claimed for themselves the management of state affairs. Various causes contributed to lead the public into the hands of the quack. The large number of ignorant physicians and surgeons, who belonged in the same class with the charlatan and decried scientific training as useless; their wrangling, the trivial character of the doctor's examinations, all undermined confidence in the medical profession. Other people, especially the clergy and the apothecaries, were very ready to grasp them by the hand. A man who every year prepared so many prescriptions for every possible ailment must necessarily become so wise as to be able to cure those ailments; no one for a moment doubted his skill, so they asked his advice and freely took his medicines. This class embraced, besides the barbers, bath-keepers and midwives, other wise people, apothecaries and old women, root-gatherers and alchemists, shepherds and blacksmiths, hunters, hangmen and other riff-raff (*Lumpenpack*). The army of pretenders was countless. They all enjoyed unquestioned confidence and, as the rabble believed, possessed a supernatural gift of healing. The peasant found conversation with a shepherd far more to his taste and to him more intelligible than with a physician. He feared he might not be treated with proper care by the physician, and moreover that he would be obliged to pay more for it. Furthermore there prevailed among the peasantry the idea that their diseases formed a distinct class which the physicians of the rich did not sufficiently understand. But quackery was also to be found in the better classes, among people of rank and education. With them blind faith had its roots in the taste for everything new and extraordinary, which indeed so despotically rules many people. They reproached the physicians because they uniformly clung to the old ideas and never sought out anything new. They vested great confidence in those who agreed with their own preconceived opinions, and ignored those whose treatment was in the least disagreeable. Human life was intrusted to the quack, but in all other things he was considered rude and ignorant. On the one side was the desire to become healthy, on the other the eagerness to make money; both of these conspired to unsettle the reason of the sick. People were imposed upon by anything and put faith in the most shameless promises, until at last the empty purse and disillusionment brought the victim to his senses. That the charlatan knew better how to gain confidence and was much oftener consulted than the scientifically trained physician, is a fact just as true today as it was one, two, or three centuries ago. In the sixteenth century all Europe swarmed with quacks, whose name (*Quack-salber*) arose at this time, when syphilis raged frightfully, and the medical pretender made an unwise and excessive use of mercury (*Quecksilber*). Bacon wrote of that time: "The rabble had in all times considered every old woman and every charlatan as a natural rival of the best physician and worthy to contest with him the preference at the sick-bed." In the seventeenth century the clamor over this nuisance was still unabated, and what Primrose then said of England might be written of Germany a hundred years later: "It is surprising that most people are so careful in the choice of their physician, that if a physician settles in

a place they venture to trust him only after a long time; on the other hand, they immediately trust a traveling mountebank, if he remains in one place only a few weeks, and people of the poorest class, who on the plea of their poverty do not employ physicians, sometimes waste large sums of money on these itinerants. And these quacks, devoid of all merit, who in no country would be considered competent to attain honor and dignity, enjoyed respect and great honor, and were sometimes accorded the same rank as physicians."

Besides those, who along with their trade occasionally dabbled in medicine, there was a class of men called mountebanks (*Marktschreier*, *Medicastro*) who made a special business of quackery. To this class belonged the dealer in nostrums, the itinerant truss-maker, cataract coucher and lithotomist.

The *mountebanks* went from city to city, from one village to another, hence the name "storks" (*Störcher*). At every fair (*Jahrmarkt*), the Tyrolese stood beside the coucher and from a dirty medicine-case in his booth sold at an enormous price to the gullible peasant the remedies secretly and very cheaply obtained from the apothecary shops. They paid the state a few *kreuzers* as a tax, just as the player, who was obliged to pay one *guilder* for each performance. A printed announcement, rich in Latin and Greek phrases and scriptural quotations, shamelessly promised to cure everything in the shortest time with the help of God. They even warned the public against other mountebanks, and as proofs of their own skill produced testimonials, written by themselves and false patients. Those who had already made money came in their own carriages with two beautiful horses, if dun-colored so much the better, and had themselves announced in the village as a court-physician, dentist, oculist and rupture specialist licensed by some German prince. Not satisfied with coachmen and servants to carry the proclamation throughout the whole town it was announced from the pulpit that everyone suffering from diseases of the teeth, ears or eyes, or with rupture, would be guaranteed a complete cure without having been previously seen or examined. One itinerant, John George Drenkler, called himself, in his prospectus, upon oath a burgomaster, operator, oculist, lithotomist, cataract coucher and trussmaker, born in the city of Hamm, in Bavaria, now a royal burgher, domiciled at Bischheim, who in various kingdoms and celebrated capitals, had cured many thousand men of different diseases. He said: "I cure all diseases of the eyes; a man whose sight has been lost for ten, twelve or fifteen years, who has gray and white cataract, I can relieve in a few minutes so that he can see the smallest bird on the roof." The peasants, in processions, journeyed to the mountebank. Painted, and clad in the ragged mantle of a theater prince, ornamented with strands of teeth about his neck, or dressed as a Turk, he prated to them that the Turks are the best surgeons. By hundreds the people stood with eyes and mouths agape, in front of his tumble-down booth, which was pasted over with advertisements, and false charters of serene highnesses and high and mighty rulers. The people were happy to be cheated out of their money by the wonderful man and obliged to pay twenty times too much for every remedy. No medicine there was too expensive for those who in life often suffered the greatest poverty. The nostrums were principally antidotes, wonder balsams, salves for burns and aromatic pellets. In the presence of the

people the mountebank swallowed his antidote and then if we assume that he did not lie, he ate ratsbane. But the poison did not harm him, because he had already filled his stomach with milk and fatty substances. Again he took his antidote, and placed vipers on his breast; and these did not hurt him because they were tame. He represented to the peasants that his marmot's grease, or his herb-salve would heal all fresh wounds in twenty-four hours; he then cut his arm with a sharp knife, bound it up with his salve, and on the following day showed the scar. The cut was however only a superficial scratch, which he had immediately drawn together with a bandage so that the healing was accomplished by that means alone. The people saw and wondered. No cure was undertaken without cash payment in advance. A deaf man being required to pay eight *thalers* in advance declined to do so, but offered to pay ten *thalers* if he should be cured, whereupon the mountebank refused the case because the man lacked confidence. Another quack cured all diseases with *aurum potabile*. The poor patient was given the strongest assurance that gold would help him, and out of pure love, he was furnished for fifty *ducats*, medicine which upon oath cost one hundred *ducats*. Old midwives sold pills for sterility which would be effective, even without coition. When after a few weeks in a village the charlatan, whose protruding paunch betrayed his prodigal life, received his bill, he left the place which had been levied upon for his support and blessed by his presence. The public was very willing to be deceived; it was indeed familiar enough with wonderful cures by means of plasters, oils and balsams. These were talked of much oftener than they were accomplished; the cures were followed with attention, but the mischief which quackery did was overlooked. Their fundamental principle was to condemn everything which had gone before, and to avoid every connection with physicians and surgeons. They removed all bandages and threw them away, and as they were not skilful enough to supply others, they used only a plaster or a salve. The healing of an ulcer or a wound they left to nature, and so occasionally accomplished a cure whereby other people were misled.

The Hamburg and Frankfort periodicals as well as other advertising mediums teemed with names of nostrums. Pills were extolled for gout, powder for goitre, blue water for murrain. The swindlers were blindly trusted. The more shamelessly they boasted, the better success they had. They were a plague upon the land and worked more devastation than diseases.

Only a powerful reason could induce a physician to renounce his science and become a charlatan, *par excellence*. There was such a reason, as an honest colleague in the year 1761 confessed, that is, hunger. As an upright man he had not been able to earn a living, although he despised all humbug and served his patients faithfully. Nevertheless the young swindlers were given the preference over him. For a long time he endured the ridicule and humiliation, until at last hunger overcame his pride. He went to another town and became a charlatan. He prepared worm cake, *aurum potabile*, heart powder and tooth powder. He took a clown along as a servant and together they took their place in a booth. The servant whom he represented as a doctor, extolled the wonderful remedies; he himself undertook the roll of harlequin, and said to the rabble: "That is a fakir whom misfortune has brought so low that he dupes the

people in this way." Nevertheless they crowded to the booth and bought. He soon became a rich man. Finally a harsh city physician had him arrested, put into prison on bread and water for six weeks, and his wares confiscated. He owed his freedom to a baroness who had read in his prospectus, that he possessed an infallible means of preserving the skin against wrinkles for a hundred and forty-five years. She bought him out of custody.

The *rupture surgeons* held a prominent place among the surgical mountebanks. Those suffering from hernia have always been exposed to the basest deceptions. No disease created more quacks than rupture. Most men looked upon this ailment as a defect in their organization, as a disease which drained their strength and their generative powers. This fear was so deeply rooted that they were made miserable by it. The impostors reaped their profit therefrom; they knew that a man was careful to keep this defect a secret, believing it to have a syphilitic origin, and that he desired most earnestly to be cured of it, cost what it would. A. Paré had indeed already recommended the truss, and had provided it with a larger opening, and had introduced a new method in place of the cruel operation. But the truss was very crudely made and very painful, so much so that one could not rightly lean his weight upon it. It is no wonder that the rupture surgeon found a large field, when even the physicians were so ignorant of the theory of rupture that a certain Dr. Lange in his *Surgery* (1776), recommended that a child suffering from a rupture be drawn through a cleft oak sapling, whose forks were held apart; this remedy, which was very general among the peasants, helped many children. The honorable surgeon could only recommend to the patient the permanent wearing of a truss. The charlatan made capital of this poor relief, and maintained that the surgeon understood nothing of the proper treatment, since the bandage could not cure the rupture and only an operation could completely remove the evil. The boastful promises corresponded with the wish of the patient to become well, so that consent to an operation was readily given. Many a mother dreaded the trouble of attending to the truss for her child year after year, and chose as a shorter way the operation, *i. e.*, castration, the nature of which the rupture surgeon naturally kept to himself: It was better that the child should die, than to live with so horrible an affliction, and instead of buying a truss for two guilders, they gladly gave the rupture surgeon twenty to thirty thalers for an operation which a regular surgeon would have performed much better for five thalers. Money induced the charlatan to perform the operation, as one of them frankly informed Heister. For the truss he charged only one thaler, while on the other hand for the operation he received twenty thalers. In England ten guineas were often paid for the operation. When, upon the reappearance of the rupture, the deception was exposed, the people kept it quiet, because they were not willing to admit their delusion. By the side of the rupture surgeon stood the dreadful quack, who did not venture to use the knife, but advertised his specifics, rupture plasters and the like, in the newspapers, and in this way extracted the money from the pockets of the poor. If the surgeons complained of this imposture, they were accused by the public of professional envy. Among the peasants rupture was very common, often from three to six cases in one village, so that the opportunity for an operation

occurred often enough. In Breslau one rupture surgeon mutilated over two hundred children. Rupture was especially frequent in Switzerland, where athletic exercises, wrestling and jumping, were very popular, and after the battle of Vilmengen, there were found among the fallen Swiss an extraordinary number with hernia. This was a headquarters for the rupture surgeons, of whom not less than eighteen sojourned for a time in Lucerne alone, within three months.

Until in the second half of the eighteenth century, operation was preferred by most as a radical cure. The rupture surgeons, who styled themselves country operators (*Landopérateure*), and were allowed princely privileges, were traveling through Germany as late as the seventeenth year of the century. There was little or no talk of civil supervision. The operators, both men and women, had begun as horse or swine surgeons, and had gradually acquired a little anatomic and surgical knowledge, until finally they ventured to treat human beings. Like an heirloom, the calling was handed down in a family. Their operations consisted in tearing out and cutting out the testicle together with the seminal duct. They considered castration necessary because they believed that the intestines and the testicles were enclosed in the same sac; there followed, if the testicle was not removed, a relapse, and the healing of the ruptured peritoneum could not be accomplished. The castration practiced at that time was a principal reason why learned surgeons, in the earlier times, would not undertake operations for rupture, but left them entirely to the rupture surgeons. A knife, long nails on the fingers, and a single strand of strong pack-thread, were the only instruments. They laid the patient upon a table, the head lower than the abdomen, and bound him fast. The rupture surgeon pressed the intestines back into the abdomen and had them held there by the hand of an assistant, then an incision three or four fingers long was made in the scrotum through the skin and fat, extending back to the hernial bag, which was freed from its environment, drawn out, and a pack-thread wound twice around the hernial bag and the seminal duct, by which these vessels were laced together. Then the rupture surgeon, at the expense of fearful pain to the patient, tore out the testicles, but concealed them in his hand, like a juggler, and quickly made an incision, a finger breadth under the pack-thread. In case of double rupture, both testicles were removed, whereby the patient became impotent. The operation, accompanied by all kinds of benedictions and foolishness, lasted only a few minutes. They filled the wounds with lint, drew them together with plaster, and on the following day, bound them with oil of eggs, Johannes oil and other balsams. As a rule, the rupture surgeon, after he had been properly paid, left his cruelly martyred patient in two or three days, without troubling himself further about the after-treatment; only the better ones among them allowed the patient to lie in bed twelve or fourteen days, and attended him. A few were cured, and on the other hand, many look fever and died from inflammation and loss of blood, or in other cases, after a little time the rupture returned. The rupture surgeons operated in different ways. Those from Norcia in Italy, who enjoyed a special reputation, inasmuch that a certain Horaz performed about 200 operations a year, practising very commonly the barbarous method of castration. The Spanish rupture surgeons did not cut out the testicle, but pressed it back in the intestinal cavity, and usu-

ally wound a gold thread around the hernial sac; other Italians burned the seminal organs with a hot iron. The barbarity went so far that, as Dionis relates, one was accustomed to throw the severed testicles to his large dog, which always lay under the operating table and eagerly snapped at the booty.

The state allowed the rupture surgeons to practise under certain restrictions. In the year 1685 the Kurprince of Prussia had issued an edict "that the operators, oculists, lithotomists, rupture surgeons, dentists, etc., should not practice without previous examination at the collegia medica, and should not remain over four days at the yearly markets." The edict of 1725 also allowed the rupture surgeons, as well as the dentists and root dealers, to travel around to the fairs in Prussia, and to stand publicly in the cities, if they had previously obtained a license. One of the first who opposed the nuisance was Heister, who in the year 1728 wrote a special dissertation "de kelotomiae abusu tollendo," and demanded that the authorities prohibit entirely the methods of the rupture surgeons, in those cases where the patient could get along with the help of a truss. In general an upright surgeon dared not risk an operation at all, because they endangered life, were terribly painful, sacrificed the testicle, and after all did not insure against a relapse. Exactly one hundred years later the trade of truss- and bandage-making was conditioned upon an examination and a license. Louis XIV. commanded the surgeons to discover a method by which rupture could be operated for without destruction of the testicle. He himself dispensed for rupture a nostrum he had received from a Prior. Later, Haller turned his attention to his mutilated countrymen. In Germany the Margrave of Baden-Durlach, Charles Frederick, has the credit of forbidding (in 1766) the treatment of rupture by means of castration in his country. The French ministry discovered, when in 1779 the Royal Society of Parisian physicians was established, that a great number of the conscripts had lost one or both testicles. Several French bishops had observed that some mountebanks had advertised, with trumpet-flourishes, in their diocese, a preventive for rupture for thirty livres, which was nothing less than castration. The bishop of St. Papaul found in his district over 500 castrated children, from whom the shameless rupture surgeons had taken the elastic trusses which he himself had provided. As a warning, the Paris Medical Society published the names of those rupture surgeons whom they could discover. The previous century indeed recognized the barbarity of castration, but regarded it very leniently. So Dionis, who considered castration a transgression of divine and human law, did not disapprove of it in the case of priests, since they must be celibate, and would in this way have the double advantage of relief from the annoyance of those organs, and at the same time be cured of hernia. The Catholic church had laid its law upon the castration of boys; nevertheless, such boys sang everywhere in the masses, and they were well paid. Rome and the other great cities of Italy swarmed with these singing martyrs. There were special operators, boy-cutters (Knabenschneider), some of whom; in Naples, displayed publicly signs with the notice: "Here boys are cheaply castrated."

The *cataract couchers* were another kind of surgical quacks. In the sixteenth and seventeenth centuries ophthalmia, entirely neglected, lay in the hands of these mountebanks, who spread their confusion

over all Europe, and until the end of the eighteenth century overran Germany in all directions. Many of them were Italians and Frenchmen. In the larger cities, one oculist alternated with another, and the new-comer would berate the unskilfulness of his predecessors. Like the rupture surgeons, they conducted their handiwork with a peculiar shamelessness and crudity. In 1640 there came to Lübeck a cataract coucher by the name of Hilmer. He had the blind come to his room and operated on them in spite of coughing and snuffling. Without having the least knowledge of diseases of the eye, he thrust a round, somewhat dull needle in, moving it through the hyaloid to the anterior surface of the lens, detached this from above, then thrust the needle around the curve of the lens with great rapidity, so that it fell with the capsule upon the surface of the hyaloid. Then he stuck the needle again into the lens, and drawing this back into the opening thus made, it grew fast there and never again rose. In the case of soft running cataract, the needle was turned around in the lens five or six times. After the operation Hilmer was satisfied if the patient could see a snuff-box or a watch, troubled himself no further in the matter, but had the eye bandaged by his servant, who, possibly, later became a cataract coucher. The servant poured some of his master's volatile eye wash into his hand and let it evaporate into the eye, then some beaten white of egg with powdered alum and camphor was laid upon it, for which the servant received an extra thaler from the patient. Hilmer operated with reckless self-confidence, and was so rough that he gave a certain woman a sharp box on the ear, because she cried loudly when the needle was in her eye. After the bandaging the patients could go home at pleasure, either riding or walking. Almost all became incurably blind a few days later. But Herr Hilmer did not await this period; he put his money in his pocket and disappeared. Out of fifty who were operated upon for cataract, in the vicinity of Lübeck, not more than four retained their sight. After him came the cataract coucher Garing, who likewise understood nothing of anatomy, whose hand trembled badly, and who himself could not see ordinarily well.

The clever swindler, John Taylor, from England, made the greatest sensation since 1730. He had studied in Leyden, and traveled through all Europe and half Asia under the title of a papal, royal, imperial, princely, grand-ducal and ducal court oculist and knight. Like the mountebank, he exhibited on his journeys pictures, on glass and copper plates, of the diseases of the eye. Frederick the Great denied him entrance into Prussia, therefore the patients traveled to him. His reputation was so great that several princes, the Prince von Holstein, the Princess von Georgien, the Duke von Mecklenburg-Schwerin and others, sought his advice. The last mentioned had him come to Rostock, but out of caution, invited also E. F. Heister from Helmstadt, who together with Dr. Eschenbach should attend him. Dr. Eschenbach freely opposed Taylor and convinced himself, as well as his colleague, of the crudeness as of the frequent unsuccessful issue of the operations. Occasionally the knight made a great fiasco; in the opera house in Lübeck, he was publicly rebuked by an eminent gentleman, whose mother Taylor had unsuccessfully operated upon for cataract in Rostock, and had swindled her out of considerable money; on this account Taylor went away discouraged. He operated upon all cataracts indiscriminately; he made an

incision in the cornea with a lancet, one and one-half to two lines under the middle, opened the capsule with a needle, plano-convex at the point, and either pressed the lens down or drew it out. In ophthalmia he rubbed the conjunctiva with a bunch of barley-grains. In a large number of writings, whose prefaces were scattered here and there with verses from Ovid and Horace, he showed only a superficial knowledge of ophthalmology, although perhaps no oculist of that time had seen so many patients with diseases of the eye as he. Confused in his ideas, he created many new and useless names, and often contradicted his earlier assertions. In a letter to the Académie de Chirurgie, he repudiated David's method of extracting cataract (*Extractions Methode*). To generate the necessary humbug and self-glorification, he arranged for the publication of a collection of criticisms of the most eminent academies of Europe, in which were presented countless testimonials from faculties of medical colleges, especially in Spain and Portugal. He also caused one translation to follow another, insomuch that his account of the mechanism of the eye has been rendered into eight languages. A few new instruments invented by him were forgotten after his death, which occurred in a cloister in Prague in 1772.

(To be continued.)

PECULIARITIES OF THE SURGICAL DISEASES AND INJURIES OF THE NECK.

BY EDMOND SOUCHON, M.D.

PROFESSOR OF ANATOMY AND CLINICAL SURGERY, TULANE UNIVERSITY,
NEW ORLEANS, LA.

(Continued from page 364.)

The diseases of the skin of the infra-hyoid region present nothing peculiar. The presence of the beard in the upper part of the region renders the part liable to the diseases of the beard described in the affections of the face.

Neuroses of the region present nothing peculiar.

Softening and induration also have no special features.

Congestion of the infra-hyoid region presents no peculiarities.

Inflammations of the region are not so frequent as those of the lateral supra-hyoid and of the sternomastoid regions; they may occupy the skin (erysipelas, furuncles, carbuncles); the connective tissue, the few small lymphatic glands situated along the anterior aspect of the larynx and trachea, or the thyroid body (the latter affection will be treated separately). Inflammations beginning in the prevascular or retrovascular space are not frequent and are usually due to injuries.

Cellulitis and abscess of the antero-lateral superficial region present nothing special. Antero-lateral deep or subaponeurotic cellulitis when median or suprahyoid or submental, occupies the space between the mylo-hyoid and the fascia; this form is not to be confounded with the cellulitis developed upon the mylo-hyoid and invading the floor of the mouth. Abscesses of the thyro-hyoid and epiglottic spaces originate in the fatty lobules and lymphatic glands between the epiglottis and the thyro-hyoid membrane; they may be due to lesions of the tongue, larynx or thyroid body. Laryngo-tracheal abscess causes much dyspnea and shows a tendency to extend down along the trachea.

Such lesions are often the starting points of the peculiar broad or diffuse cellulitis of Dupuytren; they are sometimes secondary to cellulitis of the substernomastoid connective tissue; they are at times produced by cold, by crying loud, so that the public criers and street vendors are more often affected; usually it is women in bad health that are most commonly thus afflicted; men very seldom. These diseases are usually connected with some general diathesis; they may extend from the ear to the clavicle and from the nucha to the larynx; they may involve also the other side. The pus is infiltrated into the muscular interstices and the connective tissue; gangrene is not infrequent. The pressure symptoms are very great. This description resembles that of the disease called diffused cellulitis of Gray, Coly and Hannon, which they say is mostly limited to the anterior region of the neck; it is due to cold and humidity and resembles erysipelas; it gives the sensation of hard edema without fluctuation. The inflammation of the infra-hyoid region gives rise to more risk of edema of the glottis and to fusing in the mediastinum.

Gangrene of the infra-hyoid region is rare and presents nothing special.

Ulcers are like those of other regions.

Fistulæ due to congenital malformations have already been described. Those due to chronic inflammatory causes, to chronic adenitis, to bone lesions are very rare. Acquired laryngeal fistulæ are the most frequent; they may be due to abscess, syphilitic ulceration, tuberculous ulcer, lesions of typhoid fever, foreign bodies, accidental and suicidal wounds, tracheotomy and other surgical operations. The symptoms are passage of air with mucus and pus, alteration of the voice; loss of speech unless the orifice is closed; all thoracic and abdominal efforts are impossible. These fistulæ remain permanently. The treatment consists in closing the orifice by an autoplasmic operation; Beyer uses two rows of sutures, deep and superficial. The forms and varieties are the following: *Fistulæ* following tracheotomy are oval in shape, the great diameter is vertical, the skin is drawn toward the mucous membrane, it is puckered by cicatricial contraction. *Fistula* due to large wounds of the neck in which a canula has been introduced, have the shape of a transverse fissure; the upper lip is turned in and is cutaneous; the lower is covered with granulations and is continuous by a long or short canal with the trachea. *Fistulæ* with occlusion of the larynx occur in transverse wounds in which the skin of the upper lip has been adherent to the mucous membrane of the pharynx forming a septum directed backward and downward and closing the larynx completely. *Fistulæ* following abscesses are usually small and funnel shaped. *Fistulæ* due to tumors occupy the crico-thyroid membrane, which may be perforated. In fistulæ with stricture the respiration is difficult. In fistulæ below the vocal cords the patient talks after closing the fistula, the voice is changed in its timbre.

Gaseous tumors of the infra-hyoid region are extremely rare, except traumatic emphysema and median laryngocele or tracheocele; they present no peculiarities.

Liquid tumors.—Hematoma due to traumatism is not uncommon; the contents should be quickly aspirated if the pressure symptoms are serious. Angioma varix may penetrate down behind the sternum and prevent their total extirpation without the removal of the corresponding part of the sternum. Aneurysms

of this region mostly form a part of the group known as the aneurysms of the root of the neck, *i. e.*, arising from the arch, the innominate or the origin of the common carotid and the subclavian. They are diagnosed by the fact that the finger can not be introduced between them and the sternum. Their treatment is best conducted on medical lines. Distal ligations of the common carotids first, and later of the subclavian, on one side have been performed; also first the ligation of one common carotid and later of the other. Electro-puncture, Macewen's needling, etc., have all been employed with very few successes. Lymphangioma is very scarce in this region. Serous cysts, outside of those of the thyroid body, are very rare. They are specially represented by the congenital median cysts described above. Bursal cysts develop in the serous bursæ found in front of the hyoid bone, Adam's apple, the cricoid cartilage; they are usually called hygroma or hydrocele of the neck; they form the group of the thyro-hyoid cysts. Hydatid cysts have been observed.

Hemorrhagic cysts.—The cysts of this region, when punctured so as to be emptied will sometimes bleed dangerously and fill the cavity to great distension; but this applies specially or almost entirely to the thyroid cysts; if in these occurrences the sac is incised the bleeding is profuse and very hard to control without removing the sac, using freely double forceps and double ligatures and cutting between them.

Chronic abscess or abscess by congestion, is not uncommon over the sternal notch, on their way from the base of the skull and larynx to the mediastinum. The lymphatic glands of the region may also form chronic suppurative adenitis, scrofulous or tuberculous.

Solid tumors (i. e., those whose contents will not flow through an exploring needle).—Hematoma, semi-solid or solidified, present nothing peculiar, nor do sebaceous cysts. Dermoid cysts are not uncommon among the median cysts. The other tumors are all possible, but are all rare. All the tumors of this region present these peculiar features: First, they give rise to more grave pressure symptoms than anywhere else; second, they are usually in the way of tracheotomy, and relief can only be found by operating; they often penetrate behind the sternum, and in order to follow them it is necessary to remove the upper part of this bone. These retro-sternal tumors should be explored with the syringe first; when fluid they should be treated by incising and packing; when solid they should be explored by an incision, and, when possible, enucleated. Great care should be taken not to excise any of the deeper parts of the walls, because the large veins of the region are often adherent to them and are thus severed, and uncontrollable deadly hemorrhage supervenes; the walls should not be incised even between the two forceps, or ligatures, because if these large trunks are involved, the interruption to the circulation may be too serious. Most of these cases are operated upon for palliative purposes of a very temporary nature.

Surgical operations of the infra-hyoid region.—The surgical operations of the infra-hyoid region have been described with the diseases requiring them, but we will here again mention some points of special importance.

It must be well borne in mind that in all cases of injuries and inflammations about the neck the great danger is from suffocation due to the obstruc-

tion of the respiratory tract from swelling or edema of the glottis, or from displacements in cases of fractures or ruptures. These accidents often come on so suddenly that the surgeon has not always time to reach the patient and operate in time to save the life; therefore precautionary anticipatory tracheotomy should be performed upon the least evidence of serious suffocation; it can be well done under cocaine; it will relieve the existing symptoms of dyspnea, will prevent their aggravation or the death of the sufferer, and will not add to the risks if properly and regularly done; the tube should be long, because of the existing inflammation and the inflammation that will follow may lift the tube out of its proper position and render the procedure useless, deceptive and dangerous, since it will lead to the belief that the operation has been done with no benefit. When fractures or ruptures are strongly suspected, after the threatening suffocation has been removed by tracheotomy it is important to examine thoroughly and repeatedly with the laryngoscope to ascertain if there is any obstruction visible with the instrument; if none is seen and yet a fracture is strongly suspected, the surgeon must explore directly, cut down to the hyoid bone, the thyroid cartilage, the cricoid, the trachea and remedy all deviations causing obstruction, using catgut or silver stitches and small silver bands as splints or pins inserted through the fragments. It is of paramount importance that there should be no impediment left when the tracheotomy tube is removed; if all these efforts have not been made, the patient may have to wear a tracheotomy tube for life or submit to the above measures after the fractures or ruptures have united, *i. e.*, under the greatest disadvantages.

In cases of growing aneurysms at the root of the neck, in view of the distressingly painful condition of these patients and of the fact that they are doomed, the surgeon is justified in resecting the upper part of the sternum as an exploratory operation. When it is found that the aneurysm is one of the origin of the right subclavian, and that the innominate is not dilated beyond an inch and a half, it is advisable and justifiable to make the desperate attempt of tying the vessel by applying two or three strong catgut or kangaroo ligatures, with as much of a bloodless space as possible between, and tighten them as much as is deemed safe without rupturing the coats. The same remarks apply to the left carotid and subclavian if they are not dilated beyond one inch in diameter.

In cases of tumors of the infra-hyoid region penetrating down behind the manubrium, the same resection for exploring purposes is recommended, with a view to total removal of the tumor if it is found possible.

SURGICAL DISEASES OR INJURIES OF THE THYROID BODY.

The location of a disease in the thyroid body is recognized by the fact that the organ ascends and descends with the larynx during deglutition. Another way to determine if the tumor is of the thyroid body, is to seat the subject with the head stretched back and resting; then with the thumb communicate a slight but brisk movement from below upward; if the tumor moves, it is because it is not adherent or is little so. This is said here once for all. When the tumor is very large this is not very easy to ascertain and reliance must be placed upon the past history and information and upon some of the peculiar features of the affection described below.

CONGENITAL MALFORMATIONS.

Absence of the thyroid body has been observed occasionally, in whole or in part and congenital atrophy has been occasionally observed. Congenital hypertrophy is more common. We must bear in mind that the thyroid body grows after birth, whereas the thymus and supra-renal capsules rather diminish after birth. The hypertrophy may attain rapidly or slowly in a regular or irregular manner the large size seen in cases of goitre; it may affect the whole region or one side only, or even one part. There are also cases of aberrant thyroid due to the separate development of some of the lobules of the organ: these may be single, double or multiple, or unilateral, as low down as the sternum or even behind the manubrium.⁸

Acquired atrophic malformations are due to injuries, to diseases, and to surgical operations destroying or removing the gland in part or in whole. The total destruction or removal of the thyroid gland gives rise to a peculiar train of symptoms. The immediate sequels of total destruction of the whole gland by thyroidectomy are acute mania, tetany, hysteria, myxedema, cachexia strumipriva.⁹

Few who have been operated upon before full growth, escape; the signs begin to show on the third or fourth day; there is paleness, lassitude, weakness, anemia; swelling and coldness of the extremities; muscular tremor, swelling of fingers first, then of the rest of the body, mostly apparent in the face and neck; this swelling is not edema; it is hard and elastic without pitting; the face presents the characteristics of this swelling in the highest degree: there is also cephalalgia, vertigo; the pulse is small and filiform. In tetany there sometimes exists such swelling, but it is not infectious. The complication is prevented by not removing the whole gland, by leaving a piece, especially the one that is adherent to the trachea. The best treatment of this condition is the thyroid extract, or the transplantation of the thyroid gland of the sheep in the connective tissue of the abdomen. The changes are relative to the repartition of the mucin and other metabolic wastes. Pachydermic cachexia (or myxedema of English writers) resembles myxedema and results from the destruction of the gland by disease. Acquired hypertrophies are represented specially by the various conditions known as goitre, which will be described with the tumors of the thyroid body.

Swellings of the thyroid body are almost all due to the various kinds of goitre, more or less chronically inflamed.

Burns and freezing are only observed in cases of great and deep destruction of the neck.

Contusions are most common in all cases of much violence to the neck as have been described above, coexisting or not with fractures of the hyoid bone, larynx and trachea. The peculiar features they present are symptoms of cerebral congestion and also the fact that they may be followed by myxedema.

Wounds of the thyroid body are apt to be serious on account of the great vascularity of the organ and its friability; the bleeding is usually great, especially if breathing be obstructed or laborious.

Punctured wounds are rare in the normal thyroid body, but are comparatively frequent in the hypertrophied organ or goitre, and if deep give rise to

⁸ These are cases of supernumerary, double, triple and quadruple thyroid body.

⁹ Myxedema should be described in connection with the face. We will only recall here the most peculiar features.

serious hemorrhages. Incised wounds are usually suicidal; those of the upper angles are the most frequent and the most serious because of the presence of the superior thyroid artery; in goitres they suppurate as a rule and they usually also run a benign course. Lacerated wounds are not ordinarily followed by primary hemorrhage but may present serious secondary hemorrhage. Gunshot wounds call for the same remarks; the thyroid gland has been carried away by a missile. Treatment of hemorrhage is difficult because of the friability, which will not allow a ligature to hold tight enough to arrest the bleeding with safety against secondary hemorrhage. The same remarks apply to the forceps left *in situ*. Deep suturing succeeds best, or a chain ligature or a purse-string ligature; a pin or needle suture such as is used for hare-lip sometimes succeeds; pressure is not borne; it is useless to ligate the nearest trunk because the other vessels will keep up the hemorrhage; when the bleeding is serious tracheotomy, if practicable, sometimes stops the hemorrhage by relieving its congestion; in spite of all, death is sometimes the result of hemorrhage. As regards foreign bodies in wounds, there is not a case on record where a bullet was found buried in the thyroid body in normal thyroid. Poisoned wounds, bites and stings are rare, except in conjunction with such in the infra-hyoid region.

Neuroses of the thyroid body are most rare and present nothing very peculiar.

Softenings and indurations are rare, except those connected with diseases of which they are but a symptom.

Congestion or hyperemia of the thyroid body is frequent on account of the great vascularity, *i. e.*, simple congestion independent of any forming or formed goitre. The causes are all internal; the physiologic ones are efforts of all kinds, menstruation, coition, pregnancy, accouchement; the most common pathologic causes are impediments to the venous circulation, the existence of infectious diseases, intermittent fever, endemic influences; repeated congestions cause goitre. The pathologic changes of structure are usually absent; sometimes apoplectic foci are found. The symptoms are usually bilateral; the tumor follows the movements of the larynx; when the patient makes an effort the facial and temporal arteries diminish in strength owing to the compression of the carotids, the cervical fascia in front preventing the gland from expanding in that direction. The prognosis is usually favorable, but when often repeated from pregnancy, attitude or professional occupation, it may give rise finally to a parenchymatous goitre. The treatment consists in removing the cause and in the treatment of congestion in general. When suffocation occurs, save during pregnancy, the trachea should be raised by a tenaculum; if this is insufficient perform tracheotomy; during pregnancy, if the above means do not afford relief, the uterus might be emptied through the vagina or by Caesarean section.

Thyroiditis, sometimes called inflammatory goitre, acute goitre, strumitis, is usually unilateral. The external causes are the various traumatism, infections of any ordinary wound, the influence of cold, etc. The internal causes are an effort causing a hematoma, the influence of rheumatism, a preëxisting infectious disease, especially pyemia, puerperal fever, diphtheria, measles, pneumonin, typhoid fever and malaria. The preëxistence of a congestion or tendency to a goitre is a great predisposing cause; if it disposes itself in

a manifest goitre, small or large, it is not a true thyroiditis, but a strumitis. Suppurating thyroiditis is always of microbic origin. The pathologic peculiarities are that death may take place before suppuration has been established; when formed, the pus may burrow in the mediastinum, along the respiratory tract and the esophagus. The peculiar symptoms are: Great thirst, owing to difficulty in and aversion to drinking, on account of the pain in swallowing; raising at each pulsation of the carotid arteries; cephalic symptoms due to the pressure upon the veins; great congestion of the face and epistaxis due to the same causes; nausea and vomiting, due to pressure on the pneumogastric nerve. The course is continuous; the duration about fifteen or twenty days. The terminations are by persistent indurated spots or by suppuration, but it is very rare; sometimes abscesses are formed, fistulous openings, single or double, occur; the abscesses may open into the larynx, trachea, esophagus or may burrow in the mediastinum; gangrene of the gland sometimes takes place. The prognosis of thyroiditis is grave. The forms and varieties and their peculiarities are: In *thyroiditis a frigore* which has served as a type for the above description, the mortality is much less. Rheumatic thyroiditis usually recovers; but the thyroiditis due to and following a grave general disease presents the highest mortality. In thyroiditis due to an anterior condition of the gland, the pressure symptoms are worse; it almost always suppurates; if the patient survives, the incipient goitre is sometimes cured. The internal treatment consists in combating the cause; the local treatment, in locating the pus as soon as possible and evacuating it; the great vascularity of the organ necessitates the very cautious use of the knife; the evacuation by the method of dilating upon a guide is indicated here especially. Chronic thyroiditis of a normal thyroid body is as rare as it is frequent in goitres.

Gangrene sometimes follows serious injuries or inflammations of the gland.

Ulcers do not exist outside of goitre and tumors.

Fistulae are sometimes observed after the opening of abscesses or incised cysts and tumors.

(To be continued.)

SOCIETY PROCEEDINGS.

Associated Health Authorities of Pennsylvania.

Fourth Annual Meeting, held in the Supreme Court Room, Harrisburg, Jan. 25 and 26, 1897.

The Governor, Hon. DANIEL H. HASTINGS, presided, and opened the proceedings by some remarks on the importance of the Association.

"There is no subject in which I am more interested than this of the public health. Pennsylvania, instead of being at the head of the States and leading in sanitary matters, is really at the foot. The time has come when she should have laws enacted for the protection of the health of her people, for the collection of vital statistics, the protection of her water supplies and the furtherance of all sanitary work. At present the health laws do not cover the half of the State, and while large parts of the country districts are compelled to rely solely upon the State Board of Health for help, that body is denied the money and the authority needed to care properly for these places."

The first paper was by Dr. RANDOLPH FARRIS, instructor in physical education in the University of Pennsylvania, on

THE NECESSITY OF PHYSICAL EDUCATION IN THE PUBLIC SCHOOLS.

Physical education has been made compulsory in a great

many universities, colleges and private schools, and in a few public schools in the United States. Boston, New York, Cincinnati and St. Louis were mentioned. They have directors at the head, well trained physicians, who have made a special study of physical culture. This is well, as this work should not be entrusted to an empiric; many injurious results are thus prevented. One of the first things a child should be taught is to care for its body; this will be a preventive of disease. The problems of life can be more successfully met by a man physically developed than one not so. Dr. Hitchcock of Amherst has proved that the average attendance has been better since physical education has been required of the students, and there has been less sickness. Again, children inherit from a parent a constitution weak, predisposed to illness, as consumption, etc.; then if we add want of physical training, bad air, bad food, insufficient clothing, poor ventilation, no bathing, these diseases are very soon liable to attack the child. In large cities hundreds are found with lack of hygienic care at home, and disease is invited. It should be called physical hygiene; it deals with the development of the body, and also such factors as bathing, sleep, food, clothing, diet, all of which preserve health and prevent disease. The ordinary games are not sufficient, as often taught, to keep the children well and healthy. While true in a measure, this kind of exercise may be the cause of deformity, one group of muscles being used too exclusively. Again, weak and diseased children are prevented from taking the usual exercise of healthy ones. These must be provided for. Compulsory physical education would save a doctor's bill to many a poor man. This need is seen more strongly when we reflect upon cases where parents have sacrificed the last dollar to keep a boy at school so as to pass at West Point or Annapolis, not dreaming of the rigid physical and medical examination that is required; should he fail to reach a certain standard in weight, height and physical measurements he is rejected, without regard to his mental powers. Government needs those who can endure fatigue as well as mental exertion; directors should see to this. If this were the only reason for making physical education compulsory it would be a most important one. A special time should be set apart by the director for examining pupils, and advice be given to strengthen the parts which are weak. Gymnastic apparatus is not absolutely needed for training, hence no school need complain of a lack in this direction for not adopting physical education. If a teacher be well posted he can use a series of free movements to answer all purposes, and as the pupils advance they can enter a high school properly equipped. From 15 to 30 minutes daily should suffice. All instructors under the director should be, whether men or women, properly educated in this important branch. A director must be a specialist, or he will soon realize that some of the instructors under him know more than he does of the practical part while painfully ignorant on the scientific side. Great harm results when he is incapable of recognizing the early symptoms of injury from misapplied exercise and which are the forerunners of disease. Were the men who apply for positions as directors of physical education, examined as to their knowledge as to hygiene, physical diagnosis, anthropometry, the physiology of bodily exercise, anatomy, orthopedic surgery, and required to execute some practical work before experts as Hitchcock, Sargent, Anderson and Seaver, fewer unqualified persons would apply. Often the methods are empiric because of the ignorance of instructors. There are many pupils who require special education or none at all. Exercise is one of the most important means for affecting the different bodily tissues. Think of a lawyer practising without having studied law, or a physician who had never studied medicine. Yet this is the same as these empirics in physical culture. People with lung troubles are prescribed exercise with chest weights; the danger of hemorrhage is imminent; or running with heart disease; or an exercise producing deformity of certain muscles, etc. The purpose is the production of a healthy strong symmetrical body. Hollow chests, contracted shoulders, pale countenance, poor digestion, etc., are the result of the want of proper muscular development. Yet these are the rule rather than the exception, and every pupil who develops his brain at the expense of his body is sure to be the sufferer. In the high schools every boy on entering should be carefully measured and also on graduating. Students should be graded according to these measurements. No athletics should be permitted without special training and an examination prior to the engagement. Graded education is as necessary here as in any studies. The director should understand the construction of a gymnasium.

At the conclusion of this paper the Governor favored it with a lengthy comment. He considered physical education as equally necessary for both boys and girls as mental develop-

ment. After alluding to several points in the paper he said he had in mind for townships high-schools, at central points, with large areas of play grounds and gymnasiums, teachers in athletics and with conveyances for carrying pupils to and fro so that none might be prevented from attending by reason of inclement weather, etc.

Prof. HENRY LEFFMANN read a paper on

UNFILTERED WATER ALWAYS UNSAFE FOR TOWN SUPPLY.

Perhaps this was an extreme statement. There is much yet to be learned on the subject of water supply. This subject evidently attracted a good deal of attention from early ages. He alluded to the works of the ancient Romans, the Imperial City supplied with water by hundreds of miles of aqueducts, of the same constructed in ancient Jerusalem; even beyond that Athens had a municipal officer, the superintendent of springs. Surface waters were employed in many ancient as well as modern systems; these may be safe when the territory is undisturbed, but in populated civilized countries it is far different. By surface water he meant all collections of water in free contact with the atmosphere, in motion or at rest, including the smallest pool to the largest lake and from the rivulet to the broadest river. The chemic changes in such are not marked, the gases are apt to escape until they reach a point corresponding to the pressure of the air and the waters are apt to be flat. Rarely do surface waters contain much mineral matter, but generally do contain a variety of living structures representing almost every variety of plant and animal. We usually overlook the larger kind, still they should not be ignored in the close sanitary study as they may contribute to the injurious effects. It is said that water will purify itself as it flows, but this is rather indefinite and not to be relied upon for every river and every season. The processes to which water is subjected in its ordinary condition are not purifying ordinarily. The only plan is filtration through the soil, which is imitated by systems of sand filtration, but the natural filtrations as found in springs and wells is far more satisfactory. It is well known to chemists that well water in districts where there is high soil pollution and the contaminating influences are almost alongside of the well, will show a complete transformation of all organic matter and a practical freedom from bacteria. Waters from such polluted sources may be used for a long time without seeming to cause disease. These may be designated as "dangerous to health" without saying they are disease producing. Practically we must use surface water. Hence we must consider the sources of danger and how they may be avoided. To this audience he did not deem it necessary to describe how the water is polluted. In civilized places there is little territory free from man or domestic animals. The latter have in common with man many diseases. We must therefore consider them as sources of pollution as well as human beings. Many sanitarians have a theoretic surface water. Thus citizens meet and propose to have an area of unpolluted territory as a gathering ground and derive the supply from that. New York city has such a system, yet the water is not perfect. The trouble is that it is almost impossible to maintain such a large area free from invasion, especially where every man has a say in the government. Again the engineering operations will not be perfect because of the cost. Most municipalities are short sighted, do not take sufficient territory, then when an extra amount is demanded water must be taken from places outside.

Apart from disease pollution, there are certain liabilities to deterioration from natural causes beyond human control. Typhoid fever is the principal disease conveyed by water; authorities say that it is due to a particular bacillus, but we also have equal authority that this germ is only a form of a well known species. There is much dispute upon this point. While Philadelphia has a water supply which is constantly propagating typhoid, both Drs. Meade Bolton and A. C. Abbott say they have never been able to detect a bacillus in the Schuylkill water which they could distinctly identify as a typhoid bacillus. Vaughan of Ann Arbor has had a similar experience; he failed to find a bacillus agreeing with his own culture or with the type culture from Germany. The point is that the typhoid bacillus may not be a fixed and specific germ and that typhoid fever propagation may not depend upon infection from previous disease. If we accept Vaughan that the so-called typhoid germ is an abnormal or "involution" form of the common water bacteria we can see how a water may distribute disease, although not directly polluted. It seems to me that surface water is the form in which such conditions may most probably arise. Various conditions disturbing the organic life are constantly occurring; miscellaneous pollution with organic matter from surface washings, and in this way we can at any time have aberrant or abnormal bacteria forms which may have disease producing character. Then it is impossible to keep analytic

supervision over surface waters which shall be of any value. When the mineral contents are very high, we may condemn them. It may appear when the ingredients are low the water would be fair to use, but we here encounter another difficulty, a very pure water attacks lead and thus acquires a dangerous quality. Thus a surface water pronounced unexceptionable may be the means of producing widespread disease.

Sheffield, Eng., is supplied with water from a clean moorland, but acquires lead through the supply pipes and causes serious trouble. Again, surface water receives the rain and surface washings, and even the atmosphere, particularly of large cities, contain much polluting material. Recently another danger from surface water is known. Manson finds the mosquito is the intermediate host of the malarial parasite, and points out the probable danger from surface water as a distributor of malarial poison. This germ enters the body of the mosquitoes, carried by it to the nearest pool, and the body decomposing, sets free the parasite to infect those who use the water. Even if the mosquito does not reach the water (and Manson states that the male always dies before reaching it) the germ has the power of remaining inactive for a long time, and the dead insect blown by the wind into the water will enable the germ to develop. It seems impossible to prevent contamination of surface waters and when we have the enormous areas to deal with as in American cities with their wasteful habits we have a problem beyond satisfactory solution by the engineering and administration method of the day. Few may take such extreme grounds as I have done, but observation and reading have led up to it, hence my opinion is that every city depending upon surface water should provide for thorough purification. Such means are now at hand, and we can take a highly polluted water and render it fit for use. When propositions for filtration are made, it is usual for some one to suggest the selection of a pure supply. "Innocence not repentance," has a catching sound, but I think it is little more. Surface water is so liable to pollution that the word "pure" in regard to it has only a comparative sense, and in establishing a water supply, we should establish systems of storage and filtration, no matter how excellent may be the district whence it is collected. So far as natural waters are concerned those only are perfectly purified that are filtered through the soil; and could we protect the territory of a city from direct soil pollution we would probably find no better supply than in wells sunk to the level of the subsoil currents. "The Monetary Loss to Cities from Typhoid Fever," by Dr. Thomas Turnbull of Pittsburg gave details as to the value of life of classes of men, of loss by illness, etc. In no other civilized country is this mortality so frightful as in America. Pennsylvania stands well up in the van. The first item is the loss to the individual, second the cost of medical attendance, nursing, etc. An average of \$100 for each case. Hundreds of cases are not reported, hence we are unable to state positively the loss to the State. Taking the deaths which are reported to the number of cases reported, the fatality would appear very large. Perhaps the real rate is 10 per cent. For 1895, the loss to Pittsburg, Philadelphia and Allegheny was \$804,700.

Farr gives as the value of life to the State, the agricultural laborer \$25 at birth; \$280 at 5 years; \$585 at 10; \$960 at 15; up to \$1,230 at 25, then declining to \$5 at 70. This fever occurs most between the ages of 10 and 25. The maximum mortality is between 20 and 25. From the above we see every death from typhoid is a loss of \$1,000 to the community. Giving for the cities named a loss of \$905,000, 90 per cent. of which might have been prevented. After quoting many of the figures he concluded that this loss was enough to pay for a filtration plant, and the time is coming when negligence in sanitary matters will result in suits not only against water companies, but against the cities and towns themselves. One decided would bring up hosts of others. He drew a comparison between cities with and without pure water supply.

CAN WALLS AND WALL PAPER BE RENDERED IMPERVIOUS TO DISEASE GERMS?

was read by Dr. F. F. FRANTZ of Lancaster. We spend one-third of our lives in our bedrooms and most of that time in slumber when the system is most liable to absorb disease germs. The sides and ceilings are plastered or covered with paper, both porous, and absorb and retain disease germs as well as gases. We open windows and doors to purify the rooms, but that does not remove the foul air and germs remaining in the paper and walls. The glue and paste used in applying the

paper to the walls disintegrate under the damp atmosphere, and the noxious effluvia emerge and pervade the room. The sterilizing agents used are not practical as they only sterilize the surface. A permanently impervious covering on walls and wall paper is demanded. Paint or varnish are used; both give off unpleasant and unhealthy odors, and cease to be impervious after a time owing to the saponifying action of the lead upon the oil, which is a constituent of both paint and varnish. Varnished paper is liable to crack, such cracks providing places for the reception of bacteria. Whitewash is very porous, has deep cavernous recesses under the microscope. The essential requisites for cleanliness as well as prevention of germ lodgment are:

1. The walls or wall paper must be coated with an article which makes a smooth surface rendering them permanently impervious to moisture or gases.
2. Said surface should not be affected by proper sterilizing agents, and should bear washing with soap and water for cleanliness.
3. The surface must not be subject to chemic changes, so that the surface remains permanent and it must also be elastic so that it will not crack after it is applied. It should be so flexible that paper coated with it prior to being pasted on the wall could be readily handled without causing breaks in the surface.
4. It must be devoid of unpleasant or unhealthy odor under all atmospheric conditions.
5. It must be colorless and transparent so that it can be applied upon the richest wall decorations without marring their beauty, and should protect the gildings on paper from the bleaching action of sulphur fumes either from furnaces or when sulphur is used for disinfectant purposes. The entire residence of persons afflicted with tubercular consumption should frequently be fumigated.
6. It should be ready of application and inexpensive so as to bring it within the power of all classes to use it. The discovery which he claimed to have made and which he presented for investigation is a liquid which he believes to fill all the requirements and which from the nature of its qualities is aptly named the *Paradox Sanitary Wall Paper Finish*.

All who have tested it, including the official bacteriologist of the State Board of Health, report that it is fully able to do all that is needed as above.

Dr. BENJAMIN LEE, the secretary of the State Board, remarked that he had submitted the preparation to the bacteriologist for test in the most thorough manner. The wall was washed with 1-1000 solution of bichlorid of mercury and was rendered sterile. A 2 per cent. solution of formaldehyde also was applied with the same result. The color was not washed off either by the bichlorid or by the formaldehyde solution. It may be recommended as a reliable sanitary paper capable of being cleansed perfectly and antiseptically. The second test was regarding the wood-filler wall paper; he found it may be deluged with antiseptic solutions and in no wise is either its color or texture injured. It may be scrubbed with water, soda solution, bichlorid solution, and any bacteria finding lodgment there are thoroughly killed. It is smooth and presents a minimum amount of rough surface for the lodgment of dust. Diphtheria bacilli placed on it were effectually killed. The paper was not loosened from the board to which it was pasted after applying soda solution and other solutions. Dr. Lee did not desire by presenting this statement of the bacteriologist to commit the State Board of Health or the Associated Health Authorities to an endorsement of this sanitary wall paper. He had himself experimented on a portion of this paper which had been applied to a wall for a period of two months, and found that it could be washed with hot water and soap without injury. It must be observed however, that in each trial the paper was comparatively new. In order to entitle it to entire confidence it will be necessary for it to stand the test of time. If it proves equal to this test, it will certainly be a boon to the public.

At the evening session, Dr. W. CAMPBELL POSEY of Philadelphia read a paper on

THE PREVENTION OF CERTAIN DISEASES OF THE EYES IN CERTAIN CLASSES OF SCHOOL CHILDREN.

He explained the structure of the eye in language suitable to those who were not learned in anatomy, the factors in distinct vision, and the effect of a lower vitality in causing diseases of the eye. A frequent cause of certain diseases was scrofula due to poverty, and insanitary surroundings. These resulted in corneal troubles, ulceration, often continuing to the total loss of sight. Such cases with the best skill fail to get well until removed to better sanitary influences. Especially is this the case during the summer months, but remove them to the country or, better, the seashore, and the result is magical. A few weeks at the seaside produces wonderful improvement.

Dr. J. G. SHOEMAKER of Phoenixville read a paper on

SOME OF THE TROUBLES OF A COUNTRY BOARD OF HEALTH.

Some boards have proven themselves very efficient, while others are but moderately so, and others have been thoroughly inactive. The board with which he was connected now for five years had operated vigorously; still difficulties are met which hamper its work and test the temper of the members. Each year brings some innovation and the opposition increases in proportion. His board had adopted the plan of being sure from a legal view, then pushing to a termination. In a small town like Phoenixville (8500 inhabitants) personal friendships and business interests claim consideration, when an ordinance is about to be enforced. A board must be sweeping, regardless of all but the right. Physicians as a rule are jealous of the work, hence no board should be composed entirely of physicians. Otherwise the health laws can not be rigidly enforced. His board had been accused of interfering with the business of the doctors. This was a compliment. Measles appeared, early in 1896. Isolation was practiced, affected families were kept from access to the schools, at once a furor was raised that measles are so simple that quarantine was needless. The epidemic went on to 200 cases, why? Many did not have any medical attendance, but in many cases certificates of health were furnished by physicians long ere it was safe for the return to school, and thus others were affected. Measles is one of the most contagious diseases, often the most fatal from bad management, and many cases of eye or nose or throat disease result. The restrictions in this disease are rarely enforced. Otherwise we think there would be fewer deaths from pneumonia, which frequently carries off the little patient. If statistics could be correctly obtained, we believe the deaths from measles would equal those from scarlet fever. Statistics are a great source of trouble to the borough boards. The vaccination act produced a great deal of trouble. Friends and enemies on all sides protested against it. The school board cooperating received its share of the odium. The homeopathic physicians openly preached against vaccination, circulated literature against it and finally adopted the plan of giving a course of treatment and vaccinating the patients in the stomach with virus much diluted in medicine, after which they gave certificates of successful vaccination. These were accepted by our board as better than exciting too much opposition at first. From our view compulsory vaccination has been a success. All but six pupils of the public schools have presented certificates and these six were excluded from attendance. In the parochial school all were vaccinated. In the private school all save two complied with the law. These are attending in direct opposition to the law and a test will be made in the near future. In the Sabbath schools poorer results have been found. The Act of 1893 requires "that it shall be the duty of the president of lower council or burgess to appoint one member annually, to serve for five years," etc. This is well when this officer is a man of broad and liberal views, but where he is of the foggy type and represents obstruction to the advancement of new ideas it is wrong. Our president is of this class, so when the term of Mr. Lippert expired, in the face of a petition signed by all the prominent professional and business men of the town, asking for his return, he refused to make the appointment, and offered in his place a man who would be of no use. This simply to impair the efficiency of the board which he denounced as a "humbug." The members of the lower council refuse to confirm the appointment, and as the term of the president is out and he has not been renominated, there is hope of a better state in the future. The local board should always remember that it is a legal body, and should make a determined stand when it makes a decision and generally the council will finally agree. Still these bodies are jealous of the health board and obstinately fight against paying bills. Thus our council refused to pay the bill for vaccination; and to avoid trouble all physicians were appointed, supplied with virus, and offered the sum of 25 cents for each successful vaccination. Forms were supplied each to make returns with affidavits. This with advertisements of the Act made a bill which the councils objected to, but finally paid. We were free from contagious diseases. At the same time diphtheria raged without our borders. Our death rate for the year 1894 was 17 per thousand, 1895, 15, and for 1896, 17. The milk inspection inaugurated in 1893 was very gratifying, better milk was secured, and the dealers in watered milk were driven away. The difficulty is to prove that dealers "knowingly" sell adulterated milk. With a better law more can be accomplished. The work of the board is becoming easier. We are gaining the respect of the better classes and with more money could secure sanitary plumbing, a filtering plant and garbage crematory.

At the session on Tuesday, Dr. BENJAMIN LEE, Secretary of the State Board of Health, read a paper on

THE NEW DISINFECTANT, FORMALDEHYDE.

For a number of years, physicians and curators of medical museums have been using a preparation known as a solution of formic aldehyde, or formaldehyde, for the purpose of preserving anatomic specimens. For this purpose it is superior to alcohol. A solution has been placed upon the market under the name of formalin, and other proprietary names. It usually contains about 4 per cent. of the pure substance. All health officers are familiar with the evils resulting from sulphur fumigation, in its injurious effects upon articles of furniture and clothing, the tarnishing of all metallic surfaces, the changing of color and even actually bleaching the tissues. So serious have been these objections that many health boards have given up its use, depending entirely upon solutions of bichlorid of mercury, carbolic acid and other liquid disinfectants, which can be supplied either as a spray or wash. When, therefore, it was suggested that the substance just named was not only a preservative of animal tissue, that is to say, an antiseptic, but also a powerful germicide, and that it possessed in addition a remarkable power of destruction, sanitarians had their hopes raised that a gaseous disinfectant had now been found which was entirely free from the objections just named. It is true that like sulphurous acid, it is irritating to the lungs, but by no means to the same extent, and that while, after the use of sulphur, it is impossible to inhabit the room for one or more days, after the use of formaldehyde, the atmosphere quite rapidly returns to its normal breathable condition. At the Denver meeting of the American Public Health Association, in 1895, Dr. Kinyoun of the Marine-Hospital Service made remarks indicating the strong probability of the usefulness of this material, in the manner indicated. As the word is a new one to any but chemists, it may not be amiss to indicate the manner in which this name was formed, as this will assist in impressing upon the mind the character of the material and its generation. An aldehyde is an alcohol from which a portion of its hydrogen has been removed; that is to say, a dehydrogenated alcohol. Now, by taking the first syllable of alcohol and the first two of dehydrogenated, it will be observed that we form the name aldehyde. The aldehydes are very easily changed into acids, and the different aldehydes are named from the acids into which they change. That is to say, an aldehyde which results from the formation of formic acid is called formic aldehyde. We drop the last syllable of formic and have the word formaldehyde. The alcohol from which it is made is known to chemists as methyl alcohol, and is made from the dry distillation of wood. In the arts it is known as wood or spirit of wood alcohol, and is a very cheap form of alcohol. It is quickly changed into the vapor formaldehyde by heating in contact with platinum over the wick of an ordinary spirit lamp. If the lamp be lighted and quickly extinguished the platinum, having been heated to a cherry redness, will continue to glow as long as there is any alcohol to be evaporated. In this process the formaldehyde will be constantly generated. Many lamps have been invented for the purpose of generating formaldehyde in quantities for disinfection. At the last meeting of the American Public Health Association, 1896, two generators were described. One by Dr. F. C. Robinson, Professor of Chemistry at Bowdoin College, whose experiments were made at the instance of the State Board of Health of Maine. The lamp or generator was made with the object of generating the gases with the greatest rapidity as owing to the fact that it is when hot about the same specific gravity of air. It readily escapes from cracks or crevices, and must be obtained in a comparatively dry condition. The lamp consists in a disk of moderately thin asbestos board perforated by small holes and platinized by the use of a strong solution of platinic chlorid. This disk is placed over a shallow dish partly filled with wood alcohol. The disk is wet with wood alcohol, held in a pair of forceps or small tongs, removed from the dish and quickly lighted. By the time the alcohol burns away, the disk will be so heated that when placed over the dish it will continue heated and change the alcohol into formaldehyde. The dish being of proper depth and sufficiently loose for the admission of air, the disk keeps at the necessary heat to produce the evaporation required. The experiments of Dr. Robinson were made in a room containing about 3,000 cubic feet of air space and having three large windows with very loose sash. In about three hours and a half the evaporation of from two to two and one-half quarts of alcohol resulted in complete sterilization of diphtheria and typhoid cultures. All parts of clothing, including seams, insides of pockets, etc., were sterilized in every part of the room. The typhoid bacillus was destroyed even when buried half an inch deep in sand. The cultures of diphtheria and typhoid were embedded in bed clothing, pillows and mattresses, and were killed by the use of two quarts of alcohol, in seven hours. It is desirable in its use that each room should

be treated separately, rather than that a number of rooms or a whole house be disinfected at once. Any ordinary living room would require at least a quart of alcohol. With three lamps such as Professor Robinson exhibited, he disinfected a house of sixteen rooms, using ten gallons of alcohol.

The other method was presented by E. A. de Schweinitz, Ph.D., M.D., Chief of the Bio-Chemical Laboratory, Department of Agriculture, Washington, D. C. His experiments were rather with reference to the destruction of animal parasites, and for this purpose he found it admirably suited. The amount generated in a given time by this method is not as great. An ordinary lamp wick is used, which may be round or flat, and to the top is attached by a wire a piece of sheet asbestos about 1½ inches long. The asbestos is impregnated with platinum and copper, or with one of these alone. This wick is placed in any ordinary lamp it will fit. The lamp is filled with wood alcohol and the capillary attraction of the wick draws up sufficient alcohol to generate the gas. A lamp with a central draught gives by far the best results. The lamp is lighted, allowed to burn a minute until the asbestos begins to glow with a cherry-red heat; the flame is extinguished, the asbestos maintains its heat while the alcohol remains. Dr. de Schweinitz said: "The fact that this gas and its solutions are practically without injurious effect upon metal, wood or clothing, and most colors, and the minute amount required to secure the destruction of bacteria, make formaldehyde practically the best gas known for disinfecting purposes." But the most perfect form of generator has not yet been devised. A convenient portable apparatus for this purpose, is offered by a New York house, who claim for it a capacity for disinfecting a room of one thousand cubic feet capacity. The 40 per cent. solution already referred to may be used for washing walls or furniture and may be also applied as a spray. It is very volatile and if allowed to evaporate in a room will unquestionably sterilize the atmosphere, but it is doubtful if a sufficient quantity of the formaldehyde will be generated with sufficient rapidity to deeply penetrate the clothing and furniture. A 1 per cent. solution has been demonstrated to be sufficient to destroy the germs of anthrax in fifteen minutes, the material of course being submerged in the solution. One hundred parts of the 40 per cent. solution added to 3,900 parts of water gives a solution of this strength. Undoubtedly at an early date we shall be able to avail ourselves of this very valuable and unquestionable disinfectant.

The subject was freely discussed by many of those present. A. M. SLOAN, Esq., President of the Board of Health of Greensburg, read a paper on

SHOULD THE ERECTION OF SCHOOL BUILDINGS BE REGULATED BY ACT OF ASSEMBLY?

The matter was so exhaustively treated that but little could be said in debate. He believed there were breakers ahead of our educational ship, and as a faithful pilot he sounded the warning of dangers inside our beautiful intellectual structures. To turn out of the school on graduation day an intellectual giant with a diseased body and call such a man or woman was an absurdity. If there be anything in our school management that tends to produce disease of the body our first duty is its extirpation. Some of his deductions were: The percentage of near-sighted children when they enter school is less than 7 per cent., the number thus afflicted increases yearly until colleges and universities number among their pupils over 50 per cent. thus troubled. Evils existing in school buildings are to be remedied by legislation, not education, because school boards constantly changing are not usually judges of sanitary science. County superintendents have no knowledge of this subject and architects as a rule are ignorant of the laws of health.

