The second point in Dr. Ingals' review states: "It is claimed that nearly all cases of asthma are the result of disease in the nasal cavities." I very distinctly stated in the introduction to and in the course of my paper, that the only form of asthma which I wished to consider was that perennial form which is more or less independent of the seasons, and not complicated with organic disease, etc., namely,—"*Asthma nervosum seu essentiale.*" This is, comparatively speaking, a rarer form of asthma (*vide* Niemeyer's Spec. Path. and Therap., 10th ed.), and therefore the reproach quoted above falls to the ground.

Dr. Ingals' third point is: "It is also claimed that cauterization of the nasal mucous membrane will cure the majority of the cases of asthma." This statement is controverted by my objection to Dr. Ingals' second point. Very truly yours,

EDWIN J. KUH, M.D.

Central Music Hall, Chicago, March 9, 1887.

ASSOCIATION ITEMS.

AMERICAN MEDICAL ASSOCIATION.

The Thirty-eighth Annual Session will be held in Chicago, Ill., on Tuesday, Wednesday, Thursday and Friday, June 7, 8, 9 and 10, commencing on Tuesday, at 11 A.M.

"The delegates shall receive their appointment from permanently organized State Medical Societies, and such County and District Medical Societies *as are recognized by representation in their respective State Societies*, and from the Medical Department of the Army and Navy, and the Marine Hospital Service of the United States.

"Each State, County, and District Medical Society entitled to representation shall have the privilege of sending to the Association one delegate for every

ten of its regular resident members, and one for every additional fraction of more than half that number: *Provided*, however, that the number of delegates for any particular State, territory, county, city or town shall not exceed the ratio of one in ten of the resident physicians who may have signed the Code of Ethics of the Association."

Secretaries of Medical Societies, as above designated, are earnestly requested to forward, *at once*, lists of their delegates.

Also, that the Permanent Secretary may be enabled to erase from the roll the names of those who have forfeited their membership, the Secretaries *are, by special resolution*, requested to send to him, annually, a corrected list of the membership of their respective Societies.

SECTIONS.

"The Chairmen of the several Sections shall prepare and read, in the general sessions of the Association, papers on the advances and discoveries of the past year in the branches of science included in their respective Sections. . . " *By-Laws*, Art. II, Sec. 4.

Practice of Medicine, Materia Medica and Physiology.—Dr. J. S. Lynch, Baltimore, Md., Chairman; Dr. J. B. Marvin, Louisville, Ky., Secretary.

Obstetrics and Diseases of Women and Children.—Dr. F. M. Johnson, Kansas City, Mo., Chairman; Dr. W. W. Jaggard, Chicago, Ill., Secretary.

Surgery and Anatomy.—Dr. H. H. Mudd, St. Louis, Mo., Chairman; Dr. A. M. Pollock, Pittsburg, Pa., Secretary.

State Medicine.—Dr. George H. Rohé, Baltimore, Md., Chairman; Dr. Walter Wyman, U. S. M. Hospital, New York, Secretary.

Ophthalmology, Otology and Laryngology.—Dr. X. C. Scott, Cleveland, O., Chairman; Dr. J. H. Thompson, Kansas City, Mo., Secretary.

Diseases of Children.—Dr. DeLaskie Miller, Chicago, Ill., Chairman; Dr. W. B. Lawrence, Batesville, Ark., Secretary.

Oral and Dental Surgery.—Dr. John S. Marshall, Chicago, Ill., Chairman; Dr. A. E. Baldwin, Chicago, Ill., Secretary.

Medical Jurisprudence.—Dr. I. N. Quimby, Jersey City, N. J., Chairman; Dr. H. H. Kimball, Minneapolis, Minn., Secretary.

A member desiring to read a paper before a Section should forward the paper, or its *title* and *length* (not exceeding twenty minutes in reading), to the Chairman of the Committee of Arrangements at least one month before the meeting.—*By-Laws.*

Committee of Arrangements.—Dr. Charles Gilman Smith, Chicago, Ill., Chairman.

Amendment to By-Laws.—Create a new Section, to be known as the Section on Dermatology and Venereal Diseases.

Wm. B. Atkinson, M.D.,
Permanent Secretary.

Philadelphia, 1400 Pine St., S. W. cor. Broad.

Chicago College of Pharmacy.—At the recent annual meeting of the College, George Buck was elected President; Judson S. Jacobus, Treasurer; and D. H. Galloway, Secretary.

INTERNATIONAL CONGRESS.

NINTH INTERNATIONAL MEDICAL CONGRESS.

In reference to demands from various quarters for information as to hotel rates here in Washington, and what arrangements have been made for a reduction of the same, by our committee, in favor of those who will attend the International Medical Congress, I beg to announce the following scale of prices:

The Arlington Hotel, from $3 to $3.50 per day.
Riggs House, from - - $3 to $3.50 per day.
Willard's Hotel, from - $3 to $3.50 per day.
Metropolitan Hotel, - - - - $3.00 per day.
National Hotel, - - - - - $3.00 per day.

Other hotels, conducted on European style, will furnish rooms at from $1 to $2 a day. First-class lodging houses will also furnish rooms from $1 to $1.50 a day.

A. Y. P. Garnett, M.D.,
Ch'n Com. of Arr. Int. Med. Congress.
1319 New York Ave., Washington, D. C., March 14, 1887.

Since the statement concerning reduced rates on the transatlantic steamers, given in this journal for Feb. 26, page 241, we have been officially informed by the Committee of Arrangements that, in addition to the steamship lines then given, the North German Lloyd Line has agreed to give physicians and members of their families the round trip from Bremen to New York and return at $187.50, and the Cunard Line agrees to deduct ten per cent. from usual rates for members of the Congress only.

We are further authorized to state that Albaugh's and the National Theatre and Willard's Hall, in Washington, have been secured for the use of the Congress. The last-named will be headquarters and the place of registration.

Congress, before its recent adjournment, appropriated $10,000 from the National Treasury to aid in defraying the necessary expenses of the Medical Congress.—Editor.

MISCELLANEOUS.

Western Reserve University.—A very elegant and complete new building for the Medical Department of Western Reserve University in Cleveland, Ohio, had been completed and was formally dedicated on the evening of March 8, 1887. The entire cost, about $175,000, was the donation of Mr. John L. Woods, a wealthy and liberal citizen of that city.

NOTES AND ANSWERS.

ARMY SURGEONS ON SICK LEAVE.

Sir:—An answer to the following question will be highly appreciated: Can an Assistant Surgeon U. S. A. on sick leave practice medicine in the town where his home is, hold a State position, and keep a drug store, all at the same time?

Inquirer.

Key West, Fla., March 7, 1887.

We are not familiar with the Army regulations concerning the rights and duties of Assistant Surgeons on *sick leave*. Will some reader give "Inquirer" a correct answer?—Editor.

DEEP TUBING OF THF LARYNX AS A SUBSTITUTE FOR INTUBATION.

With a Report of Nine Cases and Presentation of New Instruments.

Read before the Chicago Medical Society, March 7, 1887.

BY A. E. HOADLEY, M.D.,

PROFESSOR OF ANATOMY, CHICAGO COLLEGE OF PHYSICIANS AND SURGEONS, PROFESSOR OF SURGERY IN THE CHICAGO POLICLINIC, ETC.

In April, 1886, I became convinced that intubation of the larynx was a justifiable surgical procedure, and a valuable substitute for tracheotomy in selected cases. I therefore procured a set of the O'Dwyer instruments and tubes. Although I had handled the tubes and seen them introduced, and a year previous had introduced them myself on the cadaver, I did not until this time give serious consideration to the position of the tube after the introduction. I had no difficulty in coming to a conclusion in this matter. From my knowledge of the larynx, and the contour of the head of the tube, I decided that the head of the tube was designed to rest within the larynx, with its projecting flange resting upon the false vocal cords, with the straight part of the tube behind resting against the posterior straight wall of the larynx. (Fig. 1.)

It was not until I had in this manner tubed five cases that I was informed that it was not the design of the inventor, Dr. O'Dwyer, to have the head of the tube rest within the larynx, but on the contrary to have the flange project laterally and posteriorly above the opening into the larynx, resting upon the arytenoid cartilages behind, and the aryteno-epiglottidian folds on each side, with the head of the tube in such a position that when the epiglottis is closed, it would come in direct contact with the tube, closing its orifice but allowing its flange to project beneath it. (Fig. 2.) It now became necessary for me to either acknowledge my error and turn the tube around, or justify the position and claim an improvement. I examined the five cases and was fully convinced that the deep position was at least worthy of further trial. I can now present a summary of nine cases which I have thus treated. Seven of the operations were performed for other physicians; for Drs. R. N. Hall, G. M. Emrick, E. E. Holroyd, Wm. Rittenhouse and Caldwell. Two were performed where there had been no physician in attendance until I was called and found it necessary to tube immediately. I have not as yet had an opportunity of watching the patients as closely as I could desire, and for the main facts relative to the subsequent behavior of the patients I am indebted to the physician in attendance. Of the two cases above referred to, I saw one six hours after the operation. She was perfectly comfortable as far as breathing and wearing the tube were concerned. The other died twelve hours after the operation, before I saw her a second time.

FIG. 1.—Deep tubing.

FIG. 2.—Intubation.

The ages of the patients ranged from 2 to 6 years. All had diphtheritic laryngeal stenosis. They were all bad cases and all died in from twenty-four hours to four days after the operation. The stenosis was promptly relieved in all. Eight out of the nine were able to drink several consecutive swallows immediately after the operation, and continued to do so as long as they could swallow. The eight suffered little or no pain from the presence of the tube, nor was the cough particularly troublesome. Four coughed but very little. In one the presence of the tube in the larynx did not excite cough; on the contrary, there was less coughing than before the tube was introduced. In one case the tube was coughed out, and a larger tube was introduced, which remained until the child died from extension of the exudate below the tube. In no case was there subsequent obstruction above the tube. In one case the obstruction seemed to be in the fauces and pharynx, and I feared that tracheotomy would be necessary, but "deep tubing" gave prompt relief. In two cases while

pressing the tube down deep into the larynx, it was felt to slip by an obstruction and pass beyond reach. In these two cases I believe the head of the tube was lodged in the ventricle of the larynx, resting upon the true vocal cords. There was no unusual inconvenience from the presence of the tube in this situation. I removed the tube in one of these cases and I had as little difficulty as in any, which I think would be equally true had the child been living. I might state while giving this opinion, however, that I have never extracted a tube from the living subject.

One case suffered severe and continual pain from the presence of the tube, and could not drink one drop without strangling and having a violent fit of coughing following the attempt; she was fed by means of a tube in the œsophagus. She died on the fourth day from pneumonia, the development of which was probably favored by the irritation of the tube. This was Olga L., a girl 5 years of age, a patient of Dr. Emrick's. About two years previous, she swallowed, by mistake, some concentrated lye, causing extensive destruction of the tissue followed by a violent inflammation. After a long and desperate struggle she recovered her general health; but there remained two almost impervious strictures of the œsophagus. She had been under my care six months for the surgical treatment of the strictures when she contracted diphtheria, for relief of which the "deep tubing" was practised. It was to these changes in the pharynx and œsophagus caused by the lye that I attributed her intolerance of the laryngeal tube.

In seven cases death was caused by constitutional diphtheria, in one by extension of the exudation below the tube, and in one from pneumonia. While this summary of nine fatal cases of intubation of the larynx for diphtheria would show that intubation does not cure; it does not prove that intubation is an unjustifiable practice. On the contrary, it shows that the practice is one capable in the simplest manner of affording the greatest possible relief and allowing the patient to die a less horrible death than that of suffocation, and at the same time give one more chance for life.

In comparing the two methods of introducing the tube, I would call attention to what I regard as the most objectionable feature of the O'Dwyer method. It is the projection of the head of the tube over the top of the larynx in such a manner that it prevents the glottis from folding down and adapting itself to the top of the larynx in the usual manner. This leaves a margin of laryngeal mucous membrane exposed, which has been in the habit of being covered at every act of deglutition. The projections of the tube do not cover it perfectly, so that in every act of swallowing the food is allowed to come in contact with this surface, which is excessively sensitive to everything but air, and must necessarily excite coughing. I have no doubt but what the glottis will close the orifice of the tube perfectly, thus preventing any food from getting into the tube, but it cannot close the larynx by the side of the tube, and food, fluids especially, are forced into the larynx, thus causing the most distressing paroxysms of coughing at every attempt at swallowing. All this is obviated by the method that I have adopted, as the head of the tube is within the larynx and well below the opening, so that the glottis does not touch the tube and can therefore perfectly guard the larynx.

In reference to the removal of the tube, it is my opinion that the tube can be more quickly engaged by the extractor while it rests within the larynx, than while the head of the tube rests above the larynx. The head of the tube being surrounded by the upper extremity of the larynx, greatly facilitates the operation, as it is not easy to get the extractor down by the side of the tube, which is the source of the greatest annoyance with the tube in the high position. With reference to the danger of introducing the tube into the trachea, I would state that it is certainly a remote danger, as any one will admit that attempts to push the head of a well fitting tube beyond the chink.

The modifications in the tube that have suggested themselves for the better adaptation to this mode of intubation, and which have been constructed for me by Sharp & Smith, of Chicago, are:

Shortening the tube to the length of the larynx, or perhaps a trifle longer. (Figs. 1 and 3.)

Fig. 3.

Fig. 4.

Making the head of the tube conform more nearly to the shape of the interior of the upper part of the larynx.

Making the upper surface of the head of the tube slightly cup shaped for the purpose of favoring the introduction of the extractor.

Having that portion of the posterior border of the tube, which corresponds to the arytenoid cartilages stand on a plane anterior to that of the rest of the tube, so that the pressure at this point may be slight. As the arytenoids are supported by muscles we should avoid putting them on the stretch. Constructing the obturator so that it will project three-eighths of an inch from the lower end. My tube, being a little shorter than the most convenient length for introduction, the longer tip of the obturator enables one to pass the tip to the proper position below the chink, when the tube should be detached, and pressed home with the finger before the obturator is withdrawn.

The greatest objection to using the tubes of the present construction for "deep tubing" is their length. The O'Dwyer tubes (Fig. 4) when placed deep in the larynx, will reach to the seventh ring of the trachea, as shown by an autopsy. This, owing to the mobility of the lower end of the tube in the trachea in the varying positions of the neck, is a source of irritation exciting cough and inducing pain. One of my patients would invariably point to that locality when asked to locate the tube.

Finally, I would recommend "deep tubing" of the larynx as being preferable to "intubation," even though the long tubes are used, holding that long tubes are preferable only in very exceptional cases.

EMMET'S NEW OPERATION FOR PROLAPSE OF THE POSTERIOR VAGINAL WALL,

Or So-called Laceration of the Perineum.

Abstract of a Paper read before the Obstetrical Society of Philadelphia, February 3, 1887,

BY J. M. BALDY, M.D.,

OF PHILADELPHIA.

Since I have become familiar with the subject it has each day seemed more incomprehensible to me why the Emmet operation has not come into more general use. I have come to the conclusion that the fault lay in defective description of the operation as set forth in most cases, and in the fondness of men for working on the skin perineum, and not in the operation *per se*. The operation, as described by most of the writers on the subject, is hopelessly mixed up with long discourses on side issues. Too much is left to be understood from diagrams alone, with insufficient attention to details in the procedure. These are prominent faults in the descriptions given by Drs. Emmet and Dudley. Dr. Dudley also obscures his paper, as presented in "Pepper's System of Medicine," by introducing several "modifications." The first of these is one of the essential steps in the operation, though not clearly described by Dr. Emmet in the third edition of his "Gynecology." It consists in carrying the denudation into the vaginal sulci. The second consists in passing deep sutures where Dr. Emmet passes superficial ones. In reality, Dr. Emmet's "superficial" stitches are only relatively superficial. His description of them distinctly calls for their being passed deeply enough to include the posterior wall. My excuse, therefore, for offering a contribution on such an old subject, is to attempt to make the steps of this operation clear; and if I seem tedious in detail to those who are familiar with the subject, I hope you will bear with me patiently.