The whole matter was referred to the Committee on Legislation, with instructions to prepare for presentation to this session of the Legislature the draft of an Act appropriate.

Prof. G. G. GROFF of Lewisburg, a member of the State Board of Health, presented an able report on

THE TEACHING OF HYGIENE IN THE PUBLIC SCHOOLS.

There is increased interest in this matter, but as yet no improvement. The text-books are absolutely worthless. Every year there are at least 20,000 deaths among children by preventable diseases, yet not a word is taught the children as to what constitutes prevention. In the discussion it was asserted that no proper American book existed, and the books now in use were not only useless, but a curse to the schools. Some even urged that the teaching of hygiene be dropped from the curriculum. It was unanimously resolved that the subject be referred to the appropriate committee.

Among the reports of the several committees, that on legislation offered the draft of an Act to urge the Legislature to provide for the appropriation of money to pay the expenses of

the delegates from the borough boards of health in attendance at these sessions, and the cost of publication of the proceedings. This and several other drafts of Acts were referred to the incoming committee to prepare and present.

The subject of milk inspection was thoroughly discussed and Acts to that effect were also prepared and referred.

Allusion was made to the approaching meeting of the American Public Health Association in Philadelphia, in September, and an appropriation of the sum of \$1000 was asked of the Legislature to aid in the extending of hospitalities to that body.

The officers elected for the new year were: President, Daniel H. Hastings, Governor, ex-officio; first Vice-President, Crosby Gray of Pittsburg; second Vice-President, A. M. Sloan, Esq. of Greensburg; third Vice-President, Moritz G. Lippert, C. E., of Phoenixville; Treasurer, Jesse C. Green, D. D. S., of West Chester; Secretary, William B. Atkinson, M. D., of Philadelphia; Executive Committee, Benjamin Lee, M. D., C. P. Weaver, Norristown; A. H. Halberstadt, M. D., Pottsville; J. G. Shoemaker, M. D., Phoenixville; J. A. McLaughlin, Allegheny; W. B. Atkinson, M. D., Philadelphia.

This was perhaps the most important session of this Association yet held, and it is much to be regretted that so many of the local boards of health are prevented from being in attendance. This is due to the fact that many boards are not granted funds with which to pay the ordinary expenses of their boroughs and hence do not feel like paying an additional amount from their pockets in order to attend the sessions.

Chicago Ophthalmological and Otological Society.

Annual meeting held at the Chicago Athletic Association Rooms, January 12, 1897.

Dr. HENRY GRADLE in the Chair.

The Treasurer's report was read and adopted.

Dr. WM. T. MONTGOMERY was elected president; Dr. W. F. COLEMAN, vice-president, Dr. C. P. PINKARD, secretary, and Drs. BROWN, HOTZ and COLEMAN, committee on membership. Minutes of the last meeting were read and approved.

Drs. J. W. Heustis of Dubuque, Ia., and Will Walter of Marquette, Mich., were elected members.

The secretary read a letter from Dr. Casey A. Wood in which he stated that the article in the *Chicago Times-Herald* of January 3 on the "Effect of Veils on the Eye-sight" had been published without his knowledge or consent, and was evidently a garbled copy of an article in the *Boston Medical and Surgical Journal*.

Dr. HENRY GRADLE demonstrated a patient with the rare combination of one-sided paralysis of the motor oculi nerve in all its branches with typical Argyll-Robertson pupil of both eyes.

The rest of the meeting was devoted to a discussion of "Asthenopia not due to Refractive Errors." (See page 447).

C. P. PINKARD, Secretary.

Department of Public Health.

Senator Gallinger has introduced in the Senate the Bill proposed by the Second Pan-American Medical Congress. The Bill is Senate Bill No. 3652, and is accompanied by the official report of the United States Committee of the Medical Congress, as read in Mexico November last.

REPORT OF COMMITTEE OF THE FIRST PAN-AMERICAN MEDICAL CONGRESS ON DEPARTMENT OF PUBLIC HEALTH FOR THE UNITED STATES.

Mr. President and Fellow-Members of the Second Pan-American Medical Congress:

I have the honor to make the following report from the Committee on Department of Public Health for the United States:

The First Pan-American Medical Congress, in general session at Washington, D. C., Sept. 8, 1893, unanimously adopted the report of the International Executive Committee, which embraced the following, viz.:

Resolved, That in conformity to general regulation 5, the International Executive Committee hereby authorizes the appointment of the following international American committees, viz., . . . under which resolution, among others, a Committee on Department of Public Health was appointed, whose duties were defined as follows:

"Committee on Department of Public Health.—A committee consisting of one member from each constituent county or colony, whose duty it shall be to cooperate with the object of placing the care of the public health in charge of experienced and educated medical men, and to secure the establishment in

each of the several Governments of a Department of Public Health, with parity of voice and influence in national and colonial councils and with independent executive authority under limitations common to other Departments in the same Government. Each member of this committee may, at his discernment, appoint such coadjutors resident in his respective county or colony as may be required to carry out the purpose of this committee."

The International Executive Committee under the following resolution,

Resolved, That the ex-officio President of the International Executive Committee shall appoint the president of each of the foregoing committees from among those appointed as members of the same, and that the president of each committee shall appoint the secretary of his respective committee from among either the members or the coadjutors of the same, appointed Dr. Henry L. E. Johnson of Washington, D. C., president of this committee, and he, with authority duly invested, appointed Dr. William Pepper of Philadelphia, Pa., and Dr. Charles A. L. Reed of Cincinnati, Ohio, coadjutors to the said committee, and Dr. H. L. E. Johnson of Washington, D. C., secretary *pro tempore*.

In conformity with the fifth resolution covering the special committees, which says, "The president of each committee shall prepare a final report of the detailed work of his respective committee and submit the same to the Second Pan-American Medical Congress," the President, on behalf of the Committee, makes the following report:

We recommend the adoption of the following draft of a bill to be made a law by the Congress of the United States, to-wit:

A BILL TO ESTABLISH A DEPARTMENT OF PUBLIC HEALTH.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, There shall be established a Department of Public Health. There shall be appointed by the President from the medical profession, by and with the advice and consent of the Senate, a Secretary of Public Health, who shall be intrusted with the management of the Department herein established. He shall be paid an annual salary of \$8,000. There shall be appointed by the President, with the approval of the Senate, an Assistant Secretary of Public Health, at an annual salary of \$5,000. The Secretary of Public Health shall, with the approval of the President, provide suitable offices for the Department, and shall employ such assistants and clerks as may be necessary.

SEC. 2. That it shall be the duty of the Secretary of Public Health to obtain through all accessible sources, including State boards of health, municipal authorities, and the Surgeons-General of the Army, Navy, and Marine-Hospital Service of the United States, weekly reports of the sanitary condition of all ports and places within their territories and departments, and he shall publish weekly abstracts of the information thus obtained and other pertinent matters received by his department. The said department also shall, as far as possible, by means of the voluntary cooperation of State and municipal authorities, of various general and special hospitals, sanitariums, public associations and private persons, procure and tabulate statistics of marriage, births (noting those that are illegitimate), stillbirths, with cause thereof, and period of utero-gestation, and deaths from epidemic, endemic and all other diseases, specifying those of a degenerative character, such as malignant growths and affections of the nervous, circulatory, respiratory, secretory, digestive and reproductive organs, and from violence, accident, suicide, murder, and data concerning the fruit of consanguineous marriages and the transmissibility of insane, alcoholic, syphilitic, nervous and malignant types of constitution to offspring, and to evils of race miscegenations. He shall also procure information relating to climatic and other conditions beneficial to health, and especially in reference to the most favorable regions in the United States for the cure or relief of chronic diseases, particularly consumption. He shall also procure information as to the prevalence and ruinous effects upon the body and mind of intemperance and prostitution. He shall endeavor to ascertain the extent, the origin and classification of insanity in the several States and Territories of the country. He shall investigate the state of comfort of the laboring classes in respect to their lodgment, their trades, occupations, the healthfulness of their workshops and the contents of the atmospheres they habitually breathe, and the prevalence of premature degeneration of the nervous and muscular system by the exactions of piecework employment. He shall obtain information in regard to the soundness

of their food and purity of water supply. He shall ascertain the ages at which the children of the poor are put to work and its hindrance to their physical development, and their lack of common school education. He shall seek, through the State boards of health, information of the hygienic state of public school buildings respecting their illumination, ventilation and presence of noxious elements in the circumambient air. He shall seek information in regard to the pollution of streams and navigable waters and public and private wells. He shall attempt, through the cooperation of the authorized medical schools in all States, to promote the most extended and thorough training of students in order to fit them for the responsible duties that devolve upon practitioners of medicine. He shall, whenever an epidemic disease is spreading abroad, or in any country which by commercial or other relation may endanger the health of the inhabitants of the United States, have power to call a conference of the Surgeons General of the Army, Navy, and Marine-Hospital Service and the executive officer or officers of the various State boards of health throughout the country to consider and advise with him in regard to the best methods to pursue to protect the country against the invasion of any such epidemic disease, and the results of such conference shall be, by the secretary of public health, communicated to the President and his Cabinet for such action as they may deem wise and expedient. Besides the reports of the state of the public health which he shall make from time to time, the secretary shall make an annual report to Congress, with such recommendations as he may deem important to the public welfare, and the report if ordered printed by Congress, shall be done under direction of the department. The necessary printing of the department shall be done at the Government Printing Office, upon the requisition of the secretary, and in the same manner, and subject to the same provisions as that of other printing for the several Departments of the Government.

SEC. 3. That the President is authorized, when requested by the secretary of public health, and when the same can be done without prejudice to the public service, to detail officers from the several Departments of the Government for temporary duty, to act under the department of public health to carry out the provisions of this act, and such officers shall receive no additional compensation except for actual necessary expenses incurred in the performance of such duties. When a detail of such officers can not be made, the secretary, approved by the President, may employ such experts, and for such time and in such manner as the funds at the disposal of the department may warrant.

SEC. 4. That to defray the expenses in carrying out the provisions of this act, the sum of fifty thousand dollars, or so much thereof as may be necessary, is hereby appropriated, to be disbursed, with the approval of the President, under the secretary of said department.

SEC. 5. That this act shall take effect sixty days after its passage, within which time the secretary and assistant secretary may be appointed.

We further recommend—

The passage of uniform national and State laws regulating the importation, exportation, sale, inspection, and standard of meats, fruits, and food stuffs, water supply, ice, milk, and beverages, prohibiting adulteration and providing adequate penalty for violation.

The passage of uniform laws, national and State, regulating the manufacture, importation, exportation, and sale of drugs and chemicals, with provision for their inspection, and penalties for their adulteration. And a further provision requiring the labeling with exact formula all proprietary medicines and compounds, and providing penalties for violation.

The passage of uniform laws, national and State, regulating the sanitation of railroad cars, both steam and street, barges and ships, steam and sail, public vehicles, ambulances, laundries, slaughterhouses, morgues, hospitals, and dispensaries, jails and reformatory institutions, with penalties for violation.

The passage of uniform laws, national and State, regulating the hygienic management of contagious diseases, personal and house quarantine, vaccination, hygiene of dentistry, barber shops, public baths and gymnasiums, amusement halls, migration of tramps and profligate persons, disposal of dead bodies, garbage and sewage, draining of land and removal of weeds and decaying vegetation, and providing penalties for violation.

The passage of uniform laws, national and State, providing for and regulating disinfecting plants, steam, dry heat and chemicals, for mails, foreign and domestic, clothing, bedding, money, persons, etc. Bacteriologic laboratories, animal industry and inspection plants, State and national hospitals, and retreats or sanitariums for the treatment of habitués, inebriates, venereal, tubercular and insane persons, with special laws

for commitment to and discharge from the same. District nursing for the poor, sick, obstetrical, contagious diseases, etc.

The passage of uniform laws, national and State, providing for the appointment of State and national medical experts and the punishment of medical crimes.

The passage of uniform laws, national and State, regulating State and interstate medical, surgical and dental practice, which will protect the same as a science and not as a trade.

We further recommend adequate appropriation of money by the several States and the General Government for the scientific investigation of public health matters in this and foreign countries, and the suppression of diseases, endemic and epidemic.

We further recommend that appointment to and the tenure of medical offices shall depend upon professional ability and efficiency, and not upon political influence.

Respectfully submitted.

HENRY L. E. JOHNSON, M.D., Washington, D.C.
President Committee on Department of Public Health.

WILLIAM PEPPER, M.D.,

CHARLES A. L. REED, M.D.

Coadjutors.

Report accepted by the second Pan-American Medical Congress in general session, Nov. 19, 1896, at Mexico City, Mexico.

NOTE.—The Committee of the AMERICAN MEDICAL ASSOCIATION, of which Dr. U. O. B. Wingate is chairman, is also engaged in the preparation of a bill for a Department of Public Health, which will be introduced at the Special Session of Congress.

PRACTICAL NOTES.

The Tuning Fork as a Therapeutic Appliance.—E. N. Malouine of Moscow announces that the tuning fork, struck and applied to the vertex, transmits its vibrations to the vocal chords, and causes them to vibrate in unison. He cured in this way, with vocal exercises, a case of hysterical aphonia that had resisted all other treatment, including suggestion. He adds that the process might be found effective in training and improving the voice of singers.—*Semaine Méd.*, January 20.

Jacksonian Epilepsy Cured by Suggestion.—An interesting case is described in the *Semaine Méd.* of January 20, the complete cure of severe cephalalgia with frequent epileptic attacks resulting from the fall of a flower pot on the head of a young man five years before. Professor Spehl (Brussels) suppressed the bromid treatment that had been used previously, and suggested to the patient that his attacks were diminishing and the cephalalgia less, following this in a few days by the command not to let them occur again, uttered in severe tones. There has been no attack since and the headache has also disappeared. It is too early yet to state whether the cure is permanent.

Success of Antipyrin in the Treatment of Nephritis.—Modinos of Alexandria, Egypt, describes in the *Gaz. d. Osp. e d. Clin.* of December 20, several cases of nephritis successfully treated with one gram of antipyrin each twenty-four hours (0.75 to 1.25). He considers himself justified in emphasizing the value of antipyrin in nephritis. Administered in small quantities, it causes the decrease and final disappearance of the albumin from the urine. The general health improves as the albumin disappears, showing improvement in the renal infection. He ascribes the improvement to the neutralization of the toxic constituents of the urine, owing to some special affinity of the alkaloid.

Effect of the Thyroid Products on the Female Pelvic and Thoracic Organs.—Hertoghe of Antwerp has found that the continued administration of the thyroid extracts exerts a depressing effect upon the functions of the pelvic organs and a stimulating effect upon the lacteal glands. In every case menorrhagia was cured by them and menstruation became normal, while the lacteal secretions were remarkably increased. He confirmed his observations experimentally by administering to a milk cow eighteen to thirty-six thyroid tablets a day, and noting the amount of milk secreted. For fourteen days before the

experiment, the cow yielded an average of 11.50 liters; for the first ten days after the thyroid tablets were given her, the average rose to 12.55 liters, and from the tenth to the twentieth day, the average was 13.80 liters. He also found it effective in arresting hemorrhage of the pelvic organs. He recommends it for all congestive disturbances in the pelvis. He gives one B. W. tablet a day, increasing to three.—*Cbl. f. Chir.* January 9, from *Bull. de l'Acad. de Méd. de Belgique*.

Surgical Treatment of Hypertrophied Prostate.—Herhold in the *Deutsche med. Woch.*, January 14, adds three new cases to the forty-one on record (resection or ligature of the vas deferens) to date. Thirty were entirely relieved of their troubles, a proportion of 75 per cent. The operation is simple and is followed by no serious after-effects, except in the rarest cases, when there have been unfavorable complications present. Dréznigé reports in the *Bull. Méd.* of January 3, twenty-two cases on which he performed resection of the vas deferens with notable improvement in each case. The effect seems to be the same whether the vas is resected or merely cut. No effect is produced by operating one side alone.

Incomplete Tamponing of the Nasal Cavities.—The Gottstein method of treating ozena with a tampon of cotton fitted into the nasal cavities, proves very beneficial as it prevents the formation of crusts and their fetid decomposition. But owing to the interference with the breathing, the tampons have to be frequently removed so that much of the benefit is lost. F. Bruck now suggests that tarletan instead of cotton be used; the patient can easily breathe through it and replace it with another piece when soiled, while it keeps the mucous surfaces moist and answers the same purpose as the cotton tampon. In severe cases it might supplement the Gottstein method.—*Semaine Méd.*, January 20.

Phosphorus as Stomachic in Chloro-Anæmia.—A. Casati has derived great benefit from phosphorus in the anorexia that so frequently and seriously interferes with the success of the different hygienic and medical measures employed to fight chlorosis and anæmia. He administers it in capsules of phosphorated oil, each capsule containing 0.001 milligram phosphorus. The patient takes one capsule a day, adding a capsule every second day, until the maximum of five capsules a day is reached, when they are discontinued in the same gradual way, and the appetite is usually found completely restored. If not, the treatment is resumed after a ten days' rest. He also recommends the following formula for iron and arsenic treatment: Ferrico-potassic tartrate and Fowler's solution, each 4 grams; aq. dist. 12 grams. Five to ten drops of this mixture are to be taken in a little wine immediately before each meal.—*Gaz. degli Osp. e delle Clin.*, January 10.

"Modifying" Catheterization.—In an article in the *Presse Méd.* of January 13, Professor Guyon emphasizes the dangers that may and usually do follow the use of catheters introduced with force or even friction. There should be no friction, as the mere contact of the instrument with the walls of the urethra produces a vascularization sufficient in itself to modify powerfully the condition of the membranes and dilate strictures. He prefers the "bayonet" bougies with their eccentric curved ends, as they can be gently brought in contact with every part of the passage; and always uses a bougie several sizes too small, according to the usual acceptance. Friction and pressure are worse than useless, as they substitute a pathologic phenomenon for a regular physiologic action. The failures that result in practice are chiefly due to neglect or ignorance of this principle. If these means fail, then there is no resort but division or urethrotomy, with preference for the latter.

Resection of the Trachea.—In the session of the Medical Society of Vienna, held Nov. 13, 1896, Förderl presented a 6 year old boy upon whom he had performed resection of the trachea with circular suture. The child's trachea had been cut entirely

through just below the cricoid cartilage. The posterior wall had been sutured immediately and five days later the rest of its circumference was sutured except where a canula was kept in place. There was so much contraction in the scar that phonation was completely lost and symptoms of stenosis developed. Förderl performed tracheotomy low down, resected the scar tissue to the extent of 2½ cm., and brought the ends together by a circular suture. The result was perfect.—*Medical News*, January 2.

Effects of the Bromids in Continuous and Large Doses.—Dr. J. A. Hodges, in the *Maryland Medical Journal*, writes that it is difficult to determine what is a safe dose and that some effects of the bromids produce symptoms which are attributed to the disease and not to the remedy. The following is the summary: Increased irritability of temperament; depressed spirits with a tendency to moderate melancholia; impairment of memory and also of contractility of muscles; an irritant to the gastric mucous membrane; an aphrodisiac action; disturbed circulation; extraordinary susceptibility to toxic effects in cerebral lesions, etc.; a tendency to homicidal and suicidal impulses as well as a weakening of the nervous system. To all of these our own testimony may be added of an encrusted deposit upon the anterior tibial regions, brown and dense, which promptly disappeared with a clean detachment upon a suspension of the chemical. In the instance given the patient was a young girl, who continued for years the repetition on her own account of a prescription given when the bromid of potash was a somewhat fashionable remedy for epilepsy.

Injections of Artificial Serum in the Treatment of Dermatoses.—Prof. P. Tommasoli reports encouraging success in the treatment of chronic eczema, etc., with injections of artificial serum (sodium chlorid and bicarbonate) to stimulate the secretions and excretions and increase the vital energy of the organism. The injections (30 to 200 c.c.) were always well received and several cases of long standing promptly yielded to them. Among these was a case of senile genito-anal pruritus, dating from thirty years past cured with forty-four injections (8 liters of serum in all); a case of lichen planus, extremely pruriginous, yielded in thirty-six days to thirty-three injections, equal to 3 liters in all. Two cases of diffuse, symmetrical chronic eczema, were cured with twenty-two and twenty-seven injections respectively, and a case of generalized folliculitis was cured with twelve injections (scarcely more than a liter of serum). He tested the treatment in twenty cases, but it was ineffectual with fungoid mycosis, diathetic pruritus, pemphigus vegetans, lupus, syphilis and a few additional cases of eczema.—*Semaine Méd.*, January 20.

The Roentgen and Other New Rays.—The *Academy* thinks that a full list of rays should include seven items, which may be arranged chronologically as follows: 1. Kathode rays, existing inside an exhausted bulb placed in the path of an electric discharge, and demonstrated long ago by Crookes and others. 2. Lenard's rays, which are the kathode rays brought outside the bulb by means of an aluminum window. These rays are sensitive to magnetic action, and can be deflected by a magnet. They will also act on a photographic plate through many opaque substances. 3. Roentgen's rays, existing in combination with Lenard's rays, but not deflectable by a magnet, and possessing more pronounced powers of photographing the invisible. 4. Uranium rays, or the phosphorescent rays discovered by Becquerel to be given off by uranium and its salts, which are capable of acting on a photographic plate. They differ from Roentgen rays in the circumstance that they can be both refracted and polarized, and there is no doubt that these are transverse rays of a high ultra-violet order. 5. The glowworm's rays, which have recently been shown to have a faint photographic action through aluminum and through copper. 6. The rays emitted by phosphorus, which will penetrate black paper, but

not aluminum. 7. There are still possibilities of other undifferentiated rays existing within the compass of the Crookes' tube, for in an interesting experiment performed before the Royal Society, Professor Thompson showed that, during the course of exhausting a bulb, before the Roentgen rays made their appearance, some other rays appeared which were different from the others in this list.

Case of Poisoning from External Application of Ext. Belladonnae.—Eichenberger describes the following case in the *Corr.-Bl. f. Schw. Aerzte*, No. 22. He prescribed for a woman of 64, after he had instilled 3 drops of a 3 per cent. solution of atropin into her left eye, ungt. ciner. 15.0 and ext. belladonnae 1.0, to be rubbed into her forehead, about as much as a bean, morning and evening. Two days later she developed a typical case of acute atropin poisoning; pupils enormously dilated, violent mania, modified sensorium, palpitation of the heart, frequently imperceptible pulse, extreme thirst, difficulty in swallowing and burning in the throat. With repeated injections of morphin and the use of excitants such as injections of camphor and ether, strong coffee, etc., the patient gradually recovered. There were still 13.0 grams of the salve in the box, consequently in the five times that it had been used, 3 grams of the mixture, or 0.19 of the belladonna extract, had been applied in the course of the two days and a half, or 0.08 ext. bell. a day. This amount is not only far below the allowable dose for external application, but is below the maximal dose for internal administration. The three drops of the atropin solution first instilled must also be taken into account. The case can only be explained by a peculiar capacity of absorption on the part of the skin, combined with an individual intolerance of the drug.—*Therap. Woeh.*, January 10.

Indications for Venesection.—Recent articles by Kroenig and Albu state that the indications for venesection according to their experience, and with the exception of chlorosis, they are agreed on all points. Kroenig has found small repeated venesections very beneficial in chlorosis. The medicines administered hitherto in vain assert their effect, and recovery is prompt. It is always indicated in cases of acute intoxication of the blood, either by the natural toxic products; carbonic acid, and uremia, or by poisons from without, which affect the circulation, such as carbonic oxid, illuminating gas and potassium chlorate. In apoplexy it is especially indicated, and if practised in the early stages often produces marvelous effect. In severe pneumonia also, it relieves and assists recovery to an astonishing degree. The cyanosis, dyspnea, etc., vanish as the blood flows. The overworked and insufficiently aided heart is relieved of part of its burden, and the medicines begin to take effect. Kroenig advocates venesection when all other means have failed, but Albu goes farther and prefers it to all other means for treating young, vigorous, sanguine persons in severe pneumonia with extremely elevated temperature, delirium, cyanosis, and feeble pulse. They also advocate this measure in diffuse capillary bronchitis, and in pneumonia with considerable displacement of the heart and secondary venous stasis.—*Presse Méd.* January 13, from *Berl. klin. Woeh.* Nos. 42-43, 1896.

Twin Bearing and Prolificacy.—Before the Edinburgh Obstetrical Society, at the December meeting, the above subject was under discussion. Dr. J. W. Ballantyne read a paper on the "Causation of Twins as Illustrated by Some Clinical Histories." After giving the history of several cases he mentioned that of a woman who was one of a family of seventeen, no twins; one of her sisters had had triplets and another twins; she herself had had twenty-two children in eighteen confinements, viz., four times twins and fourteen single births. In all the cases referred to there was good evidence to show that the twins were of the binovular or dichorionic kind. He mentioned the association of twin bearing and prolificacy and deduced that

the daughters of a woman who has borne twins are usually highly prolific, and conversely the mothers of twins are usually the daughters of specially prolific women. He mentioned the theory that the ovaries of the twin bearer resemble those of the fetus in the great number of Graafian follicles they contain. Pleural pregnancies result from the simultaneous rupture of several ovisacs and that this is a consequence of the existence of a relatively or absolutely large number of ova in the ovaries. Dr. Haig Ferguson mentioned the case of a woman who had seven children in three years, twice twins and once triplets. Dr. James Ritchie referred to a mother who had borne thirty-two children; it had been mentioned in an application for life insurance and he had verified the statement.—*British Medical Journal*, December 5.

Traumatism of the Liver.—Terrier and Auvray contribute an important article to the *Revue de Chir.* No. 10, reviewing the various forms of traumatism that can happen to the liver and the surgical cases on record. These show a mortality of fourteen in forty-five cases (stabs and cuts, twenty with five deaths; gunshot wounds, fourteen with four deaths; contusions, eleven with five deaths). They remark that earlier operating might have saved some of the cases, by combatting hemorrhage and preventing local and general infection. In regard to the operation they recommend a large median incision with resection of ribs if necessary, combined with a transpleural opening if there is reason to suspect injury to the diaphragm. This allows the liver to be completely inspected, especially on its convex side, and the hilus, as well as the other abdominal organs. To arrest the flow of blood the results of the operations already reported and of the writer's experimental research proclaim the advantages of a deep, wide-embracing suture of the liver parenchyma with unpointed needles and thick silk, with ligature of the vessels, of course, when possible. If this is impossible on account of the depth of the wound or friability of the tissues, gauze tampons for two to four days with thermo-cauterization. Projectiles and foreign bodies should only be removed when this can be accomplished without further injury to the organ. Gauze tampons with drainage also seems the best treatment in cases where portions of the liver have been crushed. The abdomen and pleural cavity must be carefully cleansed of all blood, bile and secretions with gauze pads.

Ambulant Treatment of Fractures.—M. Haudek recently exhibited a child to the K. K. Medical Association of Vienna, who had fractured the middle third of the femur three weeks before, and had been treated by the application of a Hessian fracture splint apparatus the ninth day, a combination of splints, pelvic band and foot piece, made over a plaster cast of the limb in extension, applied over a tricot stocking, and a bandage wound from the toes up to prevent edema of the extremity. This apparatus allowed him the use of his limb so that he had not been confined to his room or bed at all. The time of recovery from a fracture is much shortened by this ambulant method of treatment. The callus formation and consolidation of the bone is much more rapidly accomplished, owing to better circulation, and any slight atrophy of the muscles is easily counteracted by massage. The ability to be up and about in the open air instead of remaining in bed, favors recovery; the appetite, digestion, etc., continue normal, while there is none of the depressing effect on the spirits of a long confinement. Any one who has ever treated a fractured limb in this way is soon convinced of its many advantages over the usual methods. The child could stand and walk, if led by the hand, without pain, immediately after the light apparatus was applied, and in a day or two could walk alone and even go up and down stairs. In sixteen days he could walk without the apparatus, and it was removed to allow this several times a day, with daily massage of the limbs. The joints were left free from the first.—*Wien. klin. Rundschau*, January 17.

Eucala.—One of the latest drugs which is now attracting attention is eucain, and although several American and German periodicals have recently contained notes upon its uses, no English investigations have been published until the *British Medical Journal* recently printed a very instructive and useful paper upon its use as a local anesthetic in the surgery of the throat, nose and ear. This article (which, by-the-by, is only a "preliminary communication," based upon an experience of thirty-two cases) is the result of the joint investigations of Dr. Jobson Horne and Mr. Macleod Yearsley in their clinic at the Farringdon General Dispensary and Lying-in Charity. Their communication first deals with the history of the drug, giving a short summary of the work done up to date, both as to chemistry, pharmacology and therapeutics. Their own experiences are then detailed, and unlike many modern investigators, they very wisely insist that, although they have so far formed a favorable opinion as to the merits of eucain, it is but tentative, and they withhold their final verdict until they have still further examined into the uses of the drug. The points to which they appear to have specially directed attention are: 1, strength of solution required; 2, rapidity, intensity and extent of anesthesia; 3, general and local action upon the circulatory system; 4, after-effects. Out of thirty-two cases they only met with three in which there were any ill effects, and these seem to have had ample cause for not blaming the drug. Some of their results appear to be somewhat at variance with those of other observers; they have, for instance, noted slight ischemia rather than hyperemia of the turbinated bodies after its use. They also direct attention to a point which does not seem to have hitherto attracted attention, namely, the occurrence of salivation after its use. If the value of eucain as a substitute for cocain for local anesthesia be established, general practitioners will hail with delight the advent of a drug which, so far as the general result of present experience goes, is credited with all the advantages of cocain without its disadvantages.—*London Medical Times*, January 23.

A Case of Addison's Disease Treated with Suprarenal Extract; Death.—Dr. Osler, in the December *Bulletin of the Johns Hopkins Hospital*, records a case of Addison's disease fatal during treatment with suprarenal extract. The patient, a female, aged 21, had been sick with her present ailment about a year. She often became suddenly dizzy, everything became black before her and she would have to catch hold of the nearest object to prevent falling. She states that these sudden weak feelings would come on also when she was sitting still. She had lost in weight in two years from 115 to 96 pounds. A symptom, too, of which she complained a good deal was itching of the skin. She was a bright, intelligent looking girl, not much emaciated. She had no fever, and for the eleven days she was in hospital the temperature did not rise above 99.5 degrees, and the early morning temperature was often 97 degrees. There was anemia. The blood count on admission was 4,500,000 red per cubic millimeter, and on the 25th it was above 5,000,000. There was no leucocytosis, and the differential count gave polynuclear leucocytes, 33 per cent.; small mononuclear, 45 per cent.; large mononuclear, 12 per cent.; transitional, 2 per cent.; eosinophiles, 4 per cent. The condition of the skin was as follows: The scalp had a shining yellow color, the hair was dry and very coarse. The face had a yellow, dark color, with blackish brown splotches situated just above both eyebrows, across middle half of nose and involving the whole of upper lip. The eyelids and the inner canthi of the eyes were also very dark. The face showed from fifteen to twenty very small, almost black pigmented areas, some of which resembled moles. The abdomen, chest, back, legs and arms had a similar dark yellow-brown color. The areolæ of the nipples were large and deeply pigmented. Below and to the left of the umbilicus there was a bean-sized brown-black area. Both flanks were almost black in color. The backs of both

hands were deeply colored, especially the joints and about the roots of the nails. No large leucodermic patches were present. There were a few patches of pigmentation on the buccal mucous membrane. The lungs were negative; she had no cough and no expectoration. The heart sounds were rather weak and not well heard. There was a venous hum in the right side of the neck. The pulse ranged from 76 to 96 and was regular. There was no enlargement of the liver or spleen, and there was no dilatation of the stomach. The examination of the lower abdomen was negative. There was no enlargement of the external glands. The urine was acid, amber colored, specific gravity 1015. On June 22 the adrenal glycerin extract was begun. It was made in the following manner: Fifty-four perfectly fresh pig's adrenals were finely chopped up and thoroughly mashed with pestle and mortar. They weighed 114 grams. To this 114 c.c. of pure glycerin was added and 114 c.c. of aqua chloroformi. This was allowed to macerate after thorough mixing for twenty-four hours. It was then strained several times through towels and twice through filter paper, the latter in a refrigerator. The last filtrate was a rather cloudy, reddish, thick fluid with a meat-like odor. About 200 c.c. remained after filtering, so that 3.7 c.c. represented one gland. The patient was started on 5 ss t. i. d.—2 c.c., or one-half a gland. On the day following the administration she complained of cramps in the lower part of the abdomen and slight headache, symptoms which she said she had frequently had on previous occasions. July 1, at 2:45 this morning she became very noisy, screaming and calling out, and the pulse was very weak. The temperature was 97.5 degrees. She became quiet again, but did not seem quite rational. At 8 o'clock she lay with her eyes half closed, breathing rapidly and noisily. The pulse at the wrist could not be felt. She would not protrude her tongue, and when aroused she became very restless and tossed herself about, throwing off the clothes. The pupils were of medium size and reacted to light. The heart impulse could not be felt; the sounds were very feeble, and the pulse was 128 to the minute. At times the respiration became extremely weak, almost sighing. A few minutes after this note was made the patient died suddenly. The autopsy showed both suprarenal glands were the seat of extensive caseous disease, chiefly in the form of nodules, which were partially calcified. There was no trace of normal gland tissue remaining. The caseous process extended beyond the limits of the gland into the adjacent lymph glands, which, though little enlarged, were also involved. Peyer's patches in the ileum were a little swollen, and the solitary follicles in the large intestine were somewhat enlarged. The left lung showed a thin, wedge-shaped, triangular area near the base with caseous nodules, some as large as a pea. At the right apex there was some thickening and retraction of the pleura covering an old caseous, partially calcified nodule and the pleura on this side was obliterated. There were no other tuberculous foci in the body. The heart looked normal. The first question which suggests itself is whether the toxic symptoms, of which this patient died, were due to the suprarenal extract. Addison's disease may prove fatal either by gradual asthenia, the result of the vomiting and diarrhea; by sudden syncope, which may occur at any stage of the disease; by extension, local or general, of the tuberculous process, and lastly by a sort of toxemia, in which the patient for several days may have nervous symptoms, such as this patient presented. In the *International Medical Magazine* for February, in which Dr. Osler has reported six cases of the disease, a patient of Dr. Mullins, at Hamilton, for forty eight hours before death had the following group of symptoms: a slight convulsion, which was followed by a dazed condition in which he did not seem to appreciate what was said, great feebleness and rapidity of the pulse, sighing respirations, cold hands and feet, and subsequently much restlessness, pulling at the bed clothes and tossing about from side to side. The symptoms were much the same as those of Dr. Osler's patient, and the extract should not be held to be responsible for them. The dosage was not excessive.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the ASSOCIATION living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, MARCH 6, 1897.

THE MATERIA MEDICA COLLECTION OF THE
SMITHSONIAN INSTITUTION.

A former French minister to the United States, is reported to have said that Washington, with one exception, has more essentials for a good dinner than any other place in the world, and that exception is the absence of good cooks. This Gallic remark, the truth of which all familiar with the National Capitol will admit, applies not only to gastronomy but to other things as well; for with all its fine collections, libraries, museums, and the like, there is in Washington a lamentable absence of some one to give concise, crystallized information, and the stranger in search of the same will find no one to give it, unless it be a few ignorant guides with purely mercenary motives. To be sure the functionaries of the various departments are, as a rule, civil and obliging; but it is most discouraging to be turned over to a small boy, as the writer was a short time since at the Patent Office, when looking for certain information regarding water motors. All the models were shown and the specifications, which it would take at least two weeks to read, were placed at disposal, but life being too short to get information this way, a letter addressed to a practical mechanic in New York brought by return mail what two hours' search in the Patent Office had failed to accomplish. Again, it is far from satisfactory to visit such a place, in quest of the latest information on any special subject, to be obliged to stop in a hot stuffy reading room occupied mostly by negroes who make it a kind of loafing place, and to

be met by an ignorant clerk whose indifference, as a human machine, is the result of years of official discipline inimical to the requirements of civil life.

Perhaps the most notable exception to this state of affairs in the Capitol City is Professor OTIS T. MASON, the curator of the National Museum. No one in search of scientific information ever quits the Professor empty-handed or dissatisfied.

Medical visitors to the Museum, especially those interested in pharmacology, may observe and study the materia medica collection to their heart's content. Here an effort is made to expose all substances brought into relation with the diseased organism, having for their end or property the modification of this organism in the sense of healing. Specimens of medical forms and crude drugs in all varieties, commercial and botanical, represent the article as samples found in the markets, and these are supplemented by rare samples having notable peculiarities. Each specimen has its label giving special and condensed information, such as scientific and vernacular name, source, commercial variety, and other brief facts, and each group of specimens, arranged under one head, has a similar descriptive card. A colored plate of the plant from which it is derived is displayed with each crude drug, also a pressed and dried specimen of the flowering plant. Sections and magnified drawings, with a view to assist in identification and show physical characters, add to the completeness and accuracy of the exhibits; while official drugs and preparations and those not official nor found in any pharmacopeia, but which are or have been used as medicaments, help to complete the display.

The classification and grouping of the collection follows the order of fundamental elementary constituents, the primary divisions being that of inorganic and organic materia medica. With each elementary substance are arranged the chemie compounds of that element used in medicine and pharmacy, and the preparations of which that element, or any of its compounds, constitutes the fundamental ingredient. These preparations include the official ones of the United States Pharmacopeia; unofficial preparations not worth a place in the collection, and poisonous salts liable to be mistaken, on account of similarity of appearance, for those less active.

The vegetable products are classed according to the botanical affinities of the plant from which it is derived; the products of fermentation and distillation include the products of acetous and vinous fermentations, and the derivatives as well as distillates; while medicines of animal origin follow the zoologic classification of the animal from which the crude drug is obtained.

To be thoroughly appreciated, the collection should be seen, since no amount of writing can convey correct notions of a display that each man sees through his own spectacles and from an individual vantage point.

It does not detract from the practical merits of this admirable collection to say that it represents much that is antiquated, obsolete, curious and unused in medicine at the present time. The therapeutist studying medicaments can hardly be expected to know all about ichthyology, because cod-liver oil is obtained from the *gaddus morrhuae*, nor is the surgeon to be up in metallurgy, or be a master of cutlery, because his instruments are made of steel.

In this time of improved medical education, when laboratory, clinical and dead-house teachings, with improved hygienes, tend daily to make the administration of drugs the opprobrium of medicine, and much of the study of our own profession a mere meditation upon death. The mellowing influence of time only impresses us anew with the remark of the late Dr. LOOMIS, of New York, who was accustomed to say to his classes in his native and unaffected way: "You young men prescribe the drugs, but we old fellows don't believe in them."

SUBSTANTIAL GAINS FROM THE TWENTY YEARS' SANITATION OF BERLIN.

It is said of the city of Berlin that, in 1875, there were only fifty-seven houses connected with sewers, and the general mortality of Berlin was equal to 32.9 per 1,000 of the population. Ten years later the drainage of the town had been pushed forward with considerable energy. The teachings of Professor VIRCHOW had taken root in the minds of the people. The labor party gave energetic support, and as their voting power was daily increasing the sanitary regeneration of Berlin soon became an accomplished fact. In 1885 no less than 15,895 houses were connected with the sewers, and the death rate was down to 24.4 per 1,000, inhabitants. Finally, in 1895 the work of connecting houses with sewers and abolishing the ancient cesspools and pails had been pretty well completed. There were then over 22,000 houses connected with the sewers, and the death rate was only 19.4 (even lower than that of London for the same year, viz., 19.8 per 1,000). Thus in twenty years the death rate has been reduced by considerably more than one-third. Of course this is not due exclusively to the improved drainage, but it is quite safe to say that it is the principal cause of the great progress achieved. There are now but very few houses in and about Berlin not connected with the drainage system. Perhaps there may still be some houses in this condition, but they are rapidly disappearing, and it is calculated that soon they will have ceased to exist, and that about 23,000 houses will then drain directly into the sewers.

Berlin is situated upon a sandy plain, affording a deficient fall to the sewers. These are, therefore, not self-cleansing and imperfectly ventilated; in some districts they at times become water-logged so that

there is great risk of the sewer gas escaping into dwelling houses, particularly as the closets are often placed away from the outer wall, and that effective trapping is not very scrupulously and strictly controlled. Nor is proper care taken that the number of closets shall be in proportion to the number of inhabitants. This grievance becomes especially flagrant when, as is so often the case in large centers, what was formally a private dwelling-house is converted into a factory or workshop. Under the presidency of Dr. CZADICK the Berlin workmen organized a Sanitary Commission. It was formed almost exclusively of workmen and had no official power whatsoever, but the reports resulting from the inspections made by this Commission show how much there is still to be done to improve the domestic hygiene of Berlin. As many as 200 people have been found working in a house where there are only two closets. To this must be added all those grave defects that are to be found in all large towns where poverty leads to overcrowding and where vice and drunkenness engender carelessness, dirty habits and general recklessness. Though Berlin suffers from all this, it must be recognized that very little of it is to be seen on the surface.

Next to the complete system of drainage the greatest sanitary advantage is the new broad streets which almost exclusively compose the great town. Considering the important position Berlin occupies in the politics of Europe, it is difficult to realize how modern a town it is. In ancient times Berlin was a very insignificant place, and even so recently as the Thirty Years' War its population, which had comprised 12,000 inhabitants, was reduced to 6,000. Under FREDERICK the Great (1740-86), the population rose to 145,000. After the peace of 1815 the population was a little over 200,000. With the development of railways the population naturally increased, and amounted to 496,000 in 1860. Then came the great historic period which resulted in the creation of the German Empire with Berlin for its capital. The population of the capital increased in due ratio to the increased power, first of Prussia then of all Germany. After the Austrian war there were 702,000 and after the French war more than a million inhabitants. Now there are a million and a half persons living in Berlin, so that the population has more than doubled in twenty years. Of course this gives to Berlin an enormous advantage over other towns. The great difficulty is always with ancient property—property which has acquired considerable vested interests, but which was constructed long before the laws of public health were known or enacted. Berlin, on the contrary, was built after the principal laws of health had been demonstrated and proved. It was therefore possible to prevent the repetition of the errors of the past, and this in some measure has been done. On all sides there are broad straight streets. The fronts

of the houses are swept by the passing winds and are bathed in direct rays of sunshine. This in itself suffices to mitigate a number of minor shortcomings. Then, so that the fullest possible advantage should be derived from these broad streets, they are kept marvelously clean. The army of scavengers is set to work with the method and the spirit of discipline and organization which make the strength of the German people. The general aspect of Berlin is therefore very impressive. As an English writer observes, "there is poverty always with them, but it does not show itself in public. In large English towns we see adult men and women going about in filthy, torn rags, looking very pictures of misery and degradation, who nevertheless probably obtain in the course of the year and in one way or the other, more money than the trim, well-brushed and well-clothed poor of Berlin. The German woman is a much better housewife than the British workman's wife, and she knows how to mend and patch clothes, so that, however old and poor the material, it always looks neat and clean. The man, thanks to his severe military training, brushes himself carefully and has always a trim look about him. The clean people in the clean broad streets give at once a healthy appearance to the town. At the same time there is a reverse side to the question. The Germans, if clean and neat in their clothes, are not so clean and neat in their persons. Even among the upper classes and in the best houses the English visitor is surprised to find that a bath room is quite an exceptional luxury."

Berlin being, as already stated, situated in the midst of a sandy plain, it has been easy to find, in the immediate neighborhood, soil suitable for the creation of sewage farms. More than this, sewer farms could be established not in one or two directions, but all around the town. Thus there are a series of farms both north and south of Berlin which receive the sewage water of the town. Corresponding with these farms there are nine pumping-stations, so placed that the difficulties due to the want of fall are reduced to a minimum. In the year 1892-93 at these pumping stations a total of 61,207,240 cubic meters of sewage, coming from 22,107 houses, was raised and sent on to the farms. This was equal to an average of 7.59 cubic meters per day per house. The total population served by this system of drainage was 1,550,038 persons, which is equal to 0.108 cubic meters each day per head. The cost of pumping was 655,481.06 marks, or 0.423 mark per head. The sewage arrives by gravitation to a very large well at the station, from which it is pumped up into the closed mains and sent on to the sewage farms. The highest point on the sewage farms is 24 meters above the pumping station, and the surface of the sewage in the well at the station is $3\frac{1}{2}$ meters below the engine-room. The farthest point of the system of sewers that converge

to this pumping station is at a distance of 5,300 meters and it is calculated that the sewage does not take more than two hours to reach the pumps from this the furthest distance. In some cases the sewers are made of German hardware pipes; in other instances they are of cemented masonry, and large enough to admit a man to clean. In both instances the sewers are not self-cleansing. This is but natural, as the fall is in the majority of cases absolutely insufficient.

There are, under the ground, drains to carry away the water after it has been purified by filtering through the soil. This water goes to the neighboring water courses. At first there was an outcry raised that the rivers would be polluted and the fish killed. To meet this the authorities dug out a big pond, let the purified sewage water fill this pond, and stocked it with fish. Gold fish, carp and even trout lived and prospered here. This convinced the population of Berlin that there was nothing to fear from the purified sewage. So great was the success of the experiment that other ponds were constructed and now the municipality has added pisciculture to its many other productive enterprises. Near Weissensee there are several large ponds where fish are bred for stocking streams and for sale. The week previous to the writer's visit no less than 7,000 carp were taken from these waters and sold; some of them weighed nine pounds.

The question as to how far these farms are a nuisance and a danger to public health is still the subject of much controversy. Though there were but few cases of cholera in Berlin, itself, there were 22 suspicious cases on the sewage farms to the south of Berlin during the summer and autumn. Twenty of the patients were adults, and the disease was described as cholera nostras. A physician who lives on the spot, has written various reports in which he maintains that workers on the sewage farms drink the water from the drains and suffer from typhoid fever. Careful investigations have been made, and a full official report gives the very definite impression that there is no sufficient evidence to justify the assertion that the patients suffered from drinking the water from the drains in the sewer farms. Both in the north and south districts numerous bacteriologic examinations have been made. Not only was the water in the drains, that is, the purified water, free from the bacteria of typhoid fever, but so also was the raw sewage, when examined at its arrival at the farms. Nevertheless, it is recognized that the condition of the wells is far from good, and orders have been given to protect them more carefully from contamination by surface water. Orders have also been given to the workers on the farms not to drink the water from the drains. Apart from the question of contaminated water, it must be confessed that there are numerous pungent and very unpleasant odors. Of course, when raw sewage is thrown on the soil and comes

out of the pipe with great force, there is a general stirring up of its foul contents, which naturally causes very unpleasant odors.

Nevertheless, and though it is easy to criticise details, and though undoubtedly many defects exist, the broad fact remains that Berlin is drained throughout. There is a method of disposing of all the sewage. The death rate on the sewage farms is low in spite of occasional accidents, such as cases of typhoid fever and cholera nostras; but, above and before all, there is the great, grand result already mentioned, and which can not be repeated too often, that concurrently with the draining of Berlin the death rate has fallen from 32.9 to 19.4 per 1,000 of the population, a rate that indicates that Berlin of all the million-souled cities of the civilized world, in 1895 touched low-water mark in respect of a sanitarily depleted mortality. (London in 1894, however, touched an even lower point, namely 17.4 per 1,000.) Roughly computed this same low rate implies a gain in life-saving of between eight and nine thousand lives; or, in other words, had the rate of twenty years ago prevailed in 1895 a sacrifice of not less than 8,500 lives would have resulted, over and above the actual death-toll. Or, again, if a human life be appraised as worth to the state the average sum of \$700, as the computation of some authorities is, Berlin was the gainer by not far from six millions of dollars in the year 1895. A handsome return that is, in part at least, to be claimed as flowing from the great public works carried out in the cause of sanitation and by sanitarians.

Continuing this train of illustration a step further, let us, à la PETTENKOFER, assume that there is a loss of 36 cents for each day's sickness, for medicines, nursing, etc. We will still further assume that each registered death means thirty-four cases of illness, averaging twenty days, *i.e.*, 680 sickness-days, whose cost will be \$245, for each death. Applying this valuation to the deaths that did not occur, in 1895, as above computed at 8,500, there were 289,000 of Berlin's citizens spared from illness, and a saving in money-worth amounting to \$2,082,500.

MUSIC AS A THERAPEUTIC RESOURCE.

"Sweet Music! Sacred tongue of God."

CHAS. G. LELAND—"The Music Lesson of Confucius."

One of the daily papers of Chicago gave an account in its issue of last Sunday of the trial on a large scale of music at the Eastern Illinois Hospital, to witness the effect if any on the insane.

The paper with a childlike simplicity says that to the musical director and the superintendent "belong the honor of making the first scientific experiment of this character in the history of medicine and music."

It is indeed quite probable that the experiment on so large a scale has not before been tried, as there were about 2,000 present according to the account, but the utility of music as a therapeutic measure has been

known ever since DAVID played the harp to soothe the madness of SAUL, and ASCLEPIADES of Bithynia, at the height of his Roman popularity recommended declamation, laughter, chants and music in the treatment of disease in that early day—

"When music, heavenly maid was young
While yet in early Greece she sung."

The first systematic writer on legal medicine, PAUL ZACCHIAS (1620), recommended music in the management of insane, believing with CONGREVE that

"Music hath charms to soothe the savage breast,
To soften rocks, or bend a knotted oak."

NICOLAI, of the University of Halle, a disciple of HOFFMANN and of the iatro-mathematical school, sought to prove that the vibratory movements of the tympanum produced oscillatory movements of the nerves, which thus soothed the fiery brain.

HENRY WARD BEECHER, who, if not a physician, was yet learned in psychology, said that "music cleaves the understanding, inspires it and lifts it into a realm which it would not reach if left to itself." If we turn to that most wonderful of all collections on the subject of insanity, BURTON's "Anatomy of Melancholy," we shall find that music is recognized as one of the potent means at the command of the alienist. "RHASIS, ALTOMARUS, ÆLIANUS, MONTALTUS, FICINUS FAVENTINUS," says BURTON, "are almost immoderate in the commendation of it; 'a most forcible medicine,' JACCHINUS calls it; JASON PRATENSIS, 'a most admirable thing and worthy of consideration that can so mollify the mind, and stay those tempestuous affections of it.' *Musica est mentis medicina mæsta*, a roaring-meg against melancholy, to rear and revive the languishing soul; 'affecting not only the ears, but the very arteries, the vital and animal spirits, it erects the mind and makes it nimble, (Lemnius). This it will effect in the most dull, severe and sorrowful souls, 'expel grief with mirth, and if there be any clouds, dust, or dregs of cares yet lurking in our thoughts, most powerfully it wipes them all away.'" Numerous quotations with the quaint commentaries of BURTON follow, and he says, "besides that excellent power it hath to expel many other diseases, it is a sovereign remedy against despair and melancholy and will drive away the devil himself."

The writer of this article twenty-four years ago¹ reported a case of cerebro-spinal fever where the restlessness of the patient, who finally recovered, was controlled by the playing of a violin, and the patient slept sweetly under its power, soothed by the influence of music which

"Waves eternal wands
Enchantress of the soul of mortals."

The voice of antiquity while thus commending it, seems insensibly to have yielded much to the general power of music in making these concessions, but some of the ancients counseled caution; PLUTARCH affirm-

¹ New York Medical Journal, "Cerebro-spinal Fever," by J. B. Hamilton, XXI, 1875, pp. 113-126.

ing that music made more men insane than wine, and "THEOPHRASTUS prophesied," says BURTON, "that diseases were either procured by music or mitigated."

Educators have always recognized the value of music as a controlling influence in building up the mental strength of children.²

We can only add that in Illinois, the superintendent of the Institution for the Feeble Minded at Lincoln, Dr. MILLER, has long considered musical organizations the strong arms of the Institution, a senior band, an orchestra, a juvenile band, and a general chorus, have been organized from among the children with fairly satisfactory results.

But to be useful as an educational aid or as a therapeutic resource, the music must be carefully selected and adapted to the particular mental condition of the individual. The dancing mania of the middle ages was accompanied by a tune which, if anything may be inferred by a glance at the music as printed in Hecker, would make a lunatic of almost anybody.

SOME POINTS OF INTEREST TO THE MEDICAL PROFESSION IN THE REPORT OF THE COMMISSIONER OF EDUCATION FOR THE YEAR 1894-95.

In comparing the number of medical colleges and their attendance with the number of institutions and students in other professions; we find, as is expected, that medicine is far in the lead. There are 151 schools of medicine with 22,887 students, an increase of 1,085 students over the preceding year. There are 149 schools of theology with 8,050 students, an increase of 392; 72 law schools with 8,950 students an increase of 1,639; 45 dental schools with 5,347 students, an increase of 1,195.

A review of the preceding figures shows that the number of medical students is as great as that of all the other professions combined, but there is a marked disparity between the proportionate increase in the attendance of medical colleges and colleges of other professions. With far fewer institutions and students, both the law and dental colleges have gained more in attendance than the medical schools, showing that there is an inclination to leave the over-crowded profession of medicine to enter other fields.

Another point of interest is the gradual change in the center of medical education that is taking place. Comparing the statistics of 1888-89 with those of 1894-95, we find that the Chicago medical institutions have increased in attendance from 1,338 to 2,294, while the New York medical colleges show a decrease in the attendance, which has fallen from 2,081 to 1,893. Baltimore has almost doubled its attendance and now has 1,293 students. St. Louis now takes fourth place, having passed Baltimore, Cincinnati and Louisville; and it now stands fourth with an

attendance of 1,399, while Louisville is sixth with 947 students, a decrease of 43. Philadelphia, which was over 500 behind New York in the first period, is now over 300 ahead with an attendance of 2,201, a gain of 686 over the figures of 1888-89.

There seems to be no special reason that will answer for the change in all these cases. Better clinical advantages, increased scientific advantages together with the westward trend of population will account for such progress as is seen in Chicago and St. Louis.

BRITISH MEDICAL PEERS.

The *British Medical Journal*, with that philistinism which makes it occasionally unreliable on the history of the English-speaking medical profession, remarks that Sir JOSEPH LISTER was the first medical man to be made a peer. Had the *British Medical Journal* added, "for medical reasons," it would have been correct, but as the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION pointed out (Vol. XXVIII), when urging the creation of medical peers, SMITHSON, the present family, which succeeded the proud PERCYs in the Dukedom of Northumberland, was founded by a medical man marrying the heiress of the PERCYs. Nor was SMITHSON the only medical man who became a peer. As JEFFERSON remarks (Book about Doctors): "More than once a physician has won admission into the noblesse, but the battle resulting in such success has been fought in the arena of politics or the bustle of the law courts." SYLVESTER DOUGLAS deserted the profession in which he commenced life, and after a prolonged servitude to political cliques of the House of Commons was rewarded with an Irish peerage and a patrician wife. On his elevation he was, of course, taunted with the humility of his origin and by none with greater bitterness than by a brother *parvenu* and brother poet.

"What is this title to be," asked SHERIDAN, as he was playing a game at cards, "what's SYLVESTER DOUGLAS to be called?" "Lord GLENBERVIE," was the reply. "Good Lord," replied SHERIDAN, and then he proceeded with an impromptu that morning industriously prepared in bed.

Glenbervie, Glenbervie,
What's good for the scurvy?
But why is the doctor forgot?
In his arms he should quarter
A pestle and mortar,
For his crest an immense gallipot.

HENRY BICKERSTETH, Lord LANGDALE, was the luckiest of physicians and lawyers. He used the medical profession as a stepping-stone and the legal profession as a ladder, and had the fortune to win two of the brightest prizes of life, wealth and a peerage, without the humiliation of serving a political party. The second son of a provincial surgeon, he was apprenticed to his father and educated for the paternal calling. On being qualified, he became medical attend-

² "That she trained all to music, that real moonlight in every gloomy night of life; 'without poetry and art,' she added, 'the spirit grows weary and wooden in this earthly clime.'"—(Jean Paul F. Richter).

ant to an Earl of Oxford during that nobleman's travels on the Continent. Returning to his native town, he for a while assisted his father in his practice, but resolved on a different career from that of a country doctor, and became a member of Caius College, Cambridge, and studied mathematics with great success. As late as 1807, however, he was still consulted medically by his father. In 1811 he was called to the bar by the Inner Temple; from that time to his elevation to the Mastership of the Rolls, he was the most hard working and hard worked of the lawyers in the Equity Courts, to which his practice was confined. In 1827 he became a Bencher. In 1835, although a staunch, zealous liberal and strenuous advocate of JEREMY BENTHAM'S opinions, he was offered a judgeship by Sir ROBERT PEEL. This he declined, though he fully appreciated the compliment paid him by the Tory chieftain. In 1836 he was made, by the Liberals, Master of the Rolls and created a peer of the realm, with the additional honor of being a Privy Councillor. He died at Tunbridge Wells in 1851, in his 68th year. It would be difficult to point to a more enviable career in legal annals than that of this medical lawyer, who won the most desirable honors of his profession without ever sitting in the House of Commons, or acting as legal adviser of the Crown, when he had not been called quite twenty-five years. A romantic element in the picture is that Lord LANGDALE after rising to eminence married a daughter of that Earl of Oxford to whom he had formerly been traveling medical attendant. The Lord PLAYFAIR, to whom the *Medical Record* lately referred, is not a medical man. Lord KINNEAR is therefore the first medical man made a peer for professional eminence.

CORRESPONDENCE.

Monopolistic Control of Medical Literature.¹

PHILADELPHIA, Feb. 20, 1897.

To the Editor of the *Medical Record*:—In your editorial columns (issue of Feb. 13, 1897, pp. 234-5) you permit a letter to be published as your own ("Both editors and publishers") which is so diametrically opposite in view to that you personally gave myself (in company with Dr. Pyle) when calling upon you that I must beg for a word of explanation in reply. Where is now your "dead line" across which you repeatedly said your publishers could not go in control of your editorial utterance? Moreover, who are the "editors" of the *Medical Record*? Your announcement cites yourself as the single editor. If there are others they should certainly be named, as the profession should know its members who take this attitude to professional interests.

And now, sir, of what use is it for you to allow such statements to appear in your columns as the following: That you would be "the last to countenance any action which might interfere in the slightest degree with the fullest and freest dissemination of medical knowledge." "The *Medical Record* has always allowed the free use of the original matter contributed to it for all reputable purposes, provided that due credit is always given to the original source of publication," etc., etc.

¹ This journal, believing in giving all sides a fair chance, publishes Dr. Gould's letter because, as he states, the *Record* refused to print it.

Now, my dear doctor, you know this is all untrue, and that it is easily proved untrue.

Let me first attend to the insult conveyed in the words, "reputable purposes." Of course you were fully aware of the intended inference and insult. Since your employer's refusal to allow the American Year-Book to use articles from your columns in its digests which you say is never refused for "reputable purposes," it follows plainly enough that all the editors of the American Year-Book are, in your opinion, engaged in a disreputable or non-reputable undertaking. We thank you for your high opinion of us, but can hardly agree with you. Neither does the medical profession, judging from appearances.

Let me make another quotation from your editorial: "The letter above referred to, while plausible on its face, is misleading in its intent, inasmuch as it implies that our course in this one instance might be considered as characteristic of our general policy, than which nothing is more untrue." This aspect of the affair is evidently worrying your publisher a great deal, and so he makes the most sweeping denials possible that he is not guilty of trying to prevent the dissemination of medical knowledge. The denial will avail nothing. American physicians have already decided that the American Year-Book is not disreputable and so long as you and your publisher keep your reasons absolutely hidden, you will be credited with a very evident and very sordid motive. Your contributors must smile derisively when they hear you say that you "would be the last to countenance any action, etc.," and yet in the same editorial you confess that they can not have their articles noticed in the Year-Book. Something more than stentorian proclamations of self-righteousness is necessary to deafen them to such wonderful logic.

What then will they say when they learn that this one instance is by no means single and that these same "publishers and editors" have for eight years persistently refused the same privileges to Dr. Sajous and his sixty-six editors of the Annual, a publication that has had to go on as best it could all these years, with the same denial on the part of the *Medical Record* publishers. Of course the Annual again by necessary inference is "disreputable," but, again also, the profession disagree.

Now, sir, as a physician you well know the wondrous service to the science, the art and the practice of medicine, rendered in Europe by the epitomes of the world's medical knowledge, Jahrbücher, Handbücher, etc. Their use is simply incalculable. Your publisher (and also you, since you pronounce his cause just) must yet settle with an outraged profession for refusing to allow the use of the gratuitously given literature over which the profession has unwittingly given you a legal control, and in the only two "reputable" and thorough-going attempts to supply this want to English and American medical men.

And I can not see that our just indignation is softened any by the claim that this outrageous action is motivated now on "personal," now on "sound business" reasons. It seems to me that such a claim makes your case all the worse before a professional jury, and that in making such a sorry excuse you confess that you are willing to harm the profession to any degree so that you satisfy some private grudge or financial aim. This is all the more noteworthy coming from a firm that has for many years in similar handbooks made most sweeping and wholesale use of all serial medical literature, not only that given gratuitously to lay publishers by the profession, but whole books and by the dozens. (See Dr. Murrell's letter in *British Medical Journal*, Oct. 11, 1890.)

I had intended not noticing the personal insult leveled at me. Despite your publisher's and your own great solicitude to reduce this controversy to "personalities," "peculiarities," and "sound business reasons" neither of these things has any-

thing whatever to do with the whole matter. If your reasons are honorable, for Heaven's sake out with them! "If not a settled policy" we may be able to find more than nine years of history and two competing publications to prove it. I by no means intend that the principles at issue shall be allowed to be made confused by any such alarms to distract the enemy's attention. In the present instance your contemptible charge that I have no higher motive in this whole matter than to advertise a book of which I am one of 28 editors, and that I allow my publisher to use my editorial utterances purely as his advertising medium, is—well! What may a gentleman say to such an insult? I am perfectly willing to leave such impertinence to be answered by the three publishers with whom I have had close business relations and with the readers of the *Medical News*. Some men, my dear sir, are very prone to ascribe low motives to others, but the reason is proverbially known. Oh, no, the instances are too few, but they exist, of editors who are not the jumping-jacks of their publishers. No publisher could have forced into my editorial columns such an editorial as this of yours under discussion. Mr. Saunders had no hand in the writing of that circular, was not consulted about it, knew nothing about when, or where it was mimeographed, mailed, etc. It was solely and wholly my own work. He has no more knowledge concerning this letter. Instead of all this shameless trying to turn the issue and of all these blank denials, it would be far more to the point if you would explain to your contributors how it is not against their interests to refuse to allow their gratuitously given articles to be abstracted and illustrated in the only two (not in only *one* as you say) earnest attempts that have been made to get up in English something comparable to the immensely serviceable and necessary German Jahrbücher and epitomes of medical progress. Also please explain how it is your action does not prevent the dissemination of medical literature. If it does not do so the necessary inference is that your two journals in your own estimation contain nothing worthy of being thus used in a résumé of medical science and progress! Lastly will you not explain to the sixty-six departmental editors of Dr. Sajous' Annual, and to the twenty-seven gentlemen connected with the American Year-Book in what way these two publications are disreputable, or non-reputable? Are they not quite as reputable as your publisher's similar Handbook, etc., and his pirated whole books of our English colleagues republished without their consent, and sometimes against their command and to their financial loss, as in those instances when other American publishers would have paid them for the right to reprint had it been possible to guard against the American pirate?

I reserve a little clarifying discussion of your publisher's position until a later date. Cordially yours,

GEO. M. GOULD.

119 S. 17th Street.

Medical Ethics.

WICHITA, KAN., Feb. 10, 1897.

To the Editor:—I am informed, I think creditably, that one or more specialists in the west are offering as inducement to the profession for their patronage, to divide fees. In one instance there is a verbal agreement to give 25 per cent. I would like the JOURNAL's opinion of the practice. To me it savors much of bribery, both parties sharing in the guilt, the specialists in large cities, like Chicago for instance offering the profession such inducements.

I might be tempted to do likewise if it was a case of bread and butter, but it seems to me my financial condition must be much straitened before I would even listen to the tempter. Perhaps I am wrong! Perhaps in the struggle for fame and fortune my patronage ought to go to the highest bidder but it seems to me I ought to be influenced entirely in dispensing

patronage by fitness and merit. I do not care to have my name used in print in this connection. I should of course lay myself liable to the charge that I am influenced by jealous motives which is not the case. Should you decide to answer privately or through the medium of the JOURNAL, which I highly prize, I shall be pleased. I am fraternally yours, M.D.

ANSWER: The offering or giving any portion of a fee to one who procures cases for another is the worst possible means of obtaining practice. Both parties are equally guilty of a breach of honorable dealing. Such conduct is on a par with the acceptance by a physician of a percentage from an apothecary to whom he directs his prescriptions to be taken. So patent did this appear to those who framed the Code of Ethics that they did not deem it necessary to insert any clause in regard to it.

W. B. ATKINSON, M.D.

PHILADELPHIA, Feb. 15, 1897.

PUBLIC HEALTH.

lavicious Discrimination Against the Profession in the Proposed Charter of the Greater New York.—Dr. Z. T. Emery, in his capacity of Commissioner of Health of Brooklyn, has addressed a communication to the charter commission regarding an undesirable discrimination proposed to be made against medical men by making it impossible for any one of them, however competent he may be, from becoming the head of the department of health. The text of the section of the now pending charter relating to the organization of the department of health reads as follows:

SECTION 1.—There shall be a health department whereof the head shall be the board of health. Said board shall consist of the president of the board of police, the health officer of the port and two officers to be called commissioners of health, one of whom shall have been a practicing physician for not less than ten years preceding his appointment. The commissioner of health who is not a physician shall be the president of the board and shall be so designated in his appointment. The commissioners of health shall, unless sooner removed, respectively hold their offices for four years, and until their successors shall be respectively appointed and have qualified, except the first commissioners, of whom the president of the board of health shall be appointed for two years, and the other commissioner for four years, and until their successors are respectively appointed and have qualified.

The remarks of Dr. Emery are, in part, as follow: "The first section provides that the head of the health department shall be a board, to consist of the president of the board of police and the health officer of the port and two officers to be called commissioners of health, one of whom shall have been a practicing physician for not less than ten years preceding his appointment. The commissioner of health who is not a physician shall be the president of the board and shall be so designated in his appointment. I desire to make emphatic protest; first, against making the head of the department of health a board composed of four members; and second, against the discrimination which is here made against the members of the medical profession by the provision that under no circumstances shall a physician become the president of such board. It is respectfully submitted to the commission that the head of the department of health should consist of one member, for the reason that in addition to the ordinary routine work of obtaining compliance with the laws and ordinances relating to public health, the duties of the health department consist largely in dealing with the emergencies which continually arise, affecting the welfare and lives of considerable portions of the community, and it is my observation that more prompt and efficient action can be obtained by a health department having a single head. Such emergencies demand immediate decision and action and do not admit of divided opinion and judgment, nor can they wait for a meeting of the board and an adjustment of differences of opinion. Further, I believe that

the head of the health department, being a single head and a commissioner, should be a practicing physician of not less than ten years' standing and should have had experience in sanitary matters. It is the experience of the health department of the city of Brooklyn, which has been presided over for the last sixteen years by a single head, that in legislative matters all of the advantages, to be derived from a multiple-headed commission, have been obtained by a single head, having properly chosen advisers and aids, and at the same time, the disadvantages and often discordant opinions of a multiple head have been avoided. If, however, it shall be determined in the wisdom of the commission to advise the establishment of a health department having more than one head, I respectfully suggest that these heads shall consist of men of acknowledged ability and experience in sanitary matters, and I believe the smaller the board the better, and in any case, it should consist of an odd number of commissioners instead of an even number, and one member of this board of three or more should be the health officer of the port. I consider it prejudicial to the best interests of the public health to inject into the constitution of the board of health, as ex-officio members thereof, persons who because of lack of training, knowledge and experience are not sanitarians. Inasmuch as medical men, as a class, by reason of their education and instruction and the necessities which arise in the practice of their profession, are especially trained in sanitary and hygienic matters, and further, because the best known sanitarians in the country belong to the profession, I respectfully urge upon your attention the injustice and unwisdom of discriminating against them as a class by making it a charter provision that the president of the board of health shall not be a member of this profession. With as much propriety a provision might be made that the presiding justice of the court of appeals should not be a lawyer."

The Bacteriologic Aspects of the Oyster Trade.—The Local Government Board of England has issued an important report upon the relations of oyster culture to disease in man. Dr. Klein was detailed to the bacteriologic branch of the research, and has shown that the typhoid bacillus and the cholera vibrio retain their vitality in sea-water and has found the bacillus coli in oysters from dangerous ground, while they were absent from those taken from places free from risk of sewage contamination. Further, he has recovered the typhoid bacillus from the mingled body and liquor of oysters from a sewage-laden dock at Great Grimsby. Dr. Klein's study has not been concluded, and Dr. Thorne, in his presentation of the data already obtained, remarks that bacteriology can be trusted to indicate danger, but not safety nor purity; and that beside bacteriology, we must have in regard to the oyster trade information as to the conditions surrounding and affecting the culture and storage of oysters along our coasts. He indicates that the conditions necessary to the inception of disease by an individual arising from the consumption of oysters are numerous, and that they have all to operate in their several places and times to produce the result in man, hence the relative infrequency of disease attributed to molluscs. Again, the oyster seems to have the ability to free itself from its contained organisms in a short time when placed in waters free from contamination. Further, the assimilation of different microbes within the living oyster is rapid, while the typhoid bacillus does not multiply, and Koch's vibrio even tends soon to lose its physiologic properties. As to the local dangerous circumstances attending oyster culture and storage, these admit of remedy. There should be some supervision of beds, ponds and the like, but, on the other hand, storage prior to despatch to market of oysters, in water of unquestioned freedom from sewage pollution, seems to be necessary. Summing up the results so far ascertained, Dr. Thorne says the results of Dr. Klein's investigations which bear more immediately on the culture of oysters would appear to be as follows: 1. The cholera vibrio, and

still more the typhoid bacillus, are difficult of demonstration in sewage known to have received them. 2. Both these organisms may persist in sea-water tanks for two or more weeks, the typhoid bacillus retaining its characteristics unimpaired, whilst the cholera vibrio tends to lose them. 3. Oysters from sources which appeared to be free from risk of sewage contamination exhibited none of the bacteria, specific or otherwise, which are commonly regarded as being concerned with sewage. 4. Oysters from a few out of numerous batches derived from sources where they did appear to be exposed to risk of sewage contamination were found to exhibit colon bacilli, a circumstance which, notwithstanding the comparative universality of this intestinal organism, may be regarded as having some significance by reason of the absence of this bacillus from oysters which appeared to have been exposed to no such risk. 5. In one case where the circumstances were especially suspicious, Eberth's typhoid bacillus was found in the mingled body and liquor of the oyster.

Notice of the Board of Health of the Village of Saranac Lake, N. Y.—

WHEREAS, The expectorated matter discharged by persons having any disease of the air passages (lungs, throat, mouth and nose) usually contains germs capable of communicating the same disease to other persons; therefore be it

Resolved, That the Board of Health of the Village of Saranac Lake does expressly declare that the indiscriminate discharge of such expectorated matter in any place where it may be the means of communicating disease to other persons is a nuisance dangerous to public health, and that this board does hereby adopt the following ordinance concerning expectoration:

Section 1.—All persons who expectorate in consequence of any disease of the air passages (lungs, throat, mouth and nose) are positively forbidden to spit or discharge such expectorated matter upon the floor of any house, store, church, schoolhouse, hall or upon any sidewalk or in any dooryard or other place where such matter may be the means of communicating disease to other persons.

Sec. 2.—Any person who shall violate the first section of this ordinance shall be liable to a penalty not exceeding \$5 for the first offence, nor more than \$25 for a subsequent offence, which penalty shall be imposed by and at the discretion of the board of health.

[I hereby certify that the above is a true copy of a preamble, resolution and ordinance adopted at a regular meeting of the Board of Health of the Village of Saranac Lake, N. Y., held Dec. 12, 1896. F. P. CALKINS, Secretary.]

Public Health Notes.—Owing to an epidemic of measles the schools of Dousman, Wis., have been closed.—An epidemic of measles has broken out in the Deaf, Dumb and Blind Association of Berkley, Cal.—Measles are epidemic in Toledo, Ohio, and certain portions of Chicago.

ASSOCIATION NEWS.

Fiftieth Anniversary of the American Medical Association.

ANNUAL ANNOUNCEMENT.

OFFICE OF THE PERMANENT SECRETARY,
1400 PINE ST., PHILADELPHIA.

The Forty-eighth¹ Annual Session will be held in Philadelphia, Pa., on Tuesday, Wednesday, Thursday and Friday, June 1, 2, 3 and 4, commencing on Tuesday, at 10 A.M.

"The delegates shall receive their appointment from permanently organized State medical societies, and such county and district medical societies as are recognized by representation in their respective State societies, and from the medical departments of the Army and Navy and the Marine-Hospital Service of the United States.

"Each State, county and district medical society entitled to representation shall have the privilege of sending to the Association one delegate for every ten of its regular resident members, and one for every additional fraction of more than half that number; *Provided*, however, that the number of dele-

¹ There were no meetings held by the Association during the years 1861 and 1862.

gates for any particular State, Territory, county, city or town shall not exceed the ratio of one in ten of the resident physicians who may have signed the Code of Ethics of the ASSOCIATION."

Members by Application.—Members by application shall consist of such members of the State, county and district medical societies entitled to representation in this ASSOCIATION as shall make application in writing to the Treasurer, and accompany said application with a certificate of good standing, signed by the president and secretary of the society of which they are members, and the amount of the annual subscription fee, \$5. They shall have their names upon the roll, and have all the rights and privileges accorded to permanent members, and shall retain their membership upon the same terms.

The following resolution was adopted at the Session of 1888 :

That in future each delegate or permanent member shall, when he registers, also record the name of the Section, if any, that he will attend, and in which he will cast his vote for Section officers.

Secretaries of medical societies, as above designated, are earnestly requested to forward, at once, lists of their delegates.

Addresses: The Presidential Address, Nicholas Senn, Chicago; Address in Surgery, Wm. W. Keen, Philadelphia; Address in Medicine, Austin Flint, New York; Address in State Medicine, John B. Hamilton, Chicago.

Committee of Arrangements.—H. A. Hare, 222 S. 15th Street, Philadelphia.

AMENDMENTS TO THE CONSTITUTION AND BY-LAWS.

Offered by I. N. LOVE :

Art. IV.—Officers. Amend to read "Each officer shall hold his appointment for one year, and until another is elected to succeed him."

Offered by the EXECUTIVE COMMITTEE :

That there be made an Executive Council of five consisting of the three officers of the Executive Committee and two officers chosen by election. Of this Council of five, one must belong to the Section on Practice of Medicine and one to the Section on Surgery and Anatomy. To this Executive Council shall be delegated all the duties of the Executive Committee during the interval between its meetings.

Offered by H. B. ELLIS :

Art. IX.—Conditions for further representation. "Any State or local medical society, or other organized institution whose rules, regulations and code of ethics agree in principle with those of this ASSOCIATION may be entitled to representation on the advice or agreement of the Judicial Council."

Offered by L. D. BULKLEY :

To change the name of the Section on Dermatology and Syphilography to that of "Cutaneous Medicine and Surgery."

EXTRACTS FROM BY-LAWS.

"The Chairman of each Section shall prepare an address on the recent advancements in the branches belonging to his Section, including suggestions in regard to improvements in methods of work, and present the same to the Section over which he presides, on the first day of the annual meeting. The reading of such address not to occupy more than forty minutes."—By-Laws.

"It shall be the duty of every member of the ASSOCIATION who proposes to present a paper or report to any one of the Sections, to forward either the paper or a title indicative of its contents and length (not to exceed twenty minutes in reading) to the Secretary of said Section, at least one month before the annual meeting at which the paper or report is to be read."—By-Laws.

1.—The Publication of Papers and Reports. "Every paper received by this ASSOCIATION and ordered to be published, and all plates or other means of illustration, shall be considered the exclusive property of the ASSOCIATION, and shall be published and sold for the exclusive benefit of the ASSOCIATION."—By-Laws.

OFFICERS OF SECTIONS.

Practice of Medicine.—J. H. Musser, Philadelphia, Chairman; J. T. Priestley, Des Moines, Iowa, Secretary.

Obstetrics and Diseases of Women.—Milo B. Ward, Topeka, Kan., Chairman; Geo. H. Noble, Atlanta, Ga., Secretary.

Surgery and Anatomy.—Reginald H. Sayre, New York, Chairman; Bayard Holmes, Chicago, Secretary.

State Medicine.—Elmer Lee, Chicago, Chairman; Louis Faugères Bishop, New York, Secretary.

Ophthalmology.—G. E. de Schweinitz, Philadelphia, Chairman; H. M. Starkey, Chicago, Secretary.

Diseases of Children.—Jas. A. Larrabee, Louisville, Ky., Chairman; H. E. Tuley, Louisville, Ky., Secretary.

Dental and Oral Surgery.—R. R. Andrews, Cambridge, Mass., Chairman; Eugene S. Talbot, Chicago, Secretary.

Neurology and Medical Jurisprudence.—W. J. Herdman, Ann Arbor, Mich., Chairman; Chas. H. Hughes, St. Louis, Mo., Secretary.

Dermatology and Syphilography.—A. Ravagli, Cincinnati, Ohio, Chairman; T. C. Gilchrist, Baltimore, Md., Secretary.

Laryngology and Otolology.—Wm. E. Casselberry, Chicago, Chairman; D. Braden Kyle, Philadelphia, Secretary.

Materia Medica, Pharmacy and Therapeutics.—W. B. Hill, Milwaukee, Wis., Chairman; F. Woodbury, Philadelphia, Secretary.

Physiology and Dietetics.—A. P. Clarke, Cambridge, Mass., Chairman; Ephraim Cutter, New York, Secretary.

Section on Obstetrics and Diseases of Women.—The program for this Section is now being made up, and members are requested to send in the titles of their papers without delay.

GEO. H. NOBLE, Secretary.

Section on Physiology and Dietetics.—Papers for the Section of Physiology and Dietetics, are wanted as follows :

1. Physiology of Air—Ear Hairs as Ultimate Organs of Hearing, with demonstration.
2. Comparative Physiology of Deglutition, specially of Whales.
3. Effects of Odors upon Blood Circulation.
4. Autonomy of Organs, specially of Epithelia.
5. Are there Nerves in Teeth?

Address A. P. CLARKE, Chairman, 825 Massachusetts Ave., Cambridgeport, Mass.

E. CUTTER, Sec., 120 Broadway, New York.

Section on Surgery and Anatomy.—On the evening of the first day of the meeting of the ASSOCIATION in Philadelphia, Tuesday, June 1, the Section on Surgery and Anatomy will have a dinner. The price of tickets has been fixed at Three Dollars (\$3.00) a plate, without wine.

Members of the ASSOCIATION who desire to attend the dinner of this Section will please cut out the accompanying slip, fill it out and mail it to the chairman of the Section, Dr. Reginald H. Sayre, 285 5th Ave., New York. This should be done at once in order that proper arrangements can be made in accordance with the number who will be present.

....., 1897.

Dr. REGINALD H. SAYRE, 285 5th Ave., New York, N. Y.

Dear Sir: I will take . . . ticket for the dinner of the Section on Surgery and Anatomy of the AMERICAN MEDICAL ASSOCIATION in Philadelphia, on Tuesday, June 1, 1897, at Three Dollars each (\$3.00) without wine.

Name

Address

The JOURNAL train will run special from Chicago to Philadelphia.

SOCIETY NEWS.

The New York Neurological Society.—The Neurological Society of New York has a committee on legislation consisting of Drs. C. L. Dana, N. Allen Starr, G. W. Jacoby, Joseph Collins and G. M. Hammond, whose duty it will be to secure amendments to the Lunacy Law, that took effect last July. The new law wiped out the old provision for the care of the patient pending the initial inquest after two qualified physicians had given their certificate. The amount of difficulties that have been thrown in the way of certifying medical men—the new process being both more expensive and tedious—has been such that not a few physicians have found it advisable to commit insane patients to institutions outside of that State, so far as has been possible. In regard to the pauper insane, the new procedure is ultra

vires in many cases; they have neither friend nor relative to pray the judge that examination be had, so that that stipulation has been a dead letter, or the task has been thrown upon the city examiners, whose duties do not normally include that work. The New York Society of Medical Jurisprudence has also taken up the subject, in like spirit, and a committee of conference has been ordered to use all proper efforts toward amelioration of the troublesome features of the Act in question. It is expected that the New York county associations will also take part in the movement.

Iowa State Medical Society.—The forty-sixth annual meeting will be held in Marshalltown, May 19 to 21, 1897, one month later than last year, and you are earnestly requested to be present and bring your medical friends.

Chairmen of Sections: Surgery, Dr. R. W. Hill, Davenport. Nervous and Mental Diseases, Dr. E. R. Smith, Toledo. Theory and Practice, Dr. Geo. A. Smith, Clinton. State Medicine, Dr. F. S. Thomas, Council Bluffs. Obstetrics and Gynecology, Dr. J. R. Guthrie, Dubuque. Ophthalmology and Otology, Dr. F. E. Sampson, Creston. Materia Medica and Therapeutics, Dr. H. A. Leipzig, Burlington.

Chairmen of Committees: Finance, Dr. C. S. Chase, Waterloo. Trustees, Dr. Calvin Snook, Fairfield. Arrangements, Dr. H. L. Getz, Marshalltown. Publication, Dr. H. B. Young, Burlington. Ethics, Dr. D. S. Fairchild, Clinton. Legislation, Dr. D. C. Brockman, Ottumwa.

All personal communications, pertaining to Sections or Committees, should be addressed to its chairman.

J. C. SCHRADER, M.D., Pres., Iowa City.
JAMES W. COKENOWER, Sec'y, Des Moines.

Tri-State Medical Society.—The fifth annual meeting of the Tri-State Medical Society of Iowa, Illinois and Missouri, will meet in St. Louis, April 6 to 8, 1897. A large number of valuable papers will be read. Dr. Joseph Price of Philadelphia will hold the surgical clinic, Dr. James T. Whittaker of Cincinnati the medical clinic, and Dr. Dudley Reynolds, ophthalmic clinic. Dr. G. Frank Lydston of Chicago will entertain the members with an original story during one of the evening sessions. The officers are: President, A. H. Cordier, M.D., Rialto Bldg., Kansas City. First Vice-President, Hugh T. Patrick, M.D., Chicago. Second Vice-President, H. C. Eschbach, M.D., Albia, Iowa. Secretary, G. W. Cale, M.D., 4403 Washington Boul., St. Louis. Treasurer, C. S. Chase, M.D., Waterloo, Iowa.

Western Ophthalmological, Otological, Laryngological and Rhinological Association.—The second annual meeting of this Association will be held at St. Louis, Mo., April 8 and 9, 1897. A cordial invitation is extended to the profession. President, Adolf Alt. Vice-Presidents, B. E. Fryer, J. H. Martindale. Treasurer, W. L. Dayton. Secretary, Hal Foster.

The railroads have promised one and one-half fares. When buying tickets ask for a certificate, on reaching St. Louis have it signed by Dr. Alt.

Medical Society of the Missouri Valley.—The next meeting of this Society will be held at Lincoln, Neb., Thursday, March 18, 1897.
DONALD MACRAE, JR., M.D., Sec'y.

Will County (Ill.) Medical Society.—At a regular meeting of this Society held February 11, the following officers were elected: President, F. W. Werener; vice-president, W. B. Stewart; secretary and treasurer, L. J. Frederick.

The Grand Rapids Academy of Medicine has elected officers for the ensuing year as follows: President, Ralph H. Spencer; vice-president, H. W. Catlin; secretary, J. B. Whinnery; treasurer, Earl Bingham.

NECROLOGY.

WILLOUGHBY I. WOOD, M.D., Bellevue Hospital Medical College, 1890, died February 20, in Guilford, N. Y., where he had gone four months ago for his health. He was born in Brooklyn, N. Y., and was mainly educated there, becoming in time the responsible surgeon of the Norwegian Hospital as well as a gynecologist with a promising future. His age was 28 years.

JOHN HAMILTON, M.D., of Allegheny, Pa., died at Pitts' Island, Lake Worth, Florida, February 12. He was born in Ohio in 1827, and had practiced in Allegheny for several years.

WILLIAM J. BLAND, M.D., of Clarksburg, W. Va., February 20. He was born in Kingwood, Va., in 1816, living the most of his life in Weston, and since 1892 in Clarksburg. He was graduated from Jefferson Medical College and the Louisville Medical College and for many years a member of the State

Board of Health. For eight years commencing in 1881, he was superintendent of the West Virginia Hospital for the Insane at Weston. He was surgeon in the Thirty-first West Virginia Infantry and was afterward Chief Surgeon of Wm. L. Jackson's Cavalry Brigade. He at one time represented Lewis County in the Legislature.

DAVID BOYD, M.D., New York, died at his country home in Red Bank, N. J., February 17, aged 74.

EUGENE K. MOTT, M.D., of Chester, Pa., February 22. He was born in Scranton, Pa., in 1842 and was graduated from the Jefferson Medical College in 1868. In 1874 he removed to Chester.

NEW INSTRUMENTS.

A NEW MASTOID RETRACTOR.

BY FRANK ALLPORT, M.D.

Professor of Clinical Ophthalmology and Otology in the Minnesota State University; ex-President of the Minnesota State Medical Society; ex-Secretary of the Ophthalmological Section of the American Medical Association, etc.

MINNEAPOLIS, MINN.

For some years I have been using my old retractors in mastoid and similar operations, and have been well pleased with them. The only objection noticed has been the fact that, as the incision and bone opening has been growing larger, owing to our improved knowledge and operations, the retractor has at times seemed to me rather small. This difficulty has been obviated by myself and others by using two retractors, one in each extremity of the wound, being careful they do not overlap each other. This arrangement has proven eminently satisfactory, opening as it does a large and bloodless field of operation, and I still feel that in its thorough usefulness it is as good a method as can be adopted. Some operators, however, dislike to use

two retractors; others have repeatedly expressed the opinion that the blades of the retractors should be always parallel to each other, both when closed and open; others have felt that the retractors were not strong enough. To obviate the objections raised by such surgeons, I have devised and had manufactured for me, by Chas. Truax, Green & Co., of Chicago, a retractor, of which a cut is here given. It is very strongly made, nearly three inches in length, and with an expansive limit of two inches, which is large enough for any operation of this nature. It will be noticed that the blades always lie parallel to each other, and that the instrument is small, compactly built and difficult to get out of order.

BOOK NOTICES.

Telepathy and the Subliminal Self. An Account of Recent Investigations Regarding Hypnotism, Automatism, Dreams, Fanaticisms and Related Phenomena. By R. OSGOOD MASON, A.M., M.D. Pages 343. New York: Henry Holden Co., 1897.

Dr. Mason takes very broad ground; we might even say advanced ground in this work, but that it is interesting to all persons interested in psychology goes without saying. Some of the stories told are as interesting as veritable ghost stories usually are, and some of them almost as intangible. He asserts, however, that the following may be considered as established facts (p. 72). "The reality of the hypnotic condition, the increased and unusual power of the hypnotic condition and unusual power of suggestion over the hypnotized subject; (3) the usefulness of hypnotism as a therapeutic agent; (4) the perfect

reality of natural as contrasted with supernatural character of many wonderful phenomena, both physical and psychical, accepted in the hypnotic state. On these subjects" says the author, "much remains for future study. (1) The exact nature of the influence which produced the hypnotic condition is not known. (2) Neither is the nature of the report or peculiar relationship which exists between the hypnotizer and the hypnotized subject; the relationship is sometimes so close that the subject hears no voice but that of his hypnotizer, perceives and experiences the same sensations of taste, touch and feeling generally as are experienced by him and can be awakened only by him. (3) Nor is it known by what peculiar process suggestion is rendered so potent, turning for the time being, at least, water into wine, vulgar weeds into the choicest flowers, a lady's drawing room into a fish pond, clear skies and quiet waters into latent storm clouds and tempest tossed waves, turning laughter into sadness and tears into mirth" (page 26). The author insists on the reality of thought transference to a limited degree, and like Charcot he accepts certain of the claims made by those who deeply investigated this branch of science, but he admits that there is yet very much to learn in the domain of psychology. While few in our profession are at present prepared to accept all of the theories of Dr. Mason and his school in regard to these matters, or even to accept as conclusively established the fundamental principles of "thought transference" and "suggestion," all must admit as Shakespeare long ago pointed out and aptly quoted by Charcot: "There are more things in heaven and earth, Horatio, than are dreamt of in your philosophy."

Dr. Mason tells some curious stories which are almost past belief. One in particular about a young woman, who "although she had never seen that kind of work done, and had not the slightest idea how to mix colors to produce the desired tints, nor how to apply them to produce desired effects, yet at a single sitting in a darkened room, she produced a head of singular strength and character, possessing at least some artistic merit." The reproduction which appears as a frontispiece to Dr. Mason's volume gives an idea of its character. The author concludes by saying that, "in gathering up the results of these investigations it must be said that in showing the relations of science there is no thought of any detraction from the nobility and greatness of the scientific achievement in the material world. That is grand almost beyond estimation. The attitude of science is conservative and it is right, but sooner or later it must awake to the fact that here is a new field for investigation which comes strikingly within the limits of its labors and even within its methods. Many individual members of the great body of scientific workers see and know this; gradually the majority will see it."

Genito-Urinary Diseases and Venereal Diseases. By J. Wm. WHITE, M.D., and EDWARD MARTIN, M.D. Illustrated. Philadelphia: J. B. Lippincott Co., 1897.

This work of 1,061 beautifully printed pages, and profusely illustrated, brings the subject of genito-urinary diseases down to date, even to the intangible shadowgraph of renal calculus *in situ*. Nothing is omitted which is necessary for a proper understanding of the subject. The practitioner and student will find their wants intelligently understood and a faithful attempt made to supply them. The Chapters on Tumors of the Bladder, Diseases and Injuries of the Ureters, and Injuries and Diseases of the Kidneys will be found especially entertaining and instructive. The general surgeon, as a rule, will not agree with the author when in speaking of the treatment of enlarged prostate, page 991, he says, "Castration for prostatic hypertrophy, first advocated (White) in 1893, has since been performed in hundreds of cases and with results which establishes it as the safest and most radical curative operation yet proposed." We do not believe that this operation will ever become popular for surgeons, as the public at least have some rights in

the premises. Moreover, it is liable to such abuses as almost to prohibit the operation. The medico-legal standpoint alone affords a strong obstacle. Furthermore, the operation is not harmless, as cases are on record where the operation has been performed while the patient was suffering from septicemia, and had lost the power of resistance to shock, causing a fatal result and mistakes in diagnosis are not so infrequent as to make it a matter of indifference. An instance is known to the writer where a patient, sent into a hospital for the performance of this operation, for supposed enlarged prostate, was found to have stone in the bladder, and it must be remembered that castration is not here proposed for experts in diagnosis alone, but for all practitioners. Inconceivable and numberless would be the damage suits likely to follow the indiscriminate application of White's remedy. Moreover, castration has not yet been shown to have any advantage over section of the vas deferens with ligature of the spermatic artery, as it must be obvious that natural atrophy of the testicle has less constitutional effect on the patient than its entire removal. The book is, however, a very valuable addition to the subject of genito-urinary and venereal diseases.

Annual of the Universal Medical Sciences and Analytical Index. A Yearly Report of the Progress of the General Sanitary Sciences throughout the World. Edited by CHARLES E. SAJOUS, M.D., Paris, and seventy associate editors, assisted by over two hundred corresponding editors and correspondents. Illustrated, five volumes. 1896. The F. A. Davis Co., publishers, Philadelphia and New York and Chicago (Lakeside Building).

In the elaboration of the 1896 Annual the aim of the editor, he says, "has been to add to the practical value possessed by former issues." The value of a book of this kind lies largely in the index, and the extra care with which its analytical index has been prepared makes it of very much more value. The illustrations are more copious than ever and we doubt not the Annual will be correspondingly more popular. It certainly deserves to be. The publishers have spared no pains or expense to make the work what it should be.

Pictorial Atlas of Skin Diseases and Syphilitic Affections. Photolithochromes from Models in the Museum, St. Louis Hospital, Paris. With explanatory woodcuts. By ERNEST BERNIER, A. FOURNIER, TENNESON, HALLOPEAU, DUCASTEL, FEULARD, JACQUET. Edited and annotated by J. J. PRINGLE. London: Rebman Publishing Co. Philadelphia: W. B. Saunders. 1896. Part I.

The illustrations and text in this number relate to the lesions in the habitual cocain-morphin consumer, by Gaston; Ringworm of the body; syphilitic hyperkeratosis; psoriasis figurata. The plates in this number have been executed with the same care and skill that made its predecessors such accurate and truthful representatives of the great St. Louis Hospital. Fortunate, indeed, will be the general practitioner and dermatologist who has in his possession a copy of this magnificent series, for it brings to his library a faithful reproduction of the typical models of the great hospital.

A System of Medicine. Edited by THOMAS CLIFFORD ALLRUTT and W. S. PLAYFAIR. Volume II, Gynecology. Pages, 973. New York and London: Macmillan Co., 1896. Price of the book singular, \$6; that of system, \$5, cloth; leather \$7 and \$6 respectively.

The editor of this System of Medicine has returned to the plan adopted in the earlier treatises, including the treatment of diseases of women in this system, and as this department of medicine has grown so large it is found to occupy an entire volume. The contributors to the volume are eminent English gynecologists and include, J. Wm. Ballantyne, A. H. Freeland Barbour, John Halliday Croon, Alban Doran, W. S. A. Griffith, F. W. N. Haultin, Handfield Jones, Henry Morris, John Phillips, Wm. O. Priestly, Alexander R. Simpson, J. Grieg Smith, John B. Sutton, W. Balls-Headly, Robert Boxall, Chas. J. Cullingworth, Henry Gervis, D. Berry Hart, George E. Herman, Edward Malins, Robert Milne Murray, W. S.

Playfair, Amand Routh, W. J. Sinclair, Wm. J. Smyly, J. Knowsley Thornton.

The volume opens with an interesting historical chapter on the Development of Modern Gynecology by Handfield Jones, and it is followed systematically by anatomy, malformations and diseases of the female generative organs; then follow chapters on sterility, gynecologic therapeutics, pelvic diseases and diseases of the uterus proper, and concludes with a chapter on diseases of the bladder and urethra. The work is well written, quite up to date, and will be found a useful and safe guide to the practice of this branch of the art.

Deutsch's Letters. A practical Method for easy and thorough Self-instruction in the German Language. By SOLOMON DEUTSCH, Ph.D. Second and revised edition, New York, 1896. Price \$2. (We are informed by personal letter that the publisher is now J. H. Vail & Co. instead of Brentano, which appears on the title page.)

The second edition differs from the first edition in having appended to it the key to the German exercises, and it is believed that this edition will enable the sincere learner to fairly accomplish a translating knowledge of the language without a teacher from the mere study of the book, although there is no question but anyone who wishes to speak any language with accuracy and precision must in addition use a colloquial method. We commend the book as being one of the best of its kind.

MISCELLANY.

Tests of Crede's Silver Gauze and Salts as Antiseptics.—The *Cbl. f. Chir.* of January 23 contains the reports of three scientists who have been experimenting with silver to determine its value in antiseptics. The results fail to confirm Crede's experiences. Zajontschowsky states that the gauze is not sterile; that it does prevent the development of bacteria to a limited extent, but is not bactericidal at all, and that much of the effect Crede ascribes to it is due to the absorptive power of the gauze, whether impregnated with silver or not. Iodoform gauze kept in sublimate solution, 1 to 2,000, as is used in his service, is more effective than the silver gauze. Meyer of Zurich also states that in his numerous and careful tests the staph. pyog. aur. were destroyed in an irol solution (1 to 4,000) only after forty-five minutes, and in an actol solution (1 to 2,000) after thirty minutes. Albumin in the silver salt solution retards the bactericidal effect. Anthrax spores were still growing after five to seven days in a saturated irol solution and after three days in an actol solution (1 to 1,000). Silver salts added to the bouillon prevented the development of staph. and pyocy., but anthrax spores continued to grow in serum to which actol had been added (1 to 10,000). In regard to their effect in preventing the development of bacteria in albuminous media, silver salts approach very closely to sublimate, but in aqueous solutions, sublimate is a far more powerful antiseptic than the former. Other tests by Brunner show that the effect of the silver is more decided and rapid as the bacteria are less virulent.

Remarkable Case of Foreign Bodies in the Stomach; Gastrotomy and Prompt Recovery.—The *Deutsche med. Woch.* of January 21 contains an illustrated description of thirty-seven articles removed by Fricker of Odessa from the stomach of a young woman who had swallowed them in an attempt to commit suicide in an attack of nervous melancholia. They weighed in all 261.85 grams, and included a door key, a silver teaspoon, a plated spoon, a fork (20.5 cm. long), two pieces of wire, two hairpins, twelve pieces of window-pane glass, one window hook, one steel pin, nine sewing needles, one crochet needle, which had perforated the wall of the stomach, beside some buttons, etc. The patient had complained of pains and vomited, but as palpation did not disclose the presence of the foreign bodies that she asserted she had swallowed, her statements were not credited at first. Fricker tabulates the most remarkable cases of the kind on record, including one from the *JOURNAL*. One article was found alone in all but three of the fifty-three cases. In six cases a set of false teeth had been swallowed, a fork in fourteen, a knife in ten, a spoon in seven. Most of the larger

articles were taken from "professional swallows." In one case three closed pocket-knives were removed and the man afterward swallowed two more, which passed out *per anum*. The fatal cases were those in which a Japanese tooth brush, a razor, an instrument and a set of teeth had been swallowed, also the case of an insane man who had swallowed nearly two pounds of nails. A 10-year-old child recovered after having swallowed forty-two nails, ninety-three brass and tin pegs, twelve large nails, one safety pin, one needle and three shirt buttons. The proportion of recoveries in the fifty-three cases is 81.4 per cent. and deaths 18.6 per cent.

Taxing Private Clinics in Germany.—The *Deutsche med. Woch.* in its issue of January 21, protests vigorously against the new regulations which impose a tax on the private hospitals conducted by physicians. It is not ambition nor the hope of pecuniary rewards that causes physicians to start a private establishment for their patients, but pure love of science and the desire to perfect their knowledge and skill in their special branch. To class such establishments with ordinary boarding houses and hotels, is manifestly unjust. The physician will be inclined to relinquish the management and responsibility of his clinic to non-professionals, to escape the tax, which creates an invidious distinction between him and his colleagues, and the establishment will suffer, while science and the healing art will retrograde. The increase in the private hospitals in Berlin in the last few years has been remarkable:

Year	Public Hospitals.	Beds.	Patients.	Private Hospitals.	Beds.	Patients.
1879	13	4,100	39,800	2 ¹	36	159
1885	14	5,130	49,000	5 ¹	124	1,260
1888	15	5,500	53,000	19	360	2,529
1891	18	6,700	62,000	29 ¹	623	5,907
1894	18	6,570	68,000	40 ¹	808	7,983
1895			86,000			10,000

THE PUBLIC SERVICES.

Army Changes. Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from Feb. 20 to Feb. 26, 1897.

First Lieut. Robert S. Woodson, Asst. Surgeon (Jackson Bks., La.), is granted leave of absence for two months, to take effect on or about March 5, 1897.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending Feb. 27, 1897.

P. A. Surgeon G. T. Smith, detached from the "Adams" on reporting of his relief about March 2, ordered home and granted two months' leave.

P. A. Surgeon L. H. Stone, detached from the naval hospital, New York, March 15, and ordered to the "Adams."

Surgeon G. P. Bradley, detached from the "Indiana" March 3, ordered home and placed on waiting orders.

Surgeon N. McP. Ferebee, ordered to the "Indiana" March 3.

P. A. Surgeon W. F. Arnold, ordered as a member of the medical examining board, League Island navy yard.

P. A. Surgeon L. W. Atlee, detached as member of the medical examining board, League Island navy yard.

Change of Address.

Bailhache, P. H., from Stapleton, N. Y. to 1819 to N Street, N. W. Washington, D. C.; Billig, A., from 4944 S. Ashland Ave., to 360 E 42d Street, Chicago, Ill.; Bourns, F. S., from Grand Opera House to 78 Marietta Street, Atlanta, Ga.

Forrester, Jos., from Butler to 512 W. 4th Street, Erie, Pa.

Johnson, E. F., from 523 Locust to 504 Walnut Street, Chicago, Ill.

Kilbride T. F., from Ayrshire, Iowa, to Emmetsburg, Iowa.

Stoner, Geo. W., U. S. M.-H. S., from Baltimore, Md., to Stapleton, L. I., N. Y.

ADDRESS.

THE SOCIAL EVIL—SHOULD IT BE REGULATED? CAN IT BE EXTERMINATED?

Read before the Contemporary Club, Davenport, Iowa, Dec. 17, 1896.

BY W. L. ALLEN, M.D.

DAVENPORT, IOWA.

The subject for this evening's discussion is one entered into with considerable hesitation. The more the subject is studied the greater and more difficult does the question become. Philanthropists and moralists are in favor of an aggressive war of extermination. City and government officials favor, as a rule, some sort of regulation; physicians are found on both sides of the controversy. That the subject is one of most vital importance, one which threatens our very existence as a healthy race, is evidenced by the fact that it has stamped nearly three millions of the people of these United States with syphilis. That the subject is of enough economic importance for the best thought of our legislative bodies is evidenced by the statement that the men in our cities pay to prostitutes \$300,000,000 annually. This statement alone would seem of almost enough importance to cause the mathematic American to stop and call for an investigation; but there are other results far more disastrous. In order to present the different points of view of those who have opinions on this evil, it will be necessary to subdivide the matter into the following: 1. Causes; 2. Effects, *a*, destruction of morals; *b*, production of disease; *c*, production of degenerates; *d*, financial waste. 3. Remedies, *a*, regulation and taxation; *b*, prohibition.

CAUSES.

Fortunately, or perhaps unfortunately, there is little difference of opinion as to the causes of prostitution; the natural passion and inherent depravity of men and jealousy and love of dress and display, or poverty and desertion of women. Dr. Sanger in his work on prostitution, from which I shall quote quite extensively, says: "No nation has ever held its women generally in common. Still there appears to have been in every age men who did not avail themselves of the marriage covenant or who could not be bound by its stipulations, and their appetite created a demand for illegitimate pleasure which female weakness supplied." This vice which has existed and even flourished for 3,700 years or more has so fastened itself upon our own race that it might not be far out of the way to say that we have inherited it. A short sketch of its history will substantiate this. In the eighteenth century, B. C., we find the first authentic record of prostitution, when Judah, finding his daughter-in-law, Tamar, sitting in an open place with her face covered, mistook her for a harlot; for his pleasure she demanded a kid, which he promised,

leaving his ring and bracelet as pledges (Gen. xxxviii). For several centuries prostitutes were allowed outside of Jerusalem and other cities, but were excluded from the cities themselves until the reign of Solomon, who was the first to open the gates of Jerusalem to them, after which time they multiplied so fast as almost to overrun the city. The Jews, while placing the severest penalties to prevent prostitutes among their race, did not attempt to prohibit the use of foreign prostitutes. I quote: "The city of Nancratis owed its wealth and fame to the beauty of its courtesans, whose reputation spread throughout Europe, and was much celebrated in Greece. Rhadopis led the life of a courtesan in Egypt with such success that she (if the stories of the Egyptians are to be believed) built a pyramid with her savings." "In Chaldæa, religion first connived at and then commanded prostitution. Every Babylonian female was obliged by law to prostitute herself once in her life in the temple of the Chaldæan Venus, whose name was Mylitta. Herodotus claims to have seen the park and grounds in which this singular sacrifice was made. They were constantly filled with women, with strings bound round their hair. Once inside the place no woman could leave it until she had paid her debt and deposited on the altar of the goddess the fee received from her lover. Some who were plain remained there as long as three years, but the young, the beautiful, the high-born seldom needed to remain over a few minutes." Among the Greeks this class of women seemed to be less degraded, and were often held in high esteem personally by the great poets and orators. "The Hetairæ were by far the most important class of women in Greece. They filled so large a place in society that the virtuous females were entirely thrown in the shade and it must have been quite possible for a chaste Athenian girl endowed with ambition, to look up to them and covet their splendid infamy. An Athenian matron was expected to live at home, she was not allowed to be present at the games or the theater. A Milesian prostitute named Thargelia accompanied Xerxes on his invasion of Greece. Some idea may be formed of the position in society occupied by prostitutes from the fact that Xerxes employed this woman as negotiator with the court of Thessaly. Fired by her success, another Milesian girl named Aspasia established herself at Athens. She set up a house of prostitution and peopled it with the most lovely girls of the Ionic cities. But wherein she differed from rivals and predecessors was the prominence she gave to intellect in her establishment. She lectured publicly among her girls and their visitors, on rhetoric and philosophy and with such marked ability that she counted among her patrons and lovers the first men of Greece, including Socrates, Alcibiades and Pericles."

At Corinth the first-class hetairæ charged as high as a talent (\$1,000) for a single night, while in the

temple of Venus a thousand young women (slaves) were kept, who were obliged to prostitute themselves for a single obolus (3 cents).

In Rome prostitution was licensed and taxed, and for a few centuries, by the will of the people, kept in check; but among the emperors themselves were almost the worst examples of debauchery found in history. "Caligula, who made some changes in the tax levied on prostitutes and established a brothel in the palace, commenced life by debauching his sister and ended it by giving grand dinners during which he would remove from the room any lady he pleased, and after spending a few minutes with her in private, return and give an account of the interview for the amusement of the company. Nero surpassed his predecessor in recklessness. He was a habitual frequenter of houses of prostitution. He dined in public at the great circus among a crowd of prostitutes. He founded, on the shore of the Gulf of Naples, houses of prostitution and filled them with females. Commodus converted the palace into a brothel. He kept in his pay 300 girls of great beauty and as many youths, and revived his dull senses by the sights of pleasures he could no longer share. Like Nero, he violated his own sister." Thus did the Roman emperors, with scarcely an exception, set examples of depravity which were, although perhaps to a lesser degree, followed by the rulers of Europe and England down to the present century. Henry VIII. and Francis I. were quite as bad as any monarchs in history. History for the past 1,500 years has enough of just such examples to show the extent to which this vice prevailed. With such examples among the rulers, what improvement could be expected among the lower classes?

Actual want seems to be responsible for a large increase in prostitution. Thousands of poor women work in large cities for less than \$2 a week, on which they must live, feed, clothe, house and warm themselves and support others. The wages received by 2,000 women in New York prior to becoming prostitutes were as follows:

534 received, per week.	\$ 1.00
336 received, per week.	2.00
230 received, per week.	3.00
127 received, per week.	4.00
68 received, per week.	5.00
8 received, per week.	7.00
5 received, per week.	8.00
1 received, per week.	20.00
1 received, per week.	50.00
663 unknown.	

Five thousand one hundred and eighty-three prostitutes in Paris gave as the cause of their becoming such the following reasons.

Expulsion from home or desertion by parents . . .	1,255
Desire to support old or infirm parents	37
Desire to support younger brother and sisters . . .	29
Widows with children to support.	23
Girls from the country to support themselves. . .	280
Girls from the country brought by soldiers and students.	404
Servants seduced by master and abandoned. . . .	289
Concubines abandoned by their lovers.	1,425

In New York 2,000 women gave as the cause of their fall:

Inclination	513
Destitution	525
Seduced and abandoned.	258
Drink	181
Ill treatment by parents or husbands	164
As an easy life.	124
Bad company	84

Persuaded by prostitutes.	71
Laziness.	29
Violated.	27
Seduced on emigrant ship.	16
Seduced in emigrant boarding house	8

Two thousand of these women in New York give as their former occupation:

Artist, 1; school teacher, 3; boxmaker, 5; nurse, 1; fruit vender, 4; tobacco packer, 7; music store clerk, 8; shoe binder, 16, milliner, 59; attending school, 8; vest maker, 21; tailoress, 105; embroidery worker, 8; cap maker, 24; dress maker, 121; fur sewer, 8; book folder, 27; servants, 933; hat trimmer, 8; factory girls, 37; lived with parents or friends, 499; umbrella maker, 8; housekeeper, 39; flower maker, 9.

Thus over one-fourth were poor girls working at sewing or in shops where wages were a mere pittance. One-half were servants or housekeepers, employments of peculiar temptation either through the masters or boarders and guests. It was stated that in Rome in the early days nearly all servants were available for purposes of prostitution, and at the present time many large cities are reported to be little better. The large tenement houses where numbers of both sexes sleep in the same room is another frequent cause of prostitution. The report of the 2,000 girls in regard to education is another important item: 714 could read and write well, 546 could read and write imperfectly, 219 could read only, 521 totally uneducated. Of 3,103 prostitutes in London 1,773 could neither read nor write, 93 could read and write well, 1,237 could read and write imperfectly.

"M. M., a widow with one child, earned \$1.50 a week as a tailoress. S. F., a widow with three children, earned \$2 weekly at cap-making, but could not get steady employment even at those prices. M. F., a shirt-maker, earned \$1 a week. M. G. struggled hard with the world before she became a prostitute, sleeping at station houses at night and living on bread and water during the day. The chief of police in that district said he had known of fifty cases similar to her's and who are now prostitutes." Nine-tenths of the children sent out from workhouses (in England) to do day work are eventually seduced and become prostitutes. Employment of young children in factories is another cause of great evil. Three hospitals in London reported that in eight years they had received 2,700 cases of venereal diseases in young children between the ages of 11 and 16. Obscene literature is another means by which the young are corrupted. One society in London destroyed in less than three years 13,000 books and prints.

EFFECTS.

a. *Destruction of morals.*—Young men once accustomed to indulgence in prostitution become morally dull; adultery seems an unimportant matter to them either as single or as married men; these liberal views later in life often affect their wives and adultery increases enormously. This latter evil has increased to such an extent in this country that it has been recently stated that there are 250,000 adulterous people in New York city, exclusive of the 40,000 prostitutes and their customers. On the continent poverty is a bar to the marriage contract, and as a result prostitution has been made easily obtainable and illegitimate children fill the lying-in-hospitals and foundling asylums. In France the decreased birth rate is calling forth the most serious legislative consideration.

This country has been praised as the land of small homes, and these small homes and home life must be made the means for most of the moral training and

education. What then is to become of us if nearly half of our population, while avoiding prostitution, practice adultery? Early marriages are not as common as formerly and abortion and infanticide are increasing to an alarming extent. The corrupt life of the Romans was largely responsible for the fall of the Roman empire!

b. A production of disease.—Syphilis was for many years wrongfully charged to our American Indians, who, it was claimed, infected the sailors of Columbus and the explorers. For many years it was the custom in France to whip patients with venereal disease, although prostitution was at the same time fostered in many ways. Today we have to deal with the fact that there are between 2,500,000 and 3,500,000 syphilitic people in this country. Specialists claim that 80 per cent. of the men in our large cities have venereal disease. That much of this is spread by clandestine prostitution and not wholly by regular prostitutes is a point of much importance. A girl of 14 years of age infected eleven men and boys living under the same roof in one of the crowded tenements of the poor.

The reports of the British army show a startling state of affairs: In 1866 what is known as the "Contagious Disease Act" was passed. Under this and subsequent acts "réglementation" was adopted for the entire army. In the army stationed in China there were 445 cases of venereal diseases for every 1,000 men. In other divisions the amount of disease varied from 49 to 500 per 1,000 men. The commanding officer was ordered in 1886 to "see that sufficiently numerous and sufficiently attractive prostitutes were provided for every cantonment in India, and that the quarters in which the women were lodged were sufficiently comfortable and attractive to satisfy the demands of both the women and the men." The increase of disease proportionate to the number of women allowed is of especial importance, as will be shown in the following report:

	Number of men to one prostitute.	Number cases of diseases per 1,000 men.
Number of stations . . . 4	16.5	170
Number of stations . . . 3	9.9	263
Number of stations . . . 4	7.25	402
Number of stations . . . 3	3.9	546

From this it appears that the more women the greater the indulgence and the more opportunity for the spread of disease.

c. Production of degeneration.—Tarnowsky, in a recent work, claimed that there are deformities and anomalies of the head, face and ears in 42 per cent. and defective teeth in 54 per cent. of the prostitutes. In addition to this physical degeneration their psychic degeneration is shown in feebleness of intellect, depraved taste and absence of moral sense. Their life is extremely short, the average life of a courtesan being placed at five years. In Paris 17½ per cent. of the prostitutes had lived as such ten years, and only 6¾ per cent. of the prostitutes had lived as such seventeen years; in New York, 3¼ per cent. of the prostitutes had lived as such ten years, and only 2¼ per cent. of the prostitutes had lived as such seventeen years.

d. Financial waste.—The extravagance of Americans is notorious. Mr. Powell estimates that there are more than 40,000 prostitutes in New York city, whose average earnings are more than \$20 a week; in addition to this 62 per cent. more is expended for

liquor in the brothels. This would make the modest sum of \$65,000,000 the annual expenditure of the men in New York city on this vice; and if a similar proportion of expenditure be carried out in the cities of the United States the total would be about three hundred million dollars.

REMEDIES.

a. Regulation and taxation (license).—Prostitution has been licensed in the older countries for many centuries. In Rome the licensed prostitutes were compelled to wear a certain uniform and to dye their hair blue or yellow; they were allowed to charge a certain fee, which they could collect by process of law. The unregistered women, however, although under severe legal penalties, continued to exist and multiply in the same walks of life as in the present generation. For example, "the delicate, corresponding to the kept woman, whose charms enabled them to exact large sums from their visitors; the famosæ, who belonged to respectable families and took to evil courses through lust or avarice; alicariæ, or bakers' girls, who sold small cakes for sacrifice to Venus or Priapus in the form of the male or female organ of generation; the copæ, servant girls at inns and taverns, who were invariably prostitutes.

"The woman desirous of becoming a prostitute (licensed) presented herself before the public officer, giving her age, place of birth and real name together with the one she assumed; if she was young and apparently respectable the officer did his best to combat her resolution. Failing in this, he issued her a license, ascertaining the sum she was to demand from her customers, and entered her name on his roll." It was the duty of the "ædile" to arrest and drive out of the city all the loose prostitutes, but this regulation was practically unenforced.

In France, during the sixteenth century, many cities legalized and taxed prostitution to an extensive degree. The public house of Toulouse, for example, "was established by royal charter, which declared that the profits of the enterprise should be shared equally by the city and the university. The building appropriated for the purpose was large and commodious, bearing the name of the 'Grand Abbaye.' In it were lodged not only the resident prostitutes of the city, but any loose women who traveled that way and desired to exercise their impure calling. It would appear that they received a salary from the city and that the fees exacted from the customer were divided between the two public bodies to which the enterprise was granted. They were obliged to wear white scarfs and white ribbons or cords on one of their arms as a badge of their calling. When the unfortunate Charles VI. visited Toulouse the prostitutes of the Abbaye met him in a body and presented an address. The king received them graciously and promised to grant them whatever largess they should request. They begged to be released from the duty of wearing the white badges, and the king, faithful to his promise, granted the boon. A royal declaration specially exempted them from the old rule. But the people of Toulouse, no doubt irritated by the want of some distinguishing mark between their wives and daughters and the 'foolish women,' by common consent mobbed the prostitutes who availed themselves of the king's ordinance. None of them could venture to appear in public without being liable to insult, and even bodily injury. Resolutely bent on carrying their point, the women shut themselves up in the Abbaye and did

their best to keep customers at a distance. Their calculation was just; the city and the university soon felt the effects of the diminution of visitors at the Abbaye. The corporation appealed to the king and when Charles VII. visited Toulouse, a formal petition was presented to him by the capitones, praying that he would take such steps as to his wisdom might seem fit, to mediate between the prostitutes and the people and restore to the Abbaye its former prosperity. The king acted with energy; he denounced the assailants of the prostitutes and planted his own royal *fleur de lis* over the door of the Abbaye as a protection to the occupants. This was without effect, for the assaults on the Abbaye became more numerous than ever. The civic authorities proving incompetent to check the disorder, the prostitutes found themselves compelled to seek refuge in a new part of the city. For many years they inhabited their new domicile in peace and quiet. The university then dislodging them in order to occupy the spot, the city built them a new Abbaye beyond the precincts of the respectable wards. It was called the 'Château Vert,' and its fame and profits equaled that of the old Abbaye. About the middle of the sixteenth century the city yielded to the scruples of the moralists and ceded the revenues of the Château Vert to the hospitals, but the grant being made on condition that the hospitals should receive and cure all females attacked by venereal disease, it was found after six years' trial, that it cost more than it yielded. The hospital surrendered the Château to the city." After discussions lasting several years, the city adopted the policy of suppressing prostitution altogether and closed the "Château Vert." (Sanger's Report.)

During the present century the plans for regulation and license have attempted to accomplish the following objects:

1. Registration, in order to discover and control the graduated prostitutes and prevent such novices as can be saved from becoming prostitutes.
2. Inspection and examination once or twice a week, to prevent, if possible, the spread of venereal disease.
3. Police regulation to prevent liquor and gambling being indulged in about the resorts and to maintain order.
4. Taxation or fines to defray city expenditures and to pay hospitals for a part of the cost of treating the prostitutes suffering with venereal disease.
5. To prevent the use of houses of assignation unless registered or controlled by means of resident prostitutes, who may aid the police in detecting clandestine or unregistered prostitutes.

Such systems have been very thoroughly carried on in Belgium, Germany and France, with favorable results so far as the licensed prostitutes are concerned, but with an increase in illegitimacy and with uncertain results as to the total amount of venereal disease. Réglementation as adopted by the continental armies and the British army, has been the cause of much discussion, leading to its abolishment by the English in 1886. In the valuable report of Dr. Nevin, made in September of this year, it is stated and proven that syphilis has decreased since the abolition of the C. D. Acts, and Dr. Nevin claims "that réglementation has failed to prove that it has either prevented or diminished venereal diseases." Professor Mounier of Utrecht, an authority of high standing, after a careful analysis of the Dutch statistics, says: "The study of

the propagation of venereal and syphilitic diseases in the garrison of the Low Countries from 1850 to 1886 inclusive, made by the purely statistical method, does not permit me to put forward a conclusion either for or against the réglementation of prostitution."

In Hamburg the regulations are similar to those of Paris, with several additional restrictions; for example: 1, female servants or relatives of the keeper, if under 25 years of age, are excluded from the brothels; 2, no prostitute is allowed to retain children either her own or otherwise, over 10 years of age; 3, young people under 20 years of age are not allowed to enter a brothel; 4, no gaming nor liquor selling allowed in brothels; 5, no assignation houses allowed unless inscribed and having as a resident an inscribed prostitute; and only registered girls are allowed to use such houses.

Under the regulation system and medical care venereal diseases were found in less than 4 per cent. of the registered women, and furthermore such cases of syphilis as occurred were light and more easily eradicated than is usually the case. On the other hand Hamburg seems to have been one of the few cities in which procuresses were recognized and in a measure authorized by the police authorities.

Vienna has, during the last three years, adopted a system which, while including the best features of the former regulation, excludes all brothels and compels these women to live in private apartments. This change has been highly spoken of. It is absurd for us to attack the immorality of the old world while we permit the spectacular exhibits, such as are to be seen in the prostitute alleys in San Francisco, Denver and New York and which are permitted as a part of the regulations.

In St. Louis, Cleveland, New York, Omaha and Davenport a system of police toleration on the payment of specific fines, and after submitting the women to medical examination, has been adopted. In St. Louis license was tried for five years, the State legislature having amended that city's charter for that purpose. Syphilis is said to have increased among the licensed women from 3.75 per cent. before adoption to 6 per cent. at the end of the five years. Such results are misleading unless it is shown what care was taken in the medical examination and in the subsequent quarantine procedures.

In this city there have been between forty-two and sixty-four prostitutes inscribed for toleration. The medical examiners report an improvement in personal cleanliness and in general sanitary regulations, and a slight decrease in venereal diseases, although the reports will still show about 6 per cent. of syphilis and 12 per cent. of gonorrhoeal infection among the inscribed. These examiners deplore the fact that, 1, infected women are not quarantined and sent to hospitals; 2, that no measures are taken to prevent young men and boys from visiting these places; 3, that there seems to be no way to prevent clandestine prostitution, which is on the increase.

In March of this year (1896) the people of Geneva, Switzerland, declared by a vote of 8,300 against 4,068 that the government continue the license system then in force in that city. A writer in the *Philanthropist* states that the license party, called the *Lampe rouge* (the sign required by the authorities to be hung at the door of licensed brothels) marched through the streets of Geneva in ratification parade and marched into the cathedral, singing a hymn in which the Holy

Spirit was supplanted by the *Lampe rouge*, and the banner which they bore with the name *Bon Dieu* supported a red lamp above the name. Such an outrage of decency could only find adequate punishment in the dark ages.

b. Prohibition.—1. Immoral measures can only produce immoral results. 2. Legalizing prostitution causes a great increase in promiscuous intercourse and results in a great increase in both disease and immorality. 3. A large proportion of the prostitutes are, as degenerates or paupers, in all justice wards of the State, and should be protected and cared for by the State.

The great question still remains, *how* best to prohibit and suppress. Stockholm is cited against prohibition; no brothels were allowed there, and yet 2 per cent. of the adult population were in the hospitals each year for the treatment of syphilis and 42 per cent. of the births were illegitimate. A writer affirms that "every house of entertainment was a brothel and every servant a loose woman." In contradistinction to Stockholm there are many small cities, both in the United States and in Europe, where, owing to the character of the population and the decided public opinion, no prostitution is allowed. In such places the authorities, influenced and supported by such strong public opinion that no subterfuges can avail, are enabled to suppress the vice.

A COMPROMISE.

It must be apparent to all that the underlying causes of the social evil are so difficult of removal that all attempts to eradicate them by any process of law have in the large cities been unsuccessful. When poverty can be prevented, when the masses of the people become well educated both intellectually and morally, then, and not until then, will the greatest obstacle have been removed. As a compromise, therefore, the following propositions are offered:

1. Regulation and taxation in *large* cities, such taxation being made the basis of a fund for the protection and support of young or destitute or deserted women who will otherwise become prostitutes.
2. Prohibition in small cities and villages.
3. Prophylaxis.

REGULATION IN LARGE CITIES.

1. Inscription and taxation of all non-convertible prostitutes.
2. Medical examination by city physicians twice a week with power to inspect at will, the services of physicians to be paid by the city.
3. All diseased women to be quarantined by compelling removal to hospital, their expense to be borne by the city or country (as such cases are just as much entitled to be quarantined as smallpox cases).
4. All prostitutes compelled to live alone and no brothels allowed to exist.
5. No men under 25 years of age permitted to indulge in prostitution.
6. No man allowed to visit prostitutes without a certificate of health showing freedom from venereal disease (if the regulations can compel the examination of these women they can also compel them to refuse men without certificates of health). (In Europe all venereal cases in public employes, servants, waiters, etc., are compelled to enter the hospitals.)
7. The inscription of all landlords of the houses of residence of these women and of assignation houses, with additional rules as to the latter class of houses.

8. Police regulation as to maintenance of order, hours, liquor, gambling, etc.

9. All violation by women, or their customers or landlords, punishable by imprisonment or heavy fines.

10. All taxes received from the prostitutes to be devoted to the benefit of young girls or women who through poverty, desertion or any cause, are in danger of beginning a life of prostitution.

PROHIBITION IN SMALL CITIES AND VILLAGES.

Small towns do not, as a rule, contain many victims of destitution, and the people in these towns will average better morally than in the large cities, consequently the police can the more easily render prohibition more effective in such places. Those women who are confirmed prostitutes will not carry on a fight in such a place and will remove to the more congenial atmosphere of some larger city. Men also who are addicted to the habit of prostitution, will generally find it convenient to take frequent trips to the larger towns where their wants can be supplied.

PROPHYLAXIS.

This part of the question is unfortunately so little studied, and the entire question so gingerly handled, except behind closed doors, that the proper education of the public and the proper shaping of public opinion, in which rests the only power of cure, is rendered almost impossible. Public authorities and city administrations are blamed for not enforcing laws plainly placed on the statutes. Juries are condemned for not convicting abortionists. Who compose our officials and our juries, and who uphold them in their conduct and their decisions? An occasional spasmodic outburst by the press or in the pulpit, and the people are quieted. Abortion is upheld by a large percentage of the women of this country, no matter how moral they may be in all other matters. Then also, the majority of the men fail to realize the danger of prostitution, and they support those officials who are known to exercise the best judgment, in not enforcing the law. Physicians and teachers, as well as parents, are to blame in not convincing young men that personal chastity is perfectly consistent with good health.

The law is even slower in behalf of women, and the protection of young girls from seduction is very slight; in some States the age of consent still remains at 13 years. Finally, the education of the masses, the study of sociology and efforts for the prevention of poverty, and the open and frequent discussion of all these questions, may in time bring public opinion to a wise decision and some fixed policy, without which prophylaxis will remain an impossibility and the law a dead letter.

SEPTICEMIA.

Read at meeting of the Winona County (Minn.) Medical Society,
 Jan. 5, 1897.

BY CHARLES PERN ROBBINS, M.D.

WINONA, MINN.

LATE ASSISTANT SURGEON, P.B., N.H.D.V.S.

A few years past no one would have listened to the assertion that a relation exists between lower organisms and certain forms of disease. The secretions

were admitted to contain some elements of a physico-chemic character, irritative in nature and capable of producing pathologic processes. A large class of miasmatic and contagious diseases are not only admitted by the most eminent pathologists and bacteriologists of today, but are referred by them direct to the animal and vegetable parasites. Evidence is positive proof that septicemia should be mentioned in this connection. What can be clearer since Saunderson's and Bert's investigations in 1873 of the relation between intensity of septicemia and pyemia depends upon microorganisms? I desire to present to you an original research of septicemia on guinea pigs, rabbits, mice, dogs and sparrows which were carried out in the private laboratory of DaCosta and Kyle, Philadelphia, later on continued in the Laboratory of the National Military Hospital, Los Angeles County, Cal. Since then I have added some notes which have a practical bearing. I have reviewed the journalistic literature as well as considered the standard authors. Permit me to present septicemia as to history, etiology, pathology, semiology, differential diagnosis and treatment.

Definition.—Septicemia is derived from two Greek words *σηπτικός* and *αίμα*, literally meaning septic blood. This partakes of an adynamic typhoid fever, or according to Piory's definition, an alteration of blood by putrid matter.

History.—There is little to be learned from existing literature of the views which were manifested by the ancients. Prior to the birth of Christ, in regard to the morbid conditions, nothing was designated as septicemia.

In the words of Hippocrates, the Father of Medicine, it is certain it was recognized. He reports a well marked case of puerperal fever on the twentieth day of the disease, also a case in which death was unquestionably caused by septic poisoning. Here is his literal translation.¹ "Criton, in Thasno, while still on foot and going about, was seized with a violent pain in the great toe, he took to his bed, the same day had rigor, nausea, recovered his heat slightly and at night was delirious. On the second, swelling of the whole foot and about the ankle there was erythema with distension and small bullæ (phlyctenæ) and acute fever. He became furious, deranged, alvin discharge, bilious, unmixed and rather frequent; he died on the second day from the commencement." Additional information may be had by referring to his illustrious description on empyema and fever.

Prof. C. Henter says under the head of "septic fever." Hippocrates and Celsus observed fever in cases of injuries that proved so dangerous that this danger could not have originated from the inflammation or from the wound alone."