The belief that the female perineum, or perineal body, gives any support to the pelvic viscera, is an erroneous one. The distance between the uterus and the perineal body is quite measurable, and the intervening tissues, which consist merely of the mucous vaginal canal and surrounding connective tissue, are by no means of such a firm character as to be able to uphold the uterus either *per se* or through the support given by the perineal body below. The only aid this body could give the supposed support would be by the uterus resting directly upon it. Dr. Emmet puts it very happily when he says "it would be as rational to assume that a man's pantaloons were supported by the legs resting on the instep or foot." The principal support of the pelvic organs is their ligamentous attachments, on the same principle as the organs contained within the abdominal and thoracic cavities are suspended. A good proof of this is the fact that we constantly see women going about their daily work who have their superficial or skin perinea, not including the fasciæ or muscles, torn even to the sphincter ani, and who never have suffered any inconvenience therefrom, and who probably never will. The cause of all the various ailments following parturition, beginning procidentias, etc., will be found inside the vagina on the posterior wall. If any one will place his fingers on the posterior vaginal wall of a woman who has never borne a child, and move them first to one side and then to the other, he will find a firm resistance to pressure in any direction. If he now introduce his finger into the vagina of a woman who has had an injury to the pelvic floor during parturition, he will fail to meet with the resistance which he met in the first case. He will find instead a *rectocele* of greater or less extent, with deep divulging sulci running up each side of the recto vaginocele, into which he can easily sink his finger without finding much resistance, and yet the external or skin perineum may be perfect.

To fully and clearly understand this change it will be necessary to consider the attachments of the pelvic viscera. The pelvic fascia descends until it reaches its attachment on a line drawn from the symphisis pubis to the spine of the ischium, where it divides into two layers, the outer or obturator, and the inner or recto-vesical fascia. This line of separation in great part also corresponds to the line of attachment of the levator ani and coccygeus muscles. The levator ani extends from this attachment downward, and passing under the vagina is inserted into the rectum at different points. It is covered on its upper surface by a reflexion of the recto-vesical fascia, which binds it closely to the vagina and sphincter vagina muscle, and on its under surface by a reflexion of the obturator fascia, which binds it closely below. The transversus perinei, when it exists at all, arises from the pubic arch, and its fibres are lost in the sphincter vagina directly under the vagina. In speaking of the use of the sphincter vagina Dr. Goodell says that "the property of this muscle is to pull down the rigid clitoris into contact with the male organ, to squeeze out the contents of the vulvo-vaginal glands, and to compress the dorsal vein as well as the bulbs of the vagina, so as to obstruct mechanically the current of blood and produce a turgescence of these erectile organs." If this be correct, we have an explanation of the loss of sexual power and desire so often seen in women who have suffered from a tear of this muscle. The recto-vesical fascia sends out reflexions from its bony attachments also over the vagina as well as over the other pelvic contents, forming the strong ligaments which

hold them in place and give firm support to the different venous plexuses; amongst others the vaginal plexus.

The advancing head of the child, under certain circumstances, crowds the soft parts in advance as it sweeps along the pelvic floor and the fasciæ and muscles just described, becoming over-distended, separate and retract, forming deep sulci laterally. Frequently the injury is sub mucous. The external soft parts or skin perineum may be torn or not; very often it remains perfectly intact. There is no question in my mind that this injury is caused with unnecessary frequency both by the injudicious use of the forceps and by our vain efforts to "support the perineum." As a rule our patients would be far better off if we were to throw our forceps away and keep our hands off the perineum, as far as any idea of giving it support is concerned. If we hold the head back the vis-a-tergo must be spent somewhere, and that somewhere is the pelvic floor, which suffers accordingly.

The mere rupture of the fasciæ and muscles would cause the woman little trouble of themselves, but the results are far-reaching. The fasciæ being the chief support of the blood vessels, we now have these large veins with no support but their own walls; consequently we soon have a chronic engorgement, with dilatation and a very sluggish return of blood from the parts. The viscera become engorged and heavy. The anterior wall, which has lost its main support—the posterior wall—begins to roll down and out, forming a cysto-vaginocele; the posterior wall gradually pushes forward and bulges from the vaginal orifice as a recto-vaginocele. The fundus uteri becomes or remains enlarged and falls backward from its weight and the traction of the vaginal wall. Gradually but surely the ligamentous attachments of the uterus are stretched and the whole organ slowly descends, dragging everything with it. We eventually have all the phenomena of complete procidentia if things go on unheeded. This theory of the injury in the female pelvis in parturition is by no means new. It is substantially the same view held by Emmet and expressed by Hadra, in the *American Journal of Obstetrics*, April, 1884, by Wylie, in the *N. Y. Medical Record*, March, 1885; Skeene, in *N. Y. Medical Journal*, April, 1885, and by James Price, in a paper read before the Philadelphia County Medical Society last spring.

The old operations, devised on the supposition that the injury of the perineal body was the cause of all the symptoms, included far more labial tissue than had been involved in the tear, and were entirely inefficient for restoring the pelvic floor. They caused an unnecessary barrier to coition, and frequently left the patient with a certainty of return of all her ailments, and a probability of the tear being reproduced at a subsequent labor.

The only satisfactory surgical procedure suggested as a cure of the injury is that of Dr. Emmet, for "restoration of the pelvic diaphragm." The patient is placed in the dorsal position, and the labia separated by assistants; hook a tenaculum or a ligature (which remains a permanent landmark to the end of the operation) into the crest of the rectocele and draw it upwards, without undue traction, to the meatus, and place it in the hand of an assistant. Hook another tenaculum into the labial tissue on each side directly opposite to or in the lower caruncle or remains of the hymen. If slight traction in diverging directions be made in all the tenacula at the same time three triangles are formed having the crest of the rectocele for their common apex. The base of the first is a line drawn from caruncle to caruncle, and the bases of the others a line drawn from each caruncle to a point far up the sulcus of the same side. On denuding these surfaces and bringing the three tenacula together, "the vaginal canal will be found reduced in size, the perineum will have been apparently drawn up toward the arch of the pubes, and the tissues of the previously gaping outlet will have been rolled in until the vaginal entrance is no longer larger than that of any female who has not given birth to a child at full term." The posterior wall is brought firmly up against the anterior wall and bladder, giving them them their natural and necessary support, and preventing their rolling down and out. Care must be taken not to denude too much surface in the sulci, as failure may result, the sutures cutting out from undue traction. The scissors should be used for all plastic work in the vagina. Any one becoming accustomed to their use will never go back to the knife. The bleeding is infinitely less and much time is saved by the celerity with which they can be handled.

The most essential part of the operation is the introduction of the sutures. They are passed from the apex of each sulcus toward the operator. A tenaculum is hooked into the apex of one of the sulci and drawn away toward the cervix uteri, thus preserving the line on which the sutures are to be introduced. The sutures are then all passed toward the operator to the bottom and median line of the sulcus, plenty of tissue being included; the sutures emerge at the median line of the sulcus and are reintroduced in the same spots and carried away from the operator, emerging just beyond the freshened edge of the rectocele directly opposite the original point of introduction, on the other side of the sulcus, thus taking a V-shaped course. The number of sutures is usually four or more. The other side is sutured in the same manner. When these sutures are all drawn up into place and closed, there remains a small triangular space of freshened surface in front of the rectocele, which is closed by the so-called crown stitch and one or two superficial external stitches. The crown stitch is introduced through labial tissue at the lower caruncle, the original point of introduction of one of the tenacula carried across through the crest of the rectocele and then through labial tissue at the lower caruncle on the opposite side. All the other sutures are now lost to view within the vagina. The resulting shallow line directly in the median line of the perineum is closed by one or more superficial external stitches. They are passed deep enough to include a portion of the posterior vaginal wall.

The day for plunging a great perineal needle through glutoid tissues, skin, muscles, fasciæ, nerves

and blood-vessels, is past. It is as much a relic of barbarism as searing the stump of an amputation to stop hæmorrhage, and causes much pain and suffering. The material of the suture is immaterial. Catgut can be either shotted or tied. As moisture causes the gut to swell, it should be shotted as soon as passed and fastened to the pubic hair with a pair of hæmostatic forceps. This will keep them out of the way of the operator. Dr. Emmet always uses silver wire twisted and then shotted so as to be easily found; the end is bent over and lies flat on the tissues. Silkworm gut should always be shotted. It makes an excellent suture, and forms a good splint to the tissues. Whatever is used, the stitches are equally hard to find and remove. A very easy method for either wire or gut is the use of "Aveling's wire coil." These can be made by wrapping a piece of silver several turns around a straight needle or other staff, to form a close coil about half an inch in length. This coil is slipped over the two ends of the suture and secured in its proper place by a compressed shot. In removing, snip off the shot, remove the coil, and the suture has ends as long as the coil was.

The after-treatment is very simple. If the patient would stay quietly in bed she would recover with perfect union without the doctor's attention. As a rule the patient complains of no pain, and opium and alcohol are not needed. The bowels are kept soluble from the first; and the urine is passed every four or five hours, the patient getting on her hands and knees if necessary. There is no necessity for binding the knees together, nor for keeping the woman in one position for days. The stitches may be taken out on the eighth day.

A CASE OF INTRA-LIGAMENTOUS OVARIAN CYST; GENERAL PERITONITIS; UNIVERSAL ADHESIONS; OVARIOTOMY; RECOVERY.

A Paper read before the Central Kentucky Medical Association.

BY L. S. McMURTRY, A.M., M.D.,

OF DANVILLE, KY.

FORMERLY PROFESSOR OF ANATOMY IN THE KENTUCKY SCHOOL OF MEDICINE, ETC.

In previous reports of cases of ovariotomy to this Society I have described the technique of the operation, and discussed points relating to the diagnosis and pathology of ovarian tumors. So much has been written of late upon this subject, and such brilliant results have been obtained by many operators, that an eminent authority suggests the idea that the last words are said upon the subject. While this degree of perfection may apply to a few expert operators working amid the dense population of certain European countries, the subject of ovariotomy cannot be regarded "a closed chapter" by the profession of the United States, where a large population is scattered over a vast area and the work necessarily distributed among a large number of operators. Hence I make no apology for reporting in detail the following difficult and complicated case, illustrating, as it does, so many important points in advanced abdominal surgery.

On November 18, 1886, I was called to Williamsburgh, Ky., by Dr. E. S. Moss, of that town, to see Mrs. G. W., aged 29 years, the mother of six children, the youngest being 3 years of age. The patient was confined to her bed, vomiting daily, and suffering severely from the effects of intra-abdominal prepuce. The tumor was first observed two years ago. Six weeks previous to my visit she was tapped and a large quantity of fluid drawn off. This was followed by a severe attack of general peritonitis, the temperature ranging above 105° F., during which her life was almost despaired of by her physician. Three weeks before my visit she was tapped the second time, and the fluid again rapidly accumulated. A careful physical examination confirmed the diagnosis and suggested extensive adhesions.

The operation was performed at 11 o'clock on Thursday, November 18, 1886, the following gentlemen being present: Drs. E. S. Moss, Gatliff, Watkins, Parker, Blain, and Ellison. Dr. Gatliff administered ether, and Dr. Moss kindly assisted me throughout the operation. On making the incision through the abdominal wall I found the peritoneum and cyst firmly adherent, and dividing this layer the tumor was opened. Turning the patient on her side a large portion of the contents was discharged. Introducing my hand, the tumor was found to be multilocular; the additional compartments were torn open and emptied. At this stage of the operation I was first able to appreciate the immense size of the cyst and the extent of adhesion. Only three weeks having elapsed since the last tapping, and the fluid not having fully refilled the sac at the time I saw the patient, I had failed to realize the immense size of the sac. I now discovered that the tumor extended from Douglas's cul-de-sac to the diaphragm, and that the adhesions were absolutely universal.

Being unable to evert the sac, I sought for some unattached point through which I might gain entrance to the peritoneal surface and remove the cyst by enucleation. In this I failed, for the preceding peritonitis had firmly fused the peritoneum and cyst wall, leaving no unattached point. To determine this point thoroughly I enlarged the incision from three to about five inches. Finding it impossible to gain an entrance by an unattached point, I began the dissection of the cyst with scalpel and forceps at the edge of the incision. I succeeded in getting "a hold" in this way, and proceeded cautiously, but as rapidly as I could, in the work of enucleation. I stripped the cyst from the pelvis, the bladder, and the whole surface of the womb, from the ascending, transverse and descending colon. I then stripped the small intestine and omentum from the cyst. The latter was extensively and firmly adherent, and required a number of ligatures. I was careful to avoid injury to the ureters on each side, an accident not unknown in such cases, and, of course, one of the utmost gravity. The lower portion of the cyst I found included between the folds of the broad ligament, and had to be carefully enucleated. The tumor sprang from the right side. When all the adhesions were

separated the tumor came away without a pedicle. The left ovary was found to be normal, and hence was not removed.

The toilette of the peritoneum was tedious and exacting; many bleeding points had been secured with forceps and many were ligatured. After securing all bleeding points, the abdomen was washed out with pure warm water, and I began the introduction of the parietal sutures. At this stage of the operation the patient's pulse became very rapid and feeble, and, assisted by the gentlemen already named, I placed her in bed, injected brandy beneath the skin in several places, and surrounded her with bottles of hot water. Through the lower angle of the wound I then passed a Keith's glass drainage-tube, and tied the stitches closing the incision. The surface of the abdomen being thoroughly cleansed and dried, the wound was dressed with antiseptic gauze, and a bandage applied. The drainage-tube was secured in place in the usual way, and its external opening protected with sponge and rubber sheeting. The entire operation occupied fifty-eight minutes.

The patient occupied a room to which she had been removed from her home in the country, and which had been carefully cleansed, dried and prepared for the purpose. The bed, mattrass and clothing were new, and everything used was scrupulously clean. I will not describe the details of preparation of sponges, instruments and dressings, as it would be a mere repetition of previous reports made by me to this Society. I will only say that I continue to use a solution of carbolic acid, strength of 1 to 40, for the instruments and sponges, and for sutures and ligatures the best silk; and that I spare no pains in my endeavor to secure perfect cleanliness of operator, assistants, and everything coming in contact with the patient. I believe that the faithful application of the *principles* of the Listerian system is the only sure method of attaining good results after laparotomy. As to whether asepsis is attained by carbolic acid, corrosive sublimate, iodoform, hot water, or other agents, is unimportant; the principles of Listerism are essential, though the manner of their application may vary with the fancy of various operators.

The attending physician in this case was Dr. E. S. Moss, of Williamsburgh, an accomplished young practitioner, formerly an *interne* in the Louisville City Hospital. He assumed the management of the case the second day after the operation, and conducted the after-treatment. We were in daily communication by letter and telegraph. From his notes kindly sent me, I condense the following history of the progress of the case after the operation:

The shock of the operation was severe, and reaction came about rather slowly. During the first three days all went smoothly, the temperature and pulse ranging about 100. The catheter was required to relieve the bladder. On the third day, the discharge from the drainage-tube having about ceased, the tube was removed and the edges of the wound brought firmly together. On this day, also, there being some distension, an enema of warm water was administered, which brought away fæces and gas.