Tacontuis, a consultator of Hippocrates, has even mentioned putrid fever the same as Adrianeus Spigelius, who spoke of fevers which arise from putrefaction. Both authors as well as their followers did not discriminate between septicemia arising from putrescence of wounds and pyemia. In the meantime both varieties were regarded as intermittent fever.

Aretæus lived during the Christian era. In his remarks on pneumonia he spoke of metastatis in certain cases, also of the kidney and liver. He ascribes suppuration of the liver to intemperance and protracted disease, especially dysentery and colliquative wasting.

Galen and some other ancient physicians recognized the existence of septic poisoning as is shown by the opinion expressed on the subject of putrid fevers.

Ætius states, that it arises from constriction of the skin or viscosity of the humors, whereby the perspiration is stopped and the quantity of vital heat so altered as to give rise to putrefaction, first of the fluids and afterward of the fat and solid parts. Syneus and Constantus Africanus gave a similar account. Alexander gives an interesting and ingenious disquisition on the origin and nature of putrid fevers.

Palladus describes two kinds of synochus fevers, one occasioned by effervescence and the other by putrefaction of the blood; of these the latter is the more dangerous.

A new era in the literature of this subject dawned during the sixteenth century. Ambrose Paré and Bartholomew Maggi each published a work in which they pointed out the old error and announced new truths. Paré's "Treatise on Gunshot Wounds" appeared in 1551, while Maggi's appeared a year later. He states his experience at the fortress Villani near Susa, and showed clearly that those whom he had treated with turpentine and an ointment did well, while those who had the heroic measures of boiling oil without exception had fever, great pain and swelling.

Nicholas Massa, in 1553, mentions a case of abscess of the lung following injury of the head. So at this time, even in the early history of medicine, there were forced conclusions that there was supposed to be some relation between wounds of the head and multiple abscesses.

Valsava, in 1707, was induced by his own observations to say, that the viscera of the thorax were sometimes affected in wounds of the head. Desault, in 1794, considered abscesses of the liver to be a sequence of head injuries. Morgagni, 1740, somewhat obscurely limited the doctrine of reabsorption of pus; afterward it was elaborately discussed by Quesuay in 1819.

John Hunter, in 1793, and afterward Velpean demonstrated the existence of pus in the blood.

Gaspard, in 1822, published a complete work, based on experimental research, on the action of putrefying substances on living organisms. He was quickly followed by Erns and R. Virchow who repeated the experiment and discriminated with greater precision between the surgical diseases; on the one hand septicemia with its sharply defined symptoms and on the other hand, the opposite pyemia.

Pamem, in 1855, conducted a series of experiments to separate infected substances and determine its real nature.

Hemmer was awarded the prize of 1867 on the best essay on the putrefying substances in the animal organisms.

Lister, in 1867, began his antiseptic treatment for compound fracture. Feltz and Cozz, in 1872, showed that by injecting putrid liquids into the jugular vein and subcutaneous tissue, the blood of the animal thus destroyed contained infusoria. It was however left to Pasteur in 1877-1880 to demonstrate two principal vibriones, the pyogenic or producers of pus, and the septic or the producers of the properly called septicemia. From this time on a number of observers have given accurate descriptions on this subject, yet since the dawn bacteriology views have changed.

Etiology.—Septicemia, septicemic pyemia, traumatic sepsis, traumatic infection, putrid ichorrhemia, are one and the same thing. Septicemia may have its

¹ Works of Hippocrates, Adams Trans., Vol. 1, p. 377.

causes divided into predisposing and exciting. There are severe wounds causing necrobiosed tissue. And what are the wounds causing this mortification? We have wounds of soft parts and bones, generally with, sometimes without, breaking or tearing the skin, wounds of every kind of affection of various descriptions, in consequence of which there is a decomposition of the extravasated blood and stagnant pus, if death of the part is brought about. As predisposing causes of the malady may be added different affections of the bones, especially periostitis, osteo-myelitis, wounds of the head, puerperal diseases, cold abscesses, decubitus, scorbutic mortification, mortification caused by fecal and urinary infiltration, wounds of the dissecting table, also the so-called pseudo-erysipelas of the subcutaneous and of the intermuscular and other deep tissue, some inflammation of connective tissue and in the vicinity of the salivary glands, and the so-called diphtheritic inflammation of the fauces and large intestines.

Professor Wagner of Leipsic has mentioned in this connection the ordinary wound fever and surgical after-wound fever. Halbertsma of Berlin has considered the secondary or pus fever in the suppuration or maturation stage of variola as a cause. Also some hectic fever, and we may add some constitutional causes. Atmosphere (Allen) plays a most important rôle. Infusoria, one minor cause, based on the principle that decaying tissue excretion and exhalation from the body tend rapidly to increase their number; and either one is always present in septicemia.

We have studied the predisposing influences: what is, or are the exciting causes? The bacilli of septicemia observed by Klein in 1835, are rods, single or in chain; 1 to 2.5 μ . long, 3 to 5 μ . wide. These were observed in blood vessels of the smaller lymphatic glands, and are identical with the bacillus of gangrenous septicemia. Bacilli of septicemia in mice are said to be extremely minute. They are said by Koch to be .8 to 1 μ . long and .1 to .2 μ . wide. Spores have been found, which are probably immotile. They are seldom in chains but lie in pairs, and on cultivation do not appear to make threads, but lie together in masses. In mice they are found chiefly in the white corpuscles. In these they increase their number and in case of a white cell are only represented by a mass of bacilli. The bacilli or rather the spores occur in putrid liquids. Six mice are taken and inoculated with a minim amount of the putrid liquid and two die. They rapidly sicken, their eyes become inflamed, the eyelids stick together, they become soporitic, and in about two days or more, accurately 37½ hours, die. On autopsy there is a slight edema at the seat of inoculation and enlarged spleen. The bacilli are found free, and lodged in the white corpuscles, in edematous tissue, and abundant in the blood capillaries.

It is said a minim out of the putrid fluid causes death in a sparrow. Field-mice have an immunity. Rabbits and guinea pigs, when inoculated in the nose, suffered from a local erythema, which entirely disappeared in seven days, and likewise rendered them immune for some time. If inoculated into the cornea of a dog he will suffer from inflamed eyes, but no constitutional symptoms. The bacilli are easily cultivated outside the body in an aqueous humor and gelatin rendered neutral by the alkaline sodium phosphate. On plate culture of neutral gelatin specks of a faint cloud-like nature appears, but in a test-tube of the same media

they produce a delicate cloudy film along the needle track. A small quantity, after being carried through three generations, produces the disease in mice. The organs of an autopsy may be hardened in alcohol, and stained by Gram's method. Bacilli of septicemia in rabbits are short rods, slightly pointed at both ends, .6 to .7 μ . wide and .1 to .4 μ . long. They stain deeply at the ends, having an uncolored interval in the middle. Two or more may be linked together. They grow well on nearly all culture media. In nutrient gelatin plates they produce dot-like colonies. On test-tubes, little masses in the needle track, and a layer on a free surface. A smaller quantity produces rise of temperature and labored breathing in about twelve hours, and death in twenty hours. Spleen and lymphatics are enlarged and lungs congested. Mice and birds are very susceptible. The disease can be produced by contaminated water and putrid meat infusion; culture of the microbe can be made.

We have studied the various bacilli that help to produce this disease, now for the coccus. The micrococcus of Pasteur occurs singly, or in pairs, lanceolate and encapsulated. They grow best in the temperature of 30 to 35 degrees C. On a solid medium, they form a superficial, nearly transparent deposit of a gelatin-like consistency. They are pathogenic in rabbits, producing sputum-septicemia. Fowls and dogs have an immunity, and guinea pigs are less susceptible than rabbits. The blood, in the animal just dead, is more potent than a liquid culture, or than the saliva containing the coccus. The pathogene is modified by cultivation in a temperature of 39.5 to 40.5 degrees C. This organism has been supposed to cause pneumonia. The streptococcus and staphylococcus of septicemia grow well on all culture media, producing a white delicate film in agar-agar. It stains well with Gram's method, also methyl violet. But can we say any one of these produce septicemia in man? Streptococci have been found, staphylococci, also the various bacilli. Therefore as a general conclusion, we may say no one, but two or more play the most important rôle. Those two which abound most, are the streptococcus and staphylococci.

These are adopted by the best writers and investigators as the principal cause. And now the question comes, do these microbes bring about the changes of this malady by their presence by causing a change in the surrounding tissue or blood, or their toxins? Investigation on man or animals prove both.

If one should reason on the doctrine of some of the other infectious diseases, evidence would be positive proof that toxins play by far the most important part.

But how is it that in taking the solution of septic blood from a case of septicemia, and inoculating it into an animal, it produces the former disease? Yet if said septic fluid of blood be filtered, the filtered fluid has no effect, while the filtrate produces septicemia. The question remains where it was before. However, first, the microorganism must be present to produce the infection, and secondly, they must eliminate a poison toxin to develop said infection. Hence, microbes of strepto- and staphylococci are among the chief factors in causing septicemia, and bring it about chiefly by the presence of their toxins.

As septicemia is only a branch of the great tree of all septic infection, we ask ourselves in what manner does the septic virus enter into the general system. 1, manufactured by patient himself; 2, inoculation; 3, infection.

1. This is illustrated by puerperal peritonitis that springs up sporadically at a great distance from hospitals, and when the patient is surrounded by every condition antagonistic to its development. It is almost always traced to portions of placenta blood clots, or retained or infected lochia.

2. That of inoculation is known in dissecting wounds and postmortem wounds; also in secondary operations, where the finger of the physician or midwife causes gangrene and mortification to exist, or erysipelas to women in childbed.

3. By infection, mostly found in hospitals. It generally takes place through the medium of the atmosphere. It may occur in private practice if patients are in close proximation.

To come a little nearer, Bert and Saunderson have demonstrated that if septic fluid, capable of producing toxemia when injected into the veins of a living animal, be strained through a porcelain filter, this liquor so filtered may now be injected with immunity; whereas the solid residue on the filter may now be injected and retain full force of septic qualities of the original fluid. The residue contains bacteria but whether the bacteria were poisonous itself, or merely conveyers, is yet an open question. Again septic materials are not in solution. Lister based his antiseptic treatment upon these facts:

1, there are germs, both in air and upon matter, which coming in contact, under favorable circumstances induce putrefaction in fluids or solids, capable of that change, as fruit juice. 2, this putrefaction is not produced by chemic action or oxygen gas on those organisms. 3, the vitality of these germs may be destroyed by certain chemic agents, which we call in surgery, antiseptics.

What conditions now favor the development of these organisms? 1, generally an unhealthy state of the body which predisposes to decay. 2, retention of putrid products as in a wound imperfectly drained. 3, entrance of matter which sets up putrefactive processes. 4, any condition which favor absorption.

This development is hindered: 1, by a vigorous, healthy state of the body. 2, by removal of putrid products; as by cutting out tissue, or drainage, which is so suitable a feature of modern surgery. 3, by preventing the entrance of matter which sets up putrefaction; as by very scrupulous cleanliness and antiseptic methods of surgery, which represent cleanliness carried to the precision of a chemical experiment. 4, by conditions which hinder absorption; such as limiting inflammations of gangrene and healthy granulations.

As to morbid anatomy.—The pathologico-anatomic condition of septicemia occurred in my experience in guinea pigs; edematous infiltration of the skin with a brownish discoloration that is observed during life. In a long course of five to ten days' infiltration with blood, and in one case of two to four weeks, there is serous fluid. Then there is extensive suppuration of the cellular tissue with more or less extensive gangrene of the skin. The blood is dark, feebly clotted, a few petechiae beneath the peri- and endo-cardium and pleura, intense staining of the endo-cardium and lining membranes of the vessels, and often a little bloody tinge in serous cavity. Some destruction of blood corpuscles, intense congestion, and ecchymosis with some shedding of epithelium of mucous membrane of the gastro-intestinal tract. The spleen is swollen and soft, the liver likewise, but more con-

gested. The blood of animals which died after injecting 10 minims of putrid blood, generally contained a varying number of cocci bacteria and bacilli, but after inoculation it contained small bacilli. These were present in large numbers, mostly white corpuscles containing one or more of them.

Observation in man.—In man the occurrence of analogous forms is a priori likely, and cases might be quoted in which the existence of pure septic intoxication or septic infection was very probable, but the subject has not been at all fully worked out. Clinically it is usually impossible to diagnosticate between them, and the postmortem signs are very similar. Pathologic changes of a gastro-enteritis are marked. A jaundiced tint of the skin is not uncommon and petechial spots occur. Albuminuria is frequent. The red corpuscles in the blood drawn during life, run into clumps instead of rouleaux. Wide-spread stasis occur. The postmortem signs are feeble rigor mortis and early decomposition. The blood is dark and fluid, but is more often clotted. Soon after death there is deep staining of the endo-cardium and lining membrane of the great vessels, and any serous fluid in the pleura or pericardium will be blood tinged. This is owing to rapid disintegration of red corpuscles, which begins even during life.

Petechiae begin beneath serous membranes, chiefly on the back of the heart and under the pleura. Hypostatic congestion of the lungs and congestion of the abdominal viscera occur. The spleen is markedly swollen and often pulpy; lastly, the mucous membrane of the alimentary canal may be congested or much more rarely inflamed. Organisms have been found, especially the cocci, in various parts and organs in septicemia. Even when found no characteristic form has been shown to be present.

Marcus Beck states, from his experiments on dogs, 1 to 2 ounces of putrid pus or serum would be required to kill an adult man of septic intoxication. Septic infection may occur from the smallest amount of the poison. Hence we draw the conclusion that large cavities which are imperfectly drained, *e. g.*, badly fractured wounds of joints of pleura, abd. sect. and the uterus post-partum, give septic intoxication. The smallest wound, if there is evidence of inoculation, may give rise to septic infection.

As to semiology.—Septicemia may be divided as regards its symptoms into three varieties: Sapremia, or septic intoxication; septicemia proper, or septic infection; constitutional or insidious septicemia.

The symptoms of septicemia supervene after three or four days, when the wound has been received in non-surgical cases at different intervals after the beginning of the disease. They are less characteristic and intense, though somewhat resembling those of pyemia. We at first perceive that the wound refuses to suppurate, but discharges instead a thin bloody or putrid secretion, which not infrequently contains air bubbles.

Around the wound we first notice an inflammation, which becomes edematous. This edema is very rapid in developing, a day or even a few hours may suffice to produce it, and hurry the patient to his end. It contains an acute purulent edema with its destruction of tissue in such a manner, termed by the French, gangrene *foudroyante*. The skin in this form has a peculiar reddish-brown color. Ordinary septicemia most frequently begins suddenly; generally without, sometimes with, a chill. The fever at first generally

continued, but soon begins to be remittent. As soon as infection begins fever rapidly rises to 101, then from 101 to 104 and assumes a remittent character.

Exacerbation of fever high, slightly lower during remission. Pulse increases from 130 to 160 per minute. It becomes frequent but feeble. Respiration is increased, sometimes going as high as 30 to 50 per minute. The expression is anxious, color darkish icteric hue. No pain but a feeling of uneasiness before the end of twenty-four hours. If the person has a violent chill all the symptoms are increased in severity. There is perspiration after twenty-four hours, and diarrhea is not uncommon.

The discharge is dark and offensive. The tongue is coated with a dark yellowish fur, which is thrown off and the organ becomes dry and cracked. Great thirst supervenes. Anorexia is a general rule and the sensibilities are deadened, this causing no pain. The liver is somewhat swollen and enlarged, likewise the same condition is found in the splenic region. The kidney is congested. Exhalations from the body have a characteristic odor. This tissue waste is great in amount. Near the end the fever becomes higher.

The mania usually accompanying is, as a rule, quiet; seldom do we observe intense delirium with restlessness, jactitation not uncommon. Occasionally a slight icterus comes with or without an icteric consistency of the urine. If diarrhea continues, it may be accompanied with all the symptoms of Asiatic cholera. Late in the disease the skin changes from profuse perspiration to dryness. In some cases the sweats continue until death, especially if the course is rapid. The urine is scanty and dark, occasionally albumin is present. All movements are without power and general lassitude prevails.

Death arises often during an agony of long duration, sometimes after the expiration of a few days, usually at the end of a week. Mental faculties become more obtuse. The patient deepens into stupor, from stupor to coma, coma deepens and the scene is closed by death. The toxic form of septicemia or sapremia is frequently seen in obstetric cases, in which putrefaction of retained clots or placenta has taken place within the uterus, or sometimes in large wounds other than the uterus. The poison, in regard to the uterus, is absorbed through the mucous membrane of vagina or uterus or through the uterine sinuses. The disease is ushered in with a sharp rise of temperature, the chill usually being absent. The temperature continues high and is accompanied later with delirium. The pulse is rapid and running, the tongue is dry, and the thirst, as a rule, predominates. Headache with great restlessness also prevails. Some gastric irritation may be present, as nausea, or perhaps vomiting with slight diarrhea. Great prostration supervenes. Three conditions must be present in this form of sepsis, dead tissue, infection of this dead tissue with putrefactive bacteria, and a sufficient time to have enabled putrefactive bacteria to produce a toxic quantity of ptomaines.

The outlook in sapremia depends upon the dose of the poison which has been absorbed, and the possibility of rinsing and cleansing the infected focus. A prompt removal of all decomposing substances from the interior of the uterus will be followed in a few hours by a disappearance of all alarming symptoms. Conditions favorable for such a type of poisoning are rare in general surgery, although a large ill-drained wound or decomposition occurring in the contents of

a psoas or other abscess is not an uncommon cause. These conditions also may be found in abdominal wounds, where extensive injury of the peritoneum has favored oozing and accumulation of blood-clot in the peritoneal cavity.

In insidious septicemia the symptoms are so much at variance with those generally accepted as characteristic of the disease that our present methods of diagnosis must fail, and this so unfortunately that these are almost always fatal cases. If the progress is insidious the diagnosis is impossible, the prognosis favorable for something else, and the result invariably fatal.

Intuition, not medical skill, must guide us in the absence of symptoms. But whence is it that we derive these intuitive ideas that guide us in diagnosing a case in such a vague manner? The very prominent symptoms of fever and pain are the ones most usually wanting, the degree of danger being inverse to the intensity of the symptoms. The absence of symptoms and fatal results characterize this form of septic poisoning. It may be both with auto- or hetero-infection, also may begin with chill or not. We always find a state of perfect contentment and well-being. The patient is satisfied with his condition although being in bed. Another symptom is slight looseness of the bowels; not diarrhea, but a soft, natural stool, perhaps not more than twice a day, wanting in all the characteristics of septic diarrhea, without foul odor which occupies the latter. The disease begins with a chilly sensation, a feeling of discomfort with slight fever, 99.5 to 100 degrees F. These soon pass away and leave the patient without ambition. In this state he remains without desire for nourishment, but it seems from a natural want of appetite; always feeling well, but gradually sinking until he passes away, more commonly comatose than in convulsions.

As to diagnosis.—The diagnosis of septicemia is clear, the fever steadily increases and lowers in the morning until near the end, when the temperature falls even to below the normal. At times the skin is moist, the pulse is rapid, a slight icteric hue, the facies expression; also a lethargic condition from the beginning with the various cerebral, abdominal and pulmonary symptoms, and in septicemia of a wound makes it easy. The differential diagnoses are but few, and the only one of importance is that of pyemia. This may be considered from an etiologic, pathologic and semiologic standpoint.

ETIOLOGY.

PYEMIA.

1. Pyemia commences with putrefaction in an open wound, of the secondary wound fluids, pus, etc., in which there is developed globular bacteria, which enter the blood and certain tissues of the body, when they multiply and produce constitutional disturbances.

2. Pyemia is commonly preceded by some local inflammation, wound complication, such as suppuration, osteomyelitis, periostitis, etc., and rarely developed before the second week of the injury.

SEPTICEMIA.

1. Septicemia generally commences with the putrefaction of an open wound, of primary wound fluid, in which there develops rod bacteria, streptococcus and staphylococcus, which enter the blood and certain tissues of the body, where they multiply and produce constitutional disturbances.

2. Septicemia is a primary wound complication, which is generally developed within forty-eight hours after the receipt of the injury.

PATHOLOGY.

PYEMIA.

1. Increased coagulation of blood.

SEPTICEMIA.

1. Diminished coagulation of blood.

PYEMIA.

2. Metastatic abscesses in various parts of the body, especially lung, liver, kidney. Serous cavities frequently contain purulent deposits. Similar deposits are those found in joints. Abscesses in cellular tissue. During life abundant evidence of a pyemic endo- and peri-carditis.

PYEMIA.

1. Pyemia commonly commences with a chill.

2. Fever variable but rarely entirely intermittent.

3. Sudden and great change in temperature followed by profuse perspiration.

4. Pulse variable, toward the fatal end rapid, feeble and irregular.

5. Facies at the beginning flushed or pallid, toward the fatal end careworn.

6. Tongue smooth, dry and red, later brown-coated and even the teeth may be covered with sordes.

7. Diarrhea until stools are of a pappy consistency.

8. Epistaxis.

9. Mild delirium toward the end.

10. Aphthæ in mouth and throat, sudamina, vesicles, pustules and purpuric patches.

As to treatment.—Sapremia is treated by the liberal use of stimulants and the prompt removal of the cause. If a wound with a bad drainage reopens, irrigate with corrosive sublimate, 1-1000, followed by sterilized water. Also remove any dead tissue. The small pocket of a wound should be thoroughly washed and drained. All this is especially true in retained clot or portion of placenta or membrane in uterus after childbirth.

Alcohol in any form should be given for effect and not by amount; strychnia hypodermatically with morphia to stimulate the heart and respiration. Food should be given in the way of egg-nogg, milk punch, to derive the effect of nutrition and stimulation. Many methods have been laid down to treat this most dreaded disease. In insidious septicemia or constitutional septicemia, as I have classed it, little or no treatment is used, for the disease is rarely recognized as such, and if so, the patient is in the last stages of death. Heroic measures are necessary. Stimulants should be given by every avenue of entrance into the system. Prepare for the worst and hope for the best. The treatment of septic infection was as varied in times past as the remedies for rheumatism. For the most part, however, we may lay down some rules to follow, which have some practical bearing:

1. Absolute cleanliness, that is to say, daily changing of bed linen and linen of the patient; seeing after the discharges of the patient and prompt removal from the room.

2. Purity of the atmosphere. The room should be well ventilated daily. Not alone this, but a constant ventilation which does not make draft on the patient, should be looked after. A large room, which should have a sunny exposure.

SEPTICEMIA.

2. Complete absence of purulent or ichorous pus in all cases of mixed septicemia. Postmortem shows no alteration except blood with some edema of lungs.

SEPTICEMIA.

1. Septicemia commonly commences without a chill.

2. Fever steadily increases but is lower in the morning.

3. Temperature is high at the beginning of the disease, increases until near the fatal termination, when it falls below the normal. Skin is moist but without profuse sweating.

4. Pulse rapid and gradually increase in frequency toward the fatal end.

5. Facies dull, listlessness throughout the whole course of disease.

6. Tongue, lips and throat dry at beginning, toward end marked thirst.

7. Rice water evacuation, very offensive, obstinate sweating.

8. Epistaxis rare.

9. A lethargic condition from the beginning, increasing toward the end.

10. Icteric hue of conjunctiva, singultus often present. (Pepper.)

3. A moderate and equable temperature containing a proper amount of moisture.

4. Proper quantities of nutritious and easily digested diet with suitable drinks.

5. Cheerful and pleasant surroundings, especially companions, nurses and attendants.

6. The avoidance of all putrefaction in contact with the wound, especially prior to the development of sufficient granulation to completely cover its surface. This object is to be accomplished by the removal of all necrotic tissue, the avoidance of putrescent fluid by cleanliness and antiseptics.

7. Therapeutics of the case.

a. Temperature may be relieved by drugs or hydrotherapy.

b. The free use of the alkalin sulphates and hypsulphites.

c. The use of stimulants at times when needed.

d. Restlessness and pain should be quieted by morphia.

8. Antitoxin or serum treatment. I believe the day has come when septicemia like other infectious diseases can be treated by antitoxin. Since Behring has found one for diphtheria, Tizzoni one for tetanus, Richon on serum therapy of syphilis; the serum therapy of erysipelas, and Koch on anti-tubercle serum in tuberculosis of the skin. Septicemia with other diseases of like character and causes, due to microorganisms, will have similar treatment. Balance and Abbot have already reported cases. One, a physician who pricked his finger in making a post-mortem. Cellulitis and lymphangitis followed within twenty-four hours and the whole body was covered with a scarlet septic erythema. One dram anti-streptococci serum was injected and repeated every four hours and upon the third day doubled. Convalescence was established.

The most distressing symptom of fever, headache; coated tongue, rapid pulse, rapid respiration soon disappeared. The wound incised to relieve tension healed without suppuration. McKerron (*ibid.*) describes three cases of puerperal septic infection in which injection of anti-streptococci serum was made. Serum was used in doses of 10 c.c. The first received three injections, the second four injections, and the third three injections. And with but these few injections each recovered rapidly.

Callie, in his lecture of Feb. 5, 1896, at the Post-Graduate Hospital, gave a more liberal use of the antitoxin of diphtheria than for diphtheria alone in the following:

The antitoxin of diphtheria.—He used 500 units in tonsillitis with fever; 1,000 units in naso-pharyngeal diphtheria; 1,000 units in croup; 500 units in scarlet fever; 100 units in measles; 100 units in pertussis; 100 units in exposed children. These he gave from practical experience. And so with septicemia and sapremia with its varying grades of intensity, one may begin with 10 c.m. of anti-streptococci serum and given in doses depending upon the case. I have here a bottle of anti-streptococci serum of P. D. & Co., which is a splendid sample.² The serum must be given hypodermically and care is necessary in the proceeding to avoid mixed infection from the skin or from a dirty syringe or needle. A safe method is as follows: Wash out the syringe and needle repeatedly with a 5 per cent. solution of carbolic acid or satu-

² Not that I wish to praise any special manufacture, but that I have found their antitoxins and serums always up to the standard.

rated solution of boracic acid. Place the needle in a small dish of the same solution until ready for use. Now wash out the syringe with recently boiled water. The places best suited for injection are the thigh, abdomen or side of breast when there is considerable subcutaneous connective tissue. The skin at the point of injection should be scrubbed with soap and water and then rubbed with a 5 per cent. carbolic acid solution, this disinfectant acting at the same time as a local anesthetic, diminishing the pain of injection. Inject the anti-streptococci serum fairly deep into the subcutaneous tissue.

Upon the treatment of this I have endeavored to give a general conclusion from the various treatments which have been used. In fact, a paper far more lengthy than this I could have written upon the many things that have been tried. In face of these facts he is an unwise, if not an unfaithful, practitioner who does not throw around the patient every possible protection against the entrance of septic germs through the gateways open by the necessary traumatizations.

Withstand the beginnings, the remedy is applied too late, When the evil has grown strong through delay.—Ovid.

ROUND ULCER OF THE STOMACH.

A Clinical lecture delivered in Rush Medical College.

BY HENRY M. LYMAN, A.M., M.D.

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE.
CHICAGO, ILL.

The patient whom I shall exhibit to you this morning is a young woman, 23 years of age, unmarried, and by occupation a cook. She is of good figure, plump and apparently well nourished. But her countenance is abnormally pallid; the naso-labial lines are deeply chiseled around the corners of her mouth, and there is about her face an expression of painful anxiety that is unnatural in one so young. She tells us that for three years she suffered with uneasy, gnawing sensations behind the tip of the ensiform cartilage, and that these were aggravated by food or drink, or by the accumulation of gas in the stomach. Sometimes she felt a similar pain between the shoulder blades, usually near or under the tip of the right scapula. Still, she was able to work, and made very little complaint until one day, six weeks ago, she experienced a feeling as if something had given way in her stomach. This was soon followed by intense prostration, nausea and vomiting of blood. She thinks she must have thrown up fully a quart of dark, clotted blood. This hemorrhage continued in diminishing quantity for nearly twenty-four hours, and was followed by several stools composed of black, tarry matter—blood that had passed from the stomach through the small intestines. She was much blanched by this loss, and was so enfeebled that she was compelled to enter a hospital, where she remained for a month.

Examination of the thoracic viscera indicates no disease in those organs. The same thing is true of the pelvic viscera, the spleen and the kidneys. But the epigastrium is still sensitive to pressure. The liver appears to be slightly prominent below the ribs, though not painful on percussion or manipulation. Since the acute attack of hemorrhage there has been no recurrence of vomiting, nor any blackening of the stools. The patient, however, recalls the fact that once before, about six months ago, just before the menstrual period, she vomited a quantity of slimy matter in which were streaks of blood, and a small quantity of coffee-ground sediment.

With this array of symptoms you are warranted in the diagnosis of ulceration of the stomach. It is also certain that we have before us an example, not of the superficial ulcers which are often found in catarrhal inflammation of the gastric mucosa, but of the deep and grave form of disease known as round ulcer of the stomach. This disease is not very rare, since it is said to be found in about 5 per cent. of all cases upon the postmortem table. This figure is subject to considerable variation in different countries and among different races, being, no doubt, considerably influenced by the diet and mode of life of the people. Occasionally, more than one ulcer may be discovered, but usually the lesion is single. Sometimes, a similar ulceration exists in the esophagus or in the duodenum. In nearly half the cases, the ulcer is situated on the posterior wall of the stomach. In a little more than one-quarter of the patients, it occupies the lesser curvature of the organ, and in about 16 per cent., it will be discovered in the pyloric region, so that it is not a common event to find ulceration of the anterior wall, greater curvature or cardiac portion of the viscus.

The size of the ulcer is usually quite moderate—frequently it occupies less than a square inch of the gastric surface; but in some cases much larger areas have been involved.

The form of the ulcer is so characteristic that it has given its name to the lesion. Seldom do we discover any considerable variation from the round or oval shape, unless two or more neighboring points of ulceration have encroached upon each other's territory, producing a large and irregular loss of substance by coalescence of their margins.

The initial seat of the ulcer is always in the mucous membrane of the stomach, where it presents itself with a sharply defined border, as if it had been punched out of the mucosa. Seldom does it exhibit any surrounding zone of inflammation and exudation. Sometimes it penetrates no deeper than the muscular coat, which may then appear as if cleanly dissected out upon the floor of the ulcer; but it may perforate the different layers of the gastric wall, one after another, until it bursts through the serous covering of the organ. The form of the ulcer is funnel-shaped, with the point of the funnel directed toward the outer surface of the stomach. The apical point is not in the center of the crater, but is displaced to one side or the other, according to the direction of the arterial twig around which the original solution of continuity took place. When the ulcerative process approaches the serous covering of the stomach, an adhesive peritonitis is sometimes set up, and the gastric wall at that point becomes adherent to some neighboring organ. In this way is prevented the passage of the gastric contents into the peritoneal cavity; but it may happen that the ulcer may continue to eat its way into the adherent organ, and may thus finally open a communication between the stomach and the intestines, or the gall bladder, or the pleural cavities, or even the external world through the abdominal wall. In certain cases, the adhesive inflammation may be sufficiently extensive to produce an encapsulated peritonitis, forming outside of the stomach an abscess cavity into which the ulcer opens. This cavity may in its turn become connected by an ulcerative opening with other organs and cavities of the body, so that a long, fistulous track will be found between the cavity of the original gastric ulcer and its distal opening. In this way a subphrenic abscess, or even a pyo-pneumothorax may be formed.

In this connection it is worthy of note that these remote connections are more liable to occur when the ulcer is situated in the posterior wall of the stomach. When placed in the anterior wall, or in the cardiac portion of the organ, direct opening into the peritoneal cavity usually occurs, because the great mobility of the anterior surface of the stomach and of the abdominal wall prevents the formation of protective adhesions.

The healing process after ulceration is sometimes so perfect, that the presence of cicatricial tissue may be easily overlooked by an inexperienced observer. But in many cases the process of cicatrization leads to the formation of thick bands of connective tissue, which contract and lead to considerable deformity of the stomach. When adhesive peritonitis has also existed, the resulting connections may additionally hamper and deform the organ, and may become the cause of internal hernia and other fatal accidents.

Let us now consider the causes of these peculiar ulcers. It is worthy of note that by far the greater number are encountered in the female sex. Rarely do they occur before the age of puberty, but during the period between 15 and 30 years of age, they are most common—that is, during the life-period when women are most liable to chlorosis. The patient before you illustrates these facts, for she has told you that since her seventeenth year she has always been pale. Enumeration of her red blood corpuscles shows the presence of 5,450,000 in the cubic millimeter, but the ratio of hemoglobin is only 65 per cent. Another favoring cause of gastric ulceration is to be found in the chronic infectious diseases, such as syphilis, tuberculosis and chronic malarial poisoning. It is probable that it sometimes is dependent upon those forms of auto-infection that produce disease of the arterial walls.

Among the exciting causes of the disease are local injuries of the gastric wall, either by blows or pressure from without, or by swallowing corrosive or overheated substances. Fragments of bones, nuts, shells and other insoluble articles introduced with the food, or otherwise, have been responsible for the occurrence of ulceration; but it is probable that these agents do not ordinarily suffice to excite anything more serious than erosion of the mucous membrane, such as is often discovered in catarrhal inflammation of the mucosa, unless there be also a morbid condition of the walls of the blood vessels that lie in the coat of the stomach. It has been shown by numerous experiments that interference with the normal circulation of blood in the gastric vessels will cause ulceration in the territory of the obstructed artery. When blood ceases to flow through the capillary network, it can no longer maintain that alkalinity of the tissues which appears to be the natural opponent to the corrosive action of the acid gastric juice. Consequently, injuries sufficient to arrest the circulation in a given portion of the gastric wall may occasion the formation of an ulcer. Chlorosis, tuberculosis, syphilization, etc., produce fatty or amyloid degeneration of the arterial coats, so that a local injury of the mucous membrane, in such cases, is followed by circumscribed blood stasis that would not have occurred in a healthy individual. This concurrence of various predisposing causes with a local traumatism is, in the majority of cases, the means of originating a process of ulceration that differs from the ordinary simple ulcer of catarrhal gastritis in the fact that it is, in its location and evolution, closely associated with arterial distribution

and vascular conditions, instead of being placed at random wherever a local injury may chance to occur.

The duration of a gastric ulcer is exceedingly variable. Sometimes perforation speedily follows, but in certain instances the symptoms of ulceration persist for almost a lifetime. In such chronic cases, as old age comes on, there is reason to fear the development of cancer in the margin of the ulcer, or upon its scar if cicatrization has already occurred. The effect upon the general health is also variable; in many cases there is no loss of appetite or strength, and the patient, like the one before you, loses little in weight. Frequently, however, there is emaciation, loss of strength, and the sufferer becomes haggard and worn in appearance from loss of sleep and continual suffering. The temperature of the body rarely indicates any disturbance, and the urine remains without notable change. The bowels are frequently constipated.

The occurrence of perforation of the gastric wall is immediately followed by symptoms of the gravest possible character. Peritonitis is speedily established; the patient suffers intense pain; the belly is distended and painful on pressure. As exudation progresses, dullness increases; but the liver and spleen seem smaller because they are crowded upward and backward by the accumulation of gas in the intestines. It is worthy of note that, unlike what is observed in ordinary peritonitis, there is no vomiting, because the gastric contents are expressed through the opening into the peritoneal cavity, instead of finding their way up the esophagus. Consciousness persists till the last moment, and death results either from exhaustion, or from interference with respiration and circulation through excessive upward displacement of the diaphragm.

When adhesive peritonitis precedes the occurrence of perforation, the symptoms are less severe, and are circumscribed by the boundaries of the adhesion. If the pleural cavity, or the pericardium are entered, the phenomena of pleurisy or pneumo-thorax, or hydro-pneumo-thorax, pericarditis, pneumo-pericarditis or hydro-pneumo-pericarditis will be manifested. Occasionally the ulceration makes its way into the mediastinal space, and then the symptoms of mediastinal emphysema will be developed, just as perforation of the abdominal wall may lead to subcutaneous emphysema through the passage of gas from the stomach into the subcutaneous areolar tissue. Sometimes a communication is set up between the cavity of the stomach and the air passages in the lungs, so that food and gastric juice may be detected in the sputa. If the liver and the portal vein be invaded, thrombosis of the portal vein may occur, and this may lead to the formation of metastatic abscesses in distant organs, with the establishment of universal pyemia, and death as its consequence.

The occurrence of healing and cicatrization of the ulcer is not always devoid of danger. Pain is often persistent for a long time after cure of the ulceration. Sometimes the symptoms of acute disease subside, but the evidences of chronic catarrhal inflammation become prominent and persist indefinitely. When the pyloric orifice was the seat of disease, cicatricial contraction may lead to stenosis of the pylorus and consequent dilatation of the stomach. If the muscular layer has been destroyed the opposite condition will exist, and the stomach will be unable to retain its contents because of destruction of the pyloric sphincter.

The possibility of gastric carcinoma developing in the scar of an old ulcer is always to be kept in mind. This is by no means an uncommon sequel of the disease.

Sometimes death occurs in consequence of a concealed hemorrhage from a gastric ulcer. In such cases the phenomena are those of collapse, terminating speedily in death. Sometimes, however, there is a discharge of blood through the bowels, which after the decease of the patient can be traced to an open vessel in the floor of a previously unsuspected ulcer. I was once called to the bedside of a woman who had been employing the methods of the "faith cure." I found her blanched and dead. The members of the family stated that for about twenty hours she had been troubled with a looseness of the bowels, which she attributed to some error of diet, and for which she would take no medicine. When, finally, she began to groan with pain her friends sent for a physician, but it was too late, and she died before my arrival. On examination of the body the intestines were filled with black blood which could be traced to its source in a gaping arterial twig at the base of an ulcer, no larger than a five-cent piece, in the posterior wall of the stomach. In this case there had never been any suspicion of the existence of the disease before its demonstration at the autopsy.

This indicates the fact that a round ulcer of the stomach is not always easily recognized. In ordinary cases, when a chlorotic young woman complains of severe, persistent and narrowly circumscribed pain in the epigastric region, and when this pain is accompanied by vomiting of highly acid substances and by hemorrhage from the stomach, the diagnosis is comparatively easy. But when these symptoms are not all present it is often difficult to exclude the possibility of other diseases, such as gastralgia, chronic catarrhal gastritis, gastric carcinoma and biliary colic. In cases of simple gastralgia there is no increase of pain after eating; pressure over the stomach gives relief rather than aggravation of pain; there is no vomiting nor discharge of blood from the stomach, and neuralgia is frequently experienced in other regions. Sometimes the passage of an electric current through the body, placing the anode over the stomach, will give immediate relief to pain. Enthusiastic electricians often introduce the electrode into the stomach itself, but one should be very sure of the loyalty of his patient before trying this experiment.

In cases of chronic catarrhal gastritis the location of the pain is less circumscribed and the intensity of the suffering is less than in gastric ulceration. The disease is usually dependent upon errors of diet, and is more amenable to treatment than is an ulcer.

Gastric carcinoma occurs in advanced age; it quickly leads to cachexia, impoverishment of the blood and enlargement of the left supra-clavicular and inguinal lymphatic glands. The presence of a tumor in the gastric region argues in favor of cancer, though it must not be forgotten that a large scar may feel very much like a tumor under the abdominal wall. The absence of free hydrochloric acid from the gastric juice, when associated with the other symptoms is almost diagnostic of carcinoma.

In biliary colic the pain is concentrated in the region of the gall bladder and common bile duct; the paroxysms are often accompanied by vomiting and chills without fever, and are usually followed by jaundice that soon subsides with the correction of suffering.

The treatment of round ulcer of the stomach must be both dietetic and medicinal. When there is severe pain, vomiting of blood, etc., the patient must be kept in bed with a large poultice or piece of spongio-piline over the stomach. Solid food should be forbidden, and, if possible, a milk diet should be enjoined. The milk should be heated to 160 or 180 degrees F., but not boiled, before it is used. When there is hemorrhage it should be taken cold. If it sours in the stomach the acid may be neutralized with sodium bicarbonate or with lime-water, or, if the bowel be constipated, with the milk of magnesia. Patients who can not tolerate milk may sometimes take koumyss, or buttermilk or malted milk, or Fairchild's peptonized milk or other preparations that are recommended for nursing children. For more than thirty years I have found much benefit from the administration of cod-liver oil or olive oil, in tablespoonful doses as often as it can be tolerated. This acts mechanically as a protective covering for the ulcer and dietetically as an article of food.

Whenever there is intolerance of milk and oil it is necessary to give them broths and soups, out of which all solid particles have been strained. The various extracts of beef, bovine, white of egg stirred into water, etc., may be recommended. Sometimes it becomes needful to withdraw all food from the stomach and to depend wholly upon nutrient enemata. These should consist of soluble beef extracts, egg-albumin and other liquids that will not solidify in the colon. They must be slowly introduced through a long rectal tube, after the bowel has been washed out by irrigation. The addition of twenty drops of tincture of opium may be required to prevent the premature expulsion of the enema. In this way it is possible to nourish a patient for three or four weeks. When gastric feeding is resumed it should be introduced by giving small quantities of food every two hours. At first the food should be liquid; then you may give calves' brains, tripe that is stewed to a pulp, the soft part of a raw oyster, raw or soft-boiled eggs, sweet-breads, and, finally, minced meat and the tenderest of beefsteak. Bread, in the form of dry toast, may be cautiously given, if slowly and thoroughly chewed before it is swallowed. Fruits and vegetables can not be allowed until a cure has been effected.

The occurrence of hemorrhage should be treated with an ice-bag over the epigastrium. The bag should be wrapped in a soft towel before it is applied to the skin, so as to absorb the moisture that condenses upon its surface. Small pieces of ice may be frequently swallowed and a hypodermic injection of ergotole or the fluid extract of ergot should be given in doses of half a drachm every two to four hours. The internal administration of ordinary styptics by the mouth is contra-indicated by reason of the vomiting which they usually aggravate. When such vomiting occurs it should be opposed by the hypodermic injection of morphin and atropin (morph. gr. $\frac{1}{4}$, atrop. gr. 1-150). Sometimes it yields to drop doses of creosote well diluted and repeated every fifteen minutes. After the subsidence of vomiting, the tendency to hemorrhage may be met by giving ten drops of aromatic sulphuric acid in four ounces of water every two or four hours. Liquor of the persulphate of iron, or of the perchlorid of iron, may also be given in the same way.

For a local antiseptic effect upon the ulcer, benefit may be derived from the use of large doses of bis-

mouth salicylate or bismuth subgallate. These salts may be given in doses of 10 to 60 grains every two to six hours. Nitrate of silver and acetate of lead have been often used, but their utility is doubtful in comparison with that of bismuth. After the subsidence of acute symptoms, compound tincture of iodine is very useful. It should be given in doses of one drop in four ounces of water, half an hour before the three principal meals. The dose should be gradually increased to 4 or 5 drops, but it should be never carried so far as to cause irritation of the stomach. These small doses may be continued throughout the period of convalescence.

Constipation, which is an indication of chronic catarrhal gastro-enteritis, should be obviated by the use of saline laxatives. The waters of Saratoga, Rubinat, Hunyadi János, Friedrichshall and Carlsbad are especially valuable for this purpose. They should be taken half an hour or an hour before breakfast, in quantity sufficient to produce a gentle evacuation of the bowels each day. In this way the territory of the portal circulation is efficiently drained and the healing process is expedited. But these waters should not be taken longer than four or five weeks, for fear of exciting a particular inflammation on their own account. Used with occasional intermissions, they may be given for a long time. Many patients are much benefited by an annual course at the springs. Even the bottled waters taken at home are also very beneficial.

The occurrence of perforation and general peritonitis calls for the administration of opium and the external application of poultices. Laparotomy has been performed with the hope of suturing the wound and cleansing the peritoneum from the contents of the stomach, but the results have not been so far encouraging. And yet, it is the only thing to be advised outside of the routine treatment for peritonitis. Probably with larger experience a greater degree of success will be reached.

THE TREATMENT OF HEMOPHILIA WITH CHLORID OF CALCIUM, WITH REPORT OF A CASE.

BY J. CLIFFORD PERRY, M.D.

PASSED ASSISTANT SURGEON, U. S. MARINE HOSPITAL SERVICE.

The treatment of hemophilia with the usual agents recommended for this disease, has been so ineffective that much difficulty has been experienced in arresting the hemorrhage from the slightest wounds, and many patients have died from the excessive loss of blood after the most trivial injuries.

The only advance in the therapy of this disease, has been made by Dr. E. A. Wright,¹ who taking as a basis for his investigations the physiologic fact that a certain per cent. of calcium salts is necessary for the coagulation of the blood, made a series of experiments with calcium chlorid, and demonstrated its efficacy in increasing the coagulability of the blood.

In a later article the author reports the results of his examination of the blood of a case of hemophilia, and the coagulability of the blood before and after the administration of chlorid of calcium. He found that the blood contained a smaller number than normal of white corpuscles (8,400-6,500 in 1 c.mm.), and that the degree of coagulability was subnormal, being from nine to ten minutes, instead of two and one-half

to five minutes, as in normal blood. After the use of the calcium salts in one gram doses three times a day, the coagulation time was reduced from ten to five and one-fourth minutes. In another article he describes three other cases, in all of which the chlorid had a marked beneficial effect. He also demonstrated that if this agent was used in large doses for a long time, that it is not effectual in keeping up a permanent increased coagulability.

He reports the following interesting case of hemophilia: A child four years of age received a fall, and in doing so injured the frenum of the upper lip. The bleeding was so profuse that the child's life was endangered, and as the blood showed no signs of coagulating, a dose of calcium chlorid was administered, and in three hours the blood commenced to clot. A firm coagulum formed, and the hemorrhage was arrested. As the bleeding recurred several times, the action of the calcium salt was supplemented by the inhalation of carbonic acid with a beneficial result.

Another case showing the efficiency of this drug is reported by Bryant. A child four and one-half years of age, received a punctured wound in the supra-orbital region from a fall. The hemorrhage was so profuse that the patient became almost pulseless. After pressure, styptics, and all the usual means of arresting bleeding had failed, and still the blood showed no signs of clotting, chlorid of calcium was given, and in a few hours the blood commenced to coagulate, the hemorrhage gradually ceased and did not recur.

The following case that came under my care some time ago, will furnish additional proof of the value of this "physiologic styptic."

A. L., male; aged 20 years; nativity, Russia, came to my office April 2, 1895. He was suffering with an alveolar abscess, resulting from irritation produced by a carious tooth. A small incision one-eighth of an inch long was made through the mucous membrane, and a small quantity of pus evacuated. I was surprised that so small a wound should bleed so profusely, but thought that it would soon subside, consequently, a wash containing tannic acid was given and he was instructed to wait until the hemorrhage ceased. At this time I was called away from the office, and upon returning I was surprised when my assistant informed me that the bleeding still continued, and that the patient had lost a considerable quantity of blood. I then used a solution of perchlorid of iron and other styptics, but without success, and as pressure was of no avail, packing was tried, but it rapidly became soaked, and the blood showed no signs of coagulating. By this time the patient was on the verge of fainting. Finally after four hours energetic work, the hemorrhage was temporarily checked by packing the whole space between the alveolar process and the cheek with gauze saturated with a strong iron solution.

A careful inquiry into the patient's past history revealed the fact that he was one of a family of "bleeders." Two brothers had died in infancy from hemorrhage, resulting from trivial injuries. He himself had on several occasions bled until he had fainted, from mere scratches of the skin, and accidentally cutting his fingers had on two occasions nearly resulted in death from profuse hemorrhage. He was pale, anemic and showed evidences of his diathesis.

Expecting further trouble from the slight wound I had innocently made, the patient was sent to the hos-

¹ British Medical Journal, 1891, ii, 1306.

pital for observation. A few hours after his admission, Dr. Maisch, the interne, was called to see him for severe nose bleed, the epistaxis was profuse, and as the ordinary means failed to arrest it, it was necessary to plug the nares. Twelve hours later the hemorrhage from the wound recurred, the blood showed no signs of coagulating, and the bleeding only ceased when the patient was on the verge of collapse. The respite, however, was brief, and six hours later another alarming hemorrhage occurred, and after all the ordinary means had been used without success, Dr. Maisch suggested that we try the internal administration of chlorid of calcium. This was given in 1.30 gram doses, and in a few hours the effect was magical; the blood, which had showed no signs of clotting, began to coagulate, a firm clot formed, and the hemorrhage was completely arrested. The calcium salt was given in 1.30 gram doses every four hours during the first day, every six hours during the second day, and three times a day on the third, when its use was discontinued. The hemorrhage did not recur, and after the expiration of a few days the patient was discharged from the hospital, and passed from my observation. The effect of the salt in this case was certainly prompt and efficacious, and was the only agent whose use was followed by beneficial results.

The points I wish to emphasize in concluding the description of this case are:

1. The alarming hemorrhage that may result in these cases from the most trivial injuries.

2. The futility of using local styptics and the ordinary means of arresting bleeding in cases of hemophilia.

3. To impress the fact that in the use of the physiologic styptic, chlorid of calcium, we have a prompt and reliable agent, one that will render valuable results in trying moments, and will rescue apparently hopeless cases.

CONGENITAL TEETH.

BY E. A. BENTON, M.D.
CENTRAL CITY, NEB.

On reading Dr. McKee's article in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, page 253, Feb. 6, 1897, I was so impressed with its statements in regard to the etiology, treatment and non-frequency of the cases of congenital teeth, that it seemed to be my duty to register my personal experience in these cases. Dr. McKee says, "this freak of nature has been noticed at wide intervals and with great rarity for a long time." Also "these cases serve as a curiosity for doctors and students, and are a sight many do not see in a lifetime." I had not supposed these cases so rare or so much of a curiosity, for in a practice of thirty years, with a fair obstetrical clientele, I have attended three cases when there were two lower central incisor teeth at birth; and I never failed at these cases, or soon after, while it was the talk of the neighborhood to find several old ladies who had *seen* or *heard* of several such cases. My wife who is now fifty years old (don't let her know that I am telling her age, for she looks to be only forty) informs me that she had two central inferior incisors at birth and that they remained the usual length of time, when they were replaced by permanent teeth, which she still has in a perfect state of preservation. Her family and personal history is perfect. My first case was at my wife's third confinement, resulting in twins, male

and female; born at full term, both strong and healthy, with nothing out of the usual line except the girl, had two central inferior incisor teeth, firmly set in gums and well developed, but a little smaller than ordinary milk teeth developed at the natural time. The teeth were in healthy condition when she died of cholera infantum at the age of four months. My second case was at my wife's fifth and last confinement, when a strong and healthy daughter was born with two central inferior incisor teeth; one firm in the gums and the other loose and attached only to the outer gum. I removed it with my fingers without producing any hemorrhage or soreness. It has never been replaced. The other is firm and in a good state of preservation but smaller than to correspond with the other teeth. She is seven years old, and a well developed, strong healthy child. I am somewhat anxious to see if a permanent tooth will be developed where the one was extracted. My third case was a fine healthy boy, fifth child of Mr. and Mrs. J. E. B., both parents healthy and with good family history. This child was born at full term with same teeth as other cases, being as large as ordinary milk teeth and firmly set in gums. At the age of three weeks the teeth had made an intractable ulcer under the child's tongue, rendering nursing impossible. I extracted them. No hemorrhage or other trouble followed. The family soon moved from the city and I have lost track of them. My cases would indicate that no milk teeth would come to fill the vacancy caused by the exfoliation or extraction of congenital teeth; also that rickets or improper nutrition was not a causative factor in their development. It seems to me to be a more rational conclusion to assign the appearance of congenital teeth to a precocious or premature occurrence of the normal processes in the development and cutting of the milk teeth. We certainly have this precocity in the development and physiologic action of other parts of the human economy.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

CHAPTER II.—THE QUACK.

(Continued from page 455.)

Beside the rupture and cataract operations there was also lithotomy, which was practiced almost exclusively by itinerant operators, the lithotomists (Steinschneider). It is wonderful that the very most difficult operations have always been abandoned to the mountebanks. The learned men were too proud to class themselves with those, by performing the same kind of operations. Therefore it happened that there were too few surgeons who possessed any comprehensive skill. This class of crude empirics, who like other mountebanks, advertised themselves, and as a rule collected a great number of lithotomic patients about them in the spring and fall, arose out of gray antiquity. Hippocrates would not submit to this operation, and subjected himself to others, probably because in his time they regarded the operation as too cruel. So the physicians in Alexandria were obliged to take the so-called Hippocratic oath, which recites: "I will operate upon no stone-patient, but will turn over this part of my practice to the mercenaries following

that business." In Arabia, also, those who operated for stone were subjected to public scorn; there, indeed, the sight of a woman was never permitted to a man. Nevertheless there have always been people who devoted themselves principally to this operation, but practiced their art secretly, and it had descended from father to son or to some relative. In the middle ages the lithotomists traveled through all Europe; Fabricius von Hilden (born 1560) complained sorely that so few surgeons performed this operation, but abandoned it to the surgical frauds (Schnittärzte). In his time they visited the houses, offered their services, and were ready enough to perform the same upon wholly indefinite symptoms. When one of these vagrants in Cologne found no stone in the bladder and let one fall out of his coat sleeve he was seized, sentenced to be flogged and driven out. Some plied their trade so disgustingly that as a relief, especially in the case of children, he had the organ sucked, milked as it were, to draw out the stone. They did not concern themselves as to preliminary treatment, adapting diet or proper after-treatment. They surrounded the operation with such a nimbus that if a nobleman was to be operated upon his vassals must assemble in the church in prayer to implore the assistance of God. Certain lithotomists distinguished themselves particularly; thus, one Merk in Ulm had performed up to the year 1626 over two thousand stone and rupture operations. In Italy the people of Norcia, who were also famous as rupture operators, attained a great reputation. But in the fifteenth century the art of lithotomy was transplanted from their midst to France, as one from Norcia confessed to a certain Germain Colot.

The home of the lithotomist moved to Germany until in the first half of the eighteenth century. At that time the most famous itinerant lithotomist in the Fatherland was the Frenchman, Frère Jacques. Jacob Beaulieu was born in 1651, of poor parents, in the Franche Comté, and as a 16 year old boy, enlisted as a soldier, where he became acquainted with a quack, who operated for stone in the country. After he received his discharge he accompanied a Venetian lithotomist for five years, and then attempted the operations himself. He changed his citizen's clothing for the monastic habit, in which now as Brother Jacques he traveled around and operated with success in many French cities. He lived very frugally, ate only bread, soup and vegetables, and took no money for his operations except a few pfennig for the mending of his shoes and instruments. Manliness and a steady hand, in like degree, distinguished him in his operations as well as coarseness and cruelty. After the incision he was accustomed to say: "Your operation is done. God heal you." Thereupon others put on the bandages. In 1697 he came to Paris and was introduced to the body-physicians of Louis XIV., Fagon and Felix. They saw him operate and admired his skill. He secured the interest of the king, received a free residence with the chamberlain, and was regarded by the common people as a man sent from God. At every operation great crowds of the curious gathered to look on, such that they were finally obliged to place guards at the doors of the hospital to keep back the throngs. Nevertheless an evil star rose over his operations; out of sixty-five who were operated upon in the Hôtel Dieu and the Charité twenty-five died and only thirteen completely recovered, and therefore he was forbidden

to operate here. Hitherto he had used an ordinary round catheter, when Fagon induced him to use a pumping probe and furnished him bodies for experiments in operating. Henceforth the results were more fortunate, and in Versailles hospital thirty-eight incisions for stone were all successful. Fagon himself, suffering from this affliction, wished to be operated upon by Frère Jacques, but his friends restrained him and he was cured by that very skilful operator, Maréchal, whom Garengot saw perform eight successful lithotomies in a half hour. In 1703 the Marshal of Lorgues intrusted himself to the monk after he had twenty-two stone patients taken into his palace and operated upon before his eyes. They all survived, except the Marshal, who died on the following day. Through this Jacob lost his prestige in Paris, went away and would never return. After various tours in the French provinces and Holland he arrived in Amsterdam, where medals were struck in his honor. There he gave instruction in his art to Rau, then professor in Leyden. Frère Jacques then visited Antwerp, where also a medal of the value of sixty thalers, with the legend *Pro servatis civibus*, was struck. After going back to Amsterdam his popularity waned, as they had come to consider Herr Rau a more skilful man than he. Then he went to Germany. In Vienna the king had him summoned; in Rome the pope did likewise. Soon after, in 1714, he died in Besançon; he had already melted down the golden medals. His good reputation was attacked by his rivals, Mery and Saviard; Verdue also asserted that out of sixty patients operated upon, only thirteen had been cured, insomuch that in his own defense he had published in 1702 on eight-page work upon the operations. It was stated in this that he had taken a solemn oath to renounce every reward, to devote his life to helping sufferers from calculi and rupture, to accept from rich people only his traveling expenses, and to show to other surgeons his instruments without charge. In his thirty years he is said to have treated at least 4,500 stone patients, to have deceived no one and to have performed no operation without the presence of physicians and surgeons. Mery's accusation that he castrated in cases of groin rupture, he met with the declaration that he had operated upon 2,000 people without injuring the testicles, the people being the poor, who could not pay for a truss. Various testimonials from body-physicians and others concerning his skill were appended. Frère Jacques introduced the side incision. He made the incision on the left side of the peritoneum, but with no regular method, for he sometimes made it two thumb-breadths higher, and for lack of a lithotomic knife he would operate with an ordinary bread knife. In his first years, when he operated without the use of the grooved sound, he frequently came in contact with the body of the bladder, cut it through and injured the rectum and the vagina; later, with the help of the grooved sound, the operations became safer. He differed from his contemporaries in that he neither prepared his patients for the operation by bleeding and purging, nor did he bind them, but only had them held by strong men.

Rau improved upon his methods. He was also very famous as a lithotomist, and was appointed by the council of Amsterdam to the high office of city operator. In the year 1713 he asserted that he had performed 1,547 lithotomies; they even lied so much as to say that of 1,700 patients he had not lost a sin-

gle one. He kept silent as to the way in which he operated and also of the unsuccessful cases; yet they knew very well in Amsterdam that four patients out of twenty-two had died. When Heister lived there, he often saw Rau operate, but complained that the latter from jealousy and avarice, in the operation courses, for which he received considerable money, openly declared at the operation that he would give no information about it, because he must live, and when Heister also entered the profession, he would keep secret the best points. Heister followed Rau's method in Germany.

Quackery was not confined to these mountebanks, but that most approved class of men, the executioners, competed with the surgeons. They enjoyed the reputation of being able to cure those diseases which had their origin in witchcraft, and, since they heard the confessions of the witches upon the rack, they must have knowledge of the black art. They also had the privilege of treating surgical cases. They set the limbs which had been fractured by the machines of torture, and applied to the healing of the wounds made by the rack, certain salves which they prepared out of animal fats. The skill thus acquired by them was used as a means of coming in contact with people of other callings, hoping by this means to redeem their despised position. So it happened that frequently they supplanted the surgeons in the treatment of wounds, fractures and luxations, and did a great deal of mischief. The Leipzig faculty (in 1730) was called upon to attend a boy with a broken arm which had been bound so tightly by a torturer, and compressed with splints, that having become inflamed it could not be raised from the shoulder without pain and loss of blood. Dog-fat was their universal balsam. The drinking of the foaming warm blood of beheaded persons would cure epilepsy; for this purpose they sold the blood of a young woman or a young man at the highest price, while the blood of a Jew was the cheapest. They were mostly consulted by the lower classes, but the better conditioned also had resort to the hangman. C. C. von Siebold relates that even His Reverence the Abbot, who in his old age was afflicted with an ossification of the parotid, betook himself to the executioner, with whom, in a healthy condition, he would never have associated, much less allowed himself to be touched by him.

There could be no greater affront to the medical profession, than that given when King Frederick I. of Prussia, ignoring his duty to give the highest satisfaction to all, appointed the executioner, Coblenz in Berlin as court and body physician. The whole collegium medicum protested but without result. For a long time afterward, in the royal armory in Berlin the sword was exhibited with which Herr Coblenz had severed 103 heads, his father 19, and his grandfather 68. In Prussia in 1725, the executioners were forbidden to attempt cures, but this did not last long, for again in 1744 Frederick the Great allowed them after having passed a certain examination to treat fractures, wounds and sores. As the Berlin physicians strenuously opposed this, the monarch issued an order from Potsdam, which must bring the blush of shame to the faces of all German surgeons: "Since His Royal Majesty has not licensed the executioners indiscriminately, but only such as are competent to cure, he will let the matter rest there, as the public will be able to discriminate in the necessary cases; and when the surgeons have become as skilful as they

have professed in their published representations, then everyone will sooner trust them than resort to an executioner for a cure; but in any event since there are ignorant surgeons, the public must not suffer thereby, but that class must acquiesce if a man would rather be treated and cured by an executioner than please them and remain lame and a cripple. And further, let the surgeons first become properly competent and skilful, and then the cures of the executioners will cease of themselves, and without any forbidding." In Saxony also, as in Prussia, the treatment of fracture, humps and boils, was permitted to the executioners; and in the principality of Salem, in Baden, they were allowed to practice medicine as well as surgery, so late as 1807. On the other hand in Austria, as early as 1753, they were forbidden to treat both internal and external diseases.

Among the people the calling remained despicable, so that the government found it necessary to break up the prejudice. In 1731 no Austrian was considered more dishonored who ate, drank, or traveled with an executioner, or handled a carcass, or removed it from a stall; on the other hand, from this time on, it was considered no disgrace in Saxony and Brunswick for the bath-keepers, surgeons and barbers to take in charge the criminals who had been under torture. In Prussia the executioners' curing ceased of itself later, when the practice of every physician was made dependent upon prescribed examinations and the approval of the magistrates; but later in 1819 the honor of bearing arms (*Waffenehre*) was extended to them and in 1827 they received all the rights of burghers.

The business of the executioners placed the courts of justice in a position to resort to the advice of the surgeon. This was the case in the torture chamber, and necessitated the appointment of so-called rack-physicians. The Malefiz Courts still existed everywhere; as late as 1749 the last witch was burned in the German Kingdom, a 70 year old nun, in Wurzburg, while the last law against witchcraft on German soil appeared in 1782 at Glarus in Switzerland. Torture, which at the beginning of the century was still very general, was abolished in Austria in 1776. It was a professor of surgery in Vienna, Ferdinand Leber, who, by continued agitation, and written reports worked untiringly for the final abolishment of this order of penal courts. With the help of the professor of law, Baron von Sonnenfeld, he prevailed upon the empress, Maria Theresa, after long continued efforts, to carry out this reform, against which the criminal courts protested in the most vigorous manner. Leber administered for nineteen years the melancholy office of a rack-physician, and as he says, "had only too often seen that an actual criminal with strong, apathetic nerves, endured the torture with martyr-like courage, and lied as to his guilt, while the innocent, overcome by the cruelty of the pain, acknowledged crimes which they never had committed." The principal means of torture consisted of the thumbscrews, the so-called ladder (*Leiter*), which were still provided for in the *constitutio criminalis Theresiana* published in 1768, so also the boot and the bowstring (*Schnüre*). The torture was refined in a marked degree in the kingdom of Bohemia, where a torch made of twelve tallow candles was burned under the shoulders of the victim while he was stretched out upon the ladder. The cord torture gave occasion to the noble council of the resi-

dence city of Hanover in 1754, to ask of the surgeon L. Heister, his opinion as to whether it was possible for a judge, sitting some distance from the victim of the cord torture, to discern whether the cords with which the limbs were mutilated, cut to the bone. Heister answered that this was not possible, "Indeed, I will say further that a whole corps of surgeons sitting down by the victim could not be certain whether the constriction cut as deep as the bones of the arm without bending close down over the arm and feeling of it carefully." When during the French Revolution the *guillotine* was submitted to the National Convention on Executions, surgery was obliged to come to the help of justice. The guillotine was a machine which had long been in use in Persia and its forerunner may be said to be the falling ax (Fallbeil), by means of which, according to Botalli's plan, the Amsterdam surgeon John Van Horn, amputated limbs in a cruel manner. The convention considered that beheading was more fitting to a free people than the noose, and they called the Parisian executioner before them, to hear his judgment of the instrument. As he, on account of his lack of anatomic knowledge, had some doubts as to the position of the joints of the neck, the National Convention referred him to the Académie de Chirurgie. Louis, the secrétaire perpétuel of that body, gave it as his opinion (1792) that the blade of the instrument should not be square and horizontal as that which physician Guillotin had made, but should be convex and run obliquely from above downward, so as not to work as an ax but as a knife; and the back of the blade should be heavy and strong enough. He suggested that it be investigated whether it might not be necessary to sever the head of the poor victim by means of a crescent blade, which spanned the neck close to the base of the skull. On the strength of this opinion the National Convention decreed that the instrument should be made in this way and authorized the administration then in power to provide guillotines for the whole kingdom for which an appropriation of from six to seven million livres was required. The Paris Reign of Terror did not concern itself with the outcry of the English physician Kentish, who declared that death by guillotine was the most painful of all the methods of execution in war. Indeed he admitted that the beheading took place quickly, but asserted that death did not follow soon enough, since life continued for a little time. A hen whose head has been cut off runs around the room, and he argued that the sensations corresponded to the movements, and that pain followed the decapitation was proven by almost every section of a mutilated eel or angleworm. To the Englishman it was not unthinkable that the unhappy king Louis XVI., when after decapitation, his head was shown to the people by the executioner, still retained consciousness and a spectator of his own tragedy. The same ideas gained admission to the Prussian cabinet, for in the year 1804 they forbade the making of galvanic experiments with severed heads, because by that means sensation and consciousness might be re-awakened, if only for a moment.

The nuisance of the mountebanks was by no means confined to Germany, but *foreign countries* enjoyed it in a high degree. The way it appeared in France can be seen clearly from a speech of the deputy Fourcroy in the legislative assembly. He said therein: "Since the decree of the 18th of August 1792, which overturned the universities, faculties and learned societies

in France, there is no regular order of physicians and surgeons. The completest anarchy reigns in place of the former order. Those who have mastered their profession find themselves mingled with those who have not the slightest idea of it. Almost everywhere patents are granted to one, the same as to another, without distinction. The life of the citizen is in the hands of avaricious as well as ignorant men. The most dangerous empiricism, the most shameless quackery everywhere abuse confidence and credulity. Not a single proof of science and skill is demanded. Those who have studied since they were seven years old, in the three medical schools established by the law of 14 Frimaire, year 3, are scarcely in a position to prove their acquired knowledge, or to differentiate themselves from the impostors who were everywhere to be found. City and country were in like measure corrupted by mountebanks, who dispensed poison and death with a recklessness which the old laws were unable to check. The most murderous procedure had been substituted for the first principles of obstetrics. Hangmen and shameless blacksmiths usurped the title of officers of health, in order to cover their ignorance and avarice. Never has the increase of dangerous proprietary medicines been so marked as since the time of the overthrow of the medical faculties." Even in the beginning of this century the oculists in France practiced charlatany on an enormous scale; everywhere were to be found the advertisements of medical oculists and on every street corner were displayed their powders, anti-ophthalmics, collyriums etc. In Italy there were many quacks, although perhaps the nuisance was less general there than in Germany, and old women did not enjoy so much credit among the lower classes. The real physician and surgeon was more respected and oftener employed by the average man. There also, medicine and surgery were sharply separated from one another so much so, that the Italian physician almost never practiced surgery. Shaving fell entirely to the lot of the hair-dresser, and by the end of the century he no longer gave baths as a part of his business. In Italy as in Austria clysterizing belonged to the business of the apothecary in most districts; the surgeon would have considered it a great affront to have this function ascribed to him. In wealthy Italian families, all of which had their own house physician and house-surgeon, consultations were so well regarded that seldom did a rich Italian die under the treatment of a single physician. But in no country did one come upon so many mountebanks' advertisements as in England. London swarmed with charlatans who extolled their drops and tinctures in the *London Chronicle*, and their gonorrhoea specifics on every street corner where they could be most opportunely read. The quacks were numerous because the great physicians were too expensive, never charging less than a guinea for a visit. The majority resorted to the apothecary, who made his visits gratuitously and charged only for the medicine. The English apothecary whose place of business was never visited by physicians, was frequently, physician, surgeon and obstetrician, and was allowed to practice after paying the fees of one of the colleges. "The setting of limbs" was considered by the average man as a matter which required no special science and which the most ignorant blacksmith or veterinary surgeon could learn quickly and perfectly—simply the teaching of the grandfather to the father, from him to his son. The rapture surgeon preyed upon the pub-

lic, stating in his advertisements that his father and his grandfather had both suffered from rupture; the coucher sought to prove his skill by asserting that he had lost an eye in the service of the emperor and he showed his patients a large document according to which he had served among the soldiers of His Majesty the Emperor. How was it possible through such absurdities to be able to deceive the people! The epidemic of quackery spread even among the better classes, to that in the middle of the century an English judge said to the jury that he believed that a limb-setter in the country understood as much if not more about the treatment of fractures than any of the most eminent surgeons in the whole kingdom. The English government quietly allowed the nostrum swindle to increase; indeed, when a formula of a certain Bowles for the radical cure of rupture made a great sensation in the year 1725, and was bought by Thomas Renton for the state, they paid for it £5000 and £500 yearly royalty. But in spite of all swindles there was no country where there existed relatively a greater number of scientific surgeons, physicians and obstetricians, or where they stood in higher respect than in England. In Russia surgical quackery stood under the highest protection. In one village, near Moscow there dwelt in 1781, a peasant, who was consulted by the high and the low, principally in cases of fractures and luxations; he was often driven into the city with six horses. His reputation even reached the throne of the Empress Catherine. She issued an order providing that the pupils of the great war hospital in Moscow, should study with this peasant, two at a time, for two months each.

The German government tolerated the mountebanks and licensed them to practice on condition that they and their medicines should be examined by the collegium medicum. Only in the second half of the century did the light begin to break; it was seen first how general and great was the misery which these people spread over Germany, and a remedy was sought. Austria led the way, and in 1753 and at repeated intervals later, forbade all mountebanks and itinerant operators for all time to treat any kind of disease or to stand in public booths. Saxony followed in 1781. Who could expect that all the German states had advanced in like measure? As late as 1789 the oculists and rupture-surgeons operating in the principality of Lippe after passing a required examination went at it again. Supervision of quackery by the small states was elusive, for if the charlatan were called to account in any place, he quickly went into the neighboring dominions of another ruler where he was well received. The law alone was not able to remedy the evil, only a healthy common sense could eradicate this plague. It was just the same with the beggars. The state would not find it necessary to take action against mendicancy if nobody gave to beggars; so the quacks would have ceased to exist if there were not always people who placed confidence in them. The credulous had only to withhold payment, which was generally demanded in advance, and to wait until the quack had fulfilled his promises; the deception would then soon have been at an end. In order to enlighten the people: First, a physician of Lausanne published a treatise for the common people in 1761. The work created an enormous sensation, was translated into many languages, and in the following seven years, appeared in not less than sixty editions. In this book, and also in a medical weekly called *Der*

Arzt (the physician), which Dr. Unger published (12 volumes 1759-64), public attention was directed in easy, intelligible style to the great dangers which attended the methods of the mountebanks, and the people were warned not to be blinded by their gaudy equipages, and not to trust their titles and testimonials, which were false and forged. The remedies which were recommended for the nuisance of quackery were various. The most radical was a sound flogging. In Montpellier the magistrates were given the right to take every charlatan whom they caught and set him upon a lean jackass, with his face toward the tail. In this position he was led through the whole city, amid the jeering laughter of the people, was beaten by them, covered with mud, worried and railed at from all sides. It was proposed in order to check the superstition of the people to strike from the calendars all the astrological rules concerning medicine.

Some believed that it would be a check to impostures, if the clergy were instructed in medicine as they had been earlier, when the care of the sick fell to them. Up to this time they were forbidden to practice medicine in Austria, the penalty being a hundred ducats (1770), and medical practice was permitted only to the Brothers of Mercy in their cloisters and hospital after a prescribed examination, and they were allowed an apothecary for their own use. On the other hand, in the year 1773 the practice of medicine was permitted to the clergy by the parliament of Rouen, and Napoleon restored the act of the assembly, which gave them physician's privileges. In Germany there followed a decree of the Landgrave Louis of Hesse-Darmstadt, that in future no student should become a clergyman unless in the last year of his academic studies, in Giessen, he had one course. (*Tissats Anleitung für das Landvolk.*) The Universities of Würzburg and Landshut required that their divinity teachers should study anthropology. This German regulation was copied in Sweden, where, at the examination, a candidate in theology was required to have heard one course of lectures in pathology. Even Hufeland, so late as 1809, declared in favor of the medical practice of the country clergy, excepting in surgery and obstetrics, in order to limit quackery.

Has quackery died out in Germany in the last hundred years? Dare our age of progress venture to rebuke the preceding century for inaction? Not in the least. Charlatanry flourishes in our day just as rankly as then, and their lies are just as brazen. The number of the nostrums advertised daily would fill whole volumes; the newspapers teem with indecent advertisements of treatment of syphilis and sexual diseases. Old women as healers have no more died out than have blacksmiths and shepherds; it was scarcely twelve years ago, that in my home a shoemaker enjoyed the confidence of the regnant royal family. In quantity and specialization the advertisements have multiplied in a manner never before known and they enslave the people in superstition and cruelty. If at present in Germany no mountebanks stand openly in their booths in glaring raiment and sell death and misery with their pills and essences to the blinded people, and no executioner obtains permission to treat fractures, yet it is only the form which has changed, the facts remain about the same. The little principality of Schwarzburg-Rudolstadt furnishes a picture of the conditions amid which the nostrum swindle is carried on under protected privileges. Year in and year out hundreds of drug dealers, emerge from the Thuringian

gian forests and disseminate their murderous wares throughout Germany, Austria and Switzerland. In this little corner of the earth is sold more opium, aloes, rhubarb, etc., than all the physicians of Germany prescribe, or all the apothecaries of Germany sell. In the district of Königsee, there are about 1300 inhabitants, some twenty poisoners, called chemists, and 350 dealers in poisons, called balsam-traders. The majority of the specifics handled are in the form of pills. A single chemist prepares every year from four to five thousand of such pills, and uses annually from ten to twelve pounds of opium for the so-called children's pills, with which children are lulled, sometimes into a temporary, sometimes into an eternal sleep. This traffic in poisons made the dealer in a few years a rich and locally influential man, and was handed down from father to son, and to grandson. The princely authorities of Schwarzburg do nothing whatever to oppose this abomination; in fact they encourage it, because it brings a large amount of money into the country. (*Spener'sche Zeitung*, January 1874). In the year 1874 the number of quacks, officially obtained in the kingdom of Bavaria, amounted to 1156, consisting of 911 men and 245 women!

(To be continued.)

PECULIARITIES OF THE SURGICAL DISEASES AND INJURIES OF THE NECK.

BY EDMOND SOUCHON, M.D.

PROFESSOR OF ANATOMY AND CLINICAL SURGERY, TULANE UNIVERSITY.
NEW ORLEANS, LA.

(Continued from page 458.)

Tumors of the thyroid body.—Gaseous tumors do not exist in the thyroid body. Aerial goitres are really tracheoceles. Cystic tumors are represented especially by hematoma following an injury or due to a hemorrhage in a preëxisting cyst either from a traumatism or from a puncture with a too large needle and removal of all the liquid or enough to destroy the equilibrium of the pressure. The cyst originally called a hydrocele is then called a hematocele or a form of angioma. Pulsation in thyroid tumors is not uncommon, owing to the pressure on the great vessels. Lymphangioma represents a form of goitre. Congenital serous cysts of the thyroid are very rare. They must not be confounded any longer with the serous cysts of the neck; the gland is usually atrophied by the cyst, like salivary glands when cysts are located in them. Congenital mixed cysts are the most common; they contain thyroid vesicles, pavement epithelium, cartilage and muscular fibers. A peculiarity of the thyroid cysts is that, whether small or large, they may form sudden congestion or rupture, cause sudden great dyspnea, which may be rapidly fatal. Cystic growths of the thyroid should be enucleated, as this avoids any possible injury to the recurrent laryngeal nerve, and also avoids the possibility of cachexia strumapriiva by leaving all the gland that is not diseased.

Solid tumors are represented mostly and almost entirely by goitres; although they sometimes contain cavities or cysts, yet their walls are usually so thick they are considered as solid tumors and are described with such. The great majority are simple hypertrophies.

Goitre is an enlargement or hypertrophy of the

thyroid body without structural changes; it may involve the whole region or be unilateral or bilateral; it is more frequent on the right side.

The causes of goitre in general are not yet known. Women are more liable; children are seldom affected before ten years old. The alterations as regards size and shape are variable. The microscopic alterations consist in cavities, channels and compartments lined by a pavement or cylindrical epithelium. This form of goitre is the primordial form; it is epithelial or follicular; the other forms of goitre are only modifications of it.

The symptoms are those of a hypertrophied gland in general; the peculiar symptoms are the shape of a horseshoe; the movements follow the larynx; the veins developed on the surface, the peculiar deformity of the region, the pressure symptoms on the cerebral and facial circulations. The course is usually very slow and sometimes irregular. The duration is ordinarily very long.

The prognosis becomes serious with the degree of pressure symptoms and the complications. The true treatment of goitre consists in extirpation; especially if it grows and if the pressure symptoms are serious. We must bear in mind that an apparently innocent goitre may suddenly enlarge and cause suffocation or even immediate death.

The internal treatment consists in long continued thyroid feeding, which will diminish the size of a goitre and even bring on a condition of atrophy, so that the danger lies in abolishing the functions of the thyroid. Sodium phosphate has the same effect and consequences. We should be careful in using anesthesia if there are already signs of pressure; the use of morphin or cocain is preferable. Operation with cocain is often possible; the pain does not seem to be beyond endurance; the dangers of the operation are much lessened without anesthesia; there is much less turgescence of the veins than when an anesthetic is used and the dangers of complications from coughing and vomiting are thus diminished.

The incision should extend from one side of the neck to the other in a very sharp and long curve with convexity downward toward the sternum. The upper part of the tumor had better be attacked first, and the upper vessels tied, then the middle or the inferior; the hemorrhage is reduced to a minimum by careful hemostasis by means of forceps and double ligature of the larger vessels before incising between the ligatures. When the inferior thyroid artery is being dissected and tied, by engaging the patient in a conversation for a few minutes the possibility of including the recurrent laryngeal nerve in the ligation is avoided, as the altered voice immediately warns the surgeon of the danger. In the lower right angle is the part which often penetrates into the mediastinum behind the sternum; there exist usually at that point large veins. When possible lift the gland from its bed and encircle the pedicle with an elastic tubing before enucleating, as recommended by Rose and Poppert. The dangers are hemorrhage and asphyxia by blood flowing into the trachea when it is torn; to avoid these perform preventive tracheotomy when possible. In the hypertrophied thyroid the arteries are larger than in the normal, but they are in their usual situations. Be careful not to tear the trachea again; if this happen, introduce at once a tracheotomy canula, a very long one. In exophthalmic goitre Kocher resorts to ligatures and ties only three arteries. In one case,

when four arteries were ligated, tetany set in immediately. Intracapsular enucleation is the safest, but is not always feasible. When the difficulty of tracheotomy is due to pressure, division of the isthmus may afford relief.

The forms, varieties and complications are the following, according to their number and extent: Unilateral goitres, bilateral goitres, whole or entire goitres, aberrant or ganglionic goitres; plunging or retro-sternal, retro-tracheal, retro-esophageal, peri- and retro-vascular goitres; supra-clavicular goitres, colloid goitres. According to the etiology: Primordial goitre, sporadic goitre, endemic goitre, epidemic goitre, congenital goitre, menstrual goitre, pregnancy goitre, old age goitre, metastatic goitre. According to the symptoms: Goitre voice, cystic goitre, pulsating or external or aneurysmal goitre, venous or varicose goitre, cavernous goitre, solid goitre, fibrinous goitre, fibrous goitre, calcified goitre, osseous, cartilaginous goitre, hydatid goitre, aerial goitre, constricting goitre, diffuse goitre, goitre with a broad base, goitre adherent to trachea, sclerotic goitre. According to course: Acute, sub-acute, chronic. According to prognosis: Benign, malignant. According to complications: Hemorrhagic (in a cyst or interstitial) or suppurating goitre, congestive goitre, exophthalmic goitre, goitre with emphysema of lung, due to impeded respiration, goitre with chronic bronchitis or tracheo-bronchial catarrh, with pulmonary edema, goitre with dilatation of right heart, goitre with cerebral anemia due to compression of the carotids, goitre with weak pulse, inflamed goitre or strumitis. The foregoing designations indicate the meaning of the form or varieties and the peculiarities attached thereto. However, some of them need additional explanation.

Aberrant goitres are those found in the supernumerary thyroid bodies, *i. e.*, those in the lobules developed independently and which failed to unite with the body of the gland; they are sometimes called ganglionic goitres because they resemble hypertrophied lymph nodes. Peri- and retro-vascular goitres are those which send processes around and behind the large vessels of the neck. Colloid goitre is one that attains the largest proportions; it may be congenital; it begins to grow when the child attains 7 or 8 years; after 40 there is no more risk of having it; females are much more often affected (only 26 men in 551 cases); this is due to the influence of menstruation, pregnancies, accouchements; runners are much more affected by goitre, as also all professions where the neck is stretched or efforts are made; malaria, by causing internal congestion, favors the development; heredity is not as well established as for endemic goitre. Endemic goitre is peculiar on account of its connection with cretinism; in all countries, in all climates and in all races, there are regions where cretinism prevails endemically and it is associated with endemic goitre. This goitre is the initial basis of a degeneration of which complete cretinism is the last stage of culmination; the influence of heredity is undeniable; 80 per cent. of cretins are born of goitrous parents. The action of water is also undeniable, as goitre may develop or stop, according to the changes in the water, and it was thought that the absence of iodine in the water was the cause; it is now believed by some that goitre is an infectious disease whose parasite is in the water. Epidemic goitre is met with where there is an agglomeration of people,

prisons, boarding schools, barracks, but is only observed in goitre countries. Goitre in old people, after 50, gives bad results when operated upon. Cystic goitre is characterized by cystic cavities in the goitre; these may be unilocular or multilocular; they must not be confounded with the simple serous cysts of the thyroid above described; although their origin is the same yet the cysts are amenable to a different treatment as described also above, and are a separate disease clinically. Aerial goitres are simply cases of tracheocele. Sclerotic goitre is one which has undergone fibrous degeneration. Acute goitre is characterized by a sudden growth due to congestion, inflammation and hemorrhage. Hemorrhagic goitre is due to hemorrhages occurring either in the cystic cavities as in cases of cysts of the thyroid, or in the walls, or interstitial hemorrhages.

Exophthalmic goitre, or Basedow's or Graves' disease, is accompanied by protrusion of the eyeball and tachycardia with irregular, frequent, loud sounds; the heart is dilated; there is also alteration of the normal sounds; the arteries of the wrist and head throb. These symptoms are due to changes in the middle and lower ganglions of the sympathetic. Suppuration is very rare. There is a surgical exophthalmic goitre, due to the pressure upon the nerves, purely mechanical and very distinct from Graves' disease. In goitre with a feeble heart and a weak pulse great care should be exercised in operating. Inflammation of a goitre is called strumitis; it is much more frequent than thyroiditis or inflammation of a normal thyroid; it is serious because of the enlarged condition of the organ. Tracheotomy may be performed for relief until the pus is located and evacuated by incisions or by dilatation upon a guide. The diseases or complications of goitre are wounds, contusions, congestions, inflammations, hemorrhages, cancerous degenerations.

All the other solid tumors of the thyroid body are rare, sebaceous cysts, dermoid cysts, fibrinous hematoma, lipoma, adenoma, tuberculoma, syphiloma, fibroma, myxoma, neuroma, chondroma; encephaloid, melanotic, colloid, epithelioma, carcinoma, sarcoma, scirrhus.

Tuberculoma and diffuse tuberculosis are rare; they have never been observed primarily; they existed secondarily seven times out of one hundred consumptives, especially in the acute form; sometimes fistulous openings remain. Syphiloma is represented by gummata which have been found in children affected also with visceral syphilis. Fibroma of the thyroid body is barely known. A case of osteoid chondroma is reported; also a case of osteoma, but this case is doubtful. Sarcoma is more frequent, and has been observed in all its varieties; the difference between hypertrophy and sarcoma is that usually the hypertrophy has the same shape as the gland, whereas the sarcoma has not. Carcinoma is also among the frequent tumors of the thyroid outside of goitre. It is sometime connected with the esophagus or larynx; it may be metastatic from the cancer of some other part. The primitive cancer is the one here considered; it is rare, and is met especially in goitrous countries; its malignancy is great; generalization is the rule and the secondary tumors are found especially in the lungs, the mediastinum, and the bones. Such cancers are transformations of goitre; they are at first movable like all thyroid tumors but soon become adherent and immobilized; the limits soon become diffused and it is impossible to isolate them with the fingers behind

and feel the carotids pulsate; this is an important diagnostic sign. The palliative treatment consists as for the other tumors, in tracheotomy and feeding by esophageal tube.

Surgical operations on the thyroid body.—The following remark covers the peculiar features in operating on tumors of the thyroid other than goitres, that there are usually no large vessels and enucleation is possible because in growing, the tumor compresses the tissue of the gland and the vessels peripherally.

SURGICAL DISEASES AND INJURIES OF THE SUPRAHYOID OR SUBMENTAL REGION.

The *congenital malformations* of this region present no peculiarities worthy of notice. The *acquired malformations* of peculiar interest consist in the double chin produced by an accumulation of fat in the region.

The *swellings* of the region have nothing characteristic.

Burns are of peculiar importance because the resulting cicatrices may draw the skin of the chin and of the lower lip causing eversion of the lips and its consequences.

Contusions here are rare because of the protection of the chin. In hanging, the compression may often bear on the base of the tongue; the vessels, nerves and larynx are uninjured.

Wounds of the suprahyoid region are very seldom homicidal but almost always suicidal. Penetrating wounds only are of importance; punctured wounds are very rare; they are only observed in the cases of "hooking" of the chin. Incised wounds when transverse usually gape a great deal, but very little when longitudinal; usually the suicide, throwing his head back, cuts higher than he intends, in the suprahyoid region, so that the borders of the stretched sternomastoid protects the vessels. The penetrating wounds open the cavity of the mouth, injure the tongue and epiglottis; there may be suffocation due to the blood or other foreign substances, or to the tongue or epiglottis falling back and occluding the larynx; there is usually much hemorrhage from the wounding of the lingual artery. More than in all injuries of the neck we meet here with swelling and edema of the aryteno-epiglottic folds, which are directly injured. The gaping is especially great when the head is thrown back; the saliva and food pass out of it during deglutition. Wounds of the epiglottis cause much suffocation, difficulty of speech, of deglutition, coughing; thirst is a common symptom. Lacerated wounds have been observed in several cases of "hooking" of the chin. Gunshot wounds seldom penetrate posteriorly because the head being usually thrown back the revolver is naturally directed upward and rests under the chin, which is usually carried away by the shot. Poisoned wounds, bites and stings present nothing peculiar here. Foreign bodies in the wound are here represented by alimentary matter. The shock is as great here as in all injuries to the air passages on account of the dyspnea and aphonia and dysphagia.

Neuroses are of no special interest nor are softening and *indurations*. *Congestion* or hyperemia presents nothing peculiar. *Inflammations* of the skin are the same as those which affect the beard of the chin; they are of no peculiar interest.

Superficial cellulitis, *i. e.*, developed between the fascia and the skin, is of no peculiar consequence.

Deep cellulitis develops between the fascia and the mylo-hyoid muscles and is more serious; it must not

be confounded with the cellulitis developed above the mylo-hyoid and invading the floor of the mouth. Adenitis of the submental or digastric glands is the usual starting point of the inflammation of the region; it extends to the surrounding connective tissue and becomes an adeno-cellulitis and phlegmon; it is accompanied by great swelling increased by mastication and deglutition.

The inflammation of the excretory, salivary ducts is rare; it is a propagation from and through the mouth; there is retention of saliva, sometimes of pus; the needle and probe strike no calculi; in some cases the gland itself is swollen. Chronic inflammations of the region are most rare.

Gangrene presents here no peculiarities, nor do *ulcers* or *fistulae*. *Gaseous tumors* are almost unknown in this locality.

Liquid tumors are most commonly cysts. Congenital branchiogenic cysts of the region of the hyoid bone extend sometimes into the mouth and resemble ranulae, but they are independent of the submaxillary and sublingual glands. Simple serous or suprahyoid grenouillettes have been studied only recently; they are usually seated underneath the cervical fascia; they are very often an extension of sublingual cysts or grenouillettes through the muscles of the floor of the mouth. Dermoid cysts sometimes remain dormant for a while and then become apparent; if by the history the cyst may be traced to infancy it is a dermoid cyst.

The *solid tumors* of this region which are the most common and peculiar are the secondary involvement of the digastric or submental lymphatic glands in cases of erosion of the middle of the lower lip; they are comparatively seldom involved and when thus involved the whole lip is diseased; still they must be looked for, because if overlooked and neglected they may be the starting point of a new growth which will require another operation later.

Foreign bodies in salivary glands are more frequent in Wharton's duct; they may be a bristle, fishbone, straw, hair of a tooth brush. There is pain, swelling of gland, abscess, fistula. They may give rise to salivary colic. The treatment is that of all similar cases. All the other tumors are rare and present no peculiarities.

Surgical operations of the supra-hyoid region.—The deep surgical operations of the supra-hyoid region opening into the mouth are serious for all the reasons explained above in connection with the wounds of the region. These are still more so if there is loss of substance and the edges can not be united; the result is a fistula with its possible consequences.

SURGICAL DISEASES AND INJURIES OF THE SUBMAXILLARY REGION, *i. e.*, LATERAL SUPRA-HYOID OR DIGASTRIC TRIANGLE.

The *congenital malformations* present no peculiarities except that at times the orifice of a branchial fistula is observed there. *Acquired malformations* present no peculiar interest, neither do swellings.

The *diseases of the skin* most frequently observed here are morphea, sycosis, acne, sarcoma of the skin.

The *injuries* present some peculiar interest because they may injure the facial or the lingual artery, or the hypoglossal nerve and also because they may penetrate into the mouth. In regard to the diseases of the deep parts it is well to state here at the outset and

to bear in mind that the overlying lymphatic glands are more often affected than the tissue of the submaxillary salivary gland itself and that practically it is immaterial which is involved.

Neuroses present no peculiarities, nor do *softenings* and *indurations*.

Hyperemia is represented here by the *submaxillary mumps*, seated in the salivary glands, very rarely existing independently, and usually associated with parotid mumps.

Inflammation under the form of phlegmon is very common in this region. It is usually due to lesions of the face, mouth, tonsils, and especially dental caries, with periodontitis. It usually begins in a lymphatic gland as an adenitis, then invades the connective tissue around or becomes an adeno-cellulitis; this adeno-cellulitis seldom invades the neighboring regions, especially the infra-hyoid. Inflammation and abscess of the salivary gland itself is extremely rare. Osteo-periostitis from diseased teeth is often confounded with cellulitis; in the former the swelling corresponds to the body and to the border of the maxilla; its tendency is toward the face and the masseter portion of the cheek; the vestibule is painful and sometimes fluctuating. In adeno-cellulitis the swelling exists below the maxilla and has a tendency toward the neck. Chassaignac's subangulo-maxillary adeno-cellulitis is fixed under the angle of the jaw, and is due to the difficult eruption of the wisdom tooth.

Ludwig's acquired or infectious submaxillary angina is characterized by excessive swelling and pain; the tongue is swollen and immovable; the mouth is distended in front; there is difficulty of swallowing; it may terminate in gangrene; it often ends in death. The treatment of these abscesses consists in evacuating the pus as soon as possible; incisions should be made under and parallel with the inferior border of the maxilla, so that the cicatrices will not show; by using the method of dilatation on a guide the evacuation takes place when the exploring needle has located the pus, and there is no cicatrix of any consequence remaining.

Retropharyngeal abscesses often point toward this region, although they may burrow down into the mediastinum; in the former case the large vessels are between the pus and the surgeon's knife. It is best to try and evacuate through the mouth, to avoid the course of the large vessels and nerves. An incision on the middle line of the pharynx, if it will accomplish the object, is preferable as safer; it is well then to place the patient in Rose's position to prevent the entrance of pus into the larynx.

Gangrene is sometimes met with in this region as a termination of violent infectious inflammations. Scrofulous *ulcers* are not rare in children as a result of suppuration of the lymphatic glands of the region. *Fistulae* are rather common; usually they are due to diseased teeth and to the tuberculous lymphatic glands, to salivary calculi developed in the gland itself.

Gaseous tumors are sometimes seen under the form of pharyngocele.

The liquid tumors most common are various cysts. The most frequent are the salivary cysts due to retention of the saliva resulting from a more or less complete obstruction of the intra-buccal portion of Wharton's duct. Hydatid cysts have been observed. Cysts from cancerous degenerations are not rare.

The most common solid tumors are strumous, tuberculous, syphilitic adenoma. Cancerous adenoma is comparatively frequent; it is usually secondary to cancerous lesions of the face, mouth or tongue. All the other tumors have been observed but are very rare. It is very seldom that the salivary gland itself is the seat of the growth; if the saliva flows through the apex of Wharton's duct it is not the gland that is affected. Practically it is immaterial.

Salivary calculi are peculiar to this region; they give rise to pain and swelling; sometimes abscesses are followed by fistulous openings, temporary or permanent; the calculi sometimes occupy the center of the gland or the deep surface and the most important symptoms, as also the fistulous openings are in the mouth. They are diagnosed by searching carefully for the opening of the fistula and probing it, when the peculiar click will be felt; if necessary, a needle thrust deeply through the gland in several directions will strike the calculus if it be present.

Surgical operations of the submaxillary region.—Tumors should be removed through the mouth whenever possible, to avoid outside cicatrices and disfigurement. The removal of cancerous glands should be undertaken early, because they soon become adherent to the maxilla and to the deep structures with all the following evil consequences. The structures liable to be injured in an operation in this region are the facial artery, the lingual artery, the hypoglossal nerve; the mouth may be opened.

(To be continued.)

SELECTIONS.

Dr. S. Welr Mitchell's Experiments with the Mescal Button.—The *British Medical Journal* for December 5, contains an entertaining account of his personal trial of the anhelonium lewinii or "mescal button." He begins by saying:

At 12 noon of a busy morning I took fully 1½ drachm of an extract of which each drachm represented one mescal button. I had in a half hour a sense of great gastric discomfort and later of distension. At 1 p. m. I took a little over a drachm. Between 2 and 3 p. m. I noticed my face was flushed, the pupils were dilated midway, the pulse 80 and strong. I had a light sense of exhilaration, a tendency to talk, and now and then I misplaced a word. The knee-jerk and station were normal. Between 2 and 4 o'clock I had outside of my house two consultations and saw several patients. I observed that with a pleasing sense of languor there was an unusual amount of physical endurance. I went rather quietly, taking two stops at a time and without pause, to the fourth story of an hotel, and did not feel oppressed or short of breath. This is akin to the experience, as I learn, of the mescal-eating Indians and to that of many white men.

Meanwhile my stomach was more uncomfortable and I saw the first evidence of any change in my color records. On closing my eyes (while in my carriage) I held longer than usual any bright object just seen. As to this, however, I am not as sure as I am concerning the later phenomena. About 4:10 p. m. I drove home and after taking half an ounce of extract in three doses I lay on a lounge and read, becoming steadily more conscious, at first of a left frontal pain (not severe) and soon after of a dull occipital ache on both sides and at or about the occipital bosses. Yawning at times, sleepy, deliciously at languid ease, I was clearly in "the land where it is always afternoon." At 4:30 p. m., rising to make notes, I became aware that a transparent, violet haze was about my pen point, a tint so delicate as at times to seem doubtfully existent.

At this stage of the mescal intoxication I had a certain sense of things about me as having a more positive existence than usual. It is not easy to define what I mean and at the time I searched my vocabulary for phrase or word which should fitly state my feeling. It was vain.

At this time, also, I had a decisive impression that I was more competent in mind than in my every-day moods. I seemed to be sure of victoriously dealing with problems. This

state of mind may be easily matched in the condition of some men when pretty far gone in alcohol intoxication. My own mood was gently flattering, a mere consciousness of power, with meanwhile absolute control of every faculty. I wrote a long letter of advice dealing with a rather doubtful diagnosis, and on reading it over was able to see that it was neither better nor worse than my average letter. Yet the sense of increased ability was so notable that, liking to test it, and with common-sense disbelief in its flattery, I took up a certain paper on psychology, which a week before I had laid down in despair. I grieve to say that it was less to be comprehended than ever. My ignorance would have remained bliss had I not made the experiment. I next tried to do a complicated sum, but soon discovered that my ordinary inefficiency as to figures was not really increased.

A mood is like a climate and can not be reasoned with. I continued to have for some two hours this elated sense of superiority. I was for this while in that condition in which some people permanently abide.

The further test of writing a few lines of verse was tried. I found there was much effort needed. I lay down again about 5:20, observing that the outer space field seemed to be smoky. Just at this time, my eyes being closed, I began to see tiny points of light, like stars or fire flies, which came and went in a moment. My palms were now tingling, my face a little flushed. About 5:40 the star points became many, and then I began to observe something like fragments of stained glass windows. The glass was not very brilliant, but the setting, which was irregular in form, seemed to be made of incessantly flowing sparkles of pale silver, now going here, now there, to and fro, like, as I thought, the inexplicable ruck and stay and reflux of the circulation seen through a lens. These window patterns were like fragments coming into view and fading.

Hoping for still better things in the way of color, I went upstairs, lay down in a darkened room and waited. In a few minutes the silver stars were seen again, and later I found that these always preceded any other remarkable visions.

The display which for an enchanted two hours followed was such as I find it hopeless to describe in language which shall convey to others the beauty and splendor of what I saw. I shall limit myself to a statement of a certain number of the more definite visions thus projected on the screen of consciousness.

During these two hours I was generally wide awake. I was comfortable, save as to certain gastric conditions, which were not so severe as to attract attention. Time passed with little sense for me of its passage. I was critically attentive, watchful, interested and curious, making all the time mental notes for future use.

Especially at the close of my experience I must, I think, have been for a while in the peculiar interval between the waking state and that of sleep—the "prædormitum"—the time when we are apt to dream half-controlled stories; but as to this I am not very sure. As a rule, I was on guard with every power of observation and reflection in full activity.

My first vivid show of mesal color effects came quickly. I saw the stars, and then, of a sudden, here and there delicate floating films of color—usually delightful neutral purples and pinks. These came and went—now here, now there. Then an abrupt rush of countless points of white light swept across the field of view, as if the unseen millions of the Milky Way were to flow, a sparkling river before the eye. In a minute this was over and the field was dark. Then I began to see zigzag lines of very bright colors, like those seen in some megrims. I tried to fix the place and relation of these tints, but the changes were such as to baffle me. One was an arch of angled lines of red and green, but of what else I could not determine. It was in rapid, what I may call minute, motion.

The tints of intense green and red shifted and altered, and soon were seen no more. Here again was the wonderful loveliness of swelling clouds of more vivid colors gone before I could name them, and, sometimes rising from the lower field, and very swiftly altering in color tones from pale purples and rose to grays, with now and then a bar of level green or orange intense as lightning and as momentary.

When I opened my eyes all was gone at once. Closing them I began after a long interval to see for the first time definite objects associated with colors. The stars sparkled and passed away. A white spear of gray stone grew up to huge height, and became a tall, richly finished Gothic tower of very elaborate and definite design, with many rather worn statues standing in the doorways or on stone brackets. As I gazed every projecting angle, cornice, and even the face of the stones at their joinings were by degrees covered or hung with clusters of what seemed to be huge precious stones, but uncut, some being more like masses of transparent fruit. These were green, pur-

ple, red, and orange; never clear yellow and never blue. All seemed to possess an interior light, and to give the faintest idea of the perfectly satisfying intensity and purity of these gorgeous color-fruits is quite beyond my power. All the colors I have ever beheld are dull as compared to these.

As I looked, and it lasted long, the tower became of a fine mouse hue, and everywhere the vast pendant masses of emerald green, ruby reds, and orange began to drip a slow rain of colors. All this while nothing was at rest a moment. The balls of color moved tremulously. The tints became dull, and then, at once, past belief vivid; the architectural lines were all active with shifting tints. The figures moving shook the long hanging lines of living light, and then, in an instant, all was dark.

After an endless display of less beautiful marvels I saw that which deeply impressed me. An edge of a huge cliff seemed to project over a gulf of unseen depth. My viewless enchanter set on the brink a huge bird claw of stone. Above, from the stem or leg, hung a fragment of some stuff. This began to unroll and float out to a distance which seemed to me to represent Time as well as immensity of Space. Here were miles of rippled purples, half transparent, and of ineffable beauty. Now and then soft golden clouds floated from these folds, or a great shimmer went over the whole of the rolling purples, and things, like green birds, fell from it, fluttering down into the gulf below. Next I saw clusters of stones hanging in masses from the claw toes, as it seemed to me miles of them, down far below into the underworld of the black gulf.

This was the most distinct of my visions. Incautiously I opened my eyes, and it was gone. A little later I saw interlaced and numberless hoops in the air all spinning swiftly, and all loaded with threaded jewels or with masses of color in long ropes of clustered balls. I began to wonder why I saw no opals, and some minutes after each of these circles, which looked like a boy's hoop, became huge opals; if I should say fluid opals it would best describe what was, however, like nothing earthly.

I set myself later to seeing if I could conjure figures, for so far I had seen nothing human in form, nor any which seemed alive. I had no luck at this, but a long while after I saw what seemed a shop with apothecaries' bottles, but of such splendor of green, red and purple as are not outside the pharmacies of fairyland.

On the left wall was pinned by the tail a brown worm of perhaps a hundred feet long. It was slowly rotating, like a catheter wheel, nor did it seem loathly. As it turned, long green and red tentacles fell this way and that. On a bench near by two little dwarfs, made, it seemed, of leather, were blowing through long glass pipes of green tint, which seemed to me to be alive, so intensely, vitally green were they. But it were vain to find in words what will describe these colors. Either they seemed strangely solid, or to possess vitality. They still linger visibly in my memory, and left the feeling that I had seen among them colors unknown to my experience.

Their variety and strange juxtapositions were indeed fascinating for one to whom color is more than it is to most men; nor is it possible to describe the hundredth of what I saw. I was at last conscious of the fact that at moments I was almost asleep, and then wide awake. In one of these magic moments I saw my last vision and the strangest. I heard what appeared to be approaching rhythmic sounds, and then saw a beach, which I knew to be that of Newport. On this, with a great noise, which lasted but a moment, rolled out in darkness wave on wave. These as they came were liquid splendors huge and threatening, of wonderfully pure green, or red or deep purple, once only deep orange, and with no trace of foam. These water hills of color broke on the beach with myriads of lights of the same tint as the wave. This lasted some time, and while it did so I got back to more distinct consciousness, and wished the beautiful terror of these huge mounds of color would continue.

A knock at my door caused me to open my eyes, and I lost whatever of wonder might have come after.

After dinner I ceased to be able to see any further display of interest. Now and then a purple or pink fragment appeared, but that was all. For a day after I noted the fact that my visions could be easily recalled by a memorial effort, but with less and less sharpness.

These shows are expensive. For two days I had headache, and for one day a smart attack of gastric distress. This came after the first dose, and was most uncomfortable. The experience, however, was worth one such headache and indigestion, but was not worth a second.

Dr. Prentiss and others describe mesal as causing insomnia. My first experience with the tincture was made early in the morning. I became deeply flushed by noon, but had no visions. I felt drowsy and slept very well the following night. The

extract used, as stated, did make me sleepless up to 4 A.M., but neither restless nor uneasy.

Some interesting reflections are suggested by my experience with that vision-breeding drug, mescal. The effect on me was more or less like what is experienced in some ophthalmic migraines, and even my most brilliant visions can be matched by those I reported in 1887, and by some to be found in Dr. de Schweinitz's more recent paper.

The following extract from my own paper will sufficiently illustrate what I desire to point out. It concerns one of the several cases of megrim visions which I reported:

"The symptoms of onset are these: frontal and occipital sense of tension lessening toward night, good sleep follows; the next day he awakes with some pain between the eyes and slight photophobia. The second night, or the morning after it, he is aware of being flushed, but has no cerebral throbbing. In a few moments the lids feel as if pulled toward the inner canthus, and fortification zigzags appear, with next partial blurring of vision, which seems in twenty minutes to efface the lines and include more or less of the field. The lines seem to be projected one inch from the eye, and flash, and come and go with shimmering prismatic colors. The dimming of vision lasts some twenty minutes, and leaves him with slight vertigo and a feeling of fullness of the head, but pain always begins over the eye which has distinct vision, and of this he is sure. It increases as the eyesight clears, and is about one inch above the eye. Exertion, stooping, anxiety increase it. The pain lasts from one to three hours, and ceases without nausea. When it occurs over the left eye he has sometimes slight aphasia for five minutes, and in youth this was more severe and more lasting.

"As the zigzags fade he has exalted sense of hearing; loud voices hurt him for half an hour, and this is the period of vertigo. At one time he had at this period of the attack tingling in the fingers of the side opposite to that of the pain. After a number of these headaches he is subject to the curious and exceptional illusions which have caused me to report his case. At times these replace the zigzag lines, but later in a series of headaches they come on independent of the hemicrania, and occur at night, while awake or in full daylight.

"1. A common delusion with him is to see about twenty feet distant a trellis of silver covered with vines and flowers of brilliant tints. This is seen best when the eyes are open, and comes and goes.

"2. He sees a series of complex geometrical figures at the center of the field. These are brilliant pink or red.

"3. Quite commonly he sees multiple red circles intertwined and in rapid rotation, and once a red eye which seemed to approach him from a distance. Sometimes there is a milky cascade before both eyes.

"4. He saw once a crescent of silver on the wall, and suspended from it numerous heads in profile. Some were strange to him, and some were vivid revivals of faces which he had long forgotten.

"5. Six years ago he saw, during an attack, a huge red spider, which melted into a series of red rectangles revolving in swift motion.

"6. He has several times, and first on awakening, seen the door opened and a procession of white-robed veiled figures enter. They did not fade until he arose and lit the gas. These were seen with his eyes open or shut, and he could not double them by causing himself to squint by pressure on one eye."

It will have been seen that mescal supplied me with one-sided (left) frontal headache—later with occipital pain on both sides, with colored zigzags or fortification lines—the rain of silver and disorder of the stomach. I ask myself now if the migraines with visions are apt to be found in association with occipital pain in the region of the convolutions, which we believe store up our ocularly acquired memories. It is worth an inquiry.

The mode of action of mescal is somewhat curious, and may vary with the dose and with the man. At first, even at the height of drug action, the visions require one to wait with closed eyes for a minute or more. To open the eyes is to dismiss the vision, no matter how dark be the room. Suggestion availed me but little, and no act of will was competent to hold my dream unaltered.

I found in these seeming laws some resemblance to those which—in my case, at least—appear to govern a quite ordinary and normal phenomenon. From childhood I, like some others, can at night, before sleep arrives, summon visions. These are not always just what I desire. Once present I can not alter them; they shift, change and disappear under influences not within my capacity to control or to analyze. To open my eyes, even in the most intense darkness, dismisses these visions. Is it true of opium visions? The same law certainly applies to

some hysterical phantasms; but the explanation does not as yet seem attainable. My normal power to summon visions was entirely lost under mescal action. I tried to see faces, gardens, etc., but none came at command so long as I was under the influence of the drug.

For the psychologist this agent should have value. To be able with a whole mind to experiment mentally upon such phenomena as I have described is an unusual privilege. Here is unlocked a storehouse of glorified memorial treasures of one kind. There may be a drug which shall so release a mob of verbal memories, or of musical records, or in fact, of tastes and odors. I naturally speak of things seen under mescal influence as glorified memories—certainly nothing seen in these visions was altogether out of my known experiences, but everything was excessive, forms were gigantic, colors marvelously intermingled. In fact, nothing was simply the vision of a thing remembered and recognized, except the familiar Newport Beach.

I see no obvious therapeutic uses for mescal in massive doses. It is yet to be tested by continuous employment in moderate amounts, and may be of value.

The Glandular Elements in Babonic Plague.—Dr. Simon Flexner, in the *Johns Hopkins Hospital Bulletin*, explains the symptomatology of the plague as obtained from a study of the lately published observations of Kitasato and Aoyoma. A paper by the latter, who himself contracted the disease at Hong Kong in 1895, has been published in the *Mittheilungen aus der Med. Facultät der Kaiserlichen Japanischen Universität*. The symptoms of this disease are incorrectly described when called multiform or protean, as the habit of some writers is, but they are simple. Prodromata are seldom present or complained of by the more obtuse part of the Chinese; the more intelligent people take note of some slight swelling and tenderness in the glands. After a day or two the glandular symptoms become more marked, and those glands first involved may reach the size of an egg. The pain increases with the growth in size, although in some cases it may be absent excepting upon pressure. The glandular affection is characteristic, inasmuch as it begins in one group and then involves in succession others, as for example, first the inguinal, then the axillary, then those of the neck and finally the submaxillary glands. The glands of the neck, of the elbow and of the knee are seldom primarily affected. Only very rarely do several sets of glands become enlarged at once. Very soon after the swelling of the glands the periglandular tissues become involved and then later the skin. In the milder cases, suppuration may not occur and the swelling gradually diminish and finally disappear. On the other hand, suppuration may occur even in glands but little enlarged. In the rapidly fatal cases, death may occur before any considerable glandular swelling can be made out, in the severest cases taking place on the second day. As a rule death occurs from the second to eighth day, and on an average on the fourth day. As suppuration of the glands rarely occur before the tenth day it was not observed in these more rapid cases. When death takes place late in the course of the disease it may be due to a second pyemic infection. The suppuration of the glands may continue for months, so that the convalescence of the patient is rendered very slow and tedious. When suppuration does not occur the glands gradually become smaller, although the enlargement may not entirely disappear for two or three months. It is noteworthy that at autopsy the lymphatic apparatus of the stomach and intestines and the mesenteric lymph glands were never found greatly inflamed, and the last contained very small numbers of the bacilli only, or in certain cases none at all. Hence it is stated that all physicians who observed this outbreak of the pest were forced to the idea that the bacilli entered chiefly through external wounds. In the great majority of cases the deep inguinal and the axillary glands, and in a small number of cases the superficial inguinal glands, of one side were first affected and afterward other glands became involved. This fact is explicable only upon the assumption that the organism entered through small defects of the skin which were present either on the feet or the hands; and as the working class of China usually go barefoot, such small defects can easily be imagined to exist. Further, as is known, the lymphatic vessels of the feet run to the deeper and lower inguinal glands, thus exposing these first in the great majority of cases. The superficial inguinal glands receive the lymphatics of the penis and the skin over the lower portion of the abdomen, and these are but seldom primarily affected. Of the nine Japanese whom Aoyoma observed, two women showed affection of the axillary glands, one of the submaxillary glands, whereas in the other no glandular affection could be detected,

notwithstanding the fact that the bacilli were found in the blood. Of the Japanese men, four showed swelling of the axillary glands and only one of the inguinal glands. This is interesting when it is considered that the Japanese do not go barefoot. It may also be mentioned that among the Chinese the women show affection of the axillary glands rather than of the inguinal glands. The wounds through which the infectious agent enters show, as a rule, no reaction. Notable exceptions to this statement are his own case, in which a lymphangitis was present, and that of his assistant, Nakahara, who succumbed to the disease and in whom lymphangitis was also observed, in both cases beginning in the hand and extending toward the axilla. As regards the manner of diffusion of the bacilli, nothing new has been offered in this report. The period of incubation of the disease is given at from two to seven days. The increase in size of the lymphatic glands depends upon several factors, namely, hyperemia, exudation, hemorrhage, hyperplasia of the gland cells, and great development of bacteria. The bacilli which are present are found in the earlier stages in the lymph spaces about the follicles, and later they are found within the follicles, the lymph sinuses and the medullary cords. The cells of the affected gland undergo various degenerative changes and may become necrotic. They lose their nuclei in the latter case, and a variable amount of nuclear detritus is present among the degenerated and necrotic cells. The hemorrhages are not limited to the gland itself, but may be found, as well as greater or less edema, in the periglandular tissues. The usual fate of the enlarged glands is to suppurate, although in certain cases the swelling may disappear without suppuration and the glands return to normal; while in still others a fibroid induration may result. The suppuration is either of the nature of simple abscess formation, or preceding this there may be a necrosis of the gland substance; in certain cases the suppuration does not remain limited to the glands, but extends into the periglandular tissue. Sections of the lymph glands showed a variety of bacteria. It is stated that in the primary localization various bacteria may be associated. Among these can be distinguished the pest bacilli and cocci, and among the latter both streptococcus and staphylococcus forms may be discovered. Aoyama considers the association of these organisms as very important in determining the suppuration or non-suppuration of the affected glands. The spleen usually shows the presence of large numbers of bacilli, and among these more rarely micrococci. The pest bacilli were also, though not constantly, found in the interstitial substance of the kidneys and in the glomerular capillaries. They were also present in the inter- and intra-acinus tissues of the liver. The mesenteric glands sometimes contained the bacilli in small numbers; it is not stated whether or not they were found in the structures of the central nervous system.

A Case of Deciduoma Malignum.—In the *British Medical Journal*, December 26, appears a paper by Julia Cock, M.D., Senior Physician to the New Hospital for Women, on the above subject.

Considerable attention is being given at the present time to the study of the clinical characters and pathology of that form of new growth known as deciduoma malignum, and it is therefore desirable that all recognized cases should be put on record. The literature of the subject is chiefly to be found in Germany and America, though scattered notices have appeared from time to time in English medical periodicals. The recent important discussion at the Obstetrical Society of London, will bring the disease more prominently to the notice of English practitioners, and as few cases have hitherto been reported in this country, the following particulars may be of interest:

Mrs. S., aged 30, was admitted to the hospital June 19. The patient had been delivered of her fourth child three weeks previously. The labor was normal, and the placenta was examined, and considered to be complete. The loss at the time of labor was slight, and she was up on the fourteenth day. She then had slight hemorrhage, and was ordered back to bed. On June 17 she got up again, profuse hemorrhage occurred, and she was admitted to the hospital.

On admission she was blanched and exhausted; the temperature was 102 degrees, and the pulse 120. She was lethargic, and it was difficult to rouse her or to take food or answer questions. The uterus on vaginal examination was felt to be high, the os closed. Hemorrhage was slight. Nothing abnormal was

detected in chest or abdomen. On June 20, the patient was anesthetized and the cervix dilated. A mass was felt adherent to the posterior wall of the uterus, the feel and appearance being that of placental tissue. It was removed by the finger and curette, and the uterus douched and lightly packed with iodiform gauze.

On June 24 she was delirious at night and tried to get out of bed, but she had no delusions. She slept at 3 A.M., after a draught of potassium bromid. On July 7 her condition was good. Slight bleeding occurred, which was thought to be probably a normal period. On July 13, she had headache, the temperature was 101 degrees, and she vomited three times. At 2:30 A.M., July 14, the house-surgeon was sent for, and found the patient had passed two large clots, and the bed was drenched by the discharge of a great quantity of blood-stained serum. She was blanched and faint, the pulse was 130. On July 15 another large clot was passed. The uterus was felt to be high. The os was patulous, and admitted the tip of the finger; a roughish mass was felt presenting through it. There was no fever. The temperature was 98 degrees and the pulse 120. Examined under an anesthetic on July 16, the os was found to be patulous, and no dilators were needed for the exploration of the uterine cavity, which measured three inches, and was occupied by a mass of pale organized material growing from the posterior wall. This was removed, and over its site the uterine wall was felt to be extremely thin. There was little hemorrhage during the curetting. The uterus was douched, and lightly packed as before.

The case was fatal on July 26. The microscope revealed heterologous deposits in primary and metastatic sites, mostly with syncytal masses in which were embedded nuclei of various shapes and sizes. Vacuolation of the syncytium was well marked. Epithelioid cells were seen either singly or in masses adhering together.

From the varying views held at present it is clear that the last word is not yet said as to the classification of this new growth, or its relation to the more usual forms of malignant disease. All observers are agreed as to its malignancy, and as in all probability hysterectomy before metastasis has occurred is the only procedure which holds out the smallest hope of saving the life of the patient, early diagnosis is of the utmost importance. The growth has a definite structure, and can be recognized from its microscopic characters. In the case of Mrs. S. some of the most characteristic sections are from scrapings removed from the uterus during life, and it is fortunate that these easily obtained specimens give, in some cases at least, a result from which a diagnosis is possible.

The following points were characteristic in the case of Mrs. S.:

1. That the disease appeared in connection with pregnancy.
2. That the patient was a young woman.
3. That dangerous hemorrhage was present; that it was intermittent, and occurred without warning after days of quiescence.
4. That nervous symptoms (lethargy and delirium) were present. In some recorded cases delirium has been a marked feature.
5. That metastatic new growths were found in the lungs and ovary.

Cutaneous Lesions Due to the Roentgen Ray.—Professor Elihu Thomas of the Lynn Electric Laboratory, experimented upon himself with the X ray, with a view to determine what foundation existed for the lesions, sometimes styled dermatitis Roentgeni, *et al.*, that have been reported as caused by the ray. He says: "I used for this the little finger of the left hand, exposing it close up to the tube, about one and one-quarter inches from the platinum source of the rays, for one-half an hour. For about nine days very little effect was noticed, then the finger became hypersensitive to the touch, dark red, somewhat swollen, stiff, and soon after the finger began to blister. The blistering started at the maximum point of action of the rays,

spread in all directions, covering the area exposed, so that now the epidermis is nearly detached from the skin underneath, and between the two there is a formation of purulent matter which escapes through a crack in the blister. It will be three weeks today since the exposure was made, and the healing process seems to be as slow as the original coming on of the trouble, while the pain and sensitiveness have largely left the finger within the last day or two, and the blister now covers the whole exposed back and sides of the finger. I think the finger will soon heal, but I assure you that I will make shorter exposures hereafter. Figuring out the equivalent exposure at six inches distance, it would equal about ten to twelve hours. The lesion is very peculiar, and I never saw anything like it. It continued to develop and spread over the extent of the exposed surface for three weeks, and I am not sure yet that the affection has reached its limit on the exposed surface. I hope the healing process is well begun, but thus far I am not decided on that point. The exposure, it must be borne in mind, was a long one. At the distance I used, it was equivalent to twelve hours at six inches. I was fully as great a skeptic as yourself before I made the experiment, but I am now considerably more than convinced that if the exposure is long enough the results will follow. I may say, in conclusion, that my experience has been that with ordinary wounds, bruises, cuts and the like, the healing process is quite rapid, showing that there is no lack of vitality of my tissues in that respect, and it would appear from my experiment that little effect of a deleterious nature is produced at all unless the exposure passes a certain limit, assuming a given strength of X ray emanation. I would say that I have recently learned from our Harrison works, that a young man who is working on testing Crookes tubes made there, had to stop work owing to the fact that his arms began to be affected, and I understand that this effect was produced through the clothing. I have lately made some inquiries, and find that two cases have been reported in Mr. Edison's laboratory in which the effects were far more severe, since they took place over the hands and arms of the victims, and made it necessary for them to stop work altogether in connection with X rays. The story goes that one of them was told by his physician that if he continued work it would be necessary to amputate his hands. I can readily understand this, as the effect produced by long exposure transcends any effect that I ever saw or knew of as being produced by the most severe sunburn, even when attended by ulceration."—*Boston Medical and Surgical Journal*, December 10.

Frequency of Spontaneous Recovery from Appendicitis.—Rotter states in his important report of the 213 cases treated in the medical and surgical departments of the St. Hedwig Hospital at Berlin, 1893 to 1895, that the mortality in appendicitis is not so large as usually assumed, amounting in his experience to only 8.9 per cent. of the total number of cases, and to only 2.5 per cent. in the circumscribed cases. (Three of these might and probably would have been saved with prompt operation.) He reviews also the results secured by others, especially Sonnenberg, which imparts extra interest to his communication. He is more conservative than Sonnenberg, who advises removing the appendix even in mild cases, that begin "stormily," particularly if there is any chronic tendency, stating that mere incision of the abscess is never sufficient. Rotter's practice is immediate operation in diffuse peritonitis, conservative treatment in the circumscribed cases. He does not accept Sonnenberg's seven forms, but divides all cases into the two: general and localized peritonitis. He found that of the localized cases, 90 per cent recovered spontaneously, and 84 per cent. of the total number of cases received at the hospital during the first six days of the attack. He ascribes great importance to the fever, which he classifies into five groups: 1. Cases beginning with high fever, up to 40 degrees C.; decrease third or fourth

day. Rapid convalescence. 2. Begin the same, with fever up to 40 degrees. Fever lasts longer, but not over 39 degrees by fifth day. Fourteen cases of this kind, all recovered. Three required operating for circumscribed abscesses. In the absence of fever, he operates such cases the ninth day. 3. Same, with temperature over 39 degrees longer than the fifth day. Grave virulent infection. Prognosis unfavorable. In eleven cases there were two deaths. The fever disappeared spontaneously in two cases the eighth to ninth day. Four were operated. Three recovered after protracted stay in bed (perforation into the intestine). This group requires prompt surgical intervention, not later than the sixth day, and earlier than this with symptoms of progressive peritonitis. 4. After an earlier fall in the temperature, it rises again, which always indicates larger accumulations of pus. Four were operated of the six cases in this category. One died of general peritonitis, and another left after the third remission, apparently cured. These cases should be operated during the first remission. 5. General peritonitis. The temperature is low, often subnormal in severe infection, higher in progressive cases. The pulse indicates the severity of the attack. Recovery is only to be expected with surgical intervention. He believes that pus is always present in acute attacks, whether found or not. It may be discharged through the lumen or the perforation and absorbed by the peritoneum.—*Cbl. f. Chir.* October 24.

A Successful Conflict with Trismus Neonatorum a Century Ago.—The *British Medical Journal* refers to an old book, Clarke on the "Diseases of Dominica," giving a few paragraphs upon his management of trismus, with a short comment on the causes of Dr. Clarke's success.

"As the trismus infantum or jaw-fall never happens to infants after the ninth day of their age, it may be considered as a third species of this disease. For many years after my arrival in the West Indies nearly one-fourth of the negro children on the plantations died of the trismus or jaw-fall on the eighth or ninth day after they were born. It therefore became a matter of serious consideration with the planters to find out a method to prevent this mortality among their negro children. That the disease could not be cured was soon discovered, as not a single instance of such a result ever occurred. . . . I observed that the children born in the large negro huts generally recovered, and that white children, or those of free people, who had their kitchens apart from their dwelling-houses escaped the jaw-fall. I therefore suspected the smoke from the burning wood was the cause of it. In consequence of this I gave orders that no fires should be allowed in the negro houses where the lying-in women were, which answered the purpose of preventing the disease, when the order was complied with; but negroes are so fond of fire that they often lighted it up by stealth, and so frustrated my plan. I then recommended a lying-in hospital to be built on every estate near the negro-houses, with a planked floor, so that no fire could be kept in it, since which no children who were born in these hospitals, and remained with their mothers in them for nine days, have ever been attacked with this disease. . . . The fires in the West Indies are made of wood, and the smoke from them is so stimulating to the eyes, that few white people can bear it for a moment. From the foregoing observations I am of opinion that the smoke of the wood used as fuel in small huts, where it has not a proper vent, is the cause of this disease among infants in some parts of Switzerland and France, and in the Highlands of Scotland, as well as it is in the West Indies." Our knowledge of the etiology of tetanus would lead us to attribute the success of this experiment in preventive medicine to the freedom from earth infection and the greater cleanliness the wooden floors entailed, and to discount the partial success claimed as the result of the prohibition of fires in the other huts. It is noteworthy that time, race, and climate do not modify the disease. In St. Kilda in 1896, in Dominica about 1796, and in this colony it is fatal alike in eight or nine days after birth, though occurring in different races and so widely different climatic conditions. It is difficult to state accurately its prevalence in British Guiana, but in Georgetown, where nearly four-fifths of the deaths are medically certified, there were in 1895 43 deaths from this cause out of 1,745 births, 2.4 per cent. Wooden floors, frequently very dirty, are the rule. In hospital practice, on the other hand, with ordinary cleanliness and attention to the umbilical cord, the disease is not met with, and out of over 500 children born alive in the hospital in the last five years, no cases occurred.

The Gensichen Diphtheria Antitoxia Case.—The meeting of the Berlin Medical Association, December 16, was enlivened by a discussion of this peculiar case. Dr. Gensichen of Vietz was taken with light diphtheria on the left side in November, 1895, and injected himself with the curative dose of serum No. 2 in his left flank. He stated that the local process healed without irritation, showing that there had been no infection from a septic syringe, or anything of the kind. A week later urticaria appeared and lasted about a week, and in three weeks small pimples made their appearance, developing slowly into large abscesses, which soon discharged a bloody pus, recalling the glanders of horses. These abscesses were limited to the region in which the injection had been made, for six months, when they spread to the other side of the body for the next half year, and he still has some small ones. Virchow made a bacteriologic investigation with the results that only staphylococci were discovered, and no glanders microbes as might have been expected. The form of the abscesses he stated was peculiar; they passed through the cutis into the subcutaneous tissues, with which they communicated by a round, sharply cut hole. Anatomists met with similar experiences, he added, from postmortem infection, with eruptions like this and copious discharges. Heubner considered that the case was merely an attack of furunculosis, which had happened to be preceded by an injection of antitoxin. Baginsky also exonerated the serum, describing the case of a boy he had recently treated for the same affection, following a traumatism, but in his case there was no question of a preceding injection. Virchow, however, emphasized the fact that the first abscesses had occurred in the immediate vicinity of the injection, and not till afterward did they spread over the body. He considers, therefore, that the injection was directly responsible for them, but added that this did not mean the antitoxin. The injection and the serum injected are two different things. Dr. Gensichen sent a description of his case to the *Berl. klin. Woch.*, which published it with some editorial comment. A garbled account was reprinted in the daily papers, which induced Dr. Gensichen to write a correct account for his local paper. Ewald deprecated this publicity and urged that such things should be kept within medical circles and not made into sensations for the daily press. He considered the case a staphylococcus infection, as frequently happens when the injection is not made with absolute aseptic precautions.—*Therap. Woch.*, December 27.

The Exposure of Nostrums.—The editor of the *Health News* has published two small volumes on "Exposures of Quackery," at about 50 cents for the set. The following are the cordial remarks upon them in the *Lancet* for December 19:

The public, even more than the profession, owe a debt of gratitude to the editor of the *Health News* for his admirable and trenchant articles on quack remedies, which have been reissued in a convenient and handy form. Although many of the exposures were made some months ago, the vendors of several of these articles continue to flourish their wares in the eyes of the gullible. Some, it is true, have succumbed before the lurid light thrown on their dishonest practices, but not a few, we fear, have obtained too firm a foothold to be so readily dislodged. However, we trust these booklets will have a wide circulation, for they are written in a vigorous and entertaining style and contain revelations based on accurate analyses which should do something to stem the current of quackery. We have often protested against the support and one may even say the protection given to the trade in quack remedies by the Patent Medicines Act, and we agree with the writer of these brochures that the Government label serves to delude the ignorant into the belief that the contents of the phial so labeled have been tested and approved by the State. His suggestions that all patent medicines should be prepared by qualified druggists and that the composition of the medicine should be given on the label, might go some way to check the evil, and of course it would defeat the object of the inventor, whose mainstay is that his remedy is a "secret" one, although he may assign its origin to a source far remote from the actual one. The perusal of these revelations should excite ridicule if it were not so pitiful; as it is, the feelings uppermost in the reader's

mind must be mixed—amazement at the amount of credulity on the one hand and scorn and contempt on the other for those who, aware of this credulity, spare no pains to foster it by practices as unworthy as they are dishonest.