On the fifth day the pulse was over 120, and the temperature reached 104° F., with general symptoms corresponding. Being apprised of the situation, I telegraphed Dr. Moss to open the wound, wash out the peritoneal cavity, and retain the drainage-tube in place, which was promptly done. I also suggested the administration of a brisk cathartic, and Dr. Moss gave a dose of calomel and jalap, which acted freely and promptly. Our efforts were rewarded by the temperature falling below 100° F., with corresponding improvement in all the symptoms. The patient continued to progress satisfactorily for a number of days, and the tube was again removed.

On December 10, the twenty-second day after the operation, the temperature again ascended, reaching 104° F., with rapid pulse and very alarming symptoms. Dr. Moss again opened the lower angle of the wound, introduced a rubber drainage-tube, and washed out the peritoneal cavity. The improvement was prompt, but the discharge persisted until December 19, when, having altogether ceased, the tube was removed and the wound allowed to close. On December 26 the patient sat up, and she improved rapidly from that time on. The following letter from Dr. Moss, dated February 1, 1887, announces her prompt recovery:

Dear Doctor:—Enclosed I send you notes of Mrs. W.'s case from the day you left, and hope you will place them in such form as you think best. I ceased to visit her regularly on January 9, as she was then going about the house. She has completely recovered and has returned to her home, six miles in the country. Her husband informs me that she has reached her usual standard of strength and flesh, and is daily attending to her household duties. Very respectfully, E. S. Moss.

MY FIRST INTUBATION OF THE LARYNX; RECOVERY.

Read before the Denver Medical Association, February 8, 1887.

BY CHARLES DENISON, M.D.,

OF DENVER, COL.

For several months I have been on the outlook for an opportunity to use my set of O'Dwyer's intubation tubes. The first opportunity, that of diphtheritic laryngitis at the Orphans' Home, was lost through the negligence to call me in time. The little patient's heart was ceasing to beat as I reached the Orphans' Home.

On February 1, at 11 A.M., I was called in haste to see a 6 year old boy at 1016 Thirteenth St., the adopted son of J. H. T. He was a rosy-cheeked fellow, apparently in the best of health except for the dyspnœa, etc., which characterized his condition at that time. His respirations were labored, decidedly *croupy*, his face suffused, and there was aphonia. His temperature, in the groin, was normal, pulse 120, and respirations 35 per minute. On examining the throat a patch of false membrane was detected to the right of the epiglottis and just below the tonsil. Here was a case of true croup, or pseudo membranous laryngitis, that dreaded condition which, if your experience has tallied with my own, you have almost always seen end in suffocation and death.

As to the cause of this attack, it should be re-

marked that two weeks previously the boy had broken out with measles, which had run its course so easily that no physician had been called. As to a causative effect, due to this fever, it is interesting to note that of eighty-seven cases of diphtheritic laryngitis reported in the autopsy records of the New York Foundling Asylum twenty-two, or one fourth of the number, had followed immediately after measles.

For treatment this child already, during the previous night, had had syr. of ipecac and some relaxing cough mixture, like hives syrup, which had produced emesis, and thus relieved several hard attacks of dyspnœa. I prescribed wine of ipecac, a teaspoonful every ten minutes during the bad spells, the throat and chest to be rubbed with a relaxing embrocation, and covered with a poultice, which was held in place with a snugly fitting cotton jacket. I also ordered the following:

℞ Sodii benzoati..... ℥ss.
Acidi carbolici cryst..... ..... gr. v.
Listerine.....
Glycerin.....
Aquæ..... āā ℥i.
M.

Sig. Use on swab every four hours and give half a teaspoonful between times.

The attendants were informed of my movements, so that I could be found in case urgent symptoms should supervene.

At 2 P.M. the treatment seemed to have done very well. The child had vomited once or twice, the dyspnœa was not so distressing, though the respirations were 38 to 40 a minute. The use of the swab had wholly removed the false membrane from above the larynx, a fact which made me hopeful the remainder might be dislodged.

At 4 P.M. the dyspnœa was increasing; respiration 44, pulse 120 or over, and temperature normal.

After 7 P.M. I remained with the patient, expecting to have to operate at any time. Some temporary relief was afforded by the inhalation of steam from slacking lime, but the symptoms from hour to hour were getting worse.

By 10 P.M. I was impressed with the danger of longer delay. Temperature rising, pulse 130 to 140, and respirations 50 per minute. Respirations superficial, labored, and accompanied with retraction of the abdomen; lips turning purple and face suffused, and with skin of that fatal leaden hue. The eyelids would remain partly open as the child temporarily slept. Expectoration and cough had ceased for some time, and the breathing was loud and whistling. I am convinced that there would have been no further expectoration to relieve the then present suffocation. It was very soon after 10 o'clock when I had the boy held in the sitting posture on the knees of A. M. Mortimore, and while the head was steadied by Miss Launey, one of our medical students, I introduced the gag (which comes with the tube to hold the jaws apart) and, having already prepared the proper-sized tube for a 6 year old child, quickly, and as gently as possible, considering the struggling of the patient, introduced it so that the head of the tube was down in place below the rim of the epiglottis. This introduction was accomplished with the right hand, while the epiglottis was hooked up by the index finger of the left, according to the usual directions, and was successful at the first attempt, though I had not the advantage, as is recommended, of a previous trial on the cadaver or a healthy person.

I believe the plastic exudation was sufficiently detached in the introduction to occlude the lower end of the tube, for the tube was at once thrown out, together with about half a teaspoonful of false membrane and tenacious fibrin; one portion of the expelled membrane being as large as a silver five cent piece. The relief, however, was instantaneous and remarkable. The boy began to breathe freely at once; his eye brightened; the leaden color left his face to be displaced by the natural hue, and within ten minutes he drank two cups of milk, when for six or eight hours before he had taken only a swallow of liquid at a time.

I expected that the membrane would re-form, and that I would be called within three to five hours, as others have reported they had been, to reintroduce the tube. But in this expectation I was happily disappointed, for I not only enjoyed a good night's rest myself, but so did my little patient. I found him bright and smiling in the morning; respiration somewhat croupy, cough loose, aphonia continued, pulse 92, respirations 34, and temperature 99.5° F. The previous day's plan of medication was in the main continued.

About 3 P.M. I was summoned in haste, but a severe attack of dyspnœa had been relieved, when I arrived, by expectoration. Pulse then 112, respiration 36, and temperature 101.5°. After that there was continued improvement, and to-day the boy is hearty and well, except for a partial aphonia which is slowly disappearing.

Of course, taking this single case as the basis of my conclusion, and notwithstanding the unusual though favorable termination of the first attempt, I feel like ascribing to Dr. Joseph O'Dwyer, the inventor of these tubes, praise equal to that given to any of the many illustrious men who have contributed new means of saving life during the past fifty years.

Dr. W. P. Northrup, before the New York Academy of Medicine, lately summed up the advantages and disadvantages due to intubation as follows:

"It relieves dyspnœa due to laryngeal stenosis.

"There is no objection on the part of the parents and friends.

"The operation is comparatively simple, and free from danger and free from shock.

"No anæsthetic is needed, and no trained assistants.

"No fresh wound is added. The subsequent care of the case requires no trained attendant. The inspired air enters the lungs moist and warm.

"It does not preclude tracheotomy, and may be found useful as a guide upon which to cut.

"Intubation has one conspicuous fault, attested by all: it embarrasses and sometimes interferes with the swallowing of fluids."

How much the previous treatment, the steam inhalations, etc., had softened the membrane and thus prepared the way for its expulsion, we cannot, of

course, state positively. I am inclined to give this treatment some credit in this regard.

As to the choice between intubation and tracheotomy I am inclined to join the adherents of the former, though I was equally successful in my first case of tracheotomy, and that was on a 6 months old baby for œdema glottidis, performed in haste, at night, with only a piece of a flexible catheter for a tube, which after a little had to be discarded. Then I had to cut another ring of the trachea, and the child made a good recovery.

ANTISEPTIC TAMPONNEMENT OF THE VAGINA IN PELVIC INFLAMMATIONS.

Remarks made before the Chicago Gynæcological Society, January 21, 1887,

BY JAMES H. ETHERIDGE, M.D.,

GYNECOLOGIST TO THE CENTRAL FREE DISPENSARY, AND THE PRESBYTERIAN HOSPITAL, CHICAGO.

What I have to present refers to tamponnement of the vagina and supporting the uterus in cases of pelvic trouble, notably of inflammation and enlargement of the uterus, and as the work has grown upon me, other complications in the way of pelvic trouble have also been treated with a result that has rather surprised me. For it, I claim nothing original.

A year ago last fall I commenced the treatment of a case of general metritis and prolapsus of both ovaries with enlargement, which had brought the woman to a very low state. She had had all sorts of operations performed and advised,—repair of the neck of the perineum for laceration,—and had been recommended to have the ovaries removed. Upon examination I found the uterus immovable. I placed the woman in the genu-pectoral position and tamponned the vagina with absorbent cotton, saturated with boro-glycerine. The vagina was douched before the tampon was reapplied, and of course everything was removed during menstruation. This was kept up for three months and she began to have less neuralgia, which had made her life miserable. I kept up the treatment three or four months longer, when there was complete mobility of the uterus, and she went out of doors and to church. The neuralgia subsided, the tenderness of the uterus and the ovaries entirely disappeared, and her condition was so much improved that it seemed to me that this was an efficient means of treating pelvic trouble.

In the midst of this work I found that Dr. Engelmann, of St. Louis, was utilizing the same idea. He was using medicated applications, such as iodine, carbolic acid, sulphate of zinc, tannin, iodoform, etc., and he made this subject the text of annual address to the Gynæcological Society of St. Louis. I think the gist of his paper was incorporated in the report I made to the State Medical Society last summer at Bloomington. Since then, in all sorts of cases of uterine inflammation, I have been making applications of the cotton tampon, resulting in considerable dissatisfaction with the material employed, and I have commenced the use of something else. It is a preparation of wool that is called "antiseptic wool." This wool is finely carded, free from all oil and foreign substances. A piece is cut off, of such a length as will fit nicely into the vagina, and then with the patient in the genu-pectoral position, with the perineum retracted, this is stuffed into the vagina and left there. The upper end of this tampon can be soaked in any antiseptic solution, as boro-glyceride or listerine, and with a piece of string attached to the lower end of it, the patient can remove it and douche the vagina, in readiness for the next tampon, and in this way tampon after tampon can be introduced and the uterus held up to the highest possible level, and advantage taken of the natural drainage from the uterus of the superabundant amount of blood.

The inflammations of the uterus we are usually called upon to treat are not active, but chronic, and if we hold the uterus up so that it can drain itself properly through the veins, the nutritive changes which take place will be facilitated to the greatest extent. A small Sims' speculum can easily be applied without trouble to the patient, and this wool can be pushed into the vagina so that when the pa- gets up she has a soft elastic cushion for the uterus to rest upon. In this way the greatest comfort is at once experienced. I have treated between twenty and thirty cases in this way. One case was a woman with a severe laceration of the neck of the uterus; the probe went into the cavity about 4½ inches. Local treatment had been freely employed in this case. She had pain in the legs and hips and profuse menstruation, and was a total wreck when I saw her. I put her in position and applied the tampon. I found after using four or five of them the pains had nearly all disappeared. I found also that the raw edges of the torn cervix were taking on a new mucous membrane, and I had the gratification of finding, after six months, that this uterus had been reduced to its natural size. It was with difficulty the laceration could be recognized through the speculum.

I have recently been called to see a woman who has inflammation of the ovary upon the right side. I found her in bed, where she had been five months continuously. Upon moving the uterus, I found there was a great deal of tenderness throughout the pelvic tissues and around the right ovary, the slightest touch producing the greatest suffering. The woman was put in the genu-pectoral position and the vagina plugged with this wool. She got out of bed the next day, and the next night went down to dinner. Now she is going all over Chicago. Before that she had been treated nine months by means of local applications, tonics, laxatives, and everything of that kind.

The result of the support of the uterus and holding the ovary up has been almost marvelous. I make these statements concerning this method of treatment for the purpose of calling attention to it, as I am still studying the subject. These tampons are removed after four or five days without the slightest odor upon them.

When the uterus is enlarged it becomes heavy, sinks, and presses the veins which carry the blood out of the uterus, and we have strangulation. By raising the uterus up, the blood flows freely and the

nutritive changes tend always to health. One outgrowth of the use of this tampon may be that many cases of laceration of the cervix, now operated upon, may escape operation. I have been surprised to see how very nicely patients get along, even though they have extensive lacerations, under this treatment.

HOSPITAL REPORTS.

MERCY HOSPITAL, CHICAGO.

CASE OF BONE GRAFTING IN THE LOWER JAW.

SERVICE OF JOHN S. MARSHALL, M.D.,
DENTAL AND ORAL SURGEON.

(REPORTED BY A. C. BROELL, M.D., INTERNE.)

Miss S., aged 42 years, presented herself for operation on January 26, at the Mercy Hospital. Her previous history is about as follows: Nine years ago she was suffering with a disease of the lower jaw, which was diagnosticated osteo sarcoma, by a homœopathic physician, who afterwards performed an exsection for the removal of the disease. The piece exsected extended from the first bicuspid tooth backwards to, and included one-half an inch of, the ramus. This physician also made an attempt to bring the fragments of the jaw into apposition, so that bony union might occur; no such union, however, resulted, but the jaw was so displaced that the median line of the chin was situated about one-half an inch to the right of the median line of the face.

Later on the patient began to suffer with neuralgic pains about the left temporo-maxillary articulation, and in the right arm. To relieve this pain, which was thought to be dependent upon displacement of the jaw, an operation was performed by Dr. Marshall some time ago, by means of which the cicatricial tissue was removed through the mouth, and reposition of the jaw was accomplished. The fragments were held in position by a gold rod screwed into the ramus, and attached to a gold cap applied to the first bicuspid tooth, and retained by oxyphosphate cement.

The patient this day (January 26) presented herself for the second operation, by means of which the gap now existing between the fragments, one inch and a half in extent, it was hoped, might be replaced with new tissue reproduced by bone-grafts. Having been previously prepared for operation, she was at once etherized. An incision was made about four inches in length in the line of the old scar, down to the mucous membrane lining the oral cavity. Both ends of the fragments were laid bare, and well scraped. The hæmorrhage which followed, though slight, was persistent, but was finally checked with a hot solution of bichloride of mercury (1:1000 of water.)

At the same time, having etherized a half grown rabbit, both its femurs were laid bare, and with bone cutting forceps twelve small pieces of bone, ranging in size from about two to six lines in length, two to three lines in width, and one line in thickness, having the periosteum attached, were removed from the epiphyseal extremities. These pieces were placed in a solution of the bichloride of mercury (1:1000), which was kept at a temperature of 99° to 100° F., where they remained from five to ten minutes. After all oozing had stopped these pieces were transferred from the solution to the wound, being placed in two rows in such a way that the inner row had the periosteum towards the mucous membrane and the outer one had it towards the cutaneous surface, the ends of the rows being in contact with the denuded ends of the jaw-bone, and the cancellated structure of the pieces being in contact.

The incision was now closed with eight sutures of carbolized silk, with a few twisted strands of silk left in the lower end of the wound for drainage. The wound was dressed with iodoform and antiseptic gauze covered with oiled paper, the whole dressing being held in place by a bandage. Throughout the operation antiseptic precautions were scrupulously carried out.

The patient left the hospital on the following day. At home she improved rapidly, the wound healing by first intention throughout four-fifths of its extent; in the other fifth, near the drainage, the stitches cut through, retarding the healing somewhat. The remaining stitches and the silk left for drainage were removed on the sixth day. The entire wound healed without the formation of pus.

As far as can be ascertained at present, there are fair prospects that the operation will prove successful.

MEDICAL PROGRESS.