PRACTICAL NOTES.

Diagnosis of the Location of Cerebral Abscesses of Otitic Origin.—Rosa of Rome states that lesions of the occipital lobe produce temporary or permanent blindness or hemianopsia, while lesions of the cuneus produce hemianopsia. Aphasia and hemianopsia are therefore important indications in locating cerebral abscesses.—*Gaz. d. Osp. e d. Clin.*, December 13.

New Lacto-serum for Culture Media.—An artificial serum possessing all the properties of milk, for a culture medium with the advantage that it will keep indefinitely, is made by this formula: Lactose, 55 grams; albumin of eggs pulverized, 28 grams; sodium chlorid, 60 grams; distilled water, 1,000 grams; enough soda is added to give it a slightly alkaline reaction. It is filtered into test tubes and sterilized in the autoclave at 110 degrees C. for ten minutes on a layer of cotton.—*Presse Méd.*, January 13.

Cure of a Case of Intra-nasal Lupus with Guaiacol.—H. Bergaet describes in the *Munch. med. Woch.*, No. 52, a case of old lupus vulgaris of the entire external nose, cheeks and nasal cavities in a woman of 40, which he cured completely with two days' application of Klever's 10 per cent. guaiacol vasogen on cotton tampons of appropriate shape and size. The applications smarted for one to three hours, but not enough to require cocain. The tampons in the nose were removed before retiring. In one to one and one-half months all traces of the lupus had disappeared. A few months later it showed itself again in the same place, but promptly succumbed to a moderate repetition of the treatment. Before and during the guaiacol treatment airoil was insufflated into the nasal cavities and creosote administered internally. The nasal secretions were much relieved by tannin snuffed up into the nostrils.—*Therap. Woch.*, January 10.

Anatomy of Congenital Equino-varus.—Nichols (*Boston Medical and Surgical Journal*, Feb. 18, 1897, p. 153) thus summarizes the result of a study made in the Sears Pathological Laboratory of the Harvard Medical School: The deformity in cases of congenital club-foot is due to alterations in the shape of all the bones of the foot, in conjunction with contraction of certain tendons and ligaments. The chief deformity is at the "mid-tarsal" joint, and is due to an inward deviation of the articular facets of the os calcis and astragalus. A failure to correct this obliquity will result in a failure to correct the deformity. In resistant cases the obliquity can be corrected by osteotomy of the neck of the os calcis and the astragalus, followed by forcible reposition of the foot.

Sterilization of Elastic Catheters with Formaldehyde Vapors.—Oppler announces that catheters are effectively sterilized with formalin in six hours allowing 2 per cent. of the formalin to the space in the disinfecting apparatus. A patient requiring the catheter four times in the twenty-four hours can thus be supplied with only two catheters. He uses a simple tin box with a tight cover, a trifle longer than the instruments and about 20 cm. deep. The formalin in a solution, or in formaliths (six stones represent 10 c.cm.) or in the form of prioxymethylen (more expensive and requiring a longer time to sterilize) is placed in the bottom of the box and the catheters in a wire tray above it. Calcium chlorid used simultaneously prevents the softening of the instruments. The catheters must be carefully rinsed in sterilized water and dried before using. The sterilized catheter can be carried, when traveling, in a paper box containing a corresponding formalith.—*Cbl. f. Chir.*, January 9.

The Heredity of Tuberculosis.—As the result of a careful study of the subject Szegö (*Archiv für Kinderheilkunde*, B. xxi, H. v, vi, p. 328) reaches the conclusion that the inheritance of tuberculosis is either parasitic or dispositional (perhaps toxic). This heredity does not exclude the possibility of contagion. On the contrary, the predisposed subject furnishes preëminently a susceptible soil. It is difficult to determine which is the predominant factor in the transmission. This may result through infection of sperm or ovule or through the placenta. Involvement of the lungs, of the intestines, of the glands adjacent to the mouth and the nares indicates rather origin by contagion, while tuberculosis of brain, joints, bones and abdominal viscera bespeaks rather a congenital causative condition. The congenital germ of tuberculosis may remain latent in the organism for a variable period of time, and exert its influence only when the general condition of the organism is depreciated.

Heldenberg's Theory of the Etiology and Treatment of Lumbago.—Contrary to the accepted theory in regard to the origin of acute typical lumbago, Heldenberg ascribes it not to the muscles but to a sprain of the sacro-vertebral articulation, and treats it with a systematic course of gymnastics. The patient reclines on a hard couch, with the region slightly and evenly raised. The flexed limbs are then slowly lifted and the patient is soon able to raise them himself. The next step is to slowly flex the lower limb on the pelvis, then raise the limb with the thigh still flexed on the pelvis, and then stretch the limb out and down to its fullest extension. The movements are then repeated with the two limbs simultaneously. The pain is less if the patient supports his own thighs with his hands. After these gymnastics the patient can rise, stoop and attend to his usual occupations, and a repetition is not needed except in the most obstinate cases. In very severe cases Heldenberg applies a sinapism to the rear surface of the articulation, not to the muscles, just before the gymnastics. A daily injection of water or glycerin may be needed to prevent constipation.—*Semaine Méd.*, January 20.

Triturate of Mercuric Iodid as an Intestinal Antiseptic for Children and as a Membrane-solvent.—Dr. Chittick of Detroit, in the *American Therapist* for December, offers the opinion that this remedy merits a more careful attention by our profession. He prescribes a one-hundredth per cent. triturate of the red iodid of mercury with sugar of milk, commonly called "pink powder." This preparation is especially satisfactory in the treatment of the summer diarrhea of infants, especially when accompanied with depression. It is acceptable to the taste on account of its sweetness. It is thoroughly antiseptic. The required dose is necessarily very small. It can be given as a powder dry upon the tongue, or mixed with water in a glass, so that a teaspoonful will represent the required dose. It also possesses the advantage of being a solvent of pseudo-membrane, and even of croupous membranes. He has used it frequently, and with much success, in grave cases of diphtheria, especially in young children who did not tolerate any other form of oral medication. The dose is usually from three to five grains of the trituration, every one to four hours, according to the severity of the case or age of the patient.

Cod-liver Oil Condemned in Tuberculosis.—Dr. Arrowsmith of Brooklyn is the author of a bright little pamphlet on the modern aspects of tuberculosis, in the course of which he pays his respects to the hypophosphites and the cod-liver oil. As to the latter, he says that cod-liver oil has been administered as a matter of routine in larger quantities than any other remedy. His personal experience has led him to the opinion that it is very much worse than useless. The most that he has ever felt justified in hoping from it has been that it would not do harm. He has never seen it act beneficially. Patients who improve during its administration do very much better, as a rule, after discontinuing its use. "It acts as an alterative, by

changing decidedly the oxidation process of the system. But unfortunately, its alterative effects are in the wrong direction, decreasing the perfection of the proteid oxidation and often depriving unfortunate patients of the single chance of recovery which they might otherwise have retained. The free ingestion of it rapidly decreases the urea in the urine, and increases the incomplete or imperfect products of nitrogenous waste. The more perfectly it is emulsified, the more detrimental it becomes, because, thus, it is more palatable, and is less likely to produce digestive disturbance, and to be, therefore, refused entrance to the system. The emulsion also favors the absorption of an immoderate quantity, thus exhausting the oxygen supply and rendering the suboxidation of the proteid molecule, with all its ill effects, doubly certain. It disturbs digestion and prevents the utilization of other and more valuable forms of food stuffs."

Congenital Sarcomatosis of the Skin.—In detailing a case of congenital sarcomatosis of the skin Neuhaus (*Archiv für Kinderheilkunde*, B. xxi, H. v, vi, p. 366) points out that of all the new formations of childhood sarcoma is the most common, and of congenital sarcomata the most common are found in the kidneys. Metastasis of internal sarcomata to the skin is not rare, but primary sarcoma of the skin is extremely rare. The case in question occurred in a child two months old, of healthy parents free from syphilis and tuberculosis. The infant appeared normal at birth, but when bathed on the fifth day by the mother the left leg was noticed to be more curved and thicker than the right. In the following days the extremity increased in size, especially upon its external aspect. At the age of five weeks an incision was made into the leg and a cohesive, gelatinous mass as large as a hen's egg was removed. Free bleeding ensued, but the bones were apparently healthy and not connected with the growth. At about this time the mother noticed on the external aspect of the right ankle a bluish spot, which on palpation proved to be a nodule as large as a pea. Gradually similar nodules appeared upon the trunk and upon other portions of the body, increasing progressively in size and some undergoing ulceration upon the surface. The child was large and apparently well nourished. The nodules varied in size from a lentil to a small apple, were of elastic consistence and presented pseudo-fluctuation. They were sharply circumscribed and movable upon the subjacent tissues. They were variously situated in the skin and the subcutaneous connective tissue. The lymphatic glands were slightly enlarged, especially those of the groins and of the neck. There was no evidence of involvement of any internal viscus. Examination of a removed nodule disclosed the histologic structure of a round-cell sarcoma. No abnormality was found in the constitution of the blood. The condition of the child gradually deteriorated, until death took place in the course of ten days. Post-mortem examination disclosed widespread metastasis, the evidence pointing to the cutaneous covering of the left leg as the seat of the original growth, which must further, it was concluded, have been of congenital origin.

Absolute Alcohol as a Disinfectant for Surgical Instruments.—That absolute alcohol is not an absolute germicide is admitted, but that it has an area of usefulness in the care of instruments has been claimed. Dr. R. L. Randolph, in the *Johns Hopkins Hospital Bulletin*, states that his experiments as to the effect of this substance upon the keen-edged instruments of the ophthalmic surgeon have led him to prefer it to the use of heat. He is satisfied that dry heat, as well as moist heat, dulls the edges of instruments. He says: "For the past eight years I have employed absolute alcohol as a disinfectant for all cutting instruments used in operations upon the eye, and recently I instituted a series of bacteriologic experiments to test the value of this agent as a practical disinfectant. The cataract operation demands a keener knife, probably, than any operation in

surgery, and the peculiar objections to heat for sterilizing cutting instruments led me to adopt the use of absolute alcohol as the best substitute for heat." The alcohol employed in these experiments was Squibb's absolute alcohol, which is supposed to have a strength varying from 98 $\frac{1}{8}$ to 99.9 per cent. This is the grade of alcohol which he uses in operations. He presents the following conclusions: 1. That in a given number of eye instruments, by far the majority are infected by exposure to the air. 2. That absolute alcohol will seem a valuable disinfectant for instruments infected under the conditions which ordinarily surround us in everyday life. This conclusion seems warranted by the results obtained in the first and second series of experiments. Attention may be called to the fact, too, that in the second series the nails were all without a doubt infected, and it might be said that they had been exposed to conditions which, to say the least, were extraordinarily favorable for infection, so that this series, I think, is strongly suggestive that alcohol possesses disinfectant properties of no little value. 3. That the septic character of instruments infected with a pure culture of staphylococcus albus is not altered by exposure for twenty minutes to the action of absolute alcohol.

Diphtheria Antitoxin at Montreal.—The editor of *Therapeutic Progress* makes the following correction in his February issue: "In our December issue we reprinted a table, 'Mortality of Diphtheria as treated with or without Antitoxin.' The figures relative to the comparative mortality at the Montreal General Hospital (without antitoxin, 103 cases, 10 deaths; with antitoxin 10.3 per cent.) are obviously incorrect. Dr. A. T. Bazin, superintendent of the hospital, advises us that the mortality in the years previous to the advent of antitoxin ranged from 40 per cent. to 66 per cent., but that since antitoxin has been administered the mortality has fallen to less than 10 per cent., 103 cases with 10 deaths. In justice to the institution and to Dr. Bazin we take pleasure in making this correction."

Whale Oil in Acne Vulgaris.—Boeck, referring to the observations of Guldberg on whale oil, directs attention to the peculiar power of penetration which it possesses. But another remarkable property does not seem to have been previously noticed, viz., that to a certain extent it restrains the vitality and growth of bacteria in the skin; this endowment the author has specially endeavored to make of use in the treatment of acne vulgaris, and not, as is appears to him, ineffectually. He uses the following formula:

R	Powdered camphor.	30 to 50 parts
	Salicylic acid.	30 to 50 "
	Sulphur	10 "
	Zinc oxid	2 "
	Medicated soap.	1 "
	Whale oil	12 "

The ointment is applied every night, and in the morning washed off with soap and water. The camphor is added to cover the unpleasant odor of the whale oil.—*Edinburgh Medical Journal*.

Rupture of Heart.—Dr. Cecil Robertson, in the London *Lancet*, reports one of those cases of rupture of the heart, from external violence without penetration of the chest, that are of very infrequent occurrence. "Erichsen, in the last edition of his 'Science and Art of Surgery,' says that Gamgee was only able to collect twenty-two published cases. In the majority of these cases the blow was directly over the cardiac region. For two reasons I think the following case is not unworthy of being recorded: 1, the small number of recorded cases; 2, that the heart in this case was ruptured by indirect violence. An apparently healthy man aged 49 years opened the door of a railway carriage just as the train commenced to move and fell somewhat heavily on his left shoulder. On being asked by the officials if he had hurt himself he replied 'no,' and proceeded some two or three hundred yards from the station to his work,

where he died within three-quarters of an hour of his falling from the train. On postmortem examination I found the pericardium intact but distended with a mass of blood clot and fluid blood. In front of the left auricle was a laceration one and a quarter inches long through which a piece of clot protruded. The wall at the seat of the laceration was considerably thinned; both ventricles were very much hypertrophied; the whole organ weighed 22 ounces. Beyond a slight abrasion over the right knee there was no external evidence of an injury and there is little doubt that the cause of the rupture was the violent impact of the left shoulder on the platform."

Euchinin, A New Preparation of Quinia.—Dr. O. Van Noorden, in *Centralblatt für innere Medicin*, November 28, says that a preparation of quinin, called euchinin, possesses the curative properties of quinin without having its bitter taste, or producing a disturbed appetite, nausea, noises in the ears, heaviness, etc. It is formed by the action of ethyl-chlorocarbonate on quinin. Euchinin crystallizes in needles, and is readily soluble in alcohol, ether or chloroform, but is with difficulty dissolved by water. The chlorid of euchinin is easily soluble in water, the sulphate is less soluble, and the tannate least so. The base euchinin is tasteless unless it remains on the tongue for a long time, when it is slightly bitter. If given in sherry, milk or cocoa, it produces no unpleasant taste. Healthy people can stand 1 gram, and usually 2 grams, without unpleasant effects. Once 2 grams caused a sensation of heaviness in the head. No unpleasant results were noted in patients, and no complaint was made during the prolonged use of the larger doses of 1 to 2 grams in the day. In the absence of cases of malaria, the author has tried euchinin in fifteen cases of whooping-cough, fourteen cases of hectic fever in phthisis, five cases of sepsis of various origin, in pneumonia, typhoid fever, and also in several cases of neuralgia. One gram of quinin has the same action in whooping-cough and in febrile states as 1 $\frac{1}{2}$ to 2 grams euchinin. Beneficial and rapid effects were noted in twelve cases of whooping-cough. The temperature had a lower range in the fever cases after a few days. The results were especially good in one case of supraorbital neuralgia. A dose of 0.6 of quinin or 1 gram of euchinin gave relief when all other nervine tonics failed. This result was seen in eight different attacks. Euchinin is best given in tabloid form. In children it may be given in milk, soup or cocoa. The tannate is much to be recommended. The author thinks that euchinin certainly deserves a further trial, and that it will prove an addition to our resources.

Use of Steam in Puerperal Endometritis.—Dr. E. Kahn, in *Centralblatt für Gynäkologie*, December 5, describes the method of Snegirjow in the use of steam in uterine surgery as a cauterant and hemostatic. After eight years of experience it can be claimed for this agent that it checks hemorrhage, destroys odor, lessens the sensibility of the internal uterine wall and possesses valuable antiseptic properties. It has been used with some success in cases of inoperable cancer of the uterus, in hyperplastic endometritis, in putrid abortion, and recently in puerperal endometritis. The apparatus consists of a metal reservoir mounted on a stand, heated by a large spirit lamp or gas flame. From the top projects a thermometer registering up to 200 degrees C. The steam is conveyed from the dome of the reservoir by means of elastic tubes to which may be attached nozzles of various shapes and sizes. A stop-cock is provided to regulate the passage of the steam. The nozzle is passed cold into the uterine cavity through a speculum; the steam is turned on and made to play upon the affected part in a single jet or in several small jets according to the requirements of the case. The temperature of the steam is kept at 100 degrees C. for two minutes and is then raised to 115 degrees for a quarter of a minute to a minute. The steam fills the uterine cavity, stretching its walls and exciting powerful con-

traction. The patient feels no discomfort except the slight pain caused by the strong uterine contraction. No subsequent ill effects have been noticed even in cases where the infective process had already spread into the tissues around the uterus. The powerful uterine action excited by the steam is found to continue and involution is more rapid. In regulating the temperature of the steam and time of its application, the consistency of the uterine wall must be taken into account. The thinner and softer it is, the lower should be the temperature of the steam; the thicker it is, the higher may be the temperature used and the stronger will be its action. If there is inflammation without as yet pus-formation, the results will be good; but steam should not be used if there are collections of pus in the tubes. If there are blood-clots in the uterus or portions of placenta or membranes, they must be first removed by means of the finger or curette, as steam hastens decomposition in such materials. When steam is brought directly in contact with the internal uterine surface, the scalded endometrium forms a protective covering preventing fresh infection. The subsequent treatment consists of an intra-uterine douche on the second or third day of hot sterilized water or an ordinary saline solution, or a 1 per cent. lysol solution. Nine reports of cases are given, with temperature charts, and the author presents the following conclusions: 1. This form of application is without injurious results and but slightly painful. 2. It removes or diminishes uterine tenderness. 3. It arouses powerful uterine contraction. 4. It removes odor and destroys bacteria directly. 5. Through the closure of the blood and lymph vessels by the coagulation of albumin, it tends to form a protective covering beneath which fresh granulations form.

Experimental Study of Cerebral Compression.—De Gaetano has been making an extensive series of experiments on animals in which he introduced fragments of bone, laminaria or sponge into the cerebral substance, and studied the resulting processes. The tolerance was less as the animal stood higher in the zoölogic scale. The degenerative processes consist in a varicose appearance of the cylinder axes and an extensive diffusion of myelin, with vascular dilation in the zone of compression. Severe compression produces marked optic disturbances, first venous stasis in the optic papilla, more intense in the eye on the opposite side, followed by amaurosis from edematous optic neuritis, whether the pressure is in the occipital or parietal lobes. The effect of slight compression on the circulation is to decrease the pressure of the blood; with a little stronger compression the blood pressure returns to normal, or is greater than normal, increasing with the amount of compression, to become very high with violent compression. The variations in the pressure are identical, no matter in what part of the brain the foreign substance has been inserted. They are also the same whether the animal has been deprived of its cerebro-spinal fluid or not. But he found that the sanguine pressure increased in all cases, independently of the degree of compression, when double vagotomy had previously been performed. The sanguine pressure is decreased in all cases by irritating the nervous fibers of the dura mater or cerebral convolutions with the electric current, the proportion depending upon the strength of the current. The effect of irritation of the dura mater and convolutions is therefore identical with that produced by slight compression of the cerebral substance. He ascribes this effect to the fact that slight compression irritates the dura mater and cerebral convolutions, which irritate in turn the vagus and thus induce the decreased pressure of the blood. He explains the increased pressure in cases of strong compression by the irritation of the vasomotor bulbar center. If the external jugular is ligated separately and then the entire internal jugular the carotid pressure remains unaltered. The blood pressure in the jugulars of dogs is not affected by any amount of cerebral compression. The respiration becomes superficial and less

frequent in proportion to the amount of the compression, whether the cerebro-spinal fluid has been removed or not, but after double vagotomy, the tracings of the respiration cease to show these modifications, and instead it becomes very irregular. Irritating the dura mater or the cerebral convolutions increases the superficiality and rarity of the respirations, which become still more marked when the jugulars are ligated and cerebral venous stasis is thus induced. These phenomena appear suddenly the moment the ligature is completed, but pass away in time and the respiration returns to its normal frequency and grows deeper. The temperature falls with slight cerebral compression less than a tenth of a degree, a tenth with moderate and over a tenth with strong compression. The report published in the *Gaz. d. Osp. e d. Clin.* of January 10 concludes with the deductions that the effect of compression of the cerebral substance is due to the direct irritating action of the compressing body on the dura mater and the cerebrum in the first place, and to the indirect action of the increased endocranial pressure of the cerebro-spinal fluid in the second place. The therapeutic conclusion emphasizes the importance of removing the foreign body with the least possible delay.

Precocious Adolescence in a Girl of Six and a Half Years.—Wladimiroff (*Archiv f. Kinderheilkunde*, B. 21, H. v, vi, p. 360) has reported the case of a girl $6\frac{1}{2}$ years old, who came under his observation on account of rachitic deformity of the thighs and legs. On inquiry it was learned that the birth had been normal, the infant resembling other newborn children. The child was nursed at the breast for a year, when it began to walk and so continued to do for four months. Shortly afterward signs of rachitis made their appearance, and in the second year the deformity of the lower extremities was noticed. At the age of $4\frac{1}{2}$ years a slight growth of hair appeared upon the mons veneris, and at the age of $5\frac{1}{2}$ years the breasts increased appreciably in size. The child was forty-seven and a half inches in height and weighed fifty-five and a quarter pounds, while the circumference of the head was nineteen and a half inches. The girl was pale but well nourished. The musculature and the subcutaneous connective tissue were well developed, the skin was clear and elastic; skull, sternum and especially thighs and legs presented distinct evidences of rachitis. The left foot was supplied with six toes. The size, weight and general measurement were like those of a child of 11 years, while the breasts and the external genitalia were those of a girl of 16 years. While under observation a slight hemorrhagic discharge took place from the vagina for the first time and continued for a period of four days. There was no sign of psychic or nervous abnormality. The child submitted reluctantly to physical examination, but otherwise displayed no manifestation of asexual feeling and exhibited no sign of sexual irritability. The other five children in the family showed only peculiarities in stature, the oldest daughter, of 14 years, being smaller than the child under consideration, and the eldest boy, of 16 years, resembling rather one of 10 years.

The Inguinal Operation for Femoral Hernia.—Edebohl's (*Post-Graduate*, February, 1897, p. 75) expresses the opinion that the classic operation from below Poupart's ligament should be the operation of choice for femoral hernia, the inguinal operation being performed only when special indications exist. In the absence of such indications the method of Bassini (closing the hernial canal and the saphenous opening by suture), modified so that the upper sutures shall include Poupart's ligament and the periosteum of the os pubis, is to be preferred. When the inguinal operation for femoral hernia is indicated the best method consists in opening the anterior wall of the inguinal canal from the external to the internal ring, hooking the spermatic cord or the round ligament out of the way, and cutting through the posterior wall of the inguinal canal. After reduction of the hernia, liberation and high ligation of the sac

and clearing of the femoral canal, the crural ring, if small, should be closed from above by suturing Poupart's ligament to the periosteum of the horizontal ramus of the os pubis. Should the hernial aperture be large a fibro-periosteal flap should be formed and used in the manner described, to close the crural ring. In either case the irritation of the periosteum produced tends to the new formation in and about the crural ring of osseous tissue which will constitute an efficient barrier, efficiently placed against the redescend of the hernia. The saphenous opening may then be closed by sewing the falciform process to the pubic portion of the fascia lata, although this procedure is of secondary importance. The posterior wall of the inguinal canal is reunited by suture and the inguinal canal reconstructed after the manner of Bassini for the radical cure of inguinal hernia. The chief advantages of the inguinal operation for femoral hernia are the possibility and the ease of performance of high ligation of the hernial sac and of high and effective closure of the crural ring. The special indications for the inguinal operation for femoral hernia are, 1, the coexistence of complete or incomplete inguinal hernia with a femoral hernia of the same side; 2, in women the coexistence with femoral hernia of retro-displacement of the uterus which can be corrected by shortening of the round ligaments.

Aids to Cerebral Localization.—Dr. Eskridge of Denver, offers as aids in localization diagnosis a group of five speech-defects, symptoms of interesting variety that might be almost indefinitely extended, but the more valuable are among the summarized below:

1. If the lesion is in the foot of the left third frontal, Broca's convolution in right-handed persons, and in the corresponding portion of the brain on the opposite side in the left-handed individuals, the patient will be unable to speak voluntarily, to repeat words after another, to read aloud, to think in speech, and in the majority of cases to write voluntarily or from dictation so as to be understood, but he can not understand the speech of another. He usually will be able to use and understand gesture expression.

2. A lesion in the oro-lingual center (lower portion of the central convolutions) will cause paresis or paralysis of the oro-lingual muscles, including the lower side of the face, and imperfect articulation, but the patient will be able, with a decided effort, to repeat words after another, to talk voluntarily, to think in speech, and to write, although the letters may be imperfectly formed. There is, as a rule, no omission or transposition of letters or words unless the lesion is sufficiently extensive to affect the adjacent cortical centers or their commissural fibers. It is possible that this center is bilateral; that a lesion on either side may give rise to somewhat similar symptoms, and that the loss of function in the affected muscles will not be completely abolished from a unilateral lesion.

3. A lesion in the foot of the second frontal convolution on the left side in right-handed persons or on the right side in left-handed individuals (the probable orthographic center) will be attended by disturbances in writing, consisting of inability to write from inability to spell. In the only case reported of this character the patient formed all the letters of the alphabet perfectly, but he omitted, transposed and substituted letters to such an extent that his writing was unintelligible. He wrote well if the words were spelled for him.

4. A limited lesion in the posterior two-thirds of the first and second temporal convolutions will be attended by word-deafness, and inability to write at dictation, pure word-deafness. In a more exhaustive lesion in this region, mind deafness with paraphasia and some disturbance in reading and writing will be added. The greater the extent of the cortical and subcortical areas involved the more marked the paraphasia and other symptoms of sensory aphasia.

5. A lesion involving the angular gyrus and adjacent parts

will cause word-blindness and inability to read, defects in writing, copying and in speaking. In these cases paraphasia is often present. If the lesion affects the parts posterior to the angular gyrus, mind blindness may be added.—*University Medical Magazine*, January.

Mental Effects of Hasheesh.—In a recent number of the *Journal of Mental Science*, in which Dr. Clouston gives an account of the Cairo Asylum, he also gives some interesting information obtained from Dr. Warnock, superintendent of that asylum, in reference to the prevalence and the nature of the mental disturbance associated with the excessive use of hasheesh. Thus of 253 admissions to the asylum in the latter half of the year 1895, no less than 40 were admitted on account of symptoms attributed to the excessive use of the drug. In 41 per cent. of all the male patients hasheesh, alone or in combination with alcohol, caused the mental symptoms, while this was the case in only 7 per cent. of the females. As to whether there is a special recognizable form of mental disturbance produced by hasheesh, Dr. Warnock's conclusions are that in a considerable number of cases in Egypt hasheesh is the chief, if not the only, cause of mental disease, although it is doubtful whether hasheesh insanity can be diagnosed by its clinical characters alone. The usual types are three in number: 1. Hasheesh intoxication—an elated, reckless, "swaggering" state, with optical hallucinations and delusions of demoniac possession. The condition may be actual delirium, milder and less aggressive than that of alcohol, and exhibiting none of the ataxic phenomena of the latter. Recovery takes place in a day or two or less, and the patient usually recognizes the cause of his excitement. An interesting medico-legal question arises in connection with this intoxication, viz., whether the subject of it is to be held responsible for crimes committed in this state. 2. Acute mania is another form of hasheesh insanity. Terrifying hallucinations, continued restlessness, sleeplessness, incoherence and exhaustion are the prominent symptoms. Such cases usually last some months and do not always recover. 3. This insanity also takes the form of weak-mindedness. The patients are usually quiet and well-behaved, but are over-talkative, easily pleased, excitable about small things and unconcerned as to the future. Beside these three types, Dr. Warnock says there are numbers of cases of chronic mania, mania of persecution, etc., said to be produced by hasheesh, but with these he is not familiar. Female lunatics in Egypt are usually kept at home, even in the larger towns, but he also admits "it is at present quite impossible to even approximately gauge the extent to which lunacy prevails in the country generally." No doubt harmless lunatics are in some instances kept in their homes, but Egypt is now constantly traversed by English sanitary inspectors, to say nothing of police, irrigation and preventive officers, and it is difficult to understand how the more violent cases could be systematically kept in concealment. Dr. Warnock bases his conclusion that in Egypt female lunatics are usually kept at home on the ratio between the sexes in English asylums, but the conditions of life in the two countries are so different that his deductions would seem to be by no means inevitable. The general health of the inmates is not good. "Internal parasites affect nearly every patient, anchylostomas, ascariides and tapeworms being found at nearly every autopsy. Bilharzia also is very common." Melancholia is extremely rare among natives of Egypt. Five per cent. of the admissions were due to this form of insanity, but nearly all the sufferers were foreigners. The alcoholic insanities are seldom seen, and suicidal tendencies are well-nigh unknown. General paralysis of the insane, also, is not common, the admission rate for the year having been under 3 per cent. In connection with the latter affection Dr. Warnock makes the following remarks: "The idea that sexual excess and syphilis are important agents in the causation of general paralysis is not strengthened by these observations, since both these causes have free play in Egypt, and yet apparently little general paralysis results. The Egyptians are usually easy-going and are not subjected to overwork or strains, nor are they often addicted to alcohol."

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance \$5.00
Single Copies 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the Association living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, MARCH 13, 1897.

THE MECCA PILGRIMAGE.

Now that the troubles with the "unspeakable Turk" appear to be coming to a head in spite of the efforts of the powers, it is timely to ask the question if the insanitary practices of Mahomedan superstition may not receive some attention. One or two non-Moslem travelers have reported something of the conditions that exist in Mecca, during the immense annual pilgrimages and they have been pretty thoroughly shown up by ERNEST HART, PROUST and others within the last three or four years: The Turkish government, which, were it an enlightened and honest one, could do more than any other for the general welfare in this regard, cares for nothing but to have its own way and to prevent outside interference by lying and diplomacy; sanitation of any kind is altogether outside of its sphere of action and the welfare of the world in general does not trouble its calculations. So whenever an epidemic exists it puts nothing in the way of its extension and if it is not at hand it practically favors every possible means for its origination. It may also be truthfully said that the British government, which has under its control the fountain head of cholera, has also in the past been criminally remiss, and the salvation of Europe from this plague has not been due in any manner to its agency, but to the results of the labors of scientific investigators who have practically disarmed the infection by demonstrating its source and the method for its management.

The existence and spread of the bubonic plague in oriental countries at the present time puts a new face

on the matter, and brings before us another possible calamity. It may be that the danger is slight of its affecting Europe, and the fact that modern bacteriologic science is awake to meet every contingency, is perhaps an adequate safeguard, but yet it would be still more satisfactory could we feel assured that all possible precautions were being taken. The Mecca pilgrimage has been in the past, and still is one of the greatest dangers to the health of Christendom and it is possible that in a single year it might cost more of human lives and human treasure than even a Jihad or holy war of the Moslem against the Christian world. The outcome of such a war would not be doubtful, as intelligent Mahomedans are well aware, and hence the danger of its occurrence is minimal; it is only one of the bugaboos that the wily Turk employs to reinforce the timidity and jealousy of time-serving politicians. If anything, however, should result from the present critical conditions in the Levant, to bring about a more complete limitation of the powers of barbarism in that quarter, it is to be hoped that among other desirable happenings the sanitary control of the Mecca pilgrimage by some enlightened European power or powers, so as to do away with its present actual disease breeding and disease spreading function may be sometime or other secured. Such religious observances are only commendable when they work no general harm to mankind—"by their fruits ye shall know them"—and the Mecca pilgrimage as it has been and is at present conducted is a pestilential nuisance to the civilized and semi-civilized world. It may be difficult to fully control and impossible to prevent, but it is certain that it can be in some ways amended for the better, and the time will come when the necessity of this will be recognized by the nations. War in the East and general disturbance of European concord would undoubtedly be accompanied by many and great evils, but, to amend a common quotation, "peace has its slaughters as well as war," as recent history has demonstrated, and they are a part of the price paid for Mahomedan rule in the East. A much larger expense in human life is that to be attributed in the past to the Mecca pilgrimage, the greatest pestilence-transporting agency of the present century. However the Cretan and Turkish troubles may be treated, it is possible that an invasion of Europe by the bubonic plague via Mecca and the Suez Canal would bring the powers to a realization of the necessity of meeting one phase of the Eastern question promptly and thoroughly.

THE VALUE OF FLUID EXTRACTS AND OF TINCTURES PREPARED FROM THEM.

From time to time in pharmaceutic literature and to a less extent in medical literature, may be found animated discussions between pharmacists and physicians as to the value of fluid extracts, and more par-

ticularly as to whether it is proper and right to prepare tinctures from fluid extracts, particularly from those fluid extracts which have been assayed and standardized.

In the Alumni Report of the College of Pharmacy for Feb. 18, 1896, a very considerable number of its pages are devoted to the discussion of this important question, which on its surface is of little interest to the practicing physician, unless he stops to consider it thoughtfully, when it immediately becomes one of the most important questions to which he can devote his attention, for too often failures in treatment arise not from a lack of judgment on the part of the physician, but because the drugs which he employs to accomplish the results which he desires, are, for various reasons, incapable of producing the physiologic effect which is sought for. In the article which we have quoted we find a discussion by Messrs. KEBLER, ENGLAND, REMINGTON and others, in which the matter is pretty well covered.

It will be remembered that fluid extracts have become popular preparations for several reasons, the chief of which have been, 1, that they were standard preparations, or in other words, that each cubic centimeter of the fluid extract equals one gram of the crude drug, and the physician prescribing the fluid extract may therefore rest assured that his patient will develop a physiologic effect similar to that caused by the ingestion of the crude remedy, without any of the disadvantages associated therewith; 2, that being concentrated preparations, doses of the fluid extract must necessarily be small; and, 3, that if properly made and taken care of fluid extracts represent fairly permanent preparations.

But it is evident that with the processes recommended by the United States Pharmacopeia for the making of fluid extracts, that we have no absolute guarantee that the original drug from which the fluid extract is prepared, has a definite and equal strength with another fluid extract which is prepared from another lot of the crude drug coming from another source. Thus a plant or tree growing in very sterile soil and under disadvantageous circumstances, might very readily contain in its bark, leaves or other parts far less alkaloid or active medicinal ingredient than another plant of the same character growing amid surroundings that were exceedingly favorable to the development of these drugs, or their constituents, and yet the bark in each case might be so similar in appearance as to prevent the buyer from recognizing any difference between them. It would only be by chemic analysis and determination of the alkaloids which given samples contained, that the pharmacist would be able to obtain reliable crude products of equal strength, and from them prepare finished products which, because of their similarity, would not vary one from another in their physiologic action.

In other words, given a crude drug which on analysis is found to contain a certain percentage of alkaloid, or a fluid extract which contains a certain percentage of alkaloid, it must stand to reason that all fluid extracts which contain identical quantities of alkaloid must be equally valuable in therapeutics, even though the processes by which they are prepared differ with each manufacturer.

The advantages, therefore, of employing a fluid extract which contains a known and definite quantity of the active constituents of a remedy is very great, and if the physician would always prescribe a fluid extract made by some manufacturer in whose honesty he has confidence, and with whose standard he is familiar, he can vary his dose at will, with no other uncertainty as to the success of his treatment than possible variations in his patient which may arise from idiosyncrasy. In other words, any change in effect will depend upon the patient and the dose, and not upon the possibility that the dose taken on Wednesday contains in reality twice as much of the active ingredient as that taken the previous Wednesday, when the prescription was filled with the fluid extract made by a different manufacturer.

A few years ago the writer had a very good illustration of the necessity of using such standardized preparations, for he found that a tincture of nux vomica made by one of the foremost druggists in one of our large cities, was almost four times as strong in the quantity of strychnin and brucin which it contained as another tincture made by a druggist occupying an equally prominent and reliable position, so that if the physician were to double the dose of the prescription, and the prescription were to be put up at the first druggist's we have named, the patient would be receiving eight times as large a dose in reality as he had originally been taking; or, in other words, if the first dose was ten drops of the tincture of nux vomica, the second prescription would give him the equivalent of eighty drops of the first tincture. It is manifest, therefore, that the possibilities of such variations should be made as remote as possible, and for this reason it seems evident that physicians should always prescribe fluid extracts in preference to tinctures if possible, and further that they should employ fluid extracts which are carefully assayed and standardized even although different manufacturing druggists have set for themselves varying standards.

Thus, supposing there were four or eight large manufacturers, each of whom had a standard for his fluid extract, in all probability these standards would vary very little, and the variations certainly would not be as great as those which would be possible should the physician rely upon non-standardized fluid extracts, each one of which would vary with the technical skill of the retail druggist who prepared it, and there would be, therefore, a possibility of a thousand

variations in a large city, instead of four variations. It is true that tinctures are exceedingly popular preparations, but even the Pharmacopeia does not throw about them the precautions which result in desirable exactness, for pharmacopeial tinctures do not in any way represent a definite quantity of the crude drug, much less do they represent a definite quantity of the alkaloid which the crude drug contains, for the process of exhausting the crude drug is not so complete nor is it designed to be so accurate, and so far as we know, no tinctures which are made direct from the crude drug are standardized by assay.

Recognizing the facts which we have named, both physicians and pharmacists have been tempted more and more to cease employing tinctures made according to the pharmacopeial process and either to rely on fluid extracts, or to employ tinctures which are made by the addition to the fluid extract of a menstruum which will dilute it to approximately the same strength as the tincture is supposed to possess, and it is about this question that debate now seems to be most hotly waged. In the discussion which we have quoted, the point was first taken, and very correctly, that if all physicians, in writing a prescription for a tincture, are supposed to demand the tincture named in the United States Pharmacopeia, it goes without saying that the honest druggist must dispense a tincture prepared according to the process therein named; but if, on the other hand, it can be shown that the pharmacopeial process for the manufacture of a tincture does not give the best results, and if the physician has full confidence in the scientific acumen of his druggist, and further, is in touch with the facts that we have named, it certainly seems to the advantage of both physician and patient that a tincture should be employed made from an assayed fluid extract in the manner that we have described. Particularly is this the case toward the close of a decade, when the process recommended in the Pharmacopeia last issued may not represent by any means the latest advances in analysis or in the preparation of medicinal compounds. The only difficulty which we see in the way of preparing tinctures universally from standardized and assayed fluid extracts lies in the possibility that it may be impossible to dilute a fluid extract without precipitating some of the substances which it contains; but here, again, it is probable that in many instances the precipitate is practically without physiologic power and does not carry with it to the bottom of the vessel the soluble active principles which are intended to produce a given physiologic effect.

In some letters concerning this matter published in the Report of which we have spoken, Dr. E. R. SQUIBB takes the ground, which may be legally correct, but which is scientifically not advisable, that it is objectionable to resort to any practice not authorized by the United States Pharmacopeia, and that tinctures

made by dilute fluid extracts are not official, but are substitutes for the official tinctures. Mr. CHARLES RICE makes the following proposition: If a fluid extract differs from a tincture only in the quantity of the solvent or menstruum, and if the dilution of the former to the strength of the tincture by the addition of more of the solvent throws nothing out of solution, the two tinctures must be alike in the quantity of active ingredients, and therefore be alike in therapeutic effect. Second, if the dilution of the fluid extract to the strength of the corresponding tincture by the addition of even the most favorable menstruum causes a precipitation the two tinctures may be regarded as alike in therapeutic effect, for the precipitate contains none of the useful medicinal constituents.

As Dr. RICE states, these propositions are so self-evident that they can not be gainsaid, and we can therefore lay it down as a rule that physicians, when prescribing tinctures, should employ those which are made by the dilution of standardized fluid extracts, whenever such fluid extracts can be diluted in any way which will not alter their physiologic activity.

As to the third proposition, Dr. RICE states that the practice of preparing tinctures from fluid extracts in all cases where dilution causes obvious physical changes, such as precipitation and gelatinization, is not to be recommended for general use, but may be adopted in cases of necessity or urgency when a prescription calls for a tincture of a drug of which only the fluid extract is obtainable. With this proposition we also agree and believe that in many instances a tincture so prepared, with all its disadvantages, will give more definite and measurable results than the ordinarily prepared tincture, which has no definite strength.

Mr. LLOYD of Cincinnati points out that where constituents of the drug are firmly established and known, and in which no question exists concerning the exact value of the fluid extract, he can see no question but that the tincture may be made by diluting the fluid extract, and he even goes further and says that, owing to the difficulty of extraction in the case of the drug *nux vomica*, unless the tincture is assayed in order to establish its value, the method of preparation from the standardized fluid extract is to be preferred to blind extractions from the standardized drug. He also states that in his belief, certain tinctures can be made as reasonably (or even cheaper), from fluid extracts, and with a greater uniformity than from the drug.

Against the views which we have urged, Mr. JOSEPH ENGLAND strongly protests, believing that the value of standardized fluid extracts over those which have not been standardized in actual medical practice has been much exaggerated, but in this we do not agree with him and, except in a few instances, we do not think that the objection which he urges against diluting standardized fluid extracts will hold in the mind

of the practicing physician, even although Mr. ENGLAND'S objections are pharmaceutically correct. For even if the precipitate does occur on the fluid extract being diluted, the resulting medicinal preparation, while pharmaceutically inelegant, is practically as efficient from a pharmaceutic point of view, provided, as is so often necessary in other instances, the bottle is shaken before its contents are taken.

Let us use standardized fluid extracts of known and definite strength and avoid the risk of using tinctures made from them, for it is better to know that a slight decrease in activity may result, than to be in the dark as to whether the tincture is prepared from an inert or an abnormally powerful crude drug.

THE PHYSICIANS OF THE FRENCH REVOLUTION.

Among the professions particularly active in the French revolution, the lawyers and physicians are especially distinguished. Though the latter did not possess the same influence as the lawyers they nevertheless played a remarkable part in the stormy scenes of that stupendous new creation of Europe. Many of them entered into the hazardous career which often raised the lowest citizen to power and renown. Of some of them the names are engraved on the iron page of history; others are lost in the rolls of committees, directories, etc. Among the former are found, though in widely different degree and with widely different principles, MARAT, GUILLOTIN, CHAMBON DE MARVAUX, CABANIS, BAUDAT, BOUSQUIET, BOURRU, DUGERS, CLEDEL, MANNE, EUBOUCHET, SOUBERBIELLE, THIERY, FURCROY, LAVOISIER, PLISSIER, PLANCHARD-CHATTIERE, TAILLEFER, LARREY, PINEL, etc. The most luridly peculiar figure of these is that of MARAT who, previous to the time when deep sense of popular oppression so violently agitated his mind, was of a mild and peaceable temperament. He was devoted to science and ten or twelve works proceeded from his pen, witness his "Traité de l'Homme." Born in the neighborhood of Neufchatel, in Switzerland, MARAT practiced his profession in Paris. His name is inscribed in the books of the Faculty of Medicine in the year 1785. At that time he lived in the Rue de Bourgogne and was attached as veterinarian to the Duc d'Artois, afterward CHARLES X. MARAT was a thick, short man, with a degenerate face, restless with envy, pride and suspicion. A countenance expressive of a low uncompromising ferocity; withal his stature was unattractive and his manners inelegant. Yet his language and style were in singular contrast with what he always had hitherto been. The same man is hardly discernible in the author of the "Treatise on Medical Electricity," and the editor of that latterly rabid journal, *L'Ami du Peuple*. MARAT was a paranoiac degenerate. There was little in the early patience with which he bore insults from the aristocracy and the charlatans whom they promoted and

encouraged, to indicate the later development into that personification of the wild-beast spirit with which the mob met and conquered the aristocracy and plutocratic farmer-generals. MARAT'S first conflict with his brethren was about a management of phthisis practically based on lines which guide its treatment today. He brought it in professional manner before the Paris Academy of Medicine, but fiercely resented the attempt made to crush it in the interest of a wonder-working relic of a Paris church. LAVOISIER, the chemist, then a farmer-general, was not ashamed to engage in this intrigue, whence MARAT'S fierce denunciation of him as a quack. The neurotic taint in MARAT, such treatment naturally tended to develop. Of him, CARLYLE paints the following two vivid pictures, not destitute, however, of strong touches of caricature. At the States General (according to CARLYLE) MARAT thus appears:

"Surely also in some place, not of honor, stands or sprawls up, querulous, that he, too, though short, may see, one squalidest, bleared mortal, redolent of soot and horse drugs, JEAN PAUL MARAT of Neufchatel. O, MARAT, renovator of human science, lecturer on optics; O, thou remarkablest horse leech, once in D'Artois stables, as thy bleared soul looks forth through thy bleared, dull, acrid, woe-stricken face, what sees it in all this? Any faintest light of hope, like day spring after Nova Zembla night. Or is it but blue sulphur light and spectres; woe, suspicion, revenge without end!"

Of MARAT'S appearance at the fall of the Bastille, CARLYLE thus speaks:

"One poor troop of hussars has crept reconnoitering, cautiously along the quais as far as the Pont Neuf. 'We are come to join you,' said the captain, for the crowd seems shoreless. A large-headed, dwarfish individual of smoke-bleared aspect shambles forward, opening his blue lips, for there is sense in him, and croaks: 'Alight, then, and give up your arms.' The hussar captain is too happy to be escorted to the barriers and dismissed on parole. Who was the squat individual? Men answer: It is Dr. MARAT, author of the excellent pacific *Avis au Peuple*."

The same causes which revolted the French people against the English, the royal family and the aristocracy, treachery, fixed MARAT'S suspicious delusion. He suffered from a horrible dermatosis of the scrotum and perineum, which forced him to remain in his famous slipper bath for months together. It was in this bath he was stabbed by CHARLOTTE CORDAY. His body was conveyed to the Pantheon, but afterward at the Revolution of Thermidor thrown into the common sewer, where its winding-sheet was discovered by BRUNESSEAU when he inspected the sewers of Paris in 1805.

The lynch law of the French Revolution is embalmed, not in the name of MARAT, but in that of that most genial, most philanthropic, yet most ill-omenedly famous of men, Dr. GUILLOTIN. One of the most skilled sanitarians of his time, a pioneer in prison reform, a philanthropist shocked by the tortures of the public executioner, he sought to save pain by substituting the certainty of machinery for the uncer-

tainty and resultant brutality of a swordsman. His name in its horrible fame is likely to outlive CÆSAR'S. GUILLOTIN lived many years after the date of his discovery; nothing pained him more than its mention. Horrible recollections shook him, when, as sometimes happened, some mischievous fool addressed him with "Why, Doctor, how come you to have escaped—you know what death?" He died in 1814, of diabetic carbuncle on the left shoulder. Many sanitary reforms instituted by him still guide modern sanitation. His confrère, BOURRU, delivered his funeral oration. BOURRU, in 1793, re-baptized his two sons, one Hippocrates and the other Galen.

There was a curious similarity in fortune and skill between AMBROSE PARÉ and LARREY. The candid, able, modest Huguenot surgeon, who won the affection and esteem of the butcher of St. Bartholomew, CHARLES IX., resembles closely in clinical insight, in surgical skill, and in conscientious devotion to professional duty, LARREY, whom NAPOLEON I. characterized as the most virtuous man he ever knew. PARÉ, dressing the wounds of the victims of the "Bartholomew," and LARREY, dressing the wounds of the victims of the Moscou retreat, under snow, sleet and Cossack shot, are two equally pathetic pictures of professional devotion. Another pathetic picture is that of PINEL soliciting, amid the "Terror," from the potent Committee of Public Safety, permission to strike chains from the insane and thus inaugurate a reform in psychiatry which remained unaccomplished more than three-quarters of a century later in the progressive city of Chicago.

Among the other physicians remembered on account of medical practice only, is Dr. SOUBERBIELLE, who was physician during the Revolution to MARAT, ROBESPIERRE and DANTON. His case book disappeared during the Franco-Prussian War. CABANIS, an eminent physiologist, was friend and physician to MIRABEAU. LAVOISIER made up for his defense of faith-cure, by his exposure of mesmerism, of which CARLYLE ("French Revolution") draws the following picture:

"Observe Herr Doctor MESMER, in his spacious magnetic halls. Long-stoled, he walks, revered, glancing upward, as if in rapt commerce, an antique Egyptian hierophant in the new age. Soft music flits, breaking fitfully the sacred stillness. Around their magnetic mystery, which to the eye is mere tubs with water, sit breathlessly, with rod in hand, the circles of beauty and fashion, each circle a living circular passion flower, expecting the magnetic aflatus and new manufactured heaven-on-earth. O women, O men, great is your infidel faith. A parliamentary DUPONT, a BERGASSE, D'ESPREMENIL we notice there. Chemist BERTHOLLET, too, on the part of Monseigneur DE CHARTRES. Had not the Academy of Sciences, with its BAILLYS, JUSSIEUS, FRANKLINS and LAVOISIERS interfered. But it did interfere. MESMER may pocket his hard-earned money and withdraw."

This committee reported that mesmeric phenomena were the result of a subjective impression on the mind of the patient, and not due to a special force, August,

1784. Among the physicians of the time who should not be forgotten, especially by Americans, is Dr. MATTHEW LAURENT MICHEL MANNE. He was born in France, March 25, 1734, and became a navy surgeon in 1756. He followed Admiral d'ESTAING to America during the Revolutionary War and served throughout, fighting for American liberty. After the Revolution, he returned to France, where he became Surgeon-General to the Port of Toulon. He was a member of the Academy of Surgery and Commander of the Legion of Honor. He was the author of two valuable works, "Surgical Diseases of Bones," and "Fractures Dependent on Muscular Action." MANNE died March 19, 1806. The United States never even thanked him for his services to liberty.

"DR." RUTLAND IN THE TOILS.

It is with pleasure that we inform our readers that the Wisconsin Eclectic Medical College, so-called, and its proprietor, the alleged "Dr." FRED RUTLAND, have come to grief. "Dr." RUTLAND was arrested in Chicago last week, and held over in five thousand dollars bonds to appear before the federal grand jury of the Northern District of Illinois in answer to a charge of carrying on swindling through the United States mails:

For many months we had been in receipt, from time to time, from various members of the ASSOCIATION, of letters and circulars issued by this precious rascal, in which, in varying terms all more or less evasive, it was evident that diplomas were offered for sale at prices ranging from thirty-five to fifty dollars. We first induced one of the daily papers of Chicago to take the matter up. They sent a reporter to RUTLAND'S house, as already stated in a previous number of the JOURNAL. The circulars and letters continued to be sent, and in the meantime we submitted the case to the Postmaster of Chicago, and to Capt. STUART, the Postoffice Inspector, who detailed Inspector GOULD on the case. On conversation with this officer, we decided to allow one of the office boys of the JOURNAL to purchase a diploma, and he entered into correspondence with "Dr." RUTLAND to that effect. In due course of mail he received a circular signed by the said RUTLAND, in which it was stated it would be necessary for him to answer certain questions which were propounded. These questions were as follow:

EXAMINATION BLANK.

1. Give your name.
2. Have you ever studied medicine in any medical school or college?—If so, for how long and where.
3. Or under a preceptor or physician. If so give name or names.
4. Or in private studies. How and what books have you studied.
5. Have you ever practiced medicine either as a profession or otherwise?—For how long.
6. What system of medicine do you prefer? Allopath, Homeopath, Eclectic or other.
7. What do you understand by the term an element?
8. Define a chemical change.
9. Define the term Decomposition.
10. Define the term Materia Medica.
11. Define the term Therapeutics.
12. Define the term Pharmacy.
13. Define the term Toxicology.
14. Define the term Obstetrics.
15. Name say 30 or more remedies which you consider in the front rank as being of most service to man.
16. What is the

office and use of the Brain in the human anatomy and to what diseases is it most liable? 17. Same of the lungs. 18. Same of the heart. 19. Same of the Liver. 20. Same of the Spleen. 21. Same of the Kidneys. 22. Same of the Intestines. 23. Give an outline of how the bony frame work of the body is built up and name some of the more important bones. 24. Same of the Arterial and Venous system. 25. Same of the Nervous system. 26. Outline your treatment of Bronchitis, Cancer, Consumption, Diphtheria, Erysipelas, Fever (Scarlet), Measles, and any other troubles you have particularly studied or treated successfully. 27. What treatment would you give a case of poisoning by Belladonna, Digitalis, Chloroform, Carbolic acid, Nitric acid and Nit Silver? 28. What is a Tonic Medicine? 29. What is an Alternative? 30. What is an Antipyretic? 31. What is a Cathartic? Name 2 or more of each of these classes. 32. What is the first stage of childbirth? What is the second stage of childbirth? What is the third stage of childbirth? 33. How would you reduce a dislocation of the elbow joint? 34. How would you reduce a dislocation of the hip? 35. What is the essential difference between sterility and impotence? 36. Do you consider it good practice to administer as a regular thing such a class of medicine to a sick person which would under ordinary circumstances make a healthy person sick? 37. Give your ideas of what characteristics a physician should have to make him or her successful.

Do not make your answers on this blank. Use a separate sheet or sheets for this purpose. This blank must not be returned.

The following are the answers given by the applicant mentioned:

1, ———. 2, No. 3, No. 4, Only in a general way. 5, No. 6, Allopath. 7, A portion or part. 8, A change produced with aid of chemicals. 9, In state of decay. 10, Pertaining to medicines. 11, Healing remedies. 12, Drugs. 13, Science of poisons. 14, Childbirth. 15, Quinine, belladonna, opium, brandy, epsom salts, castor oil, laudanum, pepsin, tincture of arnica, mustard, Dover's powder, ginger, chloroform, ether, port wine, wormwood, iodine, whisky, tincture of iron, chloral, celery, coca, arsenic, extract of beef, cocain, kola, charcoal, codliver oil, vaselin. 16, Seat of intelligence, apoplexy, fever. 17, Breathing organs, consumption, pneumonia. 18, Circulates the blood, heart disease. 19, Strains the blood, liver complaint. 20, Use not fully known. 21, Secretion of urine, Bright's disease. 22, To digest food, dyspepsia. 23, The bony framework of the body is built up to protect the vital organs. Some of the more important bones are: skull, back, shoulder, hip and collar bones. 24, 25, 26, Treatment would vary according to severity of disease. 27, Warm water and salt, to cause vomiting, and then coffee or other stimulant. 28, Strength producing. 29, A change for the better. 30, Containing iron and sulphur. 31, Purgative. 32, 33, Force arm back into position and splint. 34, Force into place and bandage. 35, Sterility means barren and impotence the lack of sexual power. 36, No. 37, A constant endeavor to acquire more knowledge and the ability to make good use of what he or she already has.

The young man answered the questions so as to make them ridiculous as possible as he was entirely without technical knowledge. These being sent to RUTLAND, in due time a diploma bearing the coveted letters, "M.D.," was sent through the express office, C. O. D. As the young man had no particular use for the diploma, Inspector GOULD was immediately communicated with. Mr. AHNE, a young man from Wisconsin, acting on information published, it is said, in the *Tribune*, and under authority from Wisconsin, and the young man from the JOURNAL office, proceeded to RUTLAND's house in Chicago, where Mr. GOULD was introduced as a prospective student, and RUTLAND offered to sell him a diploma on reasonable terms. The interview ended, however, by RUTLAND accompanying the Inspector and his amateur assistants to United States Commissioner HUMPHREY's office, who, after a hearing, bound that worthy over to await the action of the grand jury under the sum of five thousand dollars.

The reason why a "fraud order" was not issued by the postoffice department, so as to stop the mail and circulars being sent, was that this would not prevent RUTLAND's carrying on his business through the express companies, and he would simply laugh at such an order and continue his infamous work. If, however, he becomes indicted by the grand jury, it will probably result in his speedy punishment; at least the machinery of the law has been set in motion in the proper direction.

The exposure of the books of "Dr." RUTLAND showed that he had issued his diplomas to a great many people. We print a partial list in another column.

Attorney-General MYLREA's suit in Madison, Wis., to annul the charter, came to an end March 8, by "Dr." RUTLAND's voluntary appearance and the filing with the Secretary of State of a formal notice of the dissolution of the corporation, the "Wisconsin Eclectic Medical College." This may possibly prevent his incarceration, but we shall see.

TWELFTH INTERNATIONAL MEDICAL CONGRESS.

Professor NICHOLAS SENN of Chicago has accepted an invitation to deliver the address on Surgery at Moscow. We are not advised who will give the other addresses. These orations have always been considered as the higher professional honors of the Congress.

CORRESPONDENCE.

Acute Otitis Media.

PERU, IND., March 8, 1897.

To the Editor:—In the case of acute otitis media in the person of Dr. Merrill Hopkinson of Baltimore, and reported by him in the February 27 number of our JOURNAL, the course of his ailment, infection of the middle ear by the product of a mild attack of post-nasal catarrh, after using a nasal douche, by forcibly blowing the nose, and his treatment as outlined by him does not occur to me to harmonize very well, even though he considered that his treatment obtained good results.

In the first place, if his ear was infected as he states, and by the product he mentions, the indications would have been to use a Eustachian catheter in connection with an air-bag, and have blown out the offending substance, instead of continuing to jeopardize his sound ear as well as the crippled one by holding the nose and inflating the ears in the same manner, and with the product of the acute catarrh in the post-nasal, as when the ear was first infected, as he says he did. In the second place heat and moisture are both essential to suppuration, and by using this combination he favored that condition; whereas he should have used dry heat, the hot water-bag or salt-sack, which would have burned the moisture of the involved tissue and epithelium, thereby lessening the pressure and in consequence the pain. The temporary relief from pain that he obtained from the use of the hot water as described, was from the heat alone, and the increased pain following the relief was due in a measure to the over-supply of moisture.

Thirdly, the temporary relief he obtained following his dose of pilocarpin, was due to the relaxation, partially from the shock it caused the system through the cardiac center, and partially through the diaphoretic effect (which effect is very

closely connected with the shock as mentioned above), and thereby removing the local pressure by lessening the fluid and hindering the blood supply by this drug's action on the heart center.

Now as to his recovery. His infecting substance, even though it might have been the catarrhal product (but was probably only a drop or more of the fluid he had been using) was not of a pus-producing character, and therefore we would have scarcely expected suppuration even under more unfavorable treatment than was used. He states that upon the eighth day the inflammation subsided rapidly, which I would suggest is about the usual course of all simple inflammations of like character, regardless of treatment. After the process of such an inflammation has once fully begun it passes through the three steps of engorgement, deposit and resolution, which requires ordinarily from six to ten days as in acute tonsillitis, etc.

Now, as to what the Doctor should be mindful of concerning his ear. Just such cases are the ones that most often lead to defective hearing, and once fully crippled by the process so many times following such inflammations, it is the most difficult to restore.

The preventive treatment then should be occasional mobilization of the drum membrane and ossicles together with the use of the Eustachian catheter and air-bag. This will prevent the ankylosis of the ossicles and stiffening of the drum membrane and the closing by adhesion of the Eustachian tube.

J. O. MALSBUY, M.D.

PITTSBURG, PA., March 5, 1897.

To the Editor:—The instructive report of a case of acute otitis media in the JOURNAL of Feb. 27, 1897, by Dr. B. Merrill Hopkinson of Baltimore, Md., in which he figured and suffered as a patient, leads me to give to the readers of the JOURNAL some instructions that I have for many years carefully enjoined upon patients and the profession who use the nasal douche in any form, viz., *to blow one side of the nose only at a time* after using the douche or after snuffing fluids up into the nares. It is a physical law that fluids will pass always in the direction of the least resistance. Hence, if one naris is left open as must be done to blow it in this manner, it is quite impossible to blow fluids into the Eustachian tube and thereby set up an acute otitis media and nearly all the cases of that very painful character in my practice have been caused by a disregard of this simple injunction. "Blow only one side of the nose at a time" is well worthy of attention, not alone after the use of the douche but at all times, since it is the most efficient means of not only cleansing the parts, but is nearly free from the possibility of causing dizziness and entrance of fluids into the Eustachian Tube with all the attendant evils.

I can not refrain from using this opportunity to speak of the charming sketch of a country doctor in the same issue of the JOURNAL by Dr. Thos. H. Shastid of Galesburg, Ill. It is quite worthy a place beside the lovely character portrayed by Ian McLaren in the "Bonnie Brier Bush," and the portrayal is quite as touching to one's better nature. And now, Mr. Editor, while paying compliments I feel that much is due you for the uniform improvement of our JOURNAL in all its departments. It is now the best journal in America and while its capabilities are still not all developed, they are making a headway that no one can fail to notice.

W. H. DALY, M.D.

Foreign Products Advertised.

NEW YORK, Feb. 25, 1897.

To the Editor:—For the life of me I can not see how some of our practitioners can legitimately maintain the position which they occupy. They will refuse to prescribe "mercauro" for example because it is proprietary, notwithstanding its for-

mula was long ago published in the JOURNAL, while on the other hand they will not only prescribe, but will write about and talk about foreign products which are not only proprietary in the fullest and widest acceptation of the term, but are also patented, yes, absolutely patented! These foreign products come to this country and the owners of the products will flood this country with all sorts of extracts from supposed foreign journals, and will quote high-sounding foreign names of medical practitioners. The physicians of this country swallow the whole story, use the products and then the American journals go ahead and print clinical reports regarding them. This matter strikes me as being an injustice to American progress in chemistry and therapeutics. Here we have products which have been heretofore considered chemic impossibilities, yet we have been able to produce them, in spite of the fact that chemic literature states that they can not be made. It strikes us that we should be commended for this progress and not condemned. It strikes me that we should at least be upon an equal footing with the foreign products, for we are Americans, this is America, the patients upon whom the products are used are Americans and the large proportion of physicians can be called Americans. I can not see why a foreign product should be received with open arms and taken into the ethical fold, when everything in connection with that product is doubly at odds with the code of ethics. Yet the foreign product is received with open arms, while ours is branded as the "yellow dog." This is really a serious subject and is getting more and more serious. The foreigners have a big advantage over us under the existing circumstances, for the manufacturers go ahead and make their own statements, attribute them to some doctor with a foreign name, resort to all sorts of measures to have the articles quoted, and I am sorry to say that they meet with success. I am not opposed to competition, on the contrary I am glad to see it, but I don't call it competition where one man is thrown upon the ground and tied hand and foot, and his opponent free handed is allowed to hammer him to death. I certainly feel that this subject is worthy of full discussion and comment, and would indeed appreciate the receipt of a letter from you stating your views upon the subject. With kindest regards, believe me

Cordially yours,

AN AMERICAN MANUFACTURER.

Modern Immorality.

CONANT, FLA., March 2, 1897.

To the Editor:—Dr. E. S. Bullock, in the New York *Poly-clinic* and Dr. A. R. Reynolds, in the JOURNAL, discuss the moral condition of the nation and its bearing on the future well-being of our people with varying degrees of apprehension. Each looks to the new woman as the one best fitted to take the case in hand.

From various recent publications the following quotations are gathered: "Hoodlums that glory in being 'toughs' are thicker on American soil than on any other spot on the crust of the planet." "Masturbation is well-nigh universal" among our boys and youth. Syphilis has spread until "the question is not who has but who has not" the disease. "Fifteen per cent. of all diseases of women, exclusive of prostitutes, are caused by gonorrhoea and its sequelae." "A moral nature so finely developed that it will not permit its owner to enter into the marriage state, bearing the seeds of possible direful results to wife and family, is not common among men." "Not one woman in twenty escapes solicitation" for her ruin. "Ninety out of every one hundred men cohabit with women before marriage." "City children soak and blacken soul and sense in city slime," and "human nature is no better out among the farms." "The country school grounds often prove slippery places for young feet." "Crime and hunger casts our maidens by the thousands on the streets." "If it is all true,

then American society is suspended over an abyss and it will require the engineering skill of the best elements in church and State to keep us from falling into depths of distress." If any part of it is true, then the disease is in the system and "the treatment must be constitutional and radical and preventive."

The new woman does not care to pose as a reformer, much less as a martyr, but her pledge demands of her that she endeavor to do the "whatsoever" and to follow her leader, the Healer of Gennesaret, even to the cross, but does not every manly instinct cry out against sending our virgin daughters to face Sodom and Gomorrah? God pity that people whose women stand alone against the fiercest, the most implacable, as well as the most insidious foe that ever assailed home and country. Until men and women together, with the little child in the midst and the stranger within our gates as well "hear and learn and observe to do all the laws" of that only perfect sanitary code ever formulated, written in the books of Moses so plain that a wayfaring man, though a fool, need not err therein, written in the very substance of our normal being so that violation of them brings the penalty in weakness and pain. Until we teach them diligently, father, mother, priest and doctor, to our children from the time they "know not anything" the full counsels of the God who created their bodies, we are in danger.

The story of Onan and of Baal-peor; of Eli and David and of Herodias' daughter, are not without their parallels today. If we are ashamed of and forsake the words of life, life and health will forsake us as surely as they did Canaan or Israel. When we read of a Pearl Bryan and think of the young girls unprotected by law after the age of legal consent from the wiles of the deceiver, who blights heart and soul as well as body, a crime tenfold more heinous than he commits who only destroys the body by violence. Does Jeremiah seem unmanly weeping for the slain of the daughters of his people? When we realize that from heredity, the seed of wild oats, or "the transmission of lust from unrestrained licentiousness in wedlock," little blistered feet that never walked are hastening to the grave; and infants of tender years in homes where we least expect it are children who are corrupters. What man worthy of the name will say hush! hush! to Isaiah's call: "Lift up thy voice like a trumpet and show my people their transgressions?"

When, in our practice, a young wife is fallen down at the door of her married home, fit subject for the surgeon's knife, what Christian physician but thinks of Benjamin destroyed, of Jabesh-Gilead smitten and forty thousand of Israel slain to right one woman's wrong? Not one husband's conscience, but our whole social system is at fault that our daughters, yes, and our sons, are not afforded the protection which was given the slaves from diseases more loathsome and persistent than smallpox and the plague.

"Is there no balm in Gilead? Is there no physician there? Why, then, is not the health of the daughter of my people recovered?"

W. O. E.

"Mirror Speech."

DENVER, COLO., Feb. 21, 1897.

To the Editor:—In the editorial comments of the issue of the JOURNAL for Dec. 19, 1896, page 1307, you have a paragraph on "Mirror Speech," quoted from the Bulletin of the *Progrès Médical*, November 28; you do not state where the little patient was rephined, whether on the left or right side of the head or over what portion of the hemisphere.

I have been engaged in working up speech defects of late and in one case; cyst of the brain, there was a transposition of the letters of words. The patient talked nearly normally, but writing was almost unintelligible from the transposition of the letters, but it was not "mirror speech." I will mail you a

reprint of six cases of speech defect. The one that I refer to is the fourth case of the series.

I shall feel greatly obliged for any additional facts in Baudouin's cases. I am

Yours truly,

J. T. ESKRIDGE, M.D.

Cretinism in America.

BALTIMORE, MD., March 5, 1897.

To the Editor:—Will you kindly allow me the use of your columns to ask for information on the subject of cretinism in America? I have been detailed by the Pediatric Society to take part in the discussion on *Internal Secretions* at the Congress of American Physicians and Surgeons in Washington, on May 5, and I am anxious to present the experience of American physicians on the use of the thyroid extract in the treatment of cretinism. I wish brief statements, 1, of the name, age and sex of the patients; 2, of the length of time the thyroid extract has been given, and with what results; 3, whether any case cured by treatment has been able subsequently to abandon the use of the extract; and I would also like to have photographs showing the effects of the treatment.

I shall give full credit to any of my colleagues for the information they may kindly furnish.

Very truly yours, WILLIAM OSLER, M.D.

1 W. Franklin Street.

P.S.—I have the details of the cases already published in this country, but shall be glad of any additional data as to the subsequent history.

Manufacturers in the Secular Press.

DULUTH, MINN., March 3, 1897.

To the Editor:—Permit me through your columns to call the attention of the regular profession throughout the United States to the fact that McKesson & Robbins of New York, hitherto considered by medical practitioners a reputable firm, have recently adopted the methods of the patent medicine vendors in putting upon the market a remedy for the cure of a certain disease and advertising the same to the general public through the secular press, as witness the following from the *Literary Digest* of Feb. 20, 1897.

This speaks for itself, and should not be allowed to pass unnoticed by the profession at large, to which this house is looking chiefly for support.

Yours truly, W. S. FULLERTON, M.D.

"TARTARLITHINE, the new cure for rheumatism. L. E. B., Clifton Hotel, Ottawa, Ill., writes: 'On Sunday, April 5, 1896, I was introduced to a citizen of this city who had not been able to raise his hand to his head for several weeks on account of rheumatism. He called on me one week later, and told me that after taking Tartarlithine for only one week, the improvement in him was truly phenomenal. In two weeks he was practically cured.' Pamphlet on the cure of Rheumatism by Tartarlithine sent free by McKesson & Robbins, Manufacturing Chemists, 95 Fulton Street, New York.'

PUBLIC HEALTH.

Pay for New York Village Boards of Health.—Chapter 430 of the New York Laws of 1895 provides that the members of boards of health in incorporated villages shall be entitled to receive for the services rendered by them such fair and reasonable compensation as shall be fixed by the boards of trustees, which latter are empowered to appropriate annually a sum not exceeding \$500 for such purpose. Under this law, the appellate division of the supreme court of New York holds, *People v. Board of Trustees of Village of Haverstraw*, Dec. 31, 1896, that a member of such a board of health, whose term of office did not begin until after the statute went into effect, is entitled to such fair and reasonable compensation as the board of trustees shall fix, notwithstanding there was no appropriation therefor

made before his services were rendered. It might well happen, says the court, that, in the work done by a village board of health, the value of the services could be judged much more accurately after they were performed than in advance of their rendition; and in such cases, it adds, that it can see no valid objection to paying for them by means of an express appropriation subsequently made. For non-action on the part of a board of trustees, in declining to fix a fair and reasonable compensation, it further holds that the appropriate remedy would seem to be a proceeding by mandamus.

On the Consumption of Tuberculous Meat.—It may be remarked that in Germany, to prevent the heavy loss that would attend the condemnation and withdrawal from the food supply of the flesh of animals affected with tuberculosis, it has been proposed to cook such flesh in apparatus attached to the public abattoirs, by means of superheated steam and then allow it to be issued for consumption. Already there is at least one cooking apparatus in operation at Berlin, that of Dr. Rohrbeck, and in all probability there will soon be many more at work. Thorough cooking at a high temperature will no doubt render the consumption of such flesh quite safe and it will prove a boon to the poor, as it will be sold at a low price and require no further preparation, a matter of some moment when fuel is expensive.—London *Lancet*.

Violent Deaths in 1895.—The alarming increase in the number of murders and suicides in this country is shown from statistics recently collated as they relate to 1895 compared with preceding years: From these it appears that the number of murders (including homicide) in the United States attained last year the unprecedented figure of 10,500, as compared with 9,800 in 1894, 4,290 in 1890, and 1,808 in 1885. Hence, the increase of homicidal crime is of a most rapid and serious nature. The suicides in 1895 numbered 5,750, as compared with 4,912 in 1894, 2,040 in 1890, and 978 in 1885. The legal executions in 1895 were 132, being the same as in 1894, whereas in 1890 they were 102, and 108 in 1885. The "lynchings" or illegal executions were 171 in 1895, as compared with 194 in 1894, 127 in 1890, and 108 in 1885. Hence there was a decrease of 23 last year as compared with 1894. But both as regards legal and illegal executions in the United States there is an extraordinary difference between the ratio of increase in the two classes and the amazingly rapid development of murder of recent years. Thus, the combined legal and illegal executions for the 1,808 murders in the year 1885 were 289, or nearly as many as the combined number (303) for the 10,500 murders in 1895.—Chicago *Tribune*.

Austrian Commission to Investigate the Plague in India.—The Imperial Royal Academy of Sciences has employed a portion of the Treitel Fund in sending a commission, composed of Dr. Hermann Müller, Dr. Ghon, Dr. Albrecht and Dr. Pösch, to investigate the nature of the bubonic disease now prevailing in India. Dr. Müller is assistant to Professor Nothnagel and is one of the most distinguished of our young medical men. He was born in Gratz in 1860, took the M.D. degree in Vienna at the age of 24 years and was for three years assistant to Professor Ziemssen of Munich. He is at the head of the expedition and is specially charged with the observation of the clinical features of the disease; the postmortem examinations will be performed by Dr. Albrecht, who is at the present moment assistant to Professor Weichselbaum. The bacteriologic examinations are to be made by Dr. Ghon, who is also assistant to Professor Weichselbaum and is well known to the medical world by some publications on bacteriology. Dr. Pösch, attached to the clinic of Professor Neusser, is the junior member of the commission; he is a very able photographer and will assist his colleagues generally. The four medical men set out from Trieste on February 3 and will remain at Bombay for three or four months. On January 29 they were received by Baron Gautsch, Minis-

ter of Public Instruction, who complimented them upon their courage and wished them much success in their inquiries. The Treitel Fund is so called after the late Herr Treitel, a Vienna citizen, who bequeathed to the academy all his fortune, amounting to about \$500,000.

The Sickness Rate in Germany.—If national health is national wealth, then individual wealth is the politically important unit of measure. This is emphasized in an interesting and "taking" way in the introduction to a handbook that is published by the Imperial Department of Health of the German Government. "The health of man is a precious possession. Its loss causes harm not only to the individual, but also to the community. The individual whose health is impaired suffers discomfort or pain, or both. He loses his ability to work or to earn a living and impairs his enjoyment of the pleasures of life. He must incur expense in order to regain his health, and anxiety and poverty are the results, both to himself and to his family. By the decrease of its productive labor the community suffers loss in its industries and incurs expense in the support of the sick; and when, as often happens, the sick man is attacked with an infectious disease, he becomes a danger to his neighbors. The extent of the loss arising from the impairment of health can be estimated from the returns of the workingmen's sick clubs of Germany. In 1891, out of a total membership of 6,500,000 more than 2,000,000 cases of illness occurred, each of which averaged seventeen days in duration. These clubs paid in medical expenses \$22,000,000. Since it may be assumed that among the remaining 44,000,000 of the German population, 24,000,000 of whom are old enough to work, the cases of illness were as numerous and as long-continued as among the members of these clubs, the expense caused by sickness in Germany in 1891 is not placed too high at \$120,000,000. The loss incurred by stoppage of wages is not included in this sum. The preservation and promotion of the health of mankind is the aim of hygiene. Among the tasks which it proposes are the prevention, limitation and removal of sickness and disease, and the preservation and prolongation of the ability to work and of man's life in general."

Researches Regarding the Rinderpest Bacillus and Antitoxin in India.—An Indian authority on the subject of rinderpest as it exists in the Bengal Presidency writes as follows: If the rinderpest in Africa is the same as that going under the name of rinderpest in India, then Professor Koch is going to search for a bacillus which Dr. Simpson, the well-known medical officer of health of Calcutta, has had in his possession for more than two years. The organism is a sporeless motile bacillus which can grow both with and without air, but gradually becomes attenuated by repeated growths in air. Dr. Simpson saw Professor Koch in Berlin last May and communicated to him the nature of his discovery. He was unable to show his cultures, having left them in London with Professor Klein a few weeks before. Since his return to Calcutta, Dr. Simpson has continued his inoculation experiments and has injected in larger and larger doses cultures of the diplo-bacterium into horses and cows, and has now reached over one hundred days. In the horse, troublesome abscesses were produced which led to emaciation, but the cow is not subject to abscesses, and Dr. Simpson is now inoculating cultures of the microorganism and toxins as well. The toxins produce very large swellings and have raised the temperature considerably, but he is able to give doses of cultures and toxins which would kill five animals without more than a temporary rise in temperature, and he hopes in the course of another month to have ready a supply of antitoxin which will possess a bactericidal power as well. Some regret is felt that application was made to a foreign specialist, even one so peculiarly competent as Dr. Koch; and that Dr. Simpson, who has been studying the subject, should not have had a chance of carrying on the work, which is of vital importance. There are no

epidemics of the kind in Calcutta, and hence opportunities are wanting there. Much interest was shown by eminent bacteriologists in England during Dr. Simpson's late visit here.—*British Medical Journal*, December 26.

Typhoid Fever at Paterson, N. J.—A Paterson paper has stated that twelve cases of typhoid fever have been known to occur along the line of the Passaic River above the intake of the water supply, and in the absence of better evidence these cases may be taken as the starting point of Paterson's epidemic of fever. Between September and the middle of December there had been reported 155 cases, while in the corresponding period of 1895 the number had not exceeded 57. As all the evidence pointed to the water supply as the agent of infection, Dr. Leal made a thorough inquiry, in order that the extent and the source of the pollution might be ascertained. He says: "I caused chemic and bacteriologic examination of the waters of the river to be made, and investigated all known or suspected cases of typhoid in the drainage area of the Passaic above our intake. The examinations showed the river to be free from pollution and to be possessed of the normal amount of bacterial life at a certain point. Below that point and down to the intake, evidences of sewage pollution were found and the bacterial life was enormously increased. The common colon bacilli were found and also colonies of what are believed to be the bacilli of typhoid. The investigation into the cases and suspected cases along the river disclosed what I believe was a case of typhoid at the point where the river first showed the evidence of pollution. The drainage from the home of the patient was directly into the river. If the patient's disease was typhoid, it would scientifically account for 98 per cent. of our cases of the disease, and that it was typhoid, a chain of circumstantial evidence unerringly indicates." This prevalence adds another to the long list of typhoid epidemics caused by the infection of public water supplies. In many instances the infection was derived from only one case of the disease. It is plain enough that the people of Paterson will be exposed to typhoid infection proceeding from cases of the fever in the drainage area just above the intake of the water works until the city shall have obtained and exercised the power to guard the sources of its supply or shall have purified by filtration the water received from the river. As it will not be an easy matter either to procure the needed power or to exercise it effectively, the municipal authorities should consider the expediency of resorting to filtration.

Public Water Supplies of Illinois.—The following memorial and bill has been sent to the members of the Illinois Legislature. The accompanying draft of a bill for the protection of public water supplies of the State, and the regulation of the disposal of sewage has been prepared by Joint Committee:

Dr. John A. Vincent, Springfield; Dr. Julius Kohl, Belleville; Dr. J. W. Scott, Springfield, representing the State Board of Health. Prof. Arthur N. Talbot, C.E., Champlain, Ill.; Prof. A. W. Palmer, representing the University of Illinois. Dr. O. B. Will, Peoria, Ill.; Dr. L. L. Gregory, 514 Evanston Avenue, Chicago, Ill., representing the Illinois State Medical Society. Mr. John Ericson, C.E., City Hall, Chicago, Ill.; Col. R. O. S. Burge, 6318 Stony Island Avenue, Chicago, Ill., representing the Western Society of Engineers. Mr. D. W. Mead, C.E., Rockford, Ill.; Mr. John W. Alvord, C.E., 1140 Rookery, Chicago, Ill.; Mr. Jacob A. Harmon, C.E., Peoria, Ill. (Arcade Building), representing the Illinois Society of Engineers and Surveyors. Dr. J. R. Dunham, Wenona, Ill.; Dr. H. M. Bascom, Ottawa, Ill., representing the Illinois Homeopathic Medical Association. Dr. G. R. Shafer, Morton, Ill.; Dr. Henry Wolgemuth, Springfield, Ill., representing the Illinois State Eclectic Medical Society. The appointment of this committee and the drafting by them of the bill grew out of a discussion by the Illinois Society of Engineers and Surveyors at its last annual meeting at Peoria. It is not necessary to enter extensively into a discussion of the benefits which would result from the enactment of this law. The results of such supervision and control in other States where such laws are in force, and a glance at a few statistics giving the results

following the improvement of water supplies and sewerage in the reduction of the mortality of typhoid fever alone, which is preëminently a disease produced by impure water and bad sewerage, will suffice. Twelve leading cities of Europe show deaths from typhoid fever before the introduction of a proper water supply and sewerage to have been 10.7 among 10,000 of population per annum; after such introduction, 3.5 per annum. Fifty European and American cities having no sewerage and water supply systems, or insufficient ones, show about 10 deaths per 10,000 living, while an equal number in cities having proper water supplies and sewerage systems, the number is but 2.4 per annum. The following table shows the average typhoid death rate for a period of five years, ending May, 1893, for six towns on the Merrimac River in Massachusetts: Manchester 2.95; Nashua 4.77; Lowell 10.66; Lawrence 12.72; Haverhill 3.63; Newburyport 3.60. Of these towns, Lowell and Lawrence use polluted river water and the others have pure supplies. During 1893 a filter plant was added to the Lawrence system, and in 1894 the rate was reduced to 5.00, and in 1895 to 3.07 per annum of 10,000 living. What is true of typhoid fever is true of other filth diseases. It will doubtless be conceded that each municipality within this State when confronted with the necessity of providing a water supply or system of sewerage for its people is desirous of having the problem solved in a proper and scientific manner, and if an authority on this subject were known, it would gladly seek advice therefrom. The State Board of Health being charged with the care of the health of the citizens of the State, is such an authority as should be sought in matters of this character, and it is believed by the committee which has prepared the accompanying bill, that its provisions will enable the State Board of Health to meet the exacting requirements of such a responsibility. In the furtherance of the cause of this bill, the aid is earnestly requested of every citizen of this State, who believes that its passage will in a measure accomplish the purposes desired. If it be brought to the attention of each member of the State Legislature, and its purposes and benefits briefly and clearly set forth, it would seem as though it should be unanimously passed at a very early date.

A BILL

For an Act imposing additional duties and conferring additional authority upon the State Board of Health, with reference to public water supplies and sewerage of this State.

SECTION 1.—Be it enacted by the people of the State of Illinois, represented in the General Assembly; That in order to materially promote the public health, the State Board of Health of the State of Illinois be and is hereby charged with the sanitary supervision and control of all sources of public water supply, both surface and underground, within the resources of this State, which are or may be used for domestic and culinary purposes, that said Board be and is hereby charged with the supervision and control of the methods and means of collection and disposal of sewage within this State; that the said Board be and is hereby authorized and directed to make such rules and regulations as may be necessary to enforce the provisions of this act.

SEC. 2.—No system of sewerage, or system of public water supply, shall be constructed, extended or changed by any city, village or town in this State, or by any corporation, person or persons, until the plans and specifications for such system of sewerage or system of public water supply or proposed extension or change thereof shall have been submitted to the State Board of Health and received its approval. In addition to the approval of the plans for the development of public water supplies, the State Board of Health shall examine and cause to be made, analyses of the waters from the source or sources of supply, and determine their fitness for domestic and culinary purposes before such waters shall be delivered to customers. A certificate of the finding of the Board shall be issued without delay to the municipality, corporation, person or persons, submitting plans or water for approval, which certificate shall be signed by the President of the Board and attested by the Secretary with the seal of the Board.

SEC. 3.—All analyses of water or sewage required by the State Board of Health under the provisions of this act shall be made at the laboratories of the State University at Urbana by the proper officer or officers in charge of such laboratories, and the sworn statement of the result of such analyses, under the seal of the University, shall be competent evidence in the courts and shall be prima facie evidence of the matters therein stated, so far as relating to the existing conditions of the water or sewage analyzed.

SEC. 4.—Every general rule or regulation made by the State Board of Health under this act shall be published at least once each week for three consecutive weeks in at least one newspaper in each county of this State. All special rules, regulations and instructions for any particular city or village shall be published once in a newspaper of such city or village to be affected thereby, or if no newspaper is published therein, then by posting copies in such city or village to be affected thereby.

SEC. 5.—The affidavit of the printer, publisher, or proprietor of the newspaper in which such rules, regulations or instructions are published, and the affidavit of the person posting the same, with the rules and regulations or conditions so published or posted, shall be filed in the County Clerk's office of such county, and with the State Board of Health. A copy of such affidavit, rule, regulation or instruction, certified by the county clerk, or Secretary of the State Board of Health, in whose office the same are filed, shall be conclusive evidence of such publication or posting, and of all the material facts therein stated in all courts and places.

SEC. 6.—The State Board of Health is hereby authorized to make such inspection as may be necessary to determine whether its rules, regulations and instructions under this act are complied with; and if any such inspection discloses any violation of any such rule or regulation, the Secretary of the said Board shall cause a copy of the rule, regulation

or instruction to be served upon the person or persons, corporation or municipality, violating the same, with notice of such violation, and if such person or persons, corporation or municipality, shall fail to comply with such rule, regulation or instruction, or fail to show cause satisfactory to the State Board of Health why the same should not be enforced within ten days after the service of such notice, the State Board of Health may maintain an action before any justice of the peace of the county in which such violation occurs, or in any court of record of the said county, against such person or persons, corporation or municipality for the recovery of the penalties hereinafter prescribed for such violation, and may also, upon a proper showing, have an injunction, without bond, restraining such person or persons, corporation or municipality, from the continued violation of such rules, regulations or conditions.

Sec. 7.—The penalties for the violation of or non-compliance with the provisions of this act, or the rules and regulations of the State Board of Health which may be promulgated under this act, shall not be less than fifty dollars nor more than two hundred dollars for each and every violation and non-compliance; an additional penalty of ten dollars per day shall be imposed for each day that said violation of or non-compliance with shall be continued after conviction thereof; said penalties to be recovered as provided in Section 6.

Sec. 8.—The State Board of Health shall, at its annual meeting each year, elect a consulting sanitary engineer, whose term of office shall be for one year and who shall serve until his successor shall be elected and qualified. It shall be the duty of said engineer, under the direction of said Board, to examine all plans for the construction of proposed systems of sewerage, public water supply, and extensions or changes thereof, and to perform such duties in the line of his profession as may be assigned to him by the Board; to make report to the secretary before the regular quarterly meeting of the Board of all inspections made by him; for which services he shall be paid a sum not to exceed dollars per annum, to be paid out of the regular appropriations of the Board. PROVIDED, That as soon as may be expedient after this act shall become a law the State Board of Health shall assemble and elect its sanitary engineer, who shall serve until the next annual meeting and until his successor shall be elected and qualified.

Sec. 9.—The State Board of Health shall annually, at the stated time for other reports of said Board, report to the Governor of the State, all of its acts with reference to the provisions of this act, and such reports shall be published the same as other public documents.

Sec. 10.—The provisions of this act shall not apply to any city of the first class in this State.

Sec. 11.—Since an emergency exists in that various municipalities throughout the State may desire the approval of plans so that work may be carried out during the summer and autumn of 1897, this act shall be in effect from and after its passage and approval.

BOOK NOTICES.

The Year-book of Treatment for 1897. A Critical Review for Practitioners of Medicine and Surgery. Crown octavo, pp. 448. Cloth, \$1.50. Philadelphia and New York: Lea Brothers & Co. 1897.

This is the work of twenty-six well-known British authorities, and the thirteenth year of the annual. That it has come to stay is self-evident, as it is one of the most useful of the various digests. The work covers the whole domain of practical medicine. Its very moderate price puts it within the reach of all.

Principles or Guides for a better Selection or Classification of Consumptives Amenable to High Altitude Treatment, and to the Selection of Patients who may be more Successfully Treated in the Environment to which they were Accustomed Previous to their Illness. By EDGAR A. TUSSEY, M.D. Philadelphia: P. Blakiston, Son & Co. 1896. Price \$1.50.

In a book of 141 pages the author has given us a work of immense practical value. The very questions that arise in the mind of the general practitioner with regard to the choice of climate for his consumptive patients, will be found here answered without bias. The work, however, does not stop there, for the author takes occasion to scourge the users of alcohol, and to point out the insidious sapping of the vital forces by the use of alcohol even in limited quantities.

A Pictorial Atlas of Skin Diseases and Syphilitic Affections in Photolithochromes from Models in the Museum of the Saint Louis Hospital, Paris, with explanatory woodcuts and text by Ernest Besnier, A. Fournier, Tenneson, Hallopeau, Du Castel, Henri Foulard and L. Jacquet. Edited and annotated by J. J. PRINGLE. Part VII. London: The Rebman Publishing Co.; Philadelphia: W. B. Saunders. 1897. Price \$3 per part.

We have so often written in praise of this magnificent work, that it is needless to say more than that each number increases our admiration. The present fasciculus contains Plates XXV to XXVIII inclusive, with explanatory text. The number of pages has now reached 174. The contents are: Eruption from Potassium Bromid, Hypertrophic Papular Syphilides, Rupoid and Early Gangrenous Syphilides, Gangrenous Syphilides, 1, tubercle gangrenous syphilides; 2, gangrenous gumma.

The American Year-book of Medicine and Surgery. Edited by GEORGE M. GOULD, A.M., M.D., assisted by eminent American physicians and teachers. Profusely Illustrated. 8vo, cl., pp. 1258. Philadelphia: W. B. Saunders. 1897. For sale by subscription only, price \$6.50.

This year-book is one of the best published in any language. The vast literature of the year has here been culled and condensed, and judicious criticisms written upon the topics included in the scope of the work. Those fortunate enough to have the last year's volume, will know better than any one else how to appreciate this one.

Dr. L. A. Duhring has been appointed to the department of dermatology, vice Dr. Hardaway, resigned. The editor-in-chief has not hesitated to pass his judgment on the value of most of the proposed discoveries and improvements noted in the volume, and in the main we see little to dissent from in them.

Hyde on the Skin. A Practical Treatise on Diseases of the Skin. For the use of Students and Practitioners. By J. NEVINS HYDE, A.M., M.D., Professor of Dermatology and Venereal Diseases in Rush Medical College, Chicago, and FRANK H. MONTGOMERY, M.D., Lecturer on Dermatology and Venereal Diseases, Rush Medical College, Chicago. New (fourth) edition. In one octavo volume of 815 pages, with 110 engravings and twelve full-page plates, four of which are colored. Cloth, \$5.25; leather, \$6.25. Philadelphia and New York: Lea Brothers & Co. 1897.

The exhaustion of the third edition of this work within so short a time after its publication, and the appearance of this fourth edition, afford gratifying evidence of the value of the work to the profession. This revision is a conscientious one. Old chapters have been rewritten, new ones added, and critical corrections have been made where necessary to bring the work to correspond in all respects to the recent progress in dermatology.

The enormous number of cases annually appearing at Professor Hyde's clinic, makes it possible for him to write from the standpoint of a clinician of unsurpassed opportunities for observation. That he has used his clinical opportunities to the best advantage is apparent from a perusal of the book.

ASSOCIATION NEWS.

The Journal Special Train will leave Chicago Sunday, May 30, over the Pennsylvania Line, direct to Philadelphia without change.

Railroad Rates.—The Committee of Arrangements had several meetings for arranging the work, of which I was not advised. When accidentally learning of it I asked Dr. Hare to keep me posted that I might be able to reply to questions, and since then I have been invited to all the meetings of the Committee. But already Dr. E. E. Montgomery had been assigned to the railroad work, and had arranged with them as to the rate. This was as early as last December. Of course I did not propose to put my request before the roads till the opening of the year as they always insist that it is too early to consider such work till the year comes in. From what I can learn Dr. M., has done all he could to obtain one fare. When on a previous occasion I put before the roads the fact that the G. A. R. and the Y. M. C. A., etc., can obtain one fare the excuse is that these are so much larger, etc. However, under the idea just observed in the JOURNAL that we should have more time before and after the meeting, I will reopen the matter personally and endeavor to get better terms. Please ask the profession throughout the country to bring any influence they may have to bear on the powers in the railroad pool. Also, ask the delegates and all who expect to be with us to give me notice as we are anxious to be fully provided for all. The wild idea is now that we shall have 3,000 registered, without taking thought of those who will accompany them as wives, etc.

W. B. ATKINSON, M.D., Secretary.

Intussusception in Children.—Dr. Edward Martin, 222 South 15th Street, Philadelphia, desires answers to the following questions for an ASSOCIATION paper in preparation: Intussusception in children under 12 years; seen by Dr.; in personal practice; in consultation; age of patients; cause of intussusception (polyp?); symptoms (tumor, passage of bloody mucus, tenesmus, vomiting, intense pain); treatment, medical with result, mechanical (injection of air, water, massage), result; period elapsing from first symptom to mechanical treatment. Operative (disinvagination through abdominal opening) result; resection, result; seat of invagination; amount of bowel resected; method of joining intestines; period elapsing from the first symptom to the time of operation; result of autopsies. Further details not covered by the above headings will be gladly received, such as recovery with passage of slough, etc.

SOCIETY NEWS.

Western Surgical and Gynecological Association.—The sixth annual session of the Western Surgical and Gynecological Association was held in the Senate chamber of the State House at Topeka, Kan., Dec. 28 and 29, 1896. It was one of the best meetings in the history of the Association, being largely attended, having a good program and interesting discussions. In welcoming the surgeons on behalf of Topeka Mayor Fellowe said in part: "To welcome to Topeka honored members of the most progressive of all professions is indeed a pleasure. Five years ago a few prominent surgeons met in this city and started your organization. Today it embraces among its members the leading surgeons of the West. Great as has been the growth of your Association in members and influence, it is as nothing compared to the wonderful progress of the profession you so worthily represent. During the century that is nearing the end your profession has lifted the curtain and shown a greater display of wonders and mysteries than all others combined." On Monday night a buffet banquet was served at the Copeland Hotel, at which the following surgeons responded to toasts: M. B. Ward, M.D., Topeka, "The Future of the Western Surgical and Gynecological Association." Dr. Summers, Omaha, Neb., "The Medical Profession of the West." Rev. Dr. A. S. Embree, "The Clergy's Opinion of the Profession." Dr. Grant of Denver, "A Silver Thread Among the Gold." C. A. Fellows, "The City Health Regulations." Dr. W. S. Lindsay, "Specialism in Medicine." Dr. Eastman of Indiana, "Good Night." For the ensuing year the following officers were chosen: President, Dr. Joseph Eastman of Indianapolis, Ind.; first vice-president, Dr. D. S. Fairchild of Clinton, Iowa; second vice-president, Dr. B. B. Davis of Omaha, Neb.; secretary and treasurer, Dr. Herman E. Pearse of Kansas City, Mo.; executive board, Drs. L. Schooler of Des Moines, Iowa; M. B. Ward of Topeka, Kan.; T. J. Beattie of Kansas City, Mo.; C. Lester Hall of Kansas City, Mo., and J. P. Lord of Omaha, Neb. Dr. W. W. Grant of Denver was chosen chairman of committee on arrangements.

The New York Academy of Medicine; 1847 to 1897.—From 1847 to 1850 this budding institution was cradled over a carboniferous stratum, that is it had its first home over a coal yard. Then, for twenty years, it "boarded 'round" like the country schoolma'am, a part of the time in the University Building and part of the time at the Twenty-third Street School. In May, 1875, it for the first time had a home of its own on Thirty-first Street. This was a happy mark of progress and the Academy took on new life. This building was manifestly outgrown before a decade had passed, and the new abode on West Forty-third Street became a necessity. It was opened in 1891, representing an outlay of nearly \$300,000. The Academy is free from debt, and can have all the funds it needs to keep its standard floating high. The latest proposition for adding to the useful-

ness of the institution is that made by the newly elected president, Dr. E. G. Janeway, who desires to see the board of governors establish a laboratory for pathologic research for the benefit of the members, after the example of the Royal Colleges of London.

Academy of Medicine of Cincinnati.—At the annual meeting of the Academy of Medicine of Cincinnati held March 1 the following officers were elected for the ensuing year: W. E. Kiely, president; J. C. Oliver, first vice-president; Ellen F. McCarthy, second vice-president; S. E. Allen, treasurer; W. E. Schenck, secretary; M. A. Tate, financial secretary; A. G. Drury, corresponding secretary; A. I. Carson, librarian; N. P. Dandridge, J. A. Murphy, J. T. Whittaker, trustees.

American Pediatric Society.—The ninth annual meeting will be held at Washington, May 4, 5 and 6, 1897. A session is to be devoted to the demonstration of apparatus and pathologic specimens. It is requested that announcements of such subjects be forwarded as early as possible. In order to collect papers on kindred subjects into the same session, the titles of papers are also requested at an early date. Samuel S. Adams, M.D., president. William P. Northrup, M.D., chairman of Council, 57 East Seventy-ninth Street, New York.

Kings County Medical Association, at Brooklyn.—The following officers for 1897 were elected February 9: President, J. C. Bierwirth; vice-president, L. A. W. Alleman; secretaries, F. C. Raynor and J. Scott Wood; treasurer, E. H. Squibb; member of executive committee to 1901, J. D. Rushmore; other members of committee, R. M. Wyckoff, T. M. Rochester and Jonathan Wright.

The Polish Medical Society of Chicago will hold hereafter their regular meeting every second Wednesday of each month at the Tremont House (Parlor A), cor. Lake and Dearborn Streets, 3 to 6 P.M.

Medical Association of the District of Columbia.—The following recommendations were adopted Feb. 16, 1897:

1. That any institution for medical charity shall require from every applicant for relief in a hospital or dispensary, a written certificate, to be obtained as hereinafter provided. Emergency cases are to be excepted from the operation of this rule.

2. That such certificates be obtained from physicians to the poor, the Board of Associated Charities and any registered physician.

3. That cases of sick and injured persons found upon the streets, in the stations or elsewhere, who require immediate treatment, shall be carried to the emergency hospital, or the nearest hospital having an emergency service, or to their homes, if so directed by the patient or his friends.

4. That emergency patients shall not be detained longer in such institutions than the necessity of the case imperatively demands, but shall be discharged from the service and sent to their homes, or to some public hospital as the patient may elect.

5. That members of this Association shall be entitled to the privilege of attending private patients occupying private rooms in any of the public hospitals of this city.

6. That in future the members of the medical staff of hospitals, when attending medical or surgical cases in private pay rooms, shall insist upon proper payment for their services, except in the case of such patients who are clearly unable to pay for the same.

7. That whenever a medical staff, or a majority thereof, of a hospital or dispensary resigns, and when after due hearing, this Association finds that the resignations were for just and sufficient cause, it shall be forbidden for any member of this Association to accept a position on the staff of said hospital or dispensary.

8. Whenever one or more members of the medical staff of a hospital or dispensary are dismissed, and when, after due investigation, this Association finds that such dismissal was without just and sufficient cause, it shall be forbidden for any member of this Association to fill the vacancy created thereby.

9. That complaints made under Rules 7 and 8 shall be made in writing to the Standing Committee, which, after due consideration, shall report its findings to the Association.

W. P. CARR, M.D., President.

J. R. WELLINGTON, M.D., Secretary.

NECROLOGY.

SURGEON-MAJOR ROBERT MANSER, who is the first professional victim to the plague in Bombay, joined Guy's Hospital about 1867, when he was 18 years of age. Six years later he qualified, becoming M. R. C. S., and later on, in 1877, passed into the Indian Medical Service, being attached to the Bombay army. In 1879 he first saw field service, and later on took part in the defence of Kandahar; subsequently working in the Bolan and Khyber Passes after Lord Robert's brilliant success. Going down to Bombay, he was soon appointed one of the physicians to the Jamsetjee Jeejeebhai Hospital, and a professor in the Grant College Medical School. In 1889 he became Professor of Medicine there, and in that same year took the M.D. at Durham, passed the M.R.C.P., and became a surgeon-major. In addition, he soon acquired a reputation as a consultant, and became a most popular physician among the European community of Bombay. In private Dr. Manser was one of the most unassuming of men, as well as one of the most careful clinical workers that the Indian Medical Service has seen. When the plague broke out in August, in Bombay, Dr. Manser was at once appointed President of the Plague Investigation Committee—in its work he has been unwearied. He took the plague January, and died on the 6th, cut off in mid-career, and with a brain all active; a death that he would have been the last to rebel against, rather taking it as part of a day's work, an honor to himself and to a service that has no need to produce vouchers for its nobility.

WILLIAM S. PRESTON, M.D., of Patchogue, N. Y., died at his home February 16. He was born at Ashford, Conn., Jan 15, 1810. He was a licentiate of the Massachusetts Medical Society in 1835. In October, 1837, he went to Patchogue to practice, and during his time was one of the most prominent practitioners of Suffolk County. He was also prominently identified with the affairs of this county and village. Being an ardent politician, his friends sent him to the assembly, where he served one term and made an excellent record. For several years he was School Commissioner. He was an officer in the Suffolk County Medical Society, and was always interested in medico-educational improvements. In 1871 he was one of the organizers of the Patchogue union free school, being the first president of the Board of Education. He leaves three sons and one daughter. Dr. E. Forest Preston of Amityville is his third son.

ROBERT TODD REYNOLDS, M.D., died in Chicago, Ill., February 28, in his 86th year. He was the oldest living graduate of the McGill University and retired from practice in 1891 after fifty-five years of active participation in all its responsibilities. A widow and four children are his survivors. Dr. Reynolds was the only son of Commissary-General Robert Reynolds of the British Army, who was with the 34th Infantry at Fort Marden in 1837. Dr. Reynold's mother was a daughter of Commodore Bouchette, of the British Navy. Her first husband was Peter McGill, founder of the University.

OTTO L. DUSSELDORF, M.D., of Brooklyn, died on the 5th inst., aged 68 years, at the home of his son, Dr. Louis M. Dusseldorf. The doctor was born in Germany, but early came to the United States, spending the greater part of a half century in medical practice in New York. His fatal illness was an attack of acute lobar pneumonia.

HENRY S. GROSS, M.D., University of Pennsylvania Medical Department 1862, died in Philadelphia February 21, aged 57 years. During the war he was an assistant surgeon of the 26th regiment Pennsylvania infantry and served until Oct. 17, 1863. His regiment participated in the battles of Bull Run and Gettysburg during his official term.

WILLIAM R. LITTLE, M.D., of Bloomsbury, N. J., coroner of Hunterdon County, N. J., died in Phillipsburg, N. J., Febru-

ary 13, aged 47 years. He was a graduate of the University of Pennsylvania Medical Department in 1878.

WILLIAM B. HENDERSON, M.D., one of the oldest physicians of Dauphin County, Pa., died at Steelton, Pa., February 22. He served as assistant surgeon of the 6th Pennsylvania Cavalry and served until March 27, 1865.

MICHAEL W. A. WUELFINCH, M.D., University of Amsterdam, Holland, 1876, a surgeon in the Dutch army before he came to Reading, Pa., in 1880, died there February 17, aged 55 years.

JOHN C. LEWIS, M.D., University of Buffalo, 1874, died of pneumonia February 6, aged 48 years. He was a practitioner of Panama, N. Y., and a member of Chatauqua County Medical Society.

JOHN C. CLAUDY, M.D., Bellevue Hospital Medical College 1865, died at his residence in Newville, Pa., February 20, aged 55 years. He was an acting assistant surgeon U. S. A., during 1865.

JOHN KIRBY, M.D., University of Pennsylvania 1852, for twenty-one years connected with the State Hospital for the Insane at Trenton, N. J., died February 27, aged 71 years.

HENRY KENT HUNTINGTON, M.D., N. Y. University Medical College 1871, of New Rochelle, died February 28, aged 63 years.

ERNST ILGEN, M.D., Munich, 1836, died at his residence in Brooklyn, N. Y., March 4, in his 83d year.

MISCELLANY.

Dispensary in North Carolina.—Raleigh is to have the first free dispensary in the State. It will be opened at an early date in connection with the school of medicine of Shaw University. It will furnish free advice and medicine to the needy and deserving colored people.

Unqualified Midwives in New York.—A coroner's jury in New York City, recently had before it the case of a young woman whose death had taken place after treatment by a midwife who had a license of the city health authorities but had never been examined as to her qualifications. This jury, in its verdict, passed a vote of censure as to the granting of *pro forma* credentials.

Jefferson Medical College.—At a recent meeting of the Board of Trustees of the Jefferson Medical College, Philadelphia, Dr. J. Chalmers DaCosta was elected Clinical Professor of Surgery. Dr. DaCosta has been connected with the College for many years, and has recently been Demonstrator of Surgery and Chief of the out-patients department. The new appointment is made in recognition of his long service and valuable contributions to surgical literature.

Error in too Much Evidence.—Upon the trial of an indictment that charged that the defendant, knowingly and unlawfully, and without license, prescribed medicine for a certain person named, the supreme court of New Jersey holds, in *Meyer v. State*, Nov. 20, 1896, that evidence that he had prescribed for other persons was illegal, its only effect being to show that he habitually did those things for the doing of which in a particular instance he had been indicted. Because the State, in this case, after proving the circumstances upon which it relied to establish the fact that the defendant had prescribed for the person alleged, proceeded to prove a number of instances in which he had prescribed for sundry other people, not mentioned in the indictment, the court reverses the conviction had.

New Shoes as a Factor in Accident Insurance.—John Fogarty of the firm of Winston Bros., contractors of Minneapolis, Minn., was in charge of the work of grading a roadbed on a branch of the Great Northern Railroad, and while walking from one flat car to another stepped on the iron apron, slipped and fell between the cars, the wheels passing over both legs a little below

the hips, the injury resulting in his death in a few hours. Mr. Fogarty stated after he was hurt that his new shoes were the cause of his accident; they were awkward and slippery. He claimed that if he had had on his old shoes it never would have happened. His wife was paid the \$5,000 for which he was insured. This is the second claim paid within a twelvemonth where the cause of the accident can be attributed to new shoes, the other one being that of Paul Flesher of Elkhorn, W. Va., who, in attempting to climb to the summit of Pinnacle Rock, slipped, lost his footing and fell over a precipice.—*Bulletin of the Fidelity Company*, January.

Among the Medical Colleges of New York City.—Despite the efforts of a portion of the New York medical men, the policy of consolidated interests goes on. The fruition of the higher medical education is seemingly at hand for the benefit of the public at least, if not for the amelioration of the profession at large. Yet many think that the standard can not be too high nor the emoluments too meager. The trustees of the University of the City of New York have formally accepted the deed of the Loomis Laboratory from the trustees of the University Medical College. Hereafter the trustees of the university will take charge of the Medical College, assuming all financial responsibility. The Medical College's endowment of \$100,000 and its property worth \$300,000 more pass into possession of the university. Also the Bellevue Medical College have secured 100 feet on First avenue and 150 feet on East Twenty-sixth Street, adjoining the Carnegie Laboratory, which belongs to the college. Before the fire the Charities Commissioners were anxious to secure the ground on which the original building stood for hospital purposes. The work of erection will begin at once as it is intended to have the new structure ready before September begins. Meanwhile the Commissioners are busy with new plans and devices to meet the constant increasing demands upon their resources.

John Wesley's "Primitive Physick."—Andrew Mellick, Jr., in his "Story of an Old Farm," thus writes: "In New Jersey, up to the close of the French and Indian Wars, the main reliance of the people for medical attendance was upon the pastors of the churches. It was the custom of those who came from the old country to have taken a course of medical study as a preparation for their duties in the new world. The native ministers also, even up to the close of the century, on being educated studied both professions, and often not content with two, mastered so much of the law as would enable them to draw wills, conveyances and other legal instruments. John Wesley, the founder of Methodism, not only, like many other persons, prescribed and supplied medicine, but published a book called 'Primitive Physick,' which went through thirty editions. The ignorance of the times and the extraordinary remedies in use can be best exemplified by quoting a few prescriptions contained in this precious medical volume. For a violent bleeding of the nose a piece of white paper was recommended to be placed under the tongue. Treatment for cancer in the breast was to swallow in a pint of warm ale an infusion distilled from warts taken from a horse's leg; goose dung was also to be applied externally. Consumptives were directed to breathe for fifteen minutes each morning in a hole cut in fresh turf. The sovereign remedy for apoplexy was a pint of salted water; for cuts, poultices of toasted cheese; for cold in the head, orange peel thrust up the nostrils and so on *ad nauseam*."

A Case of Congenital Umbilical Hernia.—McCosh (*New York Medical Journal*, Feb. 20, 1897, p. 248) has reported the case of a male child, born at term of healthy and well-formed parents, which presented at birth a tumor the size of a large orange in the situation of the umbilicus. There was neither constipation nor vomiting. The tumor was roundish in form, about three and a half inches in diameter, projecting two and a half inches above the level of the abdominal wall; its

surface was dark purplish in color. The external covering of the mass consisted not of skin, but of the membranes of the umbilical cord, through which the liver and the intestines could be indistinctly seen, falling and rising with inspiration and expiration. Manipulation of the tumor caused no discomfort and it was partly reducible. The temperature was slightly elevated, the pulse and respiration accelerated. Operation was advised and undertaken on the sixth day. The surface of the hernial mass had been converted into a foul, sloughing membrane, which was detached with forceps, exposing to view the liver and the transverse colon. The remainder of the membrane was removed by an incision around the base of the tumor, the liver and the intestines being held back by hot gauze pads. That portion of the liver which was contained in the sac was covered by a tenacious, partially sloughing exudate, which was scraped off with considerable difficulty. When expulsive efforts were made by the child, about one-third of the liver protruded through the gap in the abdominal wall. Approximation of the margins of the wound, after replacement of the viscera, was rather difficult on account of the excessive tension. A strip of rubber tissue was introduced into the abdominal cavity for drainage. The operation was followed by only moderate shock, but on the eighth day the pulse began to fail, cyanosis set in and death ensued.

Salivary Infection.—The *American Therapist* has gone a little outside of its *métier* to discuss the subjects of salivary infection and the sanitation of kissing. The writer pokes fun at the health official out in Indiana who has undertaken to legislate against the time-honored osculatory custom. While boards of health are proverbially lacking in those sentimental attributes which go toward making "life worth living," it has never been supposed that sanitary restriction would go so far as to heartlessly place the seal of official disapproval upon the soul-inspiring practice of labial juxtaposition between the party of the first part—the sighing swain—and the reciprocal party of the second part—the fair damsel. The demands of prophylactic science are indeed inexorable if modern sweethearts are to be debarred from following the example of the lovers of all generations, even from the period of our common Edenic ancestors down to the present time. It is always easy to pull down and destroy, but what, if any, equally innocent and soul-satisfying substitute for this delightful pastime does this particular iconoclastic sanitary solon propose? Nothing, absolutely nothing! To be sure, in his scientific complaisance he implies that the demands of modern prophylaxis can be attained by bathing the ruby lips of fair femininity with some non-irritating and innocuous antiseptic, and rinsing the bacteria-breeding teeth of the masculine donor (or recipient as the case may be) with some equally potent germicide.

The Medico-Legal Value of Antivenin in India.—An interesting annotation in the London *Lancet*, January 23, states that Professor Hankin, director of the bacteriologic laboratory at Agra, recently had submitted to him cloths which had been removed from the intestines of some cows which had died apparently from some acute poisoning. Chemical analysis being impracticable, Professor Hankin macerated the cloths and concentrated the solution obtained. Part of this was inoculated under the skin of a rabbit, which died in less than an hour with every symptom of poisoning by serpent venom. The rest of the fluid obtained from the cloths was then mixed with a small quantity of Calmette's "serum antivenimeux" and injected into a second rabbit, which showed no symptoms whatever. If this observation proves to be corroborated by further trials, the knowledge that poisoning by serpent venom can be detected by scientific methods may check the use of this agent in India, where it appears to be frequently employed to poison animals. Another agent frequently employed for this purpose is abrin, the albuminoid substance contained in jequir-

ity seeds. A serum antitoxic to abrin has been prepared by Dr. Calmette, of the Pasteur Institute at Lille, whose researches on serpent venom are so well known, and it is possible that this also may be of use in finding the exact poison that has been employed and in bringing home crime to guilty parties. It is an interesting example of the unlooked-for practical results which often spring from purely scientific laboratory experiments. The whole anilin industry, for instance, arose from the incidental discovery of one of the anilin colors by Dr. W. H. Perkin, when carrying out a patient laboratory research in the unsuccessful endeavor to prepare quinin synthetically.

Graduates of Rutland's Mill.—Fred Rutland, president of the "Wisconsin Eclectic College," was arrested at No. 1001 Congress street February 24, on a warrant issued by Commissioner Humphrey, charging him with using the mails for fraudulent purposes. He was held in bonds of \$5,000 for a hearing. Rutland's "college" is operated, he said, under a Wisconsin charter. His scheme has been carried on for some time. Diplomas were issued to all comers for a fee of from \$35 to \$50. Following is a partial list of the victims, with the dates of their "diplomas":

ILLINOIS.

Effingham—Louis F. Beemer, Register block, Oct. 24, 1896.
Chicago—William Henry Bischoff, Dec. 30, 1896; Hyman Brook, 589 South Halsted street, Dec. 31, 1896; Knead Lauritzen Boysen, 3565 Cottage Grove avenue, Jan. 30, 1897; John Alexander Conkey, 6600 Wentworth avenue, Jan. 27, 1897; Hiram Manter Dyer, Sept. 22, 1896; Frank Harry Escher, care Caradine, 167 Madison street, Feb. 3, 1897; Oscar Lawson, 240 Thirty-first street, May 6, 1896; Lindsay, 5955 Union avenue, Feb. 20, 1897; McCormick, April 3, 1896; Thomas J. McGrath, 29 Keith street, Feb. 23, 1897; William F. Nutt, 4204 Berkeley avenue, June 4, 1896; Joseph von Osinski, 928 George street, Lake View, Feb. 1, 1897; William Henry Saunders, 1208 Michigan avenue, Jan. 2, 1897; Mrs. Delia J. Wilcox, 4202 Berkeley avenue, June 8, 1896; Maud C. Williams, June 9, 1896.
New Burnside—John Newton Newberry, Feb. 26, 1897.
Harvel, Montgomery County—H. Nester De Moulin, Oct. 30, 1896.
Pekin—Francisco Josephus Masen, Jan. 18, 1896; Joseph Martin Martin, South Capitol street, Feb. 16, 1897.
Lewistown—John Quincy Moreley, Feb. 17, 1897.
Millersburg—M. F. Staunton, Oct. 7, 1896.
DeKalb—Benjamin Scarles, Oct. 7, 1896.
Wilmington—Benjamin Franklin Ward, Dec. 15, 1896.

INDIANA.

La Otto—Albert A. Bender, Aug. 12, 1896; Claude C. Chick, Aug. 12, 1896.
Owensberg—Lafayette Bridwell, Oct. 19, 1896.
Rays Crossing—G. T. Carney, Jan. 17, 1896.
South Bend—B. Webster Collins, Jan. 29, 1896.
Anderson—Dr. T. A. Dillion, 201 North Jackson street, Dec. 23, 1896; William H. Downham, Jan. 9, 1896.
Fort Wayne—Rudolph Duppeller, 32 South Columbia street, Jan. 23, 1897.
Alum Cave, Sullivan County—John W. Davis, Feb. 12, 1897.
Howell—James F. Freeman, July 13, 1896.
Monticello—Wesley H. Hull, Aug. 19, 1896.
Aetna—Frank Heath, Dec. 29, 1896.
Indianapolis—William F. Howe, 168 Bellefontaine street, Feb. 4, 1897; Henry Noel Karchner, 171 East Washington street, Dec. 15, 1896; William Herman Kluge, care Dr. J. W. Neff, 404 North W street, Feb. 6, 1897; Gustav Lender, care Dr. John W. Neff, 404 North W street, Feb. 2, 1897; Charles H. Pfuntner, 964 1/2 North Illinois street, Feb. 1, 1897.
Lilly Dale—William Robert Howe, Feb. 6, 1897.
Elkhart—William C. Johnson, box 36, Aug. 5, 1896.
Petersburg—Davis F. LeMaster, Acme Pharmacy, Dec. 8, 1896.
Charles Matsen, diploma by United States Express to Benton Harbor, May 2, 1896.
Veedsburg—Charles Albert McNeill, Jan. 18, 1897.
Frankfort—James Osborne, Oct. 1, 1896.
Coal Bluff—Thomas C. Rowe, July 9, 1896.
Blue Grass—John Richards, Aug. 27, 1896.
Garrett—John Julius Stoher, Oct. 30, 1896.

MICHIGAN.

Detroit—Edward Francis Andrews, per Van Husen, May 2,

1896; I. Barnard, Dec. 15, 1896; George H. Carpenter, July 22, 1896; Lewis M. Dickens, Dec. 14, 1896; Frederick H. Falkner, 141 Howard Street, Jan. 30, 1896; John P. Guilott, 10 Lafayette Avenue, July 6, 1896; Louis Goldberg, per C., Aug. 22, 1896; Emil Huberman, care Mehmer, 141 Gratiot Avenue, July 28, 1896; William H. Hale, 6 or 60 Washington Street, Sept. 8, 1896; Prof. Elia Le Montais, 204 Howard Street, Sept. 24, 1896; William J. Lee, Helen E. Lee, 60 Washington Avenue, Sept. 3, 1896; James McAlindon, 230 East Woodbridge Street, Feb. 18, 1897; Rudolph Carl Opperman, 482 Congress Street, May 19, 1896; George O. Pratt, 720 Antonine Street, Aug. 18, 1896; Grandville W. Stevens, per Van Husen, June 8, 1896; Frank Schaeffer, pharmacist, 871 Chene Street, Oct. 3, 1896; Clemens E. Vertal, 867 Chene Street, June 25, 1896.

Kalamazoo—Myron Hermon Bell, 213 North Burdick Street, July 2, 1896.

West Olive—William Isadore Jacques Bruinsma, July 3, 1896.
Harrisburg, Ottawa County—Chester William Bunce, July 25, 1896.

Marlette—James W. Boucher, Aug. 5, 1896.
Benton Harbor—Frank E. Brady, Avery Block, Aug. 7, 1896; Julius C. Blume, care F. E. Brady, M.D., Jan. 29, 1896; Rose Olds, June 2, 1896; R. Burt Taber, Aug. 7, 1896.

Escanaba—Adelbert Brady, 702 Wells Avenue, Oct. 6, 1896.

Hancock—Henrick Verner Bergell, Dec. 5, 1896.

Yuma—Dr. Charles S. Baker, Dec. 10, 1896.

Grand Rapids—George Albert Brink, 407 Michigan Trust Building, Jan. 21, 1896; Leonard L. Conkey, June 15, 1896; Goodwin M. Field, Aug. 17, 1896; Simon Le Roy, 72 Ottawa Street, May 12, 1896; Coleman Nockolds, Butterworth and Indiana Avenue, June 30, 1896; Samuel M. Reed, per Carpenter, June 18, 1896.

Ann Arbor—Frederick Waller Brown, 48 South Engle Street, Feb. 20, 1897.

Nunica—Earl O. Cilley, July 2, 1896; James Cilley, July 2, 1896; Annie Gilette, July 23, 1896.

Lamont—Ed. G. Cooney, July 9, 1896; John Rice, July 9, 1896; Milron Lebhrus Squier, Aug. 14, 1896.

Algonac—August A. Geisler, Pharmacist, Aug. 28, 1896.

Grand Junction—Albert D. Hurlburt, July 13, 1896.

Fenwick, Montcalm County—Albert Frederick Haskin, Feb. 6, 1897.

Big Rapids—Miss Jenks, April 25, 1896.

Columbiaville—John H. Kellogg, pharmacist, June 8, 1896.

Sunfair, Hartley A. Meyers, care C. M. Snyder, Feb. 1, 1897.
Greenleaf—A. McLeod, Dec. 22, 1896.

Port Huron—John McDonald, Jan. 5, 1897.

Toneconning Bay—Monroe Porter, Oct. 23, 1896.

Gladstone—Albert H. Powell, Feb. 20, 1897.

St. Joseph—James C. Schuler, Aug. 22, 1896.

Jackson—G. Williams Van Vleck, A.M., M.D., 708 Detroit Street, Sept. 15, 1896.

Mandie—J. Van Vleck, 708 Detroit Street, Jackson, Sept. 15, 1896.

Mulliken—J. Whesley, May 14, 1896.

Salem Station, Washtenaw County—Albert L. Walker, Jan. 20, 1897.

Holland—Jantke J. Wetmore, 15 Eighth Street, Sept. 7, 1896.

WISCONSIN.

Waukesha—Martin Henry Janer, care Boehner Bros., Feb. 12, 1897.

Trade Lake—Filip Gustav Barck, Dec. 5, 1896.

Turtle Lake—Edgar W. Brown, Jan. 9, 1897.

Wausaukee—Charles Wetherill Brewster, Feb. 19, 1897.

West Superior—Alexander A. Campbell, 714 Tower Avenue, June 17, 1896.

Stewbin—A. Earnest Dillman, May 21, 1896.

Westfield—Rolland Dickinson Earley, Dec. 22, 1896; May Rundlett, Dec. 22, 1896.

Milwaukee—Adelbert Freund, 453 Fifth Street, June 25, 1896; Herman Fleischer, per Beyer, Aug. 28, 1896; Martin W. F. Frederickson, care Beyer, Nov. 26, 1896; Fred A. Goedecke, 723 Wells Street, June 10, 1896; Konard Hahn, 309 Fourth Street, May 4, 1896; Emil Raben, National Avenue and First Street, June 30, 1896; Gustavus Schorse, per Beyer, Aug. 28, 1896; Helen H. St. John, 2220 Fond du Lac Avenue, Sept. 5, 1896.

Milton Junction—W. H. Gates, May 27, 1896.

New Lisbon—J. H. Hansen, May 20, 1896.

Underhill—George E. Hunt, per Poppe, June 4, 1896; Gustavus Jensen, per F. & A. Pope, June 4, 1896.

Poynette—Edgar E. Hinkson, June 19, 1896.

Cataract—Chester W. Johnson, May 16, 1896.

Grantsburg—Carl L. Johnson, Jan. 21, 1897.

Marinette—K. Kenyon, Arlington Hotel, Dec. 17, 1896.

Flintville—Frederick Sophie Kanute, Feb. 4, 1897.
 Monticello—Rudolph Kleiner, Feb. 16, 1897.
 Woodward—Harry S. Lester, May 18, 1896.
 Modena—Ernest B. Leid, Nov. 6, 1896.
 Milton Junction—Fred McAdams, May 19, 1896.
 Cobb, Iowa County—Gustav Newman, Dec. 11, 1896.
 Otsego, Columbus County—William A. Prase, May 18, 1896.
 Waupaca—Fred Poppe, May 19, 1896; Alfred Poppe, same address and date.
 Solder's Grove—Pere M. Randall, Dec. 11, 1896.
 Wausau—Leonard Douglass Smith, 517 Franklin Street, Aug. 20, 1896.
 Iron River—George E. Smith, Dec. 29, 1896.
 Fond du Lac—Dr. Q. Towns, Jan. 5, 1897.
 Eau Claire—Thomas E. Williams, Jan. 20, 1896.
 Barron—Charles E. Waldron, Jan. 22, 1896.

Washington.

WASHINGTON OBSTETRICAL AND GYNECOLOGICAL SOCIETY.—At the 258th meeting of this Society, held on the 19th ultimo, Dr. F. S. Nash (late U. S. N.) read the paper of the evening, entitled, "Recovery Following Right Ovariectomy Notwithstanding Left Pyosalpinx. Abdominal Stitch hole Abscesses One Year Afterward." Dr. G. B. Harrison reported an interesting case of liver colic with passage of stone, and presented the specimen.

WHAT THE "EVENING STAR" SAYS ABOUT FREE MEDICAL TREATMENT.—There can be no reasonable objection to the plan of the local physicians as outlined in the report of the proceedings of the Medical Association to restrict the free treatment of patients at the hospitals to those who are genuinely unable to pay the usual fees. The scheme of reform is simple and just. It requires those asking for free treatment to present a card bearing a certificate of worthiness signed by the police authorities, the superintendent of the Associated Charities or a reputable physician. Under such a system there is little chance of hardship or suffering for lack of proper medical attention or on the other hand of the encouragement and development of that unfortunate tendency of many people to pauperize themselves whenever the opportunity offers.

THE GEORGETOWN COLLEGE HOSPITAL.—The plans for the hospital have been prepared by the architect and have been accepted. They have in view a structure which will cost about \$40,000, and will contain from 100 to 150 beds. Of the amount needed \$10,000 has already been pledged in private subscriptions, and the immediate outlook is for about \$15,000. So soon as this amount is secured work will commence on the buildings, and it is hoped to begin work within a short time. The desire of the projectors is to have the institution completed and in operation by October next.

AN AMENDMENT TO THE APPROPRIATION BILL.—Senator Gallinger has added the following amendment to the appropriation bill (section on charities), provided, "that any legally licensed physician may attend private patients when they occupy pay rooms in any of the public hospitals in the District of Columbia."

CONTAGIOUS DISEASE AMBULANCE.—The health department has been provided with the newest design of ambulance for the use of contagious disease patients.

PROVIDENCE HOSPITAL'S OFFER.—Mr. McMillan, chairman of the Senate committee on the District of Columbia, has received a letter from Sister Beatrice, in charge of Providence Hospital, in which she offers to build and operate as a part of that institution a large ward for the treatment of contagious diseases, if a part of the proposed appropriation of \$30,000 to provide wards at two hospitals be given to Providence. Sister Beatrice calls attention in her letter to the fact that Providence Hospital has already established a contagious ward and during the recent diphtheria epidemic the hospital had many cases. She says the small ward could be extended without great expense and she cites that the government would not be under annual expense for nurses, the sisters acting in that capacity without compensation. Providence Hospital, it should be remembered, a few years ago, came to the front and admitted, free of charge, cases of contagious disease which were refused admission to any of the other hospitals of the city. It is hoped that the offer will be accepted. Such a true charity should be encouraged and assisted.

MEDICAL SOCIETY.—At the meeting of the society held on the 24th ult. George M. Sternberg, surgeon-general U. S. Army, addressed the society on "Pathogenic Microorganisms," and illustrated his lecture by the use of lantern slides. He went over and illustrated almost the entire subject of bacteriology.

Detroit.

THE DETROIT MEDICAL AND LIBRARY ASSOCIATION at its regular meeting February 22, listened to an interesting paper by Dr. Maas, entitled "Malignant Tumors of the Mammae."

THE WAYNE COUNTY MEDICAL SOCIETY adopted the following resolutions on the death of Dr. W. R. Scurr, an active member of the Society:

Dr. W. R. Scurr has been a resident of Detroit since 1885. He attended school at the Detroit College of Medicine and also at the Michigan College of Medicine and Surgery, graduating from the latter place in 1889. He held the professorial chair of nervous diseases in the latter college. Before his study of medicine he was an ordained minister, and while taking his course in the colleges, filled some well-known pulpits. As a medical man he showed his love for his calling. The interests of his patients were ever his interests, and this one thing is what led to his early, untimely death. He always showed professional courtesy to his brother practitioners. He was charitable, generous, kind-hearted, sympathetic, and with his genial nature was loved and respected by all. His early call from his labors was a loss to us and to those for whom he was laboring in the performance of his professional duties.

Resolved, That this Society learns with deep regret of the death that has removed from our midst Dr. W. R. Scurr.

Resolved, That the Wayne County Medical Society indorses all that has been said of Dr. Scurr in the above preamble, and that the same be spread upon the records of the Society.

Resolved, The secretary be and is hereby instructed to transmit to the family of our deceased brother these sentiments, together with an expression of our sympathy with them for their great bereavement.

Resolved, That the Society do, as a further mark of respect to his memory, now adjourn.

THE PUBLIC SERVICE.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending March 6, 1897.