INDICATIONS FOR THE USE OF NITRO-GLYCERINE. —DR. TRUSSEWITSCH, in an instructive paper on the use of nitro-glycerine published in the *St. Petersburger Medicinische Wochenschrift*, points out that the value of this drug in various affections—angina pectoris, migraine, and neuralgia (which he describes as angioneuroses), as also in sea sickness, some forms of anæmia, faintness, palpitation, and other diseases—depends upon the existence of an irregular distribution of blood, which condition may be inferred from a certain degree of pallor of the skin, especially of the face, often co existent with a weak pulse and a small rigid radial artery, which frequently is situated at some depth. When, on the other hand, headache and neuralgia occur in patients with chronic congestion of the subcutaneous veins of the face, nitro-glycerine is to be avoided; and similarly it is of no use in asthma, when the face is reddened in consequence of emphysema. If, however, a pale face exists with angina pectoris, migraine, giddiness, shock, toothache, or sea-sickness, the best results may be looked for by giving nitro-glycerine. The regulating effect of the drug exercises an influence over the congestion of internal organs similar to that brought about by blood-letting; and in these congestions, whether of lung, brain, or kidney, when they are of a temporary character, the pulse is generally found to be slow and of low tension—a fact which, as the author remarks, is sufficiently well-known in reference to the fever-free periods of acute hyperæmia of the lung and kidney. Dr. Trussewitsch lays down,

as a rule, that the condition of the pulse is the best indication for the employment of nitro-glycerine, and the most trustworthy guide as to the dose with which to commence the treatment. The smaller the radial artery is, the more rapidly it dilates under the action of the drug, and the less the secondary effects proceed; on the other hand, the fuller the pulse with a distended radial artery, the less it is affected; and finally, the softer the artery, with a weak pulse, the greater the secondary, and the less the general, effects. Single-drop doses of the 1 per cent. solution are sufficient in cases of small pulse, but with a full pulse it will be found that the full effects cannot be produced with less than 2-drop doses. When there is a soft artery with a weak pulse, subnormal doses only should be given—a quarter to half a drop. After the trial dose is given, the patient's sensations of pulsation and pain in the head, as well as the distension of the radial artery under the finger of the physician, will be the guides for increasing the dose. The author finds that the best modes of administering nitro-glycerine are the simple dropping of the solution on the tongue, and by means of tablets; much less satisfactory results were obtained when given mixed with water.—*Lancet*, Feb. 19, 1887.

Iodoform Injections in Cold Abscesses.—Within a few years a new method of treatment of cold abscesses has been largely adopted, which is simple, easy of performance, and apparently devoid of risk to the patient. We refer to the use of iodoform injections. It consists simply in the evacuation of the abscess by means of an aspirator, the largest-sized needle being used, and in the subsequent injection of a solution of iodoform in ether. A 4 or 5 per cent. solution is the one more commonly used for abscesses of large or moderate size, but occasionally the strength is increased to 10 per cent. when the abscess is of very small dimensions. The quantity of solution to be injected varies according to the circumstances of the case, though, in view of the danger of exciting toxic symptoms, it is generally recommended that not more than a drachm of iodoform should be used. The ether holding the iodoform in solution finds its way into every pocket and sinuosity of the abscess cavity, and there deposits a film of iodoform. Some little attention is necessary after the injection has been made, as the ether is volatilized by the heat of the body, and may cause an unpleasant degree of distention of the abscess cavity. If this occur it may be necessary to introduce the needle of a hypodermatic syringe in order to give exit to the gas. Ordinarily, however, the patients suffer little inconvenience, and are able to go about as usual after the operation. The experience of those who have employed this mode of treatment has been that one injection is often sufficient to effect a definite cure of the abscess, provided, of course, that it is not directly connected with a centre of disease in a bone or joint which is constantly secreting pus. Sometimes, however, it is necessary to repeat the operation two or more times. The chief inconvenience of this method is the pain which it causes. This is usually pretty severe, and is sometimes so great that the patients prefer to renounce all treatment than to submit to a second trial of the injections. Attempts have been made to find some less irritating substance as a substitute for the ether, but they have not hitherto been very successful.

It is not in the treatment of cold abscesses alone that the iodoform injections have been employed, but they have been used with benefit also in tubercular bone and joint affections. — *Medical Record*, March 12, 1887.

Papayotin in Fissures of the Tongue.—Professor Schwimmer reports excellent results from the use of papayotin in fissures of the tongue, after chromic acid, iodoform and nitrate of silver had failed. The papayotin was administered in the following form:

℞ Papayotin..... 1 to 2 parts.
Distilled water.
Glycerine.....āā 10 "

This solution is to be applied with a camel's-hair brush, from two to six times a day, the tongue having been previously well dried. There is no maceration, as would be supposed, but the mixture stops the pain and seems to cause a renewal of the epithelium. Schwimmer reports twenty-five cases, some of several years' duration; and complete cure was affected in all except one, which was syphilitic, though specific treatment gave us no good result. But in this case papayotin ameliorated the condition of the tongue.—*Wiener med. Wochenschrift.*

Antiseptic Collodion.—The *Journal de Médecine* of December 26 contains an account of a new kind of "collodion," which is antiseptic and promotes cicatrization. It does not cause inflammation, and may be substituted for collodion made from gun cotton, in the treatment of wounds and bruises. Like traumaticine, it is efficacious in relieving neuralgic pains, and acute or chronic rheumatism. The affected parts should be sponged with it every twenty-four hours, and in serious cases every six hours. If strips of linen or silk be soaked in this collodion, an excellent sticking plaster is obtained, which quite equals English court-plaster. The following is the formula: Mastic in globules, 3 grammes; balsam of Peru, 1 gramme; narcotine, 1 gramme. Each ingredient should be ground separately, and 5 grammes of chloroform added thereto.

Treatment of Sciatica.—Dr. Metcalf, of New York, says that no prescription for sciatica has ever equalled in efficacy the following: ℞. Tinct. aconit. rad., tinct. colchic. sem., tinct. belladonna, aā ʒ j. ♏. Sig.: Dose, six drops every six hours. He also uses triturate tablets, each containing three drops of the following: Tincture of aconite root, tincture of seeds of colchicum, tincture of belladonna, tincture of actea racemosa—equal parts by volume. Dose, one every four or eight hours.

SATURDAY, MARCH 26, 1887.

THE PATHOLOGY AND TREATMENT OF TRANSVERSE FRACTURE OF THE PATELLA.

While advance in some quarters has been made of late in the treatment of transverse fractures of the patella, there has been but very little study of the pathology of these fractures, and consequently there is considerable diversity as to treatment; the greater number of surgeons, holding the current views as to the cause of non-osseous union, adhere to the older methods of treatment. In the *Annals of Surgery*, of March, 1887, Dr. William MacEwen, the well-known surgeon of Glasgow, contributes a valuable paper on "The Pathology of Transverse Fractures of the Patella and the Olecranon, showing the chief Cause of Non-osseous Union in these Fractures and how to avoid it," which may be considered as a continuation of or sequel to a paper published by him in the *Lancet*, of November 17, 1883.

In order to study these questions Dr. MacEwen examined ten fresh patellæ from as many different subjects, the ages varying from 2 to more than 60 years. It was found that in young children "the ligamentous structures running in front of the patella were presented by a very thin film, in many places scarcely distinguishable from the cartilage. In advanced life the præ-patellar tendinous structures were attenuated especially over the centre of the patella. In the six instances ranging from 14 to 45 years of age, the aponeurotic structures ran in a distinct band over the front of the patella, continuously from the tendon of the quadriceps to the ligamentum patellæ." The antero-posterior diameter of this layer was from 1 to 3 mm. The bulk of the fibres were longitudinal, and many seemingly continuous from the tendon to the ligament, a few being oblique. The *intra vitam* examination of these structures in recently produced transverse fractures coincided with these anatomical investigations; and in applying these facts it should be remembered that the time at which this fracture is most likely to occur coincides with that in which the aponeurotic structures are most developed in front of the patella.

The three causes which have been assigned for the want of osseous union after transverse fracture of the patella are: 1. A supposed deficiency in the patellar blood supply, causing a low vitality of the part and thereby preventing an outpouring of sufficient ossific deposit to unite the fragments together. 2. The separation of the fragments, by the retraction of the quadriceps extensor carrying the proximal portion of the patella upwards and away from the lower fragment. 3. The distension of the joint by blood and serum, thus preventing approximation of the fragments. As regards the deficient blood-supply, the facts are entirely against such assumption, as shown by injected specimens of the vessels supplying the patella, from which it may be seen that the blood-supply is abundant; by the parenchymatous hæmorrhage from the cancellous tissue in transverse fracture of the bone; and by the fact that osseous union is constantly obtained in longitudinal fractures, and that ossific deposition is so abundant in some diseased states of the bone. Nor is it likely that the pressure of a bandage during treatment could so arrest the flow of blood into the proximal fragment that osseous union would be prevented, since it would also prevent the formation of connective tissue between the fragments, of which we know there is no lack of a firm and substantial growth, (and it would also prevent osseous union in longitudinal fractures, in which such union is the rule). As to the contractions of the quadriceps muscle, these might prevent union were no attempts made to bring the fragments together. But we know that such contractions soon subside, and the muscle remains in a state of comparative rest. The resistance is easily overcome, and with ordinary care could not be a cause of non-union. There is frequently a condition of effusion of blood and serum into the joint, but it is so rapidly absorbed that of itself it is seldom sufficient to prevent osseous union. "A small quantity of blood clot, on the floor and roof of the fractured edges, might even be of service in preventing the wandering into the joint of osteoblasts and in forming a medium in which they might congregate and unite together into osseous plates. The presence of coagulated blood between the fractured

surfaces of bones is constant throughout the body, and is not productive of non-osseous union."

Now what is the usual mechanism of transverse fractures of the patella? In the majority of cases they are due to violent muscular action, to an effort in which the retractile power of the quadriceps jerks the patella upwards, relatively to the femur, beyond the position where it usually lies. While it is held below by the patellar ligament it rests on the apex of its posterior vertical ridge, which is now the point of development of the greatest energy of the two opposing forces. The bone may in this position be regarded as a lever of the first order, and the lever being insufficient to resist the strain it gives way. When the bone snaps and retracts, the fibrous, and aponeurotic tissues over it, which are more elastic than the bone, still holding, bridge the space between the fragments, and they are neither ruptured at the same moment nor at the same level as the bone. If the contractions continue the ligaments are overstretched, lose their resilience, and finally give way, being torn into longitudinal strips, and the now inelastic shreds rupturing at variable distances are forced between the fragments. "The majority of these shreds remain attached to the upper fragment, and their extremities would lie loosely over the fractured surfaces were it not for the fact that, at the moment the transverse fracture ensues, the upper fragment, owing to the manner of insertion of the quadriceps extensor tendon, becomes tilted, so as to present the plane of its fractured surface anteriorly; and as it is drawn upwards, those shreds of præpatellar tissue are firmly pressed over its fractured edge by the flexing of the joint, and the action of the atmospheric pressure forcing the soft tissues inwards to fill up the hiatus." These shreds thus adhere mechanically to the bone, the serrations on the edge of the broken surface of the upper fragment acting as so many pins to which the aponeurotic structures become attached. The floor of the patellar bursa, too, is generally ruptured, and portions of it hang like curtains over the fractured extremities, or are fixed on them, over the aponeurotic tissue. With such tissue between the fragments bony union is of course impossible, and even fibrous union relatively modified.

In the cases of transverse fracture of the patella that have come under MacEwen's care the præpatellar tissues have been found between the fragments, and attached to them, as described; and three other surgeons have reported the same condition. It is then probable that in the majority of cases of such injury this is the true cause of non-osseous union, especially if the injury be caused by muscular violence. Those caused by direct violence, usually more or less stellar fractures, are seldom complicated by aponeurotic rupture, and more likely to be followed by fibrous or bony union without operative interference. Those fractures in which the lower fragment only is multiple from having been divided by contact with some external body met with in the fall subsequent to the production of the transverse fracture from direct violence, should not be included under this group.

Leaving out of consideration those cases in which the fracture is not complicated by aponeurotic rupture, if we admit the foregoing points as to the pathology of transverse fractures of the patella we will be able to choose our own treatment and measure beforehand what must be expected from it. We are justified in concluding that if osseous union be desired the soft tissues should be removed from between the fractured surfaces. Except in a few cases which result from external violence, fibrous union will ensue unless this be done. Some believe fibrous union as satisfactory; but while it looks well and appears satisfactory at first, the subsequent course seems far from good. Firmer union may occur in time, but it can never be predicted. Sometimes it takes place, not between bone and bone, but between the layers of intervening aponeurotic tissue; and when a strain is put upon it the attachments give way. "Osseous union is therefore desirable, and that method of treatment which can secure this end with a regularity which can be depended upon, is what ought to be aimed at." In regard to methods we will only say that MacEwen thinks that if wiring be resorted to the wire should be removed when it has served its purpose—in about six weeks—to prevent the possibility of its subsequently acting as an irritant.

THE TAMPON IN PLACENTA PRÆVIA.

At the meeting of the Obstetrical Society of Philadelphia, on February 3, Dr. H. A. Kelly, in speaking of the treatment of placenta prævia, gave the following advice: "The tampon should also be given up, for unless scientifically applied it is utterly useless; it induces great danger of sepsis, and, with the best applied tampon, in the absence of the necessary counterpressure above in the uterus, in the very cases in which it is used, the dangers of concealed hæmorrhage are imminent. If the bleeding has been great bring on active labor; but don't use the tampon."

Obstetricians who are partial to the use of the tampon in proper cases will be glad to know that

Dr. Parvin defended its use in the following language: That the tampon permits concealed hæmorrhage is an old objection which has gained nothing by time; it is a sort of bug-bear that does not frighten obstetricians who have used the tampon, for where it is properly applied, the membranes being unruptured, bleeding, either internal or external, to any serious amount is impossible. Indeed, if the uterus be properly compressed through the abdominal wall, and the tampon well applied, serious hæmorrhage from placenta prævia, even after the rupture of the membranes, is impossible. That septicæmia is likely to occur in cases in which there has been placenta prævia has been generally recognized for some time; this liability to septicæmia arising, not from the position of the placenta, but from the manipulations, the consequence of such position. Now, in violent cases of hæmorrhage resulting from placenta prævia, is the tampon advisable? The most natural treatment of a hæmorrhage occurring with an undilated os is arrest of the flow by pressure, that is, by the application of the tampon. Such treatment may be available in some cases when no other can be so readily applied.

It is probably about one hundred years since the use of the tampon in placenta prævia was introduced by Wigand, *accouchement forcé* being the general practice at the time; and though we may qualify somewhat his unqualified endorsement of it—that in suitable cases and properly used no death of mother occurred—there is sufficient clinical evidence to sustain an endorsement of the tampon as the proper means to employ in certain cases, and at a certain stage of the hæmorrhage; that is, when the cervix is undilated. After thorough tamponing Pajot and Bailly have left cases, as did Wigand, to nature, without disturbing by art the further progress of the labor. Wigand's tampons "of soft linen, dipped in a thin, oatmeal gruel," with the broad end, which is to be passed first into the vagina, thickly covered with powdered gum arabic and rosin, are certainly not to be recommended now; though we agree with Dr. Parvin that "really it would be much better than the sponges which are by some used to arrest uterine hæmorrhage, a practice that cannot be too severly condemned." The success of Dr. Murphy with Barnes's dilators, which really act as a tampon, is not only a very strong argument in favor of the tampon, but also of a more general adoption of that method.