Asst. Surgeon M. S. Elliott, detached from instruction at naval laboratory, New York, and ordered to the U. S. S. "Columbia."

Change of Address.

Caldwell, J. R., from St. Clairville, Ohio, to West Liberty, W. Va.
 Daly, W. H., from 135 5th Ave. to McClintock Building, 516 Market St., Pittsburg, Pa.
 Frank, J., from Ozark to East Carondelet, Ill.
 Hall, L. F., from St. Louis to Potosi, Washington Co., Mo.; Howland, Geo. T., from 815 to 825 Vermont Ave., Washington, D. C.
 McKee, E. S., from 57 to 33 W. 7th St., Cincinnati, Ohio.

LETTERS RECEIVED.

No. 12.

ADDRESS.

THE NECESSITY FOR INVESTIGATION AND OBSERVATION BY THE GEN- ERAL PRACTITIONER.

An Address to the Berks County (Pa.) Medical Society, Feb. 11, 1896.

BY THOS. LEIDY RHOADS, M.D.

ASSISTANT DEMONSTRATOR OF PATHOLOGY; ASSISTANT IN THE SURGICAL
CLINIC, JEFFERSON MEDICAL COLLEGE HOSPITAL.

Medicine is a science developed by a process of experimental induction, and by methods which lead to a complete, final evolution of undisputed facts. It is a rational science so far as the absolute conclusions, the uniform results, observable within its sphere, depend for their certainty upon comprehensive experience and complete analogy, and the reliable testimony of competent observers in the unalterable phenomena of nature. It is largely an empiric science inasmuch as the contingent methods generally accepted in the management of disease depend for their validity upon the cumulative evidence resulting from continued experimentation and observation. The institution of this method of investigation and observation formed the basis of its classification as a science.

For several centuries subsequent to its origin to a certain stage of its development, medicine, however, presents nothing that is of scientific value, and little that is of interest save from an historic standpoint, in that it is a record of the rank absurdities, the dreamy conjectures, the base impositions practiced in the ages of obscurity. Its materia medica was limited to decoctions of a few herbs common to the flora of the East; its armamentarium, a collection of agents that were used to work upon the superstitious beliefs of a credulous people—such as amulets, which were worn around the neck to chase away the ague, or an hexamer from the early Greek authors, which had power to assuage the agony of gout, or a verse from the lamentations, which was credited with the cardinal virtues of being a specific for joint affections. Mystical ceremonies, songs and incantations were used for the relief of pain, great stress was laid on the interpretation of dreams, and when death closed the scene the fatal event was attributed to want of confidence on the part of the patient. This constituted the medicine of the East in its early days, and little more can be said of surgery, which consisted principally of the extraction of the "bent and reeking spears from the breasts of the Trojan heroes," and a few crude operations with instruments of stone. No attempt was made to advancement, and thus medicine, for the dreamy blank of many centuries, was but a gaunt shadow of the infinite possibilities which the future was destined to disclose. It was little more than an instrument of deception in the hands of those instructed in the polite philosophy of the day.

What a paradox does this early history present! Medicine, created for the relief of suffering and the cure of disease, and which one would naturally expect to have been studied and developed with the greatest possible ardor and zeal in whatever age and land, made the means of artful chicanery! Medicine, noble in its purpose, infinite in its faculty, deserves a more exalted sphere. Knowledge, not superstitious tradition, should be its heritage. The spirit of investigation unchained should expand into a general movement of careful inquiry, and make the art a promulgator for public good.

On the advent of Hippocrates on the clinical stage, medicine assumed a new role. A desire for more accurate knowledge in the treatment of diseases stimulated an inquiry as to their causes and progress. It is the first evidence of the why and wherefore, the dawn of scientific advancement. It is the transition stage from the medical charlatan to the rational physician. Thus the way was led from the frauds of Priestcraft and a debasing quackery, to the significant methods based on observation and investigation, from the trammels of superstition and mental benightment to the daylight of reason, from the dictates of antiquated traditions to a sound, plausible, logical science. This investigating spirit became the epitome of medical progress. It was the nidus from which was developed a comprehensive and far-reaching science, a fountain spring whence flowed streams of energy destined to cleanse medicine of its fallacies, and to swell into a torrent of universal good. It gradually accomplished a revolution in the meaningless lethargic state in which medicine existed. A new life was infused into its followers. Once begun, its influence was incessant, and wherever medicine has since been practiced and studied and taught, this same spirit has been the dominant factor in its spread and development; and whether the seat of medical learning was in the stronghold of Grecian glory with its radiant philosophy, or was transferred from time to time from the votive tablets of the temples to the medicine of the Seven Hills, "from beneath the shadow of the cross to the empire of the crescent, from the classic shores of Italy to the warlike followers of Mahomet, and the fiery descendents of Ishmael," from the splendors of Alexandria, with its library and museum, with Herophilus and Erasistratus, to Bagdad and Salamaea, and all of those institutions which grew and flourished beneath the iron scepter of the Mamelukes, from the ecclesiastics of Salernum to the realms of Charlemagne and the West and later to the new continent, it has been the essence, the eternal element of medical scientific advancement.

Medicine today is but the outcome of this progressive spirit. With the accumulated knowledge and increased facilities for research that have resulted from its many discoveries it has attained a status which has placed it on an equal footing with the

allied sciences. Its literature, the teachings of its medical schools, the products of its laboratories, give evidence of this. But the factors which have brought it to its present state of mature development dare not cease to be dominant. Today a greater enthusiasm exists in its future development than the past has ever witnessed. All the world over there are those who are striving with the keenest interest to solve problems that have baffled workers of the past. Much of this investigation is carried on in those laboratories of whose existence the public has no knowledge until some new Röntgen ray flashes its brilliant light throughout the land. Find out something new, aid in its development, be a contributor to science, is the order of the day. Even in our schools, where but a few years ago the essential features of medical teaching were the didactic course and the clinical arena, these have largely been supplemented by the laboratory, where the student is encouraged to do original work; and the marked advance of modern medicine can be traced to the early training received in these scientific workshops. Daily there are given to the world the products of the microscope, the culture tube, and the reagent. But there are certain lines of investigation, that can not be followed out in the laboratory, and it devolves upon the general practitioner, who has opportunities for observation more particularly in certain fields, to aid in the solution of these problems, to contribute to the increase of medical knowledge, and meet the obligations which he assumed on entering a profession whose demands for observation and investigation are so urgent at the present time.

It is unnecessary to recount how these investigations are to be carried out or to quote any examples illustrating the importance and value of observation and investigation. The history of the development of the knowledge of the circulation from Erasistratus, who thought the arteries contained air, to the researches of Williams, who demonstrated the migration of the leucocytes through the capillary walls, and the later application of this knowledge to the study of inflammation by Cohnheim, is still fresh in our minds. The investigations of Priestley proving the aeration of the blood and setting aside the false views of the ancients; Galen's early and crude study of the physiology of the nervous system, to the localizing of cerebral functions of the present day, which has paved the way for successful surgical treatment of brain lesions hitherto obscure and fatal, and among the later investigations of which no name is better known than that of Keen; Alcmaeon's study of the human structure by comparative anatomy to the learned discourses of the late lamented Leidy; the weird theory set forth by Empedocles of Agrigentum to the confirmation of the illustrious Harvey's aphorism: *Omne vivum ex ovo*; the close study of the tissues and the creation of histology by the genius of Bichat, to the examination of the complex changes of the nuclear stroma in cell division—the karyokinesis of Schleicher; Koch's great discovery of the cause, which has revolutionized the treatment of tuberculous affections; the subject of callous production, of Senn, which has opened a broad field of conservative surgery, and has resulted in the saving of thousands of useful limbs; Lister's experiments on the practical use of the catgut ligature which have led to results in surgery that will ever make his name immortal. Kocher's recent announcement that myxedema fol-

lows extirpation of a goitre with the consequent cure of that disease, and the daily discovery of the bacteriologic causes of different diseases, with their consequent rational treatment—all these are but a few examples of the observations and investigations, the results of which have made the science of medicine what it is today. If the brilliant achievements of modern medicine and surgery are the direct result of these methods of investigation, future improvements must depend on the same sources of information. To aid then in enhancing the value of the science, to further its usefulness, should be the object of every physician, be he a worker in the laboratory, be he a doctor of special organs, or be he the greatest of all specialists—the general practitioner. His idea should be at once to become a close observer and investigator, his motive to promote science. In this way only can he pay the debt of gratitude he owes to his profession and meet the demands of the present investigating era.

Were there a question as to the bearing and weight which the observations of the general practitioner will have upon the medicine of the future, it is but necessary to quote a few examples of the part he has taken in its evolution during the past: How the horrors of the battle-field, the agonies of maternity, the terrible sufferings of the clinical amphitheater are dispelled by the induction of ether anesthesia, which procedure originated in a small town in the backwoods of Georgia by an obscure village doctor, Crawford Long, who is now honored, in commemoration of his discovery, by a monument in the great metropolis of Europe. How the experiments of the elder Gross on intestinal anastomosis, during the early part of his professional career in a neighboring town, decided in large measure the future of intestinal surgery and reclaimed to life those who had been left to die from wounds of the viscera. How the most formidable operation of surgery, amputation at the hip joint, designated by Percival Pott as "horrid, dreadful and an unjustifiable procedure," was first successfully performed not with the skilled assistants and the best possible surroundings of the thoroughly equipped hospital clinic, nor on the battle-field, where an urgent ultimatum might have demanded it with little or no hope of recovery, but in the wild and remote regions of Kentucky at a time when there was no consulting advice to be had, and left to his own resources in the days before antiseptics and anesthesia, Walter Brashear, the man observant, the man of daring, successfully accomplished this feat of surgery, and, strange to say, after all the half a hundred different methods have since been tried and abandoned, that of Brashear is now used by leading surgeons as the best possible procedure. How Ephraim McDowell, an obscure practitioner in the early days of the Blue Grass State, with his life in jeopardy, brave and undaunted, first removed an ovarian tumor and became the pioneer of abdominal and pelvic surgery. How in a small Southern town, after years of careful study, battling with poverty and distress in an honorable struggle for a remunerative practice, Marion Sims devised the operation for the cure of vesico-vaginal fistula, which gave relief to a multitude of suffering motherhood afflicted with this hitherto incurable malady and gained for the originator perpetual fame. How the rapidity of operations was hastened and the danger to life lessened, by the use of immediate mechanical hemostasis, by the practical Hearn applica-

ing small spring clips to the cut ends of vessels, which contrivance led to the general use of the indispensable modern hemostatic forceps. These are a few illustrations of what has been accomplished by careful investigation and observation, even under the most trying circumstances, demonstrates conclusively the varied opportunities of the general practitioner in an inexhaustible and inviting field of labor and must be a stimulus to his pursuing a course of research that will ultimately reap similar results.

But in entering upon this work of research he dare not do so with the idea that a fortnight will disclose some wonderful hidden fact which ages have shielded from the searching eyes of investigators. Progress in medicine is slow. The grand march of medical science sweeps onward, upward through the solemn pathway of the ages, not with fickle, fitful movement, but slow, calm, majestic. Every appreciable advancement of the science marks a complete cycle of human thought whose exponent was a worker of antiquity. Every era has had its blind chimeras, its fanciful theories, its experimental investigations, its new discoveries, its ultimate absolute facts by which the science has been slowly evolved. Its elucidation must be gradual, and research must be followed out in a distinct line based on the investigations of previous years. Medical truths expounded at the present day are not the result of spontaneous thought. The same grand ideas have hovered over a vista of years. They warmed and fired the genius of medical philosophers from the early days of medicine, but the proving of them, the elaboration of the idea was left for the present investigating age. The field is inexhaustible and affords ample scope for all. Lord Bacon urged upon doctors the study of those diseases incurable, and it were well to profit by his advice.

There is practically no limitation to the various subjects which might be suggested as being especially adapted to the general practitioner's opportunity for observation and research at the present time. Hygiene or preventive medicine offers probably as large a scope as any and promises much for the future. The recognition of the fact that various diseases are preventable by instituting proper hygienic surroundings is a greater boon to humanity than all drugs discovered to date—a sweeping statement, indeed, yet nevertheless evident on careful reflection. The vast opportunity for extending the usefulness of this subject in the fruitful field offered by matters of drainage, the subject of ventilation, the disinfection of clothing, the disposal of sewage and the inspection of food and water supply is open more especially to the general practitioner. The effect of peculiar local causes upon the general health and constitutions of the inhabitants within the circumscribed limits of his practice, and their influences in exciting or modifying disease; the effect of hereditary tendencies and family diatheses in producing disease; the bearing which the mode of living of the inhabitants has upon sporadic cases or endemic diseases; the influence of neighborhood and houses in the propagation of certain diseases, as cancer, are but a few pertinent questions, the correct solution of which will have much weight on medicine of the future. Or the subject of dietetics might be presented, with the rôle it played in his treatment and to what extent and with what results it has superseded the general empirical administration of drugs. Or leading his investigations into another channel of the yet hidden secrets of the deep and comprehensive science, one might suggest the need of a safer and

more agreeable anesthetic, a shorter cure for syphilis, a more extensive application of serum therapy, a hypnotic which will not form a habit, a specific for phthisis—these are but a few of the mysteries that sphinx-like stand out in bold relief, defiantly challenging to be solved.

Great as have been the discoveries of the last quarter century, who will venture to say what the next decade has in store for us. We dare not stand, awed though we be, on the brink of the twentieth century with a deaf ear to its demands. Our interest in medicine as a science would not tolerate such unconcerned inactivity. All the world over men are engaged—thoughtful, active, energetic men, in fathoming the great unknown, in recovering to us what has been lost for ages, and with this as a working basis, with exulting hearts constantly giving to the world their new discoveries, the fresh victories over disease, the taking away of the load of human suffering. They are commingling the elements which will determine the inevitable future of medicine. Let your zeal and enthusiasm swell the current of this general impulse for investigation into the mysterious workings of nature and add the results of your research to the knowledge that has been chastened and purified in the crucible of centuries, that is gradually attaining the perfection of a finished science. And when the investigating energy now spent in the laboratory of nature shall turn toward the ideal and rush into literature and the clinical arena, then there will arise authors whose works shall equal the lofty strains and discriminating judgment of a Da Costa, surgeons whose cunning hand shall have the skill of a Gross.

ORIGINAL ARTICLES.

CANCER OF THE STOMACH.

A Clinical Lecture delivered in Rush Medical College.

BY HENRY M. LYMAN, A.M., M.D.

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE.
CHICAGO, ILL.

The two patients whom I bring before you this morning are both advanced in life; one of them is 57 and the other is 76 years of age. Both are emaciated and pale; both are cachectic and enfeebled. There are, however, certain differences between them which will become apparent on closer examination. The younger man is simply pale and thin, without special discoloration of the skin. The left foot is somewhat edematous and the glands above the clavicle, on the left side of the neck, are considerably enlarged. The expression of his countenance is careworn and the face is furrowed with deep lines. The tongue is pale, covered with a gray coating, and rather reduced in size. The thoracic viscera seem to be healthy, though the cardiac beats are frequent and feeble. The liver is small and the spleen is hardly distinguishable. Placing the patient on his back and palpating the abdomen it is easy to discover an abnormal degree of epigastric tenderness on pressure. The stomach is filled with gas and extends downward as far as the navel; it is considerably dilated and there is tympanitic resonance over a large part of the belly. The intestines are not correspondingly filled with gas. In the pyloric region a tumor, rather irregular in form and nearly the size of a fist, can be distinctly felt. It moves but little during respiratory efforts; it is sensitive to pressure, and percussion brings out over its

area a dull sound quite in contrast with the note that is returned from the cardiac portion of the stomach.

The patient, who has been a large and vigorous person in former years, tells us that he was leading an active life till one year ago. He had for many years been in the habit of taking whisky before each meal on account of indigestion. He gives a history of chronic gastritis which was perhaps caused, and was at any rate aggravated, by the alleged remedy.

Nearly twelve months ago he lost his appetite; began to lose weight and strength; complained of gaseous distention of the stomach; and about seven months ago began to vomit his food. It was often very acid and irritating to the fauces; it was accompanied by a copious discharge of gastric mucus, and lately by streaks of blood and a dark, granular looking substance, like coffee grounds. During the whole time the chronic uneasiness, with which he suffered for years, became intensified, so that he complains of deep-seated, gnawing, burning, boring sensations which are aggravated by taking food. For a considerable period of time there was no tumefaction of the stomach, but about four months ago the epigastric region became enlarged, and distinct evidence of a tumor was apparent at the pyloric end of the stomach.

The older patient also states that the greater portion of his life has been passed in the enjoyment of excellent health. He was a farm laborer, sober, industrious, married in early life, and always free from venereal disease, malarial cachexia and other maladies. After his sixty-fifth year he began to suffer during cold weather with various forms of neuralgia in different parts of the body and limbs. During one of the winters, five or six years ago, he frequently experienced attacks of gastralgia and enteralgia, which were usually relieved by a few doses of bismuth and magnesia, or by a hypodermic injection of morphin, when uncommonly severe. Two years ago he began to emaciate gradually and now you see that he is much reduced, having fallen in weight from 175 pounds to 123. I give you an opportunity to inspect the patient and you can observe the total loss of subcutaneous fat and the absence of elasticity in the skin, which only very slowly retracts when pinched into folds over the abdomen. Remark also the pallor and earthy color of the skin everywhere over the body and limbs. The thoracic viscera are healthy; the scanty urine is high colored and dense, but it contains neither albumin nor sugar; there is no distention of the stomach or intestines; the liver and spleen are not enlarged; there is some tenderness over the whole upper half of the abdomen; perhaps there is a slight increase of resistance to pressure upon the epigastrium just below the ensiform cartilage; but there is no defined tumor anywhere within the abdominal cavity. The symptoms so far are quite negative and are usually explained as the result of *senile marasmus*. But during his residence for two months in the hospital he has exhibited certain phenomena of a suspicious character. Occasionally he has vomited and the contents of the stomach have been acid, owing to the presence of lactic acid. Free hydrochloric acid has been invariably absent. Giving him a solution of potassium iodid to drink, it was an hour before the salt could be detected in the saliva, though as you are aware, in a healthy subject it should pass from the stomach through the salivary glands into the mouth in less than twenty minutes. Lately the inguinal glands and those on the left side of the neck have

begun to enlarge. In view of all these symptoms, though we can discover no palpable tumor, and though the patient does not exhibit any very acute or rapidly developing evidence of failing health, I am inclined to think that he too is a victim of gastric carcinoma.¹

Let us now consider the general symptoms of cancer in the stomach. It is worthy of note that the disease has a two-fold effect upon the health, since in addition to the cachexia that is developed as the neoplasm grows, the nutrition of the body is hindered by the local derangement of digestion that is caused by the presence of the tumor in the wall of the stomach. In this particular the effect is largely conditioned by the situation of the growth; when the pylorus is invaded, there will be obstruction to the exit of food from the stomach, and the viscus will undergo dilatation; if the esophageal portion of the organ be invaded there will be difficulty about the entrance of food from the esophagus, with consequent dilatation of that tube and shrinkage of the stomach itself. When the body of the organ itself is the seat of carcinoma, the consequent phenomena will depend considerably upon the destruction and perversion of function of the peptic glands in the mucosa. In many cases, of which the elder patient before you is a type, the symptoms are for the most part connected with chronic indigestion and progressive cachexia. No evidence of a neoplasm can be localized, and the cancer develops in an obscure and latent manner, to be discovered only after death. Consequently, the discovery of a tumor connected with the gastric wall affords one of the most reliable symptoms of the disease. But when such a tumor is in its earlier stage of growth, if it be situated at the pyloric end of the stomach, or upon its lesser curvature, it will be covered by the liver until it has enlarged to such a degree that the stomach is dragged downward by its weight. Then it may become possible to feel and to percuss the growth itself. Sometimes a change of position is necessary to affect this demonstration, the tumor remaining concealed behind the liver so long as the patient lies on his back, but falling downward and forward within reach whenever he turns upon his left side or gets upon his hands and knees.

When a tumor is demonstrable, its apparent size will, of course, depend largely upon its age and its situation. Usually placed near the extremity of the ensiform cartilage, it may finally occupy the entire epigastrium, reaching even so far as the left hypochondrium or the umbilical region. Such extensive growths are more or less irregular in their shape, a fact that can be easily demonstrated after emaciation has occurred. Unlike tumors of the liver and spleen, which are so extensively displaced by the excursions of the diaphragm during respiration, these gastric tumors are but little influenced by the movements of respiration. They are much more affected by filling the stomach with air, water or food, which causes the upper portion of the organ to rise and to carry with it the new growth, until it may be entirely concealed behind the liver, whence it once more emerges after the stomach is emptied again.

When the tumor is accessible to palpation, its outline can often be clearly defined. But in many instances this is impossible, and the explorer must remain content with a sensation of diffuse resistance

¹ The patient died three weeks later and the autopsy discovered the existence of a small scirrhus cancer in the posterior wall of the stomach, just far enough from the pylorus to avoid obstruction of that orifice.

to pressure over the epigastrium. Inflation of the stomach with air often aids in displacing the mass so that it can be more easily reached. Sometimes it will rest upon the abdominal aorta, and can be felt to rise and fall with the pulsations of the vessel. But these displacements are simply rhythmical movements in a direction perpendicular to the artery, instead of being universally expansive like the pulsating dilatations of an aneurysm.

Percussion over a tumor connected with the stomach gives out a dull sound in which there is a somewhat tympanitic resonance, though not so clear and full as when the healthy organ is distended with air. Auscultation furnishes very little help in the diagnosis, unless performed with the help of the phonendoscope. With this instrument a skilled observer can often outline the tumor with great precision.

In cases where no tumor can be discovered, it is necessary to rely upon general symptoms for a diagnosis. The books advise persistent scrutiny of vomited matter and of the feces, in hopes that a detailed fragment of a carcinomatous mass may be thus captured for microscopic examination. But success has very rarely rewarded such patience. Better results are obtained by observation of the blood that in one form or another is usually vomited during the course of the disease. Unlike the copious hemorrhage that occurs in ulcer of the stomach the blood that is present in the vomited matter is usually scanty in amount, appearing in streaks among the mucus that is discharged from the cavity of the organ; or, when it has remained for some time in contact with the gastric juice, transformed into a substance that looks like coffee grounds, due to the conversion of the oxyhematin of the red corpuscles into hematin. Similar sediments are often apparent in the vomit in gastric ulcer, so that this symptom alone is not diagnostic. The stools may also contain blood, just as they sometimes do in ulceration of the stomach or small intestine.

Vomiting is a frequent event, especially in the majority of cancerous growths that encroach upon the pylorus. Sometimes the patient experiences sudden relief and permanent cessation of vomiting when the obstructive neoplasm breaks down and leaves the pyloric opening clear. In many instances, however, the appearance of relief is due either to a degenerative paralysis of the muscular coat of the stomach, or to the exhaustion that heralds the approach of death. Vomiting is sometimes replaced by hiccough or by eructation of offensive gases. This is not diagnostic since it may occur in other disorders of digestion.

The absence of free hydrochloric acid from the gastric juice is a symptom of great importance, though not by itself decisive. Cancer that has supervened upon a round ulcer of the stomach may be accompanied by an actual increase of free hydrochloric acid if the gastric glands have not undergone atrophy. Such degeneration of the glandular apparatus is the proximate cause of a deficiency of acid; the remote causes may be various. But, when free hydrochloric acid is absent from the stomach of an elderly, cachectic and emaciated patient, the probabilities are all in favor of the existence of a carcinoma as the fundamental cause. In all such cases there is also diminution of the pepsin and other ferments that are present in normal gastric juice.

Another interesting symptom of cancer of the stomach is the retardation of absorption through the

mucous membrane of the viscus. When iodid of potassium is swallowed by a healthy person it can be detected in the saliva within ten or fifteen minutes; but when cancer exists, there will be no trace of the iodid until the lapse of an hour or an hour and a half.

When a tumor can be felt through the abdominal wall, it is sensitive to pressure. Besides the pain that may be thus excited, there is a general diffusion of dull, aching, burning, boring pain all over the region of the stomach. These pains are more widely felt and are less intense than the corresponding pain in gastric ulcer. Pain is usually increased after eating, and is often worse in the night than during the day. It sometimes is felt, like other pains of gastric origin, in the thoracic nerves, in the shoulders, or even in the arms. Sometimes, symptoms of an asthmatic character are thus excited.

The tongue is usually coated with a thin white, gray, or yellowish brown coat. If there be frequent vomiting of acid and acid liquids, the tongue becomes red, smooth, shining and dry, like the "beefsteak tongue" sometimes seen in advanced cases of typhoid fever. In the "latent cancer" of old people this condition of the tongue is often one of the most conspicuous symptoms.

During the earlier stages of the disease the bowels are constipated, but, when the large intestine has become inflamed by reason of the passage of ill-digested food and acrid products of ulceration from the stomach, there may be diarrhea or dysentery.

The urine is usually scanty, high-colored, and sometimes loaded with indican, which may be demonstrated by introducing equal parts of urine and pure hydrochloric acid into a test-tube, and then adding two or three drops of a saturated solution of calcium chlorid. When indican is present, a deep blue or reddish blue color at once develops in the tube.

A symptom of great value when it is present is sometimes afforded by an enlargement of the lymph-glands in the neck, above the left clavicle, in the immediate vicinity of the orifice of the thoracic duct. In like manner, during the last days of the disease one or more of the extremities may become swollen by interference with the lymphatic circulation, or through the occurrence of marantic thrombosis in an important vein. Serous effusion into the various cavities of the body may also precede death.

Appetite usually fails, unless the position of the neoplasm obstructs the entrance of food into the stomach; hunger is then a prominent symptom. Thirst is frequently experienced. Insomnia is a common event. Emaciation and exhaustion are progressive; the skin often assumes a dirty color, and becomes thin, dry and furfuraceous. Sometimes there is dreadful itching all over the body, especially in the latent cancer of old people. Occasionally, the patient exhibits all the phenomena of progressive pernicious anemia, and only after death is the fact of a local cancerous growth made apparent.

Continuous loss of flesh is the rule in these cases, but occasionally we see patients who die before the subcutaneous fat has been all consumed. Sometimes when there is pyloric obstruction and dilatation of the stomach, a course of careful washing out of its cavity, and attention to the diet, will result in a temporary increase of weight.

The temperature of the body usually remains normal or abnormal; but in certain cases there are intermittent paroxysms of fever occasioned by septic poison-

ing from the absorption of products of disintegration in the tumor. This may be considered as one of the rather numerous complications to which the disease is liable. Among other complications may be named dilatation of the stomach as a consequence of pyloric obstruction. Sometimes such obstruction is relieved by a process of spontaneous sloughing, and the opposite condition, pyloric incontinence, is established. When the cardiac portion of the stomach is involved, the esophagus may be invaded, and the original disease becomes complicated with the symptoms of esophageal stenosis. A gastric sound can be introduced only with difficulty, and there is a change in the auscultatory sounds that should be heard during the act of swallowing liquids, when the stethoscope is placed to the left of the ensiform process; there is either no audible gurgle, or it is replaced by a tardy trickle.

Secondary growth of cancer in other organs is a not uncommon complication of the disease. Sometimes the liver is so extensively invaded by the secondary process that the primary gastric neoplasm is quite overshadowed during the life of the patient.

The duration of the disease is not easily determined because of the obscurity of the early symptoms. The course of the disease is more rapid the younger the patient is. Sometimes it proves fatal, apparently after a few weeks only; and it may be prolonged for two or three years. Ordinarily it continues for about one year. Death may occur suddenly, as a consequence of profuse hemorrhage; or perforation of the wall of the stomach, followed by peritonitis; or it may occur during coma, with collapse that is suggestive of auto-intoxication. Sometimes death results from slow starvation due to obstruction, either pyloric or esophageal. Frequently the patient gradually wastes to a skeleton, and slowly sinks into a condition of apathy that terminates in death. Albuminuria, edema of the extremities and venous thrombosis are not uncommon incidents in this mode of decease. When there is esophageal obstruction regurgitated food may find its way into the trachea, producing fatal pneumonia, abscess or gangrene of the lungs.

Despite the gravity of the symptoms it is not always easy to diagnosticate the existence of gastric carcinoma. In the absence of a tumor there may be only the symptoms of progressive pernicious anemia; or of progressive emaciation and cachexia. But when an old person without apparent cause, suffers loss of appetite, indigestion, insomnia, persistent itching of the skin, cachexia and frightful emaciation, the probability of latent cancer is very great. The gastric juice should be examined, with regard to the presence or absence of free hydrochloric acid. Some have emphasized the presence of lactic acid in excess, but this is not always the case in gastric cancer. The absence of pepsin in the urine has also been announced as an important symptom in doubtful cases. Slow absorption of potassium iodid is another valuable indication of the disease. Reduction of hemoglobin to less than 60 per cent. is another suspicious circumstance. But none of these symptoms are diagnostic; it is the concurrence of several indications that gives a high degree of probability to the diagnosis in these obscure cases.

When a tumor is present it should be, if thus accessible, explored with a sound. Sometimes it can be reached through the esophagus by the aid of a sound of extra length. From tumors of the liver or spleen

it may be differentiated by the almost total absence of movement during respiration. But it may be considerably displaced if the stomach be distended with air, water or food.

Sometimes the tumor can not be accurately defined, but gives only a generalized sense of increased resistance to pressure over the epigastrium. In such cases, it is allowable to entertain the possibility of a tumor consisting of cicatricial tissue after previous ulceration of the stomach, or of a fibroid hypertrophy of the gastric walls or of the presence of foreign bodies, or of other tumors outside of the stomach. In the last case it is necessary to discuss the differential diagnosis of all possible abdominal tumors, such as sub-phrenic abscesses, circumscribed peritonitis, enlarged mesenteric glands, intestinal tumors, coprostasis, mesenteric cancer, tumors of the pancreas, uterus and ovaries, together with aortic and other intra-abdominal aneurysms. The field for contemplation that is thus opened to the diagnostician is one of the widest in medicine.

About the prognosis in cancer of the stomach there is very little to be said, and that little is absolutely unfavorable. When the disease is sufficiently advanced to render the diagnosis reasonably certain, it is only a matter of a few months before the inevitably fatal termination. Consequently, there is nothing that is known regarding curative treatment. During the early stage the symptoms are usually vague, and merely characteristic of indigestion, the treatment then is that which is appropriate for gastric catarrh. During the later stages, when symptoms of pyloric obstruction are present, the question of resection of the tumor should be raised. When a notable tumor, that is circumscribed and not adherent to other parts, can be demonstrated, it may be very properly removed by a surgical operation. In cases of doubt, an exploratory incision may be needed in order to decide whether an operation upon the pyloric tumor can be safely performed. In many instances it will be found that what seemed, before the incision through the abdominal wall, to be a small and freely movable growth is really extensive and widely adherent. When such a state of disease exists, relief may be procured by making an opening between the cavity of the stomach and the small intestine below the tumor, gastro-enterostomy. In the majority of cases this will be the preferable operation, because less dangerous to the life of the patient. When there is esophageal obstruction the operation of gastrotomy may be resorted to. By these methods nutrition is once more established and life may be prolonged.

But, in the majority of cases, the fatal day is only delayed for a brief period. Death comes at last in every instance.

When pyloric stenosis does not exist, and when a tumor is either late in its development or can not be demonstrated, the treatment should have for its object the relief of suffering, and the improvement of nutrition. In the earlier stages of the disease much benefit may be derived from the use of sodium iodid in doses of ten or fifteen grains three times a day, with five drops of Fowler's solution of arsenic after each meal. So long as the mucous membrane of the stomach remains without ulceration, digestion may be aided by the administration of diluted hydrochloric acid, ten drops in half a glass of warm water after meals. But in the later stages of the disease, when acids are liable to cause pain, it is better to give the

various peptonized foods which are prepared by the manufacturing chemists. Being already partially digested they are more easily disposed of by the enfeebled stomach. For the same reason kumys and extracts of meat will be found useful. As a stimulant of the appetite and a preventive of nausea, the various preparations of condurango have considerable reputation, though the extravagant expectations that were aroused on the first employment of the drug have not been justified. It is, however, a valuable gastric tonic, which may be given before meals in doses of twenty or thirty drops of the fluid extract, well diluted with water. If the stomach be dilated by reason of pyloric stenosis, much relief will be obtained through daily washing out of the stomach with the gastric syphon-tube. This will prevent the accumulation of decomposing substances which liberate irritating gases and liquids that excite pain, and when absorbed into the general circulation, act as toxins upon the tissues of the body. Vomiting will be often relieved by this operation, which in any case should precede the administration of internal remedies. If the distressing nausea be not arrested by simple lavage, trial should be made of ice pellets, creosote, cocain, tincture of iodine, and the milder narcotics. If they fail to afford relief, we should give one-eighth of a grain of morphin with a drop of diluted hydrocyanic acid every hour till the pupils begin to contract. In severer cases, when pain is a prominent symptom, morphin and atropin should be freely given with the hypodermic syringe. In the later stages of the disease this often remains the only means of relief; and the comfort thus procured leads the unfortunate patient to exclaim, with the celebrated Dr. Bartlett, that "opium is God's greatest gift to man!"

THE EARLY DIAGNOSIS OF CANCER OF THE STOMACH.

Read before the Detroit Academy of Medicine. December 9, 1896.

BY CHAS. D. AARON, M.D.

INSTRUCTOR IN MATERIA MEDICA, DETROIT COLLEGE OF MEDICINE,
DETROIT, MICH.

If our treatment of cancer of the stomach shows poor results, it is due to the fact that the medical practitioner usually does not make his diagnosis early enough, and when the surgeon is called, he finds a disseminated mass instead of a circumscribed tumor to be extirpated. When we take into consideration that 5 to 25 per cent. of all deaths and 35 to 45 per cent. of all cancers are of the stomach, it is time that more attention be paid to an early diagnosis. It is because the average physician neglects a more detailed examination and resorts to bismuth and pepsin, that cancer of the stomach has been allowed to attain such development as makes an operation practically useless. What, years ago, Brinton said of cancer of the stomach, is still true today. He said, it is obscure in its symptoms, frequent in recurrence and fatal in its course. In spite of the progress made in the diagnosis of stomach diseases, the therapy of cancer of the stomach remains the same, namely, early extirpation. But when a large tumor can already be felt in the epigastrium, it is usually too late to operate, since then the surrounding tissues are involved by metastasis.

It is the intention of this paper to show how beneficial it would be, in the majority of instances, if a diagnosis were made before a tumor is palpable. We

are told of recoveries after operations on cancerous patients, when the tumor was already palpable, but these cases are extremely rare. It is possible that the diagnosis was made early by one who was able to locate the new formation. But can we make a diagnosis on the basis of the general course of the disease, even if the presence of a tumor has not been established? Boas tells us that strong Uffelmann's reaction after a test breakfast, points out the probability of cancer of the stomach. Heretofore it was believed that when we had a case of chronic gastritis, with absence of hydrochloric acid, either lactic, butyric or acetic acid fermentation takes place. This has been proven not to be true. While we were formerly able to demonstrate that lactic acid is present in cancer of the stomach, this circumstance was not given sufficient weight until Boas drew our attention more particularly to it. Boas says that in cancer of the stomach Uffelmann's test gives us a greenish-yellow reaction, due to the presence of lactic acid, and that the little quantity of lactic acid which results from other causes, does not react in the same way. Ewald tells us that the advantage of Uffelmann's test is its extreme sensibility to lactic acid found in carcinomatous patients, but in the differential diagnosis the abundance of lactic acid should always be taken into consideration.

To get an intense lactic acid reaction, it is necessary that there is a stagnation of the stomach contents and that hydrochloric acid is absent. If only one of these conditions is fulfilled, as in chronic gastritis or dilatation, we can not get this reaction. I concede that in rare instances we have a formation of small quantities of lactic acid, but it occurs in small quantity only and it does not give the characteristic reaction, as lactic acid does in carcinoma of the stomach. Whether we have a specific lactic acid or not in cancer of the stomach, I will not discuss here.

When the stomach contents show the absence of hydrochloric acid and the persistent presence of lactic acid, we are able to make a diagnosis by differentiation. There can be a choice of but one of three diseases, nervous anacidity, chronic gastritis or malignant new formation. We can always exclude nervous anacidity and chronic gastritis, on account of the persistent presence of lactic acid, which always indicates carcinoma of the stomach. It is necessary to look for a stagnation of the contents of the stomach. The patient may have vomited food which had been taken a day or two before, or we can estimate the amount of the stagnation by washing out the stomach. In chronic gastritis we never have a stagnation, there is usually a prompt forwarding of food into the intestine. In fact, in many cases of chronic gastritis, the motor function of the stomach is heightened, as I have often seen.

It is unnecessary to wait for the cachexia, edema of the joints, enlargement of the glands, fissured tongue, emaciation, obstinate coffee-ground vomit, insomnia, vertigo and the palpation of a tumor to make a diagnosis of cancer of the stomach. No surgeon can give us a good result after these symptoms have already appeared. It must not be forgotten that, in a number of cases, the liver prevents us from palpating a growth of the pylorus until it is quite large. It is frequently found that the fenestra of the stomach tube is filled with small particles of clotted blood. Professor Ewald regards this as an indication of carcinoma, even though a tumor is not yet palpable. These particles should always be examined micro-

scopically, and if cancer cells are present, our diagnosis is verified, but if absent, we can only suspect it. A diagnosis of cancer of the stomach can usually be made several months before the tumor becomes palpable.

The following points may be looked for: 1, a stubborn case of stomach disorder appears, in a person (say between 35 and 60) who was formerly in good health; 2, loss of weight and flesh; 3, vomiting occurs often; 4, a test breakfast proves that free hydrochloric acid is absent; 5, there is a stagnation of the stomach contents; 6, lactic acid is shown to be present in abundance; 7, a microscopic examination shows that long thread bacilli are present. Cases are repeatedly reported abroad in which, after a diagnosis of cancer made by the above symptoms, exsection of the pylorus was performed and the cure of the patient achieved.

It seems to me we are now able to make an early diagnosis of cancer of the stomach, before metastasis has taken place, by means of a thorough examination after a test breakfast.

I do not mean to imply that by means of the seven data I have enumerated, every cancer of the stomach can be easily recognized, but they indicate a considerable step forward in an early diagnosis, and thus open up for the surgeon opportunities which were closed to him till now.

For the examination for the presence of lactic acid, Uffelmann says that diluted solutions of neutral ferric chlorid turn canary yellow in presence of lactic acid. Should this reaction give no positive results, I would advise Kelling's modification. This consists in diluting the filtrate of the gastric contents from the tenth to the twentieth fold; to this one or two drops of a 5 per cent. ferric chlorid solution is added, and a greenish-yellow discoloration takes place. This proves the presence of lactic acid. In order to avoid the obscuration of this greenish color through the rhodan, which originates from the saliva, Kelling adds a few drops of a sublimate solution. The procedure as recommended by Strauss can also be applied. This consists in filling a burette, graduated at 5 and 25 c.c. respectively. We fill the burette up to 5 c.c. with the stomach filtrate, and add sulphuric ether up to the mark 25; this is well shaken, and through a stop-cock at the bottom, the burette is emptied to 5 c.c. and filled to 25 c.c. again with distilled water. To this are added two drops of a ferric chlorid solution (one to nine) and the whole is shaken. According to Strauss, if lactic acid up to 1 per cent is present, an intense green appears, and if the percentage is lower a pale green is noticeable.

For exact scientific data, the method of Boas is valuable. It aims at a decomposition of the lactic acid into acetaldehyde and formic acid, by adding some oxidizing agent and by the aid of heat.

The presence of lactic acid is proven by the existence of the aldehyde through the formation of iodoform, with an alkaline iodine solution or through the formation of mercuric aldehyde with Nessler's reagent.

In former years the results attained by exsection of the pylorus were far from satisfactory. This was due to the fact that it had been resorted to too late in the stage of the disease, when complications had arisen and the patient had been reduced in vitality, and metastasis had taken place. Later statistics, however,

are more favorable, and show what can be accomplished when a diagnosis has been made early. Haberkant performed 207 exsections of the pylorus, of which 114 were due to carcinoma; he had 93 recoveries and a mortality from pylorectomy in the carcinoma cases of 55.8 per cent. Hahn in 1891 had a mortality of 77 to 41 per cent. Zeller in 1893 a mortality of 61 to 34 per cent. But the most gratifying results Mikulicz reports in 1895. Out of eighteen pylorus exsections he lost only five cases. These statistics are in themselves a proof of the possibilities of success of pylorectomy, on condition of an early diagnosis. I can not warn too earnestly against the habit which physicians have, of waiting for the appearance of a palpable tumor, before they advise surgical procedure. Czerny and Rindfleisch have as far back as 1892 emphatically declared that, in the majority of cases when we make a diagnosis of cancer of the pylorus by the palpation of a tumor, no radical operation should be made.

32 Adams Avenue West.

THE FEVERS OF SOUTHWEST TEXAS.

A THIRD FEVER OF THE SOUTH.

BY R. S. WOODSON, M.D.

UNITED STATES ARMY, JACKSON BARRACKS, LA.

The differentiation of the fevers of the South has not kept pace with modern medical progress. The diagnostic dragnets, typhoid fever and malaria, have so monopolized the nomenclature of such diseases that the suggestion of a third fever is received with incredulity on the part of the profession. Many continued forms of disease, of doubtful etiology, have been reported as typhoid fever. Some local practitioners have disregarded differentiation and have adopted such terms as slow fever, Rio Grande fever, Texas fever, etc. Such looseness of diagnosis can not but be a bar to the progress of medicine.

It is conceded that the variability of the personal thermic coefficient, the different powers of resistance against the ravages of disease and the difference of intensity and virulence of bacterial infection will modify the classical course of any fever.

That saprophytic microorganisms may under certain conditions develop into pathogenic bacteria, capable of inducing infectious disease, the type of which, being dependent upon the environment of the germ, the stage of its evolution and the extent of infection may also be accepted.

The conversion, in the intestinal tract, of the colon bacillus into the typhoid bacillus, which it so nearly resembles and from which it is with such difficulty differentiated, its absorption through infection atriæ, may be regarded as a possibility. Indeed, it has been advocated that the colon bacillus itself may become the specific causative agent in the production of disease, and certainly no one will deny that the absorption of various ptomaines, developed in the intestinal tract from the decomposing contents, may be productive of continued fever.

While thus granting that mild atypical and abortive types of disease may occur, the conviction has been forced upon the writer that there exists a third fever of the South, not due to specific infection or to a hidden latent lesion; and though variously denominated by different observers, yet, from their consensus of opinion as to its symptomatology, I am led to believe that I am discussing the Texas fever (not the south-

ern cattle fever) of Assistant Surgeon McCullough, the intestinal toxemia of Surgeon Davis and the atypical typhoid of Surgeon Maus. (See report of Surgeon General, 1893-96.)

Two cases, with thermographs, illustrative of the types of the disease are presented.

Case 1.—Trumpeter Barton, Troop C, 5th Cavalry, Fort McIntosh, Texas, a man of great muscular development, gouty diathesis, exercised violently while playing the opening game of base ball, Sunday, April 12, from 1 to 4 P. M., weather intensely hot. Was much exhausted after the game. On the following day he suffered from general muscular soreness and fever. Was admitted to hospital April 15, 1896. Temperature 103 degrees F., general myalgia, headache, skin dry, constipation, partial suppression of urine, 420 c.c. in twenty-four hours, color reddish brown, strongly acid, sp. gr. 1.030, loaded with uric acid, calcium oxalate, and phosphatic deposits, pulse slow and strong. The disease dragged on with irregular thermic movement, for two months, during the course of which the subjective sensations of the patient were excellent; no emaciation occurred beyond what a light diet and confinement to bed would naturally produce. Urine continued scanty, only 450 c.c. excreted as late as May 12.

Case 2.—Blacksmith Graeff, Troop C, 5th Cavalry, a man of powerful physique and likewise of gouty diathesis, played base ball Sunday, April 26, 1896, for the first time in four

reasoned, *a priori*, from their gouty diatheses, large consumption of meat and beer, with a consequent retention and deposition of uric acid in the tissues during the cold months of comparative sedentation, and its fulmination into the blood during excessive exercise upon the advent of intensely hot weather; *a posteriori*, from the partial suppression of urine, increased excretion of uric acid, slow, high tension pulse, headache and diminished metabolism occurring during the disease.

In addition to the fever in question the following relevant facts were observed: 1, that children in this region (Southwest Texas), are to a great extent exempt from this disease; 2, that officers and women suffer from lithemia and neurasthenia; 3, that robust unacclimated cavalymen were the principal sufferers from fever.

In searching for an explanation of these observations, my attention was directed to an article by Prof. John Elliott, in the *New Orleans Medical and Surgical Journal*, 1878, entitled "Combustion and Assimilation,"¹ and to Alexander Haig's monograph, "Uric

CASE 1.

years; weather intensely hot; was much exhausted after game. He was admitted to hospital April 29, 1896. Temperature 104 degrees F., general myalgia, skin dry, bowels constipated, pulse slow and tense, headache, partial suppression of urine, 600 c.c. in twenty-four hours, sp. gr. 1.028, loaded with calcium oxalate and phosphates. Temperature steadily declined under treatment, with improvement of subjective symptoms, until discharged, May 9, 1896.

Numerous blood examinations were made in these cases with negative results. The quantitative estimation of urea was made but once, upon admission, in each case, and was found to be normal.

The treatment consisted of alkaline diuretics, baths and diaphoretics. Case 2 responded quickly to treatment, urinary secretion normal on the eighth day, while Case 1 remained obstinate to all treatment, urinary secretion remaining below 450 c.c., with dry skin and torpid bowels for four weeks, with a continuous abnormal excretion of uric acid.

The symptomatology and previous history of the two cases were identical, and although they differ greatly in their clinical course, they are believed to have been different types of the same affection.

That a uric-acidemia existed in both cases is

Acid as a Factor in the Causation of Disease." While the following is my own exposition of these subjects, and especially their application to the above phenomena, yet the credit of originality is due these authorities.

That the disease is not typhoid fever, I can do no better than refer the reader to Assistant Surgeon McCullough's able article contained in the Surgeon-General's Report, 1894. That it is not malarial has been proven by the invariable absence from the blood of plasmodia. From its non-specificity and absence of any pathologic lesion, I am convinced that it is a pure neurosis, a fever of exhaustion, involving the thermogenetic, thermo-taxic, thermo-lytic, portions of the sympathetic nervous system, and that it can be explained upon a purely physiologic basis as follows:

The manner of production of animal heat, its maintenance, distribution, control and dissipation, its

¹ The essence of this excellent and most convincing article is that the energy liberated during katabolic combustion, is utilized in lifting the food pabulum into the protoplasmic molecule. That any arrest in this process by reason of trophic inhibition, from whatever cause, is accompanied by the evolution of a lower grade of energy in the form of heat. He, therefore, briefly defines fever as an increased heat production, resulting from deficient tissue formation.

potentiality as forming the physical basis to the phenomena of life, are questions of importance in this discussion—of especial importance is the nervous system in controlling this production, distribution and dissipation. Those portions of the nervous system engaged in this functioning are the vaso-motor and trophic, the first having to do with the distribution and dissipation of heat (thermo-lysis), the second with its production (thermo-genesis).

The process of heat production is known to be an oxidation, in which, under the domination of the trophic nervous system, the potential energy stored up in the protoplasm of the cell during tissue anabolism, is converted into kinetic heat and mechanical work plus the products of katabolism, as evidenced by the appearance of carbon dioxide and water in the pulmonary exhalations, and urea, uric acid, etc., in the renal excretion. But the maintenance of the nitrogenous equilibrium in this fever, as evidenced by the lack of emaciation and normal excretion of urea, would

ing starvation, although tissue combustion is increased in the attempt to supply the requisite heat.

Under normal conditions of diet, exercise and health, the normal ratio between these two processes obtains, under the specific agency of the trophic nervous system; and with the aid of the vasomotor system in distributing and dissipating heat, the thermic balance between heat production and dissipation is maintained at 98.5 degrees F.

Now any inhibition of function of the vaso-motor and trophic nervous systems, arresting anabolism and diminishing heat dissipation, whether it be produced by surgical shock (surgical fever), in hysteria (hysterical fever), the passing of a sound (urethral fever), the irritation of bacteria or their toxins (specific fevers), exhaustion and fulminant uric-acidemia (the third fever), the transformation of energy, falling short in the work of anabolism, a lower grade of energy is produced in the form of animal heat. This heat, generated at such times and expended by the elevation of body temperature, is the mechanical equivalent of the arrested energy of anabolism.

The potentiality of the nutritive pabulum itself is of importance, the inhabitants of cold climates requiring food of higher potential energy than those of the tropics. According to physiologists 1 gram of fat = 9000 gram-calories; 1 gram of carbohydrates = 4000 gram-calories. Given a constant nutritive pabulum, with a variable thermal environment, an increased demand for animal heat will necessitate diminished tissue building, a less demand, an increase, or else an over-production of heat to be eliminated. Therefore, if an Esquimaux subsist on a vegetable diet, the entire potential energy of his nutritive pabulum would be transformed into kinetic heat, to meet the requirements of his environment, at the expense of tissue building. If an inhabitant of the tropics subsist upon fat, the high potentiality not being rendered latent in the formation of tissue (except in the case of growing children, and this explains their relative immunity against tropical environments) there would occur an over-production of animal heat.

As this theory of heat production is applicable to all fevers, it may be asked, what are the factors productive of the trophic inhibition? Beyond the physical exhaustion, incident to excessive work or exercise, involving exposure to the intense heat of a semi-tropical climate, there are produced during muscular metabolism large quantities of crystalline nitrogenous bodies, leucomains (uric acid group). In addition to this production, there is among carnivorous animals, a continuous introduction of these waste products, contained in their food. The daily consumption of 20 ounces of butcher's meat (soldier's ration) with its proportion of uric acid and allied leucomains, products of its own ante-mortem metabolism, must introduce a large quantity of these waste products into the system.

These bodies are soluble in the blood in direct ratio to its alkalinity, and are excreted in the urine. Any diminution of alkalinity must result in a deposition and consequent accumulation of uric acid *et al.* in the tissues. The alkalinity of the blood is lowered during the cold months, by reason of comparative sedentation, absence of sweating, increased consumption of nitrogenous food, combined with (at this post), excessive beer drinking. It is increased during warm months, in spite of nitrogenous and vinous ingesta, by excessive exercise, and especially through the

CASE 2.

indicate the small rôle played by morphotic combustion in its production, and while not denying the causative agency of this form of combustion in the production of the pyrexia of other diseases, yet in my opinion it has but a limited place in the etiology of this affection.

Constructive metabolism is not believed by physiologists to be attended by the evolution of heat, but the nutritive pabulum which is not lifted up into the protoplasmic molecule, the *luxus consumption* of the ancients, also undergoes oxidation and contributes largely to the maintenance of normal bodily temperature, and principally to the production of this fever.

It is evident that the bodily heat produced by the combustion of floating proteids must vary inversely with constructive metabolism, the evidence of this is the elevation of temperature observed after a full meal, where there exists a "luxus consumption" to be oxidized, and the subnormal temperature observed dur-

agency of the sweat glands in dissipating the acids of the blood.

Ninety per cent. of the heat elaborated in the human economy, is eliminated through the skin by radiation, conduction and evaporation. In this climate (south-west Texas), during three-fourths of the year, radiation and conduction are *nil* so that all the 90 per cent. of heat is eliminated by evaporation of sweat, with consequent increase of blood alkalinity. Now, any sudden excessive exercise, in a gouty subject, upon the advent of intensely hot weather, will result in a fulminating uric-acidemia, with a consequent shock to the vaso-motor and trophic nervous systems, together with the symptoms, high blood pressure, diminished metabolism, retention of waste products in muscular system, headache, partial suppression of urine, urine of high color and specific gravity.

It is to the culmination of the intense uric-acidemia that the paresis of the nervous system is due, with resultant continued fever. Children are exempt to a large extent, from this fever by reason of the fact that all of their nitrogenous ingesta is utilized in the up-building of tissue; officers and women by reason of their comparative sedentation and consequent exemption of this culmination of the uric-acidemia, do not suffer from inhibition of function of the vaso-motor and trophic nervous systems (fever), but do suffer to a marked extent from lithemia and neurasthenia.

I would define the affection as follows, a simple continued fever occurring in a gouty subject, primarily dependent upon a partial inhibition of function of the vaso-motor and trophic nervous systems, as a result of a fulminating uric-acidemia and physical exhaustion, consequent upon excessive and unaccustomed work or exercise, involving exposure to the intense heat of tropical or semi-tropical climates.

The limits of this article prevent an exhaustive discussion of all the facts and individual cases that might be advanced in support of my conception of the etiology of this affection. This paper is presented more as a suggestion than as a dogmatism, and while it represents my own personal convictions, yet a further study of the subject, with more elaborate methods of investigation, would be necessary before they can be accepted.

The writer has suggested the term *febris auto-intoxica* for reasons above indicated, but from its possible confusion with intestinal autotoxis it was withdrawn. Continued thermic fever, while a step forward, does not meet every requirement.

At the present time and in view of our uncertain ideas as regards its etiology, it is believed that "simple continued fever" expresses the condition as nearly as any.

At the time of these observations Vidal's method of diagnosis had not been presented. The writer takes this opportunity of expressing from his own limited observations, his convictions of its efficacy, and with the aid of which he hopes in the future to be able to make a further study of so interesting a subject.

Prescription Taking Done to the Letter.—Abbe Huc, the renowned French explorer and missionary, says that when a Tartar doctor finds himself without his drugs and medicines, he is not in the least embarrassed. He writes the names of the needed drugs on slips of paper, and these, being rolled up in little balls, are swallowed by the sick man. "To swallow the name of a remedy, or the remedy itself," say the Tartars, "comes to precisely the same thing."—*St. Nicholas*.

A BRIEF HISTORY OF INSANITY AND TUBERCULOSIS IN THE SOUTH-ERN NEGRO.

BY THOS. J. MCKIE, M.D.

WOODLAWN, S. C.

As a further elucidation of the subject of the etiology of tuberculosis and insanity in the southern negro is not without interest to the readers of the *JOURNAL*, as indicated by the able article of Dr. Powell and the discussion following, which appeared in the *JOURNAL* of December 5 of the year just past, the following brief history is offered as a record of the rise and progress of these allied diseases in a small portion of Edgefield County, on the extreme western border of South Carolina, and lying immediately between Stevens' Creek on the east and the Savannah River on the west.

Going back to 1848, when these observations began, it may be generally stated that tuberculosis and insanity were unknown and rarely heard of as diseases of the negro, in this section of our State; but, on the other hand, it was an admitted fact that he was peculiarly exempt from both. In 1866 the first case of tuberculosis ever seen in this locality by the writer occurred in the family of J. T. H., recently removed from the 96 section to the plantation of the late Governor Pickens, which lies in the fork of Stevens' Creek and Savannah River, nine miles above Augusta, Ga. This family (white) had already suffered a loss of several members before removal, and must therefore have brought the disease with them, or in them. No other white family has had a case.

The first case seen in the person of a southern negro happened in the family (man and wife) of J. H., who were servants to the white family H., both of whom died, as all who have since been attacked have done. Unlike the whites these two were previously considered healthy and of pure negro blood.

The next case occurred in the person of a married woman of mixed blood living seventeen miles north of the Pickens plantation, without social or other relation with any one on it, as far as could be ascertained. Soon other families began to suffer without regard to situation or social intercourse, showing, however, a predilection for certain families, whether living far or near. Especially has this characteristic been marked in the family of the woman of mixed blood, which has been well nigh destroyed, though quite a large one. In the aggregate, more families however of pure than mixed have succumbed.

Surprised and puzzled at this sudden and unaccountably new feature in the nosological table of negro complaints, it seemed not impossible that something of the true cause of tuberculosis might be gained here in a field where hitherto it had been entirely unknown, particularly in the southern negro, and a study of the diet, habits, mode of life, etc., of these stricken families was undertaken on the surrounding plantations and has been steadily pursued through the intervening year.

During this time many theories of its etiology have been advanced without having established one fact beyond the one of its wide prevalence in a region of country where before the establishment of a new order of things its existence was not known. Repeated inquiries made among fellows of the State Medical Society at their annual meetings, establishes the fact that very many have observed this change in the

character of disease in the negro, and many and various guesses have been made at the cause or causes that have brought it about. Among these, frequent mention has been made of scrofula and more of venereal, though neither seems to have anything to do with it, either as predisposing or exciting cause. In justice to the negro, be it said, taking into view his more limited moral training, his fewer social restraints, his unrestricted fields of social indulgence, his less refinement in the practice of vice or virtue, his want of knowledge of the baleful influence of the resulting evils, and he need not fear comparison with his more enlightened white neighbor, though both have kept comparative free from disease of this kind, contamination proving the rare exception in either. The co-existence of tuberculosis with syphilis, hereditary or otherwise, has not been observed in any case, notwithstanding the fact of a professional acquaintance with the diseases of several of these families which extends back to the days of slavery, when both syphilis and tuberculosis were entire strangers in the rural districts to which these observations relate.

Freedom from restraint permitting freer indulgence in all manner of excess, absence of regard for hygienic law or practice, excess in eating and drinking, the want of wholesome food, especially of the accustomed ration of fat bacon, have all had a place in the etiological table without sufficient reason for being there. In the ante-bellum ration, hog meat (bacon) and corn bread held first place for working people. For children, corn bread, pot liquor, milk, usually buttermilk, syrup or molasses formed the staple articles of diet, though meat (bacon) was not prohibited. Under the new dispensation, wheat bread of inferior quality and for the most part execrably prepared, took the place of corn bread (which the negro cooks as no other can), as milk and butter did the place of bacon. Here, it was at one time thought, might be found one of the causes which gave rise to tuberculosis, but further observation proved the fact that the most thriftless, with or without the use of milk or wheat bread, the most indifferent to the forms and usages of civilized life escaped the disease.

A population of 900 to 1,200 occupying an area of territory twenty by five miles in extent, and divided into plantations of creek, river and uplands, these latter for the most part broken and hilly, compose the material from which these observations are drawn, and will compare favorably with occupants of neighboring plantations in point of general health conditions. Continuing these observations with unabated interest it was noted that the most elegant, the most refined, well-to-do families supplied by far the greatest number of insane and tuberculous subjects. The most successful, those who seem to put forth the greatest effort to imitate the better class of their white neighbors, those living in the best houses, which are well kept and well supplied with the necessary comforts of life, are the chief if not the only sufferers. To attain this higher degree of civilization requires some ambition and far more than ordinary mental effort on the part of a people who had hitherto been totally unaccustomed to such mental strain, and who are equally unfitted either by nature, education or practice to assume these grave responsibilities, and as a consequence the penalty of an overworked nervous

organization, never strong, but delicate and sensitive in the extreme, must naturally follow.

It is a well-known fact that the negro's perceptive faculties are little inferior to those of the lower class animals. His olfactories are delicate, his vision is keen, far surpassing that of the Caucasian, particularly in the absence of strong light and at night; nor can any epicure boast the equal of his gustatory apparatus. Mentality or cerebral excitement but tends to insanity, and, when under continuous strain as in the struggle to get forward in the world, to its cousin german, tuberculosis. At least such has been the course marked in these observations. Religious frenzy has been a frequent precursor if not a cause of insanity. Several cases can now be recalled in which fatal results have followed attacks beginning in church during religious excitement. One fatal case can also be recalled in which unsatisfactory division of crops gave rise to it.

From the observations it may be concluded that in their etiologic relations insanity and tuberculosis are allied diseases; that both tuberculosis and insanity in the Southern negro have been the outcome of an overtaxed and overworked nervous organization unfitted by nature and otherwise to bear the burden imposed by newly created necessities or environment; that insanity and tuberculosis are *primarily and essentially neuroses*.

AN AORTA WITH A DOUBLE ARCH.

BY D. LEE SHAW, M.D.

ASSISTANT TO THE CHAIR OF ANATOMY, RUSH MEDICAL COLLEGE,
CHICAGO.

Congenital malformations of the aorta are comparatively rare. Quain divides such cases into six classes, viz.: 1, variations in position and extent; 2, variations of septum; 3, variations of stems; 4, variations of arch; 5, variations of descending portion and ductus arteriosus, and 6, variations in number and position of branches. The most uncommon of all, are those of the fourth variety, under which the double arch will be described.

In mammals the aorta normally passes to the left side of vertebral column, arching over the root of the left lung; in birds it passes to the right; and in reptiles it divides and passes to both sides. In this instance the arch presents a reproduction of the reptilian arrangement.

This specimen was taken from a fairly well nourished, white, male subject, in the anatomic laboratory of Rush Medical College. Previous condition and cause of death is unknown. No abnormalities were found in the venous system. The heart is 12 cm. in length, muscle normal, and the cavities are perfectly formed; no communication whatever exists between right and left sides. Pulmonary artery is normal in position and distribution, although, from its point of division, a septum 2 cm. in length extends into the main trunk.

Arch of the aorta, ascending portion, is 2.5 cm. in diameter and in its usual position. It divides, 3 cm. above the pericardial attachment, into a small left branch and a large right branch. The left division, 1.5 cm. in diameter, passes in front of the trachea, in the position of the normal arch; and 2 cm. from its origin, at the left antero-lateral aspect of the trachea, gives off the left common carotid; immediately behind which the left subclavian arises. The left arterial trunk is continued by an isthmus, .75 cm. in diameter

¹ Only two cases of syphilis happening before 1865 can now be recalled, one in a girl of 15, the other a man, both on the same plantation, and contracted in Augusta, Ga.

and .5 cm. length, which, with the ductus arteriosus, joins a dilated portion, 2 cm. in diameter and 1.5 cm. in length, which extends backward to the left of the trachea and esophagus, and communicates with the right branch. The ductus arteriosus is a firm round cord in normal position and is not patulous.

The right division, 2.5 cm. in diameter, passes upward, along the right side of the trachea, reaching the level of the third dorsal vertebra; and 2 cm. from its origin, it gives off the right common carotid and 2.5 cm. beyond this, from the highest part of the aorta, the right subclavian arises. Beyond the origin of this vessel the right branch passes downward and backward, 3.5 cm., and behind the esophagus, unites with the left to form the descending aorta, which extended downward along the right sides of the dorsal vertebrae, from the fourth to the seventh inclusive,

Malacarne's report, as described by Meckel and Quain, differs from all the others. Five valves guarded the aortic opening of the left ventricle and the arterial trunk immediately divided into two branches, which before uniting, embraced the pulmonary artery, trachea and esophagus; from each division, was given off in succession, a subclavian, an external and an internal carotid artery. In Welch's case, the posterior branch passed between the trachea and esophagus and, from each division arose a common carotid and a subclavian artery. On the posterior branch, was found an aneurysm from which the right common carotid took origin.

My specimen differs from all of those described, except Malacarne's, in that the two divisions unite behind the esophagus. It differs from all, in that the right branch is the larger, the junction of the two

Heart with large arteries. Anterior view.

Heart and aorta. Posterior view.

and, on the body of the eighth, crossed diagonally to the left side and continued below in its usual position. No septum is found in the descending aorta.

The pneumogastric nerve, on either side, lies between the common carotid and subclavian arteries. The left crosses the isthmus and its recurrent laryngeal branch winds under the ductus arteriosus, in the normal position. The right passes downward over the main arch, under which the recurrent branch of this side is given off. Similar cases have been reported by Hommel, Curnow, Malacarne, Zagorski and Welch.

Hommel, in 1737, was the first to record findings of this character. In his case, according to Meckel, the two divisions united after encircling the trachea, and passed downward on the left side of the vertebral column.

branches is on the right side and the descending aorta passes downward on the right side, to the upper border of the eighth dorsal vertebra.

This arrangement not only resembles the vascular rudiment in the reptile, but also more closely follows the distribution in the bird, than does it that in the mammal.