There has been considerable discussion as to how long the tampon should be allowed to remain. We have seen that Wigand left "the rest of the labor entirely to nature, which alone, sooner or later, by means of unusually rapid and powerful pains, will expel the living, healthy child, at the same time, also, the second small tampon, if such has been found necessary to introduce. The placenta was expelled spontaneously in all cases shortly after the birth of the child" (quoted by Parvin, who states that Madame Lachapelle sometimes left the delivery in women she had tamponed to nature, that Pajot and Weil taught that after tamponing women suffering with hæmorrhage from placenta prævia one ought to abandon the delivery to nature, this method giving the best result for the mothers; and that this plan was practised and advocated for many years by the late Dr. Mears, of Indianapolis). Lusk and Galabin agree that the tampon should be removed in at least four hours; Tarnier, however, would allow it to remain for twelve hours, while Depaul's limit seemed to be twelve or fifteen hours at least, and twenty-five or thirty at most. If the tampon be antiseptic and properly applied it may be deemed doubtful if injurious results will follow a retention of it for twenty-four hours.

As shown by the statistics of Müller, the tampon will excite uterine contractions in the majority of cases; and it has been objected to it that during contractions it may convert open hæmorrhage into a concealed one; but with a properly applied tampon this is practically impossible, if the accoucheur press it back when forced down by a contraction, or else secure it with an elastic bandage which will retract when the contraction-pressure is removed.

Finally, it may be said that obstetricians are agreed that, while the tampon is not a sovereign remedy, it is not to be rejected. It should be applied, says Müller, when the os is rigid and only slightly dilated if there is violent hæmorrhage, as immediate delivery is impossible. We gain time without danger, for though it may not stop the hæmorrhage it lessens it, and prepares the parts for labor.

LAW REGULATING THE BUSINESS OF PHARMACY IN THE STATE OF NEBRASKA.

In another department of this issue of THE JOURNAL will be found a copy of the Law recently enacted by the Legislature of Nebraska. We are informed that the law was originally framed by a committee of, and was approved by, the Nebraska State Pharmaceutical Association last May. The first Section of the law provides that "the Nebraska State Board of Pharmacy" shall consist of the Attorney-General, Secretary of State, Auditor, Treasurer, and Commissioner of Public Lands and Buildings. And as these several State officers are not presumed to know much about the business of practical pharmacists or apoth-

ecaries, the Board is required to select five skilful apothecaries of not less than seven years' experience, who shall assist the Board in conducting the necessary examinations of applicants for licenses, etc. This mode of constituting the "Nebraska State Board of Pharmacy" reminds us of the first law for regulating the practice of medicine in the Colony of New York in 1760, which read as follows: "No person whatsoever shall practice as physician or surgeon, in the City of New York, before he shall have been *examined* in *physic* and *surgery*, and approved of and admitted by one of His Majesty's Council, the Judges of the Supreme Court, the King's Attorney-General, and the Mayor of the City of New York for the time being, or by any three or more of them, taking to their *assistance* for *such examination*, such proper person or persons as they in their discretion shall see fit." Notwithstanding this ancient and honorable precedent, the question will recur to most minds, why not make the five "skilful retail apothecaries of seven years' practical experience" the State Board, instead of simply assistants?

The general provisions of the law appear to be judicious and practical, and if executed with fidelity, will do much to secure for the people of that young and vigorous State the services of educated and skilful apothecaries.

The Medical Register is a new weekly journal of medicine and surgery, published by the Medical Register Company, 1519 Walnut Street, Philadelphia, and edited by John V. Shoemaker, A.M., M.D., and William C. Wile, M.D., both well known to the readers of medical journals in this country. The *Medical Register* contains twenty-four double column pages of reading-matter, and has reached its seventh issue, furnishing abundant proof of enterprise and editorial ability.

Important New Work.—We learn that the first volume of "The American System of Gynecology," recently announced by Messrs. Lea Brothers & Co., of Philadelphia, is well through the press, and will soon be ready for delivery. The contributors to this work embrace a large number of the eminent gynecologists in this country.

Effect of Micturition on Pulse-rate.—Dr. Isaac N. Himes, of Cleveland, writes us, in regard to examination for life insurance, that the pulse rate generally falls after micturition, if the bladder be completely emptied; the pulse often falling from 80 to 76 or 74. He thinks that retention of urine may sometimes raise the temperature above normal.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, February 3, 1887.

The President, Thomas M. Drysdale, M.D., in the Chair.

Dr. J. M. Baldy read a paper on

EMMET'S NEW OPERATION FOR PROLAPSE OF THE POSTERIOR VAGINAL WALL, OR SO-CALLED LACERATION OF THE PERINEUM.

(See page 339.)

Dr. M. Price described a plan for the *temporary securing of sutures at the moment of insertion.* The ends being left long, two perforated shot are slipped on; the first one is to be the permanent fastening and is left loose, the second is compressed to secure the suture ends together and to prevent the other from slipping off until the time for final closing, when the first is pushed down and compressed.

Dr. Joseph Price described several ways of securing sutures so as to avoid imbedding the free ends of silver ones and to secure easy extraction. Over the silver wire pass the Aveling coil and shot; this will greatly facilitate its removal. He also made some critical remarks on different methods of operating for perineal restoration. The inside method of Emmet gives the best result. The use of well prepared catgut for the sulci sutures materially facilitates the operation. Set the sutures fresh from the alcohol and drop a shot over before they swell.

Dr. Chas. Meigs Wilson stated that the difficulty of representing Emmet's operation diagramatically is due to the fact that the plane of the posterior wall of the vagina is altered by the traction upon the tenaculum holding the crest of the rectocele. The needle figured upon the blackboard by Dr. Packard was not a Baker-Brown needle, as stated by Dr. Packard, but a modified staphylorrhaphy needle, the needle arm being longer, thinner, and having a greater arc of curvature than the ordinary staphylorrhaphy needle. It was first devised by Dr. E. Wilson, to use in uniting the freshened surfaces in Emmet's operation upon the cervix. The objection to its use in colporraphy operations is that, owing to the shortness of the needle arm, the shoulder of the needle, *i. e.*, the junction of the needle arm with the handle, made such a large opening in the mucous membrane of the vagina that the stitch was liable to tear out, especially if there was much tension before union had taken place.

Dr. Longaker spoke of the advisability of the primary operation. He believes all forceps with long blades and large heels will do damage to the vaginal outlet. He has seen transverse tears of the outlet after natural as well as instrumental labor. It has been remarked that perineal ruptures may exist without causing any symptoms, but this is no reason why tears in general should not be repaired. He believes in performing the primary operation in every case. He likes the Chinese silk for sutures. He

has examined a perineum immediately after labor and found it apparently intact, and a month later found a rectocele and cystocele, indicating a submucous tear.

Dr. Joseph Price, upon request of the President, remarked that he had seen Mr. Tait operate for a complete tear into the rectum, also for partial laceration and rectocele. He operates so rapidly that it is difficult to follow him. He makes two scissors cuts, one on each side of the laceration, splitting the tissues from the centre line laterally and forward. He removes no tissue, but throws one flap inside and the other out, and closes by interrupted buried sutures of silkworm-gut. In the complete rent, he splits the septum laterally, turning one flap into the bowel, the other into the vagina, and closes by interrupted transverse buried sutures, with two or more external sutures.

Dr. H. A. Kelly stated that this operation was not original with Mr. Tait. It had been originally devised by A. R. Simpson, of Edinburgh, and a description, with illustration, is to be found in Hart and Barbour's Manual.

Dr. Baldy, in closing the discussion, stated that the needle used by Dr. Emmet was round, slightly curved at the point, and from three-fourths to one inch in length. He uses it with a needle-holder, and, as a rule, prefers to have it threaded with a silk loop into which the wire sutures are hooked. Dr Baldy has now in his care a patient whose fourchette is perfect, but scar tissue can be felt inside of the perineum, and there is some little prolapse of the posterior wall. When she was delivered, some weeks ago, the need of an operation became apparent, as at that time the anterior wall and bladder prolapsed before the head in a mass as large as a base ball. He does not sympathize with the total condemnation of the forceps; they are needed sometimes, though frequently abused; neither does he approve of the so called support of the perineum either by towel or hand, nor the idea of holding the head back, because these methods deflect the force of the uterine contractions against the posterior vaginal wall and the pelvic floor. He has seen cases which had been operated on by the old method by eminent gynecologists, in which the result was a perfect external perineum, but in which the pelvic floor was as badly off as it had been before the operation. The floor was completely restored by the Emmet method subsequently.

Dr. Jos. Price read an extract from a private letter from Dr. Emmet to himself: "I am very glad that the woman who was operated on has fallen into your hands, so that you may be able to make a report of the exact condition after labor. I have not kept any accurate account, but I think I have heard of some twenty cases who have gone through labor without accident after the operation at the vaginal outlet had been done. On the other hand, I have not heard of a single case where the parts were torn after the operation, which is of more value, for I should be more likely to hear promptly of the failure than of the success."

Dr. Jas. V. Kelly reported a case of

PLACENTA PRÆVIA.

K. W., fifth pregnancy, had a vaginal hæmorrhage December 28, 1886. The bleeding was quite profuse, but ceased spontaneously. On examination, the os admitted with ease the index finger, which came directly in contact with the placenta. The patient was supposed to be nearing the completion of the eighth month of pregnancy. She was enjoined to rest in bed and dilute sulphuric acid was administered. Several days later the hæmorrhage recurred, and again ceased spontaneously. She kept on dribbling a little each day until January 11, 1887, when she had a violent hæmorrhage, and I determined on active interference. Her pulse was 120; she was very pale and had attacks of fainting. The os was dilated to the size of a half dollar, and dilatable. I gave her 15 drops of Squibb's fld. ext. ergot. There was no decided pain, though the patient said she felt some slight bearing down. I brought her to the edge of the bed, with her knees flexed, and found a decided thinning of the placenta toward the right sacro iliac symphysis. It was difficult to rupture the membranes without detaching the placenta, so I made firm pressure over the fundus, which caused the head to descend, and I then ruptured the membranes against the vertex. The waters drained off, the uterus condensed, and the bleeding ceased. I then gave 20 drops more of the ergot, and slight pains were noticed shortly afterwards. I still kept my index and middle fingers in the rent I had made in the membranes and the edge of the placenta, endeavoring to prevent any bleeding by pressing the placenta against the left side of the os. The pains became stronger and the head descended and the bleeding again returned. I endeavored to accelerate the labor by encouraging the woman to bear down and by making strong pressure over the fundus, but as these measures did not produce the desired result as rapidly as I wished, and the head having passed the superior strait, I applied the forceps and delivered. There was no further hæmorrhage, and the placenta was expressed by Créde's method in fifteen minutes. The woman received a vaginal injection of warm vinegar, as well for its antiseptic as for its hæmostatic properties.

The fœtus was of fair size for the eighth month, and was nearly lifeless. Artificial respiration, mouth to mouth, revived it and it lived thirty hours. The mother was in a very exhausted condition, and was given brandy and ammonia for nearly a week. The pulse after delivery was 140. She was also given plenty of milk and broth, and not allowed to raise her head off the pillow for a week. She has since entirely recovered. No tampon was used in this case. Ether was not administered.

Dr. M. Price had recently attended four cases of placenta prævia at full term; one, a very desperate one, had been tamponed. The cervix was dilated to the size of a half-dollar. He was urged by his consultant to introduce his hand, turn and deliver, which was, much to his surprise, accomplished in ten minutes, with child and mother both saved. The four children were all saved, and the mothers also, although one of the latter died from anæmic causes

three months later. He would at once, when called to such a case at full term, or in premature ones if he considered it advisable, dilate, turn and deliver. The method adopted in these four cases is that now adopted by the best authorities. Tamponing at term he considered dangerous and involving a loss of valuable time, hazardous to both mother and child.

Dr. Longaker thought it far better to turn the fœtus by the bipolar method before rupturing the membranes or perforating the placenta. He had lately attended a lady in her first labor at the age of 37 years. She was seized with profuse hæmorrhage while walking in the street. When called he found placenta prævia, the os was open to the size of the index finger, and large clots were in the lower segment of the uterus. He turned the child by the bipolar method, passed two fingers through the placenta, brought one leg through and left the case to nature. The child was lost, as the entire placenta was attached low down, placenta prævia centralis, and retraction of the uterus interfered with uteroplacental circulation. In a second case turning was followed by similar results in a case of placenta prævia centralis. While the two children were lost, both mothers recovered without an unfavorable symptom. In three cases respectively of lateral, marginal and partial placenta prævia, treated by rupture of membranes, and application of forceps in one of them, two children were lost. In one of these cases the fœtal heart sounds were extinct on my arrival, half an hour after a sudden and profuse hæmorrhage. All the mothers did well. The high fœtal mortality shows that we cannot place much value upon the child's life, and in view of the dangers which threaten the mother's life, would it not be best to interfere promptly when called to a case of hæmorrhage from this cause, regardless of the age of the fœtus?

Dr. H. A. Kelly exhibited a

PLACENTA PRÆVIA CENTRALIS OF THE SEVENTH MONTH,

in which he had perforated the placenta to break the amnion and, after turning, delivered, saving the mother, who had suffered from profuse hæmorrhage. He described a case in which turning proved impossible in a placenta prævia lateralis, owing to the fact that the cord was so tightly wrapped around the child's neck that only a small bight was left between the head and placenta, and when the foot was brought out at the vulva the head was felt fixed at the brim as at first. The foot was returned, and a forceps delivery of the head revealed the difficulty, which was corrected, and the mother delivered of a seven months baby, which died immediately. The mother made a perfect recovery. No one rule suits all cases. The first point of importance in event of free hæmorrhage is to rupture the membranes, and this must not be a mere puncture, but as free a separation as possible along the placental margin. The hæmorrhage comes from the separation of the uterine and placental surfaces, and this is only to be prevented by freeing the placenta on one margin, so that as the contraction goes up the placenta may, as far as possible, ascend with it. Turning is only needed in the more urgent cases. Where the pains are strong and the hæmorrhage has been but moderate, let the head engage, and more children will be saved.

(For Dr. Kelly's and Dr. Parvin's remarks on the use of the tampon in placenta prævia see editorial on this subject.)

Dr. Price's cases were at full term. He had not taken premature cases into his account. Deliveries at five, six and seven months, the fœtus not being viable, admit different principles. Emptying the uterus as early as possible is safer for the mother.

Dr. H. A. Kelly called the attention of the Society to an *external direct method of measuring the conjugata vera*, which he had found of extreme value in a large number of non-pregnant and gynecological cases which had come to him complaining of difficulties since a previous confinement.

The short vagina, or cellulitis or cicatricial contractions, often prevent the finger in the vagina from reaching the promontory. In a case he had examined in the morning, the short vagina prevented the vaginal finger reaching the promontory while the outside hand rested upon it, and on pressing deeper felt the vaginal fingers fully 3 centimetres below. This case was measured by the outside hand and determined normal. Another case had a rachitic pelvis, 8½ cm. conjugate. She had borne ten children at term through difficult labors, but without assistance.

The method is simple, avoids a vaginal examination in the virgin, is invaluable in many cases retrospectively and prognostically. The inaccuracy of the external conjugate is well known. This, of course, is of no use in the most important class of cases, the advanced pregnant, but it does often afford invaluable facts in other cases.

The method is to press deeply with the finger tips of the extended hand until the promontory of the sacrum is felt, then, by slipping the fingers up and down over this until the relations are well appreciated, let the fingers rest vertically above the angle, and at the same time mark on the palm with the finger of the other hand the position of the posterior surface of the symphysis, also vertically below. This measurement from the mark thus made to the tip of the finger is the conjugata vera thus directly measured.

Dr. Montgomery, in a paper entitled

TRACHEOTOMY AND INTUBATION IN DIPHTHERIA,

urged the importance of early operation. The symptom which should indicate the necessity for operation was depression of the substernal region during inspiration. This symptom indicates the inefficient entrance of air to fill the lungs, and the diaphragm becomes a fixed point depressing the soft tissues. The longer this condition continues the greater the danger of collapse of portions of lung tissue. The large mortality after tracheotomy and intubation is due to the postponement of operative interference in the majority of cases until these changes have occurred. This assertion is verified by his own experience in tracheotomy. In his first ten cases, in all but one of which the operation was done as a last resort, none recovered. In the next seven cases, in which, excepting two, it was done early, five recovered.

The two fatal cases were not considered hopeful at the time of operation. His eighteenth case died before the trachea was opened. Of the last ten, five recovered. Twenty-eight cases with ten recoveries. He has practised intubation in thirteen cases with six recoveries. All but one of these cases were seen in consultation, and some of them were in a dying condition when intubation was practised. In no case did death occur in less than twenty-four hours, and in all the relief from the dyspnœa was prompt and permanent. The youngest child was 18 months of age and died on the fifth day of convulsions. The youngest child to recover was æt. 2 years. In one case of recovery tracheotomy was performed the day following the intubation. A smaller-sized tube than suited for its age had been used; the dyspnœa recurring and the tube absent from the glottis, it was feared that it had been passed into the trachea. It was found that the tube had been coughed up and swallowed, and passed per anum two days later. Of course, in this case, little can be claimed for intubation. He prefers intubation to tracheotomy, and believes that the former will supplant the necessity of doing the latter. The advantages are: It is free from danger; it requires no cutting nor anæsthetic; the after-treatment does not require skilled attention, as the air is moistened and warmed by the natural passages before entering the trachea; there is therefore no dry mucus accumulating in the tube and not the same danger of secondary inflammatory lesions. As the tube does not fill up the calibre of the trachea, membrane is coughed up around instead of through it, and thus the danger of blocking is avoided.

ST. LOUIS MEDICAL SOCIETY.

Stated Meeting, February 12, 1887.

The President, S. Pollak, M.D., in the Chair.

Frank R. Fry, M.D., Secretary.

Dr. F. W. Wessler read a paper entitled

DIPHTHERIA AND BRONCHIAL CASTS.

In October last I saw a boy, 8 years old, whom I had frequently attended for tonsilitis. In three or four days I discharged him. A few days after (Oct. 25) I was called to see his sister. I found her with a high fever, vomiting, very restless, and her throat red. I suspected diphtheria, and informed the family of the fact. They removed her from the home. I visited her from Monday to Thursday, when all the symptoms seemed to have disappeared. At the time what I intended to have been my last visit, as I had my hand on the door to go, I heard the little girl cough. The mother said she had not been coughing that way. It was a croupy cough. I promised to call again the next morning, but before that time they called for me. I found the patient almost choking. I had previously administered calomel and bicarbonate of soda, and afterwards the bichloride of mercury and tincture of iron. I now concluded that I would rely on calomel, and ordered it. I called the next morning and found the exudation had been discharged (a cast of the trachea and bronchi).

We see few specimens of bronchial casts, most of our patients die before this exudation is thrown off. Eight years ago I had a case of the kind in a man 39 years of age. He was a miner from the northern part of the State. He had had measles six months prior to the time I saw him. While at the hospital he threw off the exudation, with the bifurcation of the bronchi well marked. I put it in a solution of chloral hydrate, which did not preserve it well. About the same time Dr. W. E. Glasgow presented a case. Dr. Johnson reported a case in the *Medical Review*, January 29, 1887. He calls it pseudo-membranous bronchitis. Dr. Glasgow calls it plastic bronchitis. It has been called croupous pneumonia, etc. Dr. Moore had asked whether any physician had abandoned the local treatment of diphtheria. I have. When I began the practice of medicine every physician carried a caustic-holder in his pocket, and every case of tonsillitis and sore throat was cauterized. I found that children who were not cauterized recovered equally as well or better than those who had been. That was my reason for abandoning the local treatment, and I never use anything more than a simple gargle. I have much faith in whiskey and have advocated its use for many years. I think it a disinfectant as well as a stimulant. I think more of calomel and whiskey than any other two remedies for diphtheria.

Dr. G. Hurt said that whether or not local applications are indicated depends on the cause of the disease, and the manner in which it invades the system. I believe that if there is any disease that may be referred to the bacillus as its cause, diphtheria is that disease. It must be an animal or vegetable growth foreign to the tissues themselves. If it is a parasitic disease, we ought to have a remedy that would be effectual locally. Whether nitrate of silver is a proper application or not is a question. Possibly calomel exercises its effect as it is administered and not afterwards. If, six years ago, I had openly and knowingly treated a case with calomel and lost it I would have been prosecuted for malpractice. Yet twenty-five or thirty years ago diphtheria was treated with calomel and bleeding, and according to Jacobi, with a mortality of 90 per cent. According to the same authority, without this treatment the recovery has been 90 per cent. I have not returned to the calomel treatment. In the few cases I have had during the present epidemic, I have used tonics and iron and hydrochloric acid. I have also used gargles, from which I think I have derived benefit.

Dr. Hendricks said: As to whether diphtheria is primarily local or constitutional I cannot say. Generally the constitution is evidently affected by the time I see the cases. I address my treatment to the constitution regardless of the local appearance. I started out against local treatment fourteen years ago. I abandoned it because the efforts to make applications exhaust the child. The false membrane that is in sight will do no harm, will not stop the breathing. I have had no cause to regret my course. Up to 1870 I used quinine and iron. I do not use

them now. They disturb the digestive functions. I now rely on a prescription that I found in the London *Lancet* a number of years ago:

R.	Tr. ferri chlor.	fl. ℥	iv
	Liq. ammon. acetat.	fl. ℥	ii
	Potass. chlor.	℥	i
	Aquæ, add.	℥	viii ɱ

Sig.—One teaspoonful every hour.

Dr. H. H. Mudd: The experience of the profession in the past few years tends towards the belief that it is impossible to separate croup and diphtheria. I noticed a short time ago reports of eighty-seven cases of diphtheria in which tracheotomy had been performed, where it was laryngeal and invisible from the beginning in fifty-six cases. I believe you cannot always separate the cases of membranous croup from those of diphtheria. The paper properly dwells upon nutrition and stimulation as the important points of treatment. As to the administration of some salt of mercury and the benzoate of soda, I believe from observations during the past six months where many have been using these remedies, that there is benefit in this treatment. I see the cases only when surgical treatment is needed, and the results of tracheotomies have been better than ever before. Dr. Hodgen was the first man I ever saw make a tracheotomy. He was one of the earliest and staunchest advocates of the measure. During the first ten years that he did the operation, it was with the reluctant consent of friends and against the sentiment of many physicians, and when there was almost no hope of recovery. He had fourteen cases before he was rewarded with a single recovery. He had operated ninety-two times when he died, with fourteen recoveries. I have had seventy-four operations for diphtheria, with twenty-eight recoveries. From all cases, without making a distinction between croup and diphtheria, the work of our office, viz., Dr. John T. Hodgen and myself, together with Dr. Harvey Mudd and Dr. Harry Hodgen, there is a total of 172 cases with forty-four recoveries, a per cent. of 25⅝. Since June I have had twenty-five cases and twelve recoveries. There was no difference in the class of cases.

We should always give patients the benefit of this operation before it is too late, before the residual air becomes so much that the tidal wave is almost nothing.

I have been interested in the accounts of intubation. I obtained the instruments for it, not that I had any great faith in it, but I knew I should meet many cases where the relatives would not let me make a tracheotomy. I say to the parents in these cases, that I believe tracheotomy to be the best operation. I have tried intubations in six cases. In three of these I resorted to tracheotomy afterwards. In one case the trachea filled with a large, hard cast that extended down to the second and third bifurcations of the bronchi, and came near suffocating the child. I removed the tube and performed tracheotomy. In another case in which I resorted to trache otomy, I at first used a tube of the required size; this was coughed up within twenty-four hours. I used a larger tube and it was coughed up. This was repeated four times, until the child was in a desperate condition. The case made a good recovery after tracheotomy. In the third case the child wore the tube four days, during which time he could not swallow without violent coughing; he was very weak, although he had been well fed *per rectum*. A profuse discharge from the trachea, and râles in the trachea and large bronchi induced me to remove it. The breathing was comparatively easy. But at the end of sixteen hours they sent for another surgeon, who thought there was nothing to be done. I thought so too, except to make the tracheotomy. This was done, and the child is getting well. In the other three cases the patients died. I do not believe that the intubation tube answers the indications as well as the tracheal tube. Its usefulness is in cases where tracheotomy may not be performed.

Dr. I. N. Love: I concur with those who deprecate caustics when they interfere with the proper tranquility of the patient. At the Copenhagen International Medical Congress some one reported 100 cases of diphtheria treated successfully by simple cauterization of the throat—of the membrane. Such a report necessarily makes us feel that he is too general in his interpretation of symptoms. Either his ideas of diphtheria do not obtain here, or the diphtheria which obtains in his latitude is not the kind which prevails here. I think there are measures for rendering the local conditions more innocuous. Turpentine, which has been mentioned, is a good remedy. I concur with those who disclaim against quinine. It impairs digestion. The strongest points that I tried to make in my paper were in the direction of treating diphtheria with the bichloride of mercury and benzoate of soda, antiseptic and eliminative agents, coupled with stimulative agents.

Dr. H. C. Dalton presented

A SPECIMEN OF ENLARGED KIDNEY,

taken from a patient, the notes of whose case are as follows:

Frank Schultz, æt. 19, single, peddler. About three weeks ago patient began to grow weak, four days later had hæmaturia, and coughed up blood at same time. The latter has continued at intervals up to present time. Bowels constipated. After entrance to hospital, respirations were slow and quiet; blood flowed from mouth frequently, origin not known. Hæmic murmurs were heard over pulmonary artery, aortic orifice, and at apex of heart. Few sibilant râles in lung. Abdomen tender. Patient had been on a prolonged spree up to three weeks ago. On autopsy, marked congestion of all the abdominal and thoracic viscera was found. The kidneys were enlarged as you see in this specimen. His death could only be accounted for by the general congestion of the above mentioned organs, following the prolonged spree.

Dr. T. F. Prewitt presented a patient who suffered almost continuously, with

HEPATIC COLIC,

from August, 1885, to November, 1886. During this time he was occasionally jaundiced; the attacks became gradually more severe until he was totally un-

able to work; lost flesh, and, except when he was under the influence of opiates, his sufferings were intense. On the 9th of November, 1886, I performed cholycystotomy. Cutting down on the gall-bladder, I aspirate it first to get rid of the bulk of fluid. It leaked from the puncture of the needle. It occurred to me that it is not prudent to aspirate the gall-bladder; it has been followed by fatal results. I have done it several times to relieve distension. In this case the bladder was not much enlarged, the obstruction not being very complete. After drawing off as much of the fluid as I could, I found that the bladder was so short that I could not bring it readily to the abdominal walls, and it became a lively contest to prevent the bile from getting into the abdominal cavity. This was prevented, however, with sponges in the hands of assistants. I found difficulty in getting it to the abdominal walls to secure it. One of the deep sutures suppurated and left a fistulous opening. All the bile does escape from the fistula as is evident from the color of the evacuations. His health has improved amazingly; he has a good color, and were it not for the purulent discharge, his condition would be very comfortable.

In reply to a question by Dr. Le Grand Atwood as to the condition of the ductus comminus choledochus, Dr. Prewitt said: I examined it as well as I could, but detected no thickening or narrowing. I think there was a gall stone in it, which escaped somewhere. I had a case last summer, of enormous distention of the gall-bladder; it reached down to the umbilicus. I aspirated twice: first drew off a quart, and afterwards a pint of fluid, subsequent to which the patient passed several large gall stones. She was much relieved; if she had not been I should have performed cholycystotomy. I had still another case in an old lady where there was considerable enlargement of the gall-bladder and much suffering, though not to the same extent as in these. She also had heart disease. This case was the result of chronic obstruction, possibly of the cystic duct. In these chronic cases, the contents are generally of a mucoid nature, and not bile.

Dr. R. J. Hill said: I have seen a few cases of obstruction to the passage of the bile, where there was no icterus; none marked at least. In one case the colic was so severe that the patient would throw himself across a barrel for relief. I had read a report of a case by Dr. Matthews, in which he had used sweet oil with good effect. According to his instructions I produced free catharsis and then administered a teacupful of olive oil. On the following morning the patient reported the passage of twenty-four gall stones, with great relief to his sufferings. The dose was repeated and at the end of three days, he had passed over 125 stones of that character. Relief was complete. It is now three years since he has had any trouble. I do not understand the modus operandi of the oil.

LOCAL TREATMENT IN DIPHTHERIA.

Dr. F. J. Lutz said, that at the last meeting Dr. Moore's question as to the advisability of using local treatment in diphtheria was not much dwelt upon. When we are called, in the majority of cases, we find the fauces, uvula, etc. covered with membrane In many cases, from the nostrils of the child there is exuding a fœtid, secretion, so that by the sense of smell we can make a diagnosis. I do not understand how any one can fail to have his attention called to the necessity of local applications, for cleanliness, if for nothing else. If the ulceration instead of being in the throat, were in the anus or vagina, or on the extremities, certainly nobody would undertake to cure it by internal application of medicine as iron or a febrifuge or calomel. I have been in the habit of applying the bichloride of mercury by means of a spray to the throat. Of course some exhaustion is produced by the child's struggles for the first few times, but it soon finds it far from disagreeable. You remove much of the secretions; a part of the membrane sometimes. Often a decided improvement in respiration follows. It is a valuable factor in reducing the temperature, much material is removed which would otherwise be absorbed. I think that by this means, the disease is checked—it does'nt extend down as far. I find that where the child is too small to make local applications, the results are not so good. I abhor the use of the probang; it is an outrageous proceedure. I have been in the habit of giving calomel and bicarbonate of soda; because authorities say it is valuable, also on the theory of its germicidal properties. I believe I have been more successful since I adopted this plan of treatment. I believe tracheotomy should be done so soon the patient's blood is not well oxygenated, his breathing embarrassed, and discoloration of the lips shows. I believe that many tracheotomies would be improved if we could keep the throat properly cleansed.

Dr. William Johnston said: The recent epidemic has made the treatment of diphtheria especially interesting to this community. I have never observed anything contagious about membranous croup. Diphtheria commences on the fauces, etc., with a peculiar membrane and a peculiar condition of the patient, and peculiar symptoms. There is a distinction between the diseases. Most of the modern specialists agree that diphtheria is the result of invisable organisms acting on the larynx, pharynx, etc. Burdow Sanderson and others believe this, and that we should attack them immediately with the spray. Were this theory correct, that would be good treatment. Those who believe that this membranous croup which kills in a few hours depends on bacteria, should have a spray in their satchels, and begin first thing to spray the throat, as Hunter did, for consumption, a few years ago. My experience with diphtheria is a sad one, spray or no spray; calomel or no calomel. So that when I read Morell McKenzie's report of sixty one recoveries from 100 cases of diphtheria, I sometimes think he has had cases of follicular laryngitis and called them diphtheria.

Dr. Adolph Green said, that there is not only a difference between diphtheria and membranous croup, but there is a difference between diphtheria and diphtheria. Most cases of membranous croup commence in the larynx; they are local, and not general, like diphtheria. If you perform tracheotomy

in diphtheria, it will prove a failure because your diphtheritic process kills your patient. If you have performed tracheotomy and the case gets well, you have saved time to treat the case by that means, and have proved yourself a good physician.

Dr Prewitt said: In a case in which I performed tracheotomy a year ago there was paralysis of the muscles of deglutition. The child came near starving in consequence of its inability to swallow. I resorted to the expedient of taking the tube out and putting a little bit of sponge into the larynx and then feeding the child. In the recent epidemic here, I see that 700 cases of diphtheria, with 135 deaths have been reported. I don't think any physician will believe that all those cases were diphtheria. I have seen many cases of follicular pharyngitis, but comparatively few of diphtheria.

Dr. Johnston said: There was a difference in the membrane in membranous croup and diphtheria. Virchow asserted this many years ago; but it has been denied.

Dr. William Porter said: I believe that the best operation would be that of tracheotomy without tubes. Dr. Prewitt placed a sponge in the larynx; I believe that ought to be done frequently. We know that many cases die from what we call pneumonia, because, I believe foreign bodies and particles from the inflamed mucous membrane get into the lungs. In Dr. Prewitt's case this was prevented —the sponge prevented the milk, etc. from getting into the lung. Intubation, by and by, will lose the favor for which it has been received, for the reason that it is almost impossible to prevent foreign bodies and diseased substances from getting through the tube placed in the larynx, into the lungs. So that after all, the tracheotomy is the grand operation where there is laryngeal obstruction. I endorse the early operation.

Stated Meeting, February 19, 1887.

The President in the Chair.

SCARLET FEVER.

Dr. William Johnston said: I would like to have the views and experience of the gentlemen concerning the scarlet fever beginning to prevail in St. Louis; whether this form is not diphtheritic in its character, also whether scarlet fever has a tendency to go into the croupous or diphtheritic form. I have seen but two cases of scarlet fever this winter; both were of an inflammatory type, characterized by high temperature and bounding pulse. In one case the child had not been exposed to any case of scarlet fever that we could learn. It had been confined to the house for one month, because it had had an attack of chicken-pox. The initiatory symptoms were of a character of stupor for twenty-four hours, at the end of which time the eruption came out all over the child. About the fourth day there commenced a snuffling and discharge of mucus from the nose. About the fifth day the fever began subsiding, and desquamation began.

I prognosticated that the child would recover, but on the morning of the sixth, about 3 o'clock, he commenced with that peculiar croupy cough which you all understand. I saw the child about daylight, when there was difficulty in breathing, a constant hacking cough, and great restlessness. I advised calling another physician. We both agreed that the child could not recover. The temperature came up again and continued high from Sunday morning till Tuesday evening, when he died of strangulation. Antipyrin, small doses (⅛ gr.) of calomel with soda were used. Bowels were moved, bath administered, Fleming's preparation of aconite was given. The difficulty in the trachea was not relieved; tracheotomy was suggested but not performed, and the child died with membranous croup.

Dr. I. N. Love said, that he had been partial to the local treatment; it is important, not only for relieving the discomforts of patients, not only for the soothing effect on the irritated surfaces, not only for the specific effect, but for the purpose of local disinfection, of rendering the membranous deposit innocuous, so far as possible. These local applications, I think, should be made in a manner to disturb the patient as little as possible, because, one of the important points is to husband the patient's strength, in the way of nutrition, of stimulation, and at the same time, arrange your local applications so as to secure as little disturbance as possible. The spray is preferable to gargling; it will reach further and in an easier manner. One point has not been touched upon; that is, the tendency of the deposit to increase by continuity of tissue. It is a point to keep the nasal passages clear, and in order to secure this, I have the nurse or patient use melted vaseline, carbolized (5 grains to the ounce), introduced into the nostril, either with a spoon or small dropper or syringe. Some children will snuffle it up readily. The surfaces are soothed, the accumulated secretions softened and discharged, and the passages kept open.

Regarding Dr. Johnston's disbelief in the curability of the bona fide membranous croup, I think the laryngeal trouble does not necessarily imply any more constitutional involvement, or that the disease is necessarily of a malignant form, but simply that the local deposit is in a very undesirable place, causing mechanical obstruction to breathing. We have all seen cases of membranous croup get well. I have no doubt Dr. Johnston has. I can recall five of them, in which I could not get doctors who also saw them, to say whether they were croup or diphtheria; they did'nt know. And I don't believe anybody knows. I think the health commissioner solved the problem correctly when he ordered that a case of membranous croup should be placarded as diphtheria. In the five cases mentioned they were dying, the operation was performed, suffocation was prevented and they recovered.

Dr. Adolph Green said: It was a fact that all the infectious diseases are sometimes complicated with croup, small pox, measles, etc., but they are all membranous croup. False membrane is not always deposited there. There is merely a catarrhal inflammation. For the most part, these cases of croup have nothing to do with true diphtheria, but some

times it may happen that actually there is primary affection of the pharynx.

Dr. Johnston did not mean by membranous croup, laryngitis, tonsillitis, pharyngitis, etc. He meant true membranous croup, and believes it is not curable by any means which we possess.

Dr. G. Hurt said he had been in the habit of recognizing three kinds of croup: Spasmodic croup, and a croup due to a simple inflammatory condition without membrane. That the membranous croup is most usually diphtheritic, he is willing to concede.

Dr. W. H. Ford said: A year ago a severe case of diphtheria in an adult occurred in the West End. It was attended by Dr. H. Tuholske. There were two other cases, all of which recovered. In the house across the alley from the one in which these cases occurred three other cases occurred in succession, all getting well. I afterward learned that in cleaning up after the first cases the people of that house through some of the materials from the diphtheritic room into the alley; these were afterward carried by a boy from the second house, and he had the first case of diphtheria in that house.

Dr. W. Porter said: I have tried to make a practical summary of the prevailing opinion amongst the profession as follows:

1. That the profession is not studying so much the obscure points in the nature of diphtheria, as it is the practical benefit to be derived from properly treating it.

2. That diphtheria is not an incurable disease. Those who have had the best results favor first limiting the local progress of the disease. It is not fair to say that because the cauterizing the throat has failed to cure cases, therefore local applications to the pharynx made with gentleness and tact, cannot be made so that the child will not resist. Also, those who have reported practical results favor medications that limit the progress of the poison, that render it inert. The use of the benzoate of soda has increased in favor and my experience with it corroborates the good reports concerning it. I am sure I have found good effect from using guardedly, bichloride of mercury.

3. Nutrition and stimulation should be resorted to to keep up vitality.

4. The air passages should be kept as free as possible, and, if necessary, an artificial opening should be made. I don't believe that intubation is likely to afford the great relief that its inventor now maintains. When tracheotomy is performed, the child gets air into the lungs pure and fresh; when intubation is performed, the child continues to breathe through the diseased channel; is liable to receive particles of matter into the lung, to set up pneumonia, from which it dies. Tracheotomy is not such a terrible operation; where it is done in cases not associated with this disease, it is not a dangerous operation. I don't believe in tracheotomy when the membrane has descended into the trachea, or when the child is beyond recovery. But where you find that the lungs are resonant, that there is nothing but mucous râles in the bronchial tubes, where the lower air passages are comparatively free, and the upper ones occluded, we fail in our duty if we do not practice tracheotomy.

Dr. C. H. Hughes said, that our fathers built more wisely than they knew, when, failing to draw the later scientific distinctions between diphtheria and croup, they treated them as the same thing, and used calomel so effectually. Before Bretonneau drew the line of demarcation between them, we heard very little of the fatality of diphtheria; and so far as we can discern from the literature, diphtheria is not a disease which has come of late. Now the same treatment is given since we have returned to the practical practice of our fathers, and suspended the scientific difference between tweedledum and tweedledee. A point which I have not heard discussed, is the absolute necessity in diphtheria, as well as in croup and every other affection which is taxing on the vital powers of the organism, of sustaining the vital centres by adequate and enforced sleep as well as nutrition. If there is anything in which it appears to me that practitioners are derelict in the management of diphtheritic cases, it is in not enforcing in the night adequate sleep, and that by chloral.

Dr. Johnston said, he was one of those who gave calomel freely, but his patients died.

Dr. R. Funkhouser had been accustomed to treating many cases of diseases of the throat, but during the later part of last year, and early part of this year, he had not had a case of diphtheria. He considers that a great many cases reported are not diphtheria.

In reply to a question by Dr. Rumbold, Dr. Funkhouser said: Some cases I have had have been in the neighborhood of cases reported as diphtheria; their parents were much exercised and sent to me, expecting me to pronounce them diphtheria. It may be that some of my cases might have been called diphtheria, but I have not seen a case of diphtheria this year or the last of last year.

Dr. Love said, that this point was touched upon in his paper; it was suggested, that some observers might be more liberal than others in their interpretation of the symptoms. But we do not want to go too far in either direction. The death rate is enough to indicate that diphtheria has been abroad in the city. We all know a classical case of diphtheria, but we may have mild cases, severe types and malignant types. During the time that diphtheria prevails, there is always an epidemic of sore throat. The symptoms of a case of diphtheria may vary to such a degree as to make the diagnosis doubtful.

Dr. Rumbold said: In reference to the diagnosis (and prognosis) of cases, I have noticed that when the membrane is located on the tonsil, or in the anterior portion of the throat, the case was generally a mild one; if a little further back it was increased in gravity; if in the posterior portion of the fauces, then it was a grave case.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, March 7, 1887.

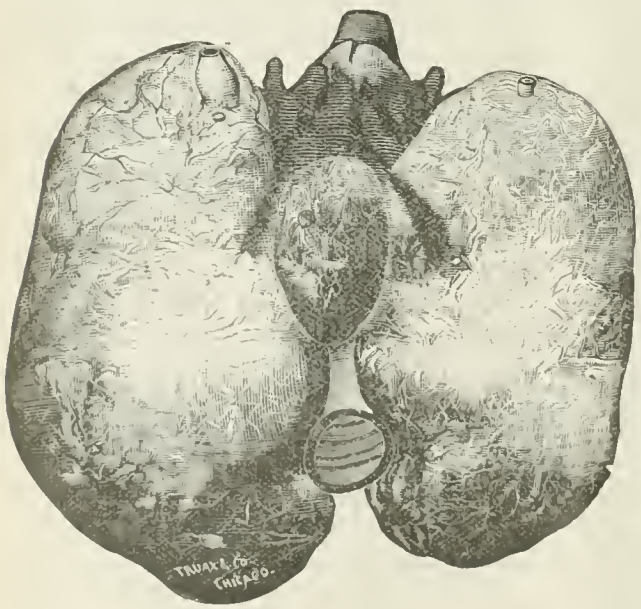
The President, Edmund J. Doering, M.D., in the Chair.

Dr. A. E. Hoadley read a paper on

DEEP TUBING OF THE LARYNX AS A SUBSTITUTE FOR INTUBATION, WITH A REPORT OF NINE CASES.

(See page 337.)

Dr. F. E. Waxham opened the discussion and said: In this connection I take occasion to present a bronchocele which produced death by pressure on the trachea. The history of this case, briefly, is this: The patient was a girl 14 years old; she had been troubled with a goitre for about a year, which increased rapidly in size and the people observed that it was at times larger than at others, more particularly after the child had taken cold; but still the goitre gave no inconvenience until three days before death, when it is stated the child had taken a slight cold and the tumor became larger. With increase in the size of the tumor and the consequent pressure upon the gland by the sterno-thyroid muscles, great dyspnœa resulted. The patient was attended by Dr. J. G. Berry, who recognized the true condition, and on the third day I was called to perform intubation. The child was now in the most desperate condition; indeed, it was moribund, the pulse was feeble, rapid and thready, hypotastic congestion had already occurred in the lungs, and the child was semi-comatose.



While in this condition the largest size intubation tube was introduced into the trachea, but it failed to give relief simply because the tube was not of sufficient length. It would not reach through the stricture, and from the pressure of the gland, as rapidly as it was pressed down in position so rapidly would it be pressed up again. The child was so near dead that tracheotomy was thought to be useless. To meet such emergencies as this I have had a much longer tube constructed, one that will pass entirely through such a stricture and consequently give perfect relief. The object in performing intubation in cases of bronchocele would be to give immediate relief, and to give us time in which we might perhaps reduce the tumor by electrolysis or the internal and external use of iodine; or these measures failing, we could then leisurely enucleate the gland. Bronchocele may produce death by pressure laterally, or by suffocation from pressure upon the trachea anteriorly; or a lobe of the gland may develop between the œsoph-

agus and the trachea and produce pressure posteriorly. In this case the pressure was exerted laterally. Coming more particularly to the discussion of the paper presented to-night, I feel that it should not go without a few words of criticism. As I believe that an old adage is that the proof of the pudding is in the eating of it, and as intubation has been performed nine times without a success by this new procedure, I would feel that there is little to recommend it. First, in regard to the position of the tube; the author recommends that the tube be reversed, and instead of placing it with the beveled surface forward and the shoulder projecting backwards, he recommends the tube turned so that the shoulder will project forward and the beveled surface backwards. A case has been reported to me in which there was complete perforation at the base of the epiglottis from the pressure of the beveled surface of a straight tube. The most perfect tubes are now made with the upper surface curved slightly backwards so that no pressure will be exerted upon the anterior wall. If we turn the tube around and place it with the projecting shoulder forwards, how much greater must be the danger from ulceration. Again, the author refers in his illustration to a tube with a shoulder broad posteriorly, a tube that has been discarded some time since, for it has been found that a tube with an olive-shaped head fits the larynx much better than the old tube. I think the author is mistaken about the head of the tube riding high and riding high and resting upon the arytenoid cartilages. It depends altogether upon the judgment used in the selection of the tube. If a tube is used larger than is appropriate for the age of the patient, it will be found that while the tube can be passed into the trachea without difficulty, yet the head will not sink into the larynx, and then it will ride high and swallowing becomes very difficult indeed; but if the tube has an olive-shaped head and is appropriate to the age, then it will sink into the cavity of the larynx, resting upon the vocal cords, and swallowing is attended with but little difficulty. In regard to the length of the tube, it

would seem to me that little would be gained by making it shorter; indeed, this was one of the reasons of Bouchut's failure thirty years ago. You can readily see if we use a short tube, one simply projecting through the larynx, there would be much greater danger from detachment of false membrane below the tube. In offering these criticisms it is with no unkind intent, or for the purpose of discouraging attempts at improvement. While I have now performed this operation over one hundred times, and with a success rarely attained by tracheotomy, yet I do not consider the instruments fully perfected.

Dr. Christian Fenger said: I shall not say anything about intubation of the larynx according to Dr. Hoadley's method, further than if there is a possibility of avoiding the difficulty in swallowing, then that is a very important point. And if a change in the position and shape of these tubes will help us to avoid that, it will make intubation still much more valuable than it has been heretofore. But I will say a few words in regard to goitre, as Dr. Waxham has shown us this very interesting specimen, and as this is of great importance. As Dr. Waxham says, pressure from the goitre on the trachea causes the so-called sabre sheath trachea with the subsequent stenosis, either from pressure or from softening of the rings from pressure and atrophy. And that is not the only danger in goitre. There are goitres where the trachea is perfectly open, and still a too often fatal dyspnœa occurs. Those are the causes where the recurrent laryngeal nerve is affected by pressure from the tumor so as to cause symptoms of posticus paralysis. Thus we see cases where extirpation of the goitre has been made to relieve respiratory difficulties. We see that thus the respiratory difficulty remains in spite of the removal, sometimes for a time, sometimes forever; the latter when no repair of the nerve is possible. Besides these two classes of danger to goitre patients, there is a third met with, of course only in severe cases. It consists of a spasm of the glottis, severe and continuous enough to terminate in sudden death. How this spasm originates is as yet unknown. The authors having paid most attention to this subject feel inclined to believe that pressure from the goitre on the pneumo-gastric nerve causes irritation of the vagus centre of the brain, and reflex contraction of the muscles of the glottis. These are the cases where goitre patients in apparently good health, with no dyspnœa, or with a slight occasional attack, will die suddenly. For instance, a patient is well and around amusing himself during the day, and in the night a sudden dyspnœa sets in and the patient dies before anything can be done. Intubation with the long tube in a goitre patient shown by Dr. Waxham may be of very great importance as a means of relieving suffocation attacks in goitre.

Dr. Ferdinand Henrotin said: My position is very strongly in favor of that taken by the author of the paper, and as Dr. Waxham says the eating of the pudding tells us about the making, my experience has been directly the opposite to that of Dr. Hoadley. I have only had a few cases, but if they are of any importance in elucidating this point, I take pleasure in giving them. I believe in having the tube facing in the way mentioned in the paper. My first case was about a year ago, the patient being brought to me from out of town. As it was my first case I took particular pains to follow the regular method as pointed out by those who had introduced it, and so introduced the tube with the upper face looking forward and upward, that is, the upper plane at the entrance. The child threw up the tube within ten minutes. I immediately replaced it, and while he remained in the office he was perfectly free in his breathing and entirely relieved from stenosis. In spite of my endeavors to have him remain, he was taken to his home in the country, the tube remaining in place. About eight o'clock the next morning he coughed up the tube. He was all right for an hour, then began to choke up again, and in another hour died from stenosis. In another case I had immediately after, there was no relief. I introduced the tube four different times; I had it in the larynx and it remained in position, but the child was not relieved. I intubed a third child, and it died. These three cases were all with the tube in the way mentioned by Dr. O'Dwyer, and they all died. Following that I had three successful cases, and the tube was introduced the other way, facing in the other direction. In one of the cases I had no particular trouble in taking the tube out, but I had more or less trouble in introducing it, a little more than the other way. These cases all recovered. I had a case that recovered. a child of seventeen months, who retained the tube four days and coughed it up himself. Following that and a little talk I had with Dr. Bartlett on the subject, I again resumed the method of Dr. O'Dwyer, and placed the tube in the other direction, and that child died. Day before yesterday I was called to place a tube, and I introduced it without difficulty. I put the tube in about 9 o'clock in the evening, and yesterday, a little less than twenty-four hours after putting in the tube according to the O'Dwyer method, it was coughed up by the patient. I went back last evening with Dr. Cunningham, and said, "Now I am going to put the tube in the other way, and see if the patient coughs it up." I replaced the same tube, facing the other way, and he has had no difficulty as yet in retaining it. I have had four cases intubed by the O'Dwyer method, with four deaths; three cases with the tube turned the other way, all recoveries. I suppose it is a coincidence, to a great extent. The eighth case has not progressed far enough to state whether the child will recover. In regard to the advantages of this method, so far I have never had a tube coughed up that was put in in that way, except one, on the fourth day, but the child recovered. It seems to me the tube holds much better, it sinks into the larynx and in most cases disappears, you cannot feel it with the finger, while if it is turned the other way you can feel the edge of it with your finger. So far as the extraction of the tube is concerned, except in two instances I had no particular difficulty. As regards swallowing liquids, so far as my observation goes I think it is speaking a little strongly to say that the patients can swallow; I do not think they can swallow much; I feed them on semi-solids; I cut a raw

oyster in pieces and let it slip down; a custard and the white of an egg that slip down easily, and that, with little pieces of ice to quench the thirst, has usually succeeded with me. The disadvantage that I consider attaches to the short tube is that the expulsive effort at coughing would frequently cause it to be coughed up. The length and weight of the tube must be an element in keeping it in place. It seems to me we are using too small tubes. I am using the second size in a child of four years, and getting along quite well. As far as the difficulty of introducing a long tube is concerned, I simply start the tube, and as it slips into the larynx withdraw the obturator, and just as it comes out of the tube my finger slips into its place and pushes the tube home.

Dr. E. Fletcher Ingals said: I have had no practical experience in putting in the tube *the wrong way*, and I do not know how well it may turn out, but anatomically it is certainly wrong unless the shape of the tube be modified. It may be that with the head of the tube modified it would sink into the larynx, as recommended by the author of the paper, but with the tube as constructed by Dr. O'Dwyer it does not seem to me a safe procedure to insert it wrong side foremost, for fear of pressure upon the epiglottis causing ulceration. As to the effects of deglutition, if the tube fitted and would set deep in the larynx and remain there, of course the patient could swallow more readily. It seems to be the experience of the last speaker that these patients do not always swallow readily even when the tube is seated deeply in the larynx, and I am inclined to believe that unless some device can be invented to prevent the entrance of fluid it is better that the patient should take none. Where I have introduced the tube it has been for other physicians, so that I was usually unable to watch the subsequent treatment, but in those that have recovered I have insisted that they should drink absolutely nothing. In the last case I insisted upon this so strongly that I cautioned the parents if they gave the child a teaspoonful of water they would kill it. The child will want to drink very badly after the first twenty-four hours, but it is not a necessity for a few days. If no fluid is allowed the patient is not nearly as likely to have bronchitis or pneumonia as when it is permitted to drink. The child may have ice, it may have enemas, and may have soft solids in abundance. As to the length of the tube, I agree with the last speaker that the long tube is the better. One of Bouchot's mistakes was that he made his tube too short. But the principal reason for his failure was that he attacked tracheotomy; he not only wanted to introduce his tube, but he wanted every one else to stop tracheotomy. I would like to know what success Dr. Waxham has had with the rubber collar in preventing the entrance of fluids into the air passages.

Dr. John W. Niles said: My observation so far leads me to think that it does not make very much difference which way you introduce the tube as regards the patient's ability to swallow fluids. In neither way can this be done without exciting cough. In the two cases in which Dr. Henrotin introduced the tube for me he introduced it the wrong way, and they swallowed fluids better than I expected they would. The next case I had I introduced it myself the wrong way, the same as he did the others. The child had more difficulty in swallowing than the others had; on the third day he coughed the tube up, and when I reintroduced it, it was in the way recommended by Dr. O'Dwyer, and there was a marked improvement in his ability to take liquids. In fact, he swallowed better than the other two. He succumbed to the disease six days after the tube was first introduced.

Dr. F. E. Waxham said: In regard to the rubber attachment which I have recently devised, I certainly think it a great improvement. Some may not desire to use the artificial epiglottis attached to the rubber collar, in which case it can be removed and the tube will still be a great improvement, inasmuch as, the head being small and surrounded by the rubber, it will fit the larynx more perfectly, there will be less irritation, and ulceration will be impossible. I have recently saved two little patients in which this device was used, and have also employed it in other cases with advantage. I agree with Dr. Ingals that it is best to keep water from the little patients as far as possible. I usually advise ice-cream, a very little at a time, or that a small piece of ice be placed in a cloth and held in the mouth. This relieves the urgent thirst without causing the frequent coughing that arises from the endeavor to swallow water.

Dr. Hoadley, in closing the discussion, said: As I mentioned in the paper, I started out in this matter of intubation really on my judgment as to the position the tube was designed to take in the larynx, for I had not given the subject sufficient attention to remember that the tube was designed to rest high in the larynx, and my experience has been so very pleasant, so far as the non-interference with the function of the throat is concerned, that I have decided in my own mind that deep tubing is preferable to intubation. The cases that I have tubed in that manner were all bad cases, and not in a single one could I give a favorable prognosis. They were all promptly relieved, and that was all I expected to attain from the tubing. I have recommended the short tube; the only advantage that the long tube can possibly have over the short one is its weight, except in rare cases, and then its length is of advantage. In the majority of cases of laryngeal stenosis the obstruction is entirely in the larynx, and when it does extend down into the trachea the probabilities are that the child will die of continued extension, and in such a case the long tube can be introduced. In the nine cases I tubed in this manner I used the long tube, so I cannot say whether the short one would have relieved the stenosis. In one autopsy where there was laryngeal diphtheria there was no diphtheritic exudation in the trachea, so that the extension of the tube to the seventh ring was unnecessary. In reference to the position of the tube resting against the epiglottis, as in the O'Dwyer method, I would state that the epiglottis folds down and bears first upon the shoulder of the tube, then closes its orifice, but it cannot perfectly close the larynx. Dr. O'Dwyer has

had ulceration of the epiglottis with perforation. You might think it would be a great deal worse to turn the tube around, that the pressure would be greater upon the epiglottis, but when I turn the tube around it goes half an inch lower, and the projection of the tube that is supposed to touch the epiglottis does not touch anything, and the mucous membrane is not pressed upon at all. Introducing the tube in the O'Dwyer method it will not go into the larynx; you can push it down and still it can be felt above the larynx, so when the epiglottis folds over, it must necessarily come against the tube. By turning the tube around, sinking it well into the larynx, it goes down so far that in a small larynx you cannot touch it with the finger, it goes down as far as the attachment of the apex of the epiglottis with the thyroid cartilage. The epiglottis folds down over the larynx, the laryngeal tube is still free below it, resting on the vocal cord, so that it can produce no ulceration of the epiglottis. As to the vocal cords, Dr. O'Dwyer says that ulceration is rare in that situation. That is because the pressure is slight, and not attended by friction, as in the epiglottis. Northrup says you must press the tube well down into the larynx. In doing this it rests against the epiglottic cartilage and its projection presses back against the arytenoid cartilages, pressing them wide apart in the most disagreeable manner. It is like putting the right foot into the wrong boot. It does not fit or rest easy at any point. Turn the tube around and it rests comfortably in the larynx without one point of pressure, the only pressure induced is that of swallowing, which is not sufficient to produce ulceration. I have never had any trouble in introducing the tube except in one little patient in whom, it seemed to me, the larynx went down to the sternum, and it was with great difficulty that I reached the orifice of the larynx, but when I did finally engage it the tube was introduced readily. To facilitate extraction I have had con structed a cup-shaped depression on the head, instead of the oval convex surface with the hole directly in the summit. With the oval head, unless you strike the aperture itself you are not likely to find it, as the extractor will invariably glide to the outside of the tube. With the cup-shaped head, partly from the tube being surrounded by the larynx, the extraction is greatly facilitated. My patients have all, with the one exception mentioned, been able to drink fluids; they have been able to drink two or three swallows without coughing. Occasionally there was some irritation; they would drink a large swallow and cough, immediately drink again and then cough, but not one refused to drink. I had one case that did recover. Dr. Waxham performed the operation for me, introducing the tube in the O'Dwyer method. That patient wore the tube nearly two weeks, so long that it took between two and three weeks before the child could again talk, but it did not wear it long enough to get used to swallowing without coughing. It could not swallow fluids at all and was fed with the greatest difficulty, a part of the time by the stomach tube. The object of the rubber collar with its valve-like attachment is, as I understand it, to close the orifice of the tube. Inasmuch as the epiglottis will close the tube by its automatic action of folding down over it, I regard the rubber top as being wholly useless. Not only is it useless, but the valve standing up in constant apposition with the epiglottis is a source of additional and continued irritation.

STATE MEDICINE.

LAW REGULATING THE BUSINESS OF PHARMACY IN THE STATE OF NEBRASKA.

SECTION 1. That there shall be established in the State of Nebraska a Board to be styled the Nebraska State Board of Pharmacy. Said Board shall consist of the Attorney-General, Secretary of State, Auditor, Treasurer and Commissioner of Public Lands and Buildings, and said Board shall appoint five examiners, or secretaries, who shall be skilful retail apothecaries of seven years practical experience, actually engaged in said business in the State of Nebraska; and said secretaries shall assist said Board in conducting all examinations herein provided for, and in the performance of any of its duties. Each of said secretaries shall receive a compensation of $5 per day for each day's service actually and necessarily performed, and such necessary expenses as shall be audited and found just and reasonable by said Board for attending the meetings thereof, said secretaries or examiners to be selected from ten practical pharmacists recommended by the Nebraska State Pharmaceutical Association;

Provided, That all such services and expenses, and all the necessary expenses of said Board, shall be paid out of the moneys received by said Board for fees. All moneys received in excess of said per diem allowance, and other expenses above provided for, shall be paid into the State treasury at the end of each year, and so much thereof as shall be necessary to met the current expenses of said Board shall be subject to the order thereof, if, in any year the receipts of said Board shall not be equal to its expenses. The Board shall make an annual report and render account to the State Auditor and to the Nebraska State Pharmaceutical Association of all moneys received and disbursed by it pursuant to this act. And the State of Nebraska shall in no case be liable for any such compensation or expenses. *And provided further*, that said Board shall have the power to discharge any of said secretaries at any time, and to fill any vacancy in the position of secretary whenever from any cause such vacancy exists.

SEC. 2. The said Board shall, within thirty days after its appointment, meet and organize by the election of a President and a Secretary from its own members, who shall be elected for the term of one year, and until their successors are elected, and shall perform the duties prescribed by the Board. Said Secretary shall, in addition to his compensation as a member of said Board, receive a further sum not to exceed $100 annually for his services as said secretary. It shall be the duty of the Board to examine all appli-

cations for registration submitted in proper form; to grant certificates of registration to such persons as may be entitled to the same under the provisions of this act; to investigate complaints and to cause the prosecution of all persons violating its provisions; to report annually to the Governor and to the Nebraska State Pharmaceutical Association upon the conditions of pharmacy in the State, which said report shall also furnish a record of the proceedings of the said Board for the year, and also the names of all pharmacists registered under this act. The Board shall hold meetings for the examination of applicants for registration, and the transaction of such other business as shall pertain to its duties, at least once in four months, said meetings to be held on the first Tuesdays of March, July and November in each year; and shall make by-laws for the proper fulfillment of its duties under this act; and shall keep a book of registration in which shall be entered the names and places of business of all persons registered under this act, which book shall also specify such facts as said persons shall claim to justify their registration. The record of said Board, or a copy of any part thereof, certified by the Secretary to be a true copy, attested by the seal of the Board, shall be accepted as competent evidence in all courts of the State. Three members of said Board shall constitute a quorum.

Sec. 3. Every person who shall, within three months after the passage of this act takes effect, forward to the Board of Pharmacy satisfactory proof, supported by his affidavit, that he was engaged in the business of a dispensing pharmacist, on his own account, in this State at the time this act takes effect, in the preparation of physicians' prescriptions, or that at such time he had been employed or engaged three years or more as a pharmacist in the compounding of physicians' prescriptions, and was at said time so employed in this State, shall, upon the payment to the Board of a fee of $2, be granted the certificate of Registered Pharmacist. *Provided*, That in case of failure or neglect to register as herein provided, such person or persons shall, in order to be registered, comply with the requirements provided for registration as a licentiate in pharmacy herein after described.

Sec. 4. No person, other than a licentiate in pharmacy, shall be entitled to registration as a pharmacist except as provided in section 3. Licentiates in pharmacy, in the meaning of this act, shall be such persons, not less than 18 years of age, who shall have passed a satisfactory examination touching their competency before the Board of Pharmacy. Every such person shall, before an examination is granted, furnish satisfactory evidence that he is of temperate habits, and pay to the Board a fee of $3; *provided*, That in case of the failure of any applicant to pass a satisfactory examination, the money shall be held to his credit for a second examination at any time within the year. The said Board may grant certificates of registration, without further examination, to the licentiates of such other Board of Pharmacy as it may deem proper, upon a payment of a fee of $2.

Sec. 5. The said Board may grant, under such rules and regulations as it may deem proper, for a fee not exceeding $1, the certificate of registered assistants to clerks or assistants to pharmacy, not less than 18 years of age, who at the time this act takes effect, shall be engaged in such service in the State, and have been employed or engaged two years or more in the practice of pharmacy, but such certificate shall not entitle the holder to engage in such business on his own account, or to take charge of or act as manager of a pharmacy or drug store.

Sec. 6. Every registered pharmacist, or registered assistant, who desires to continue the practice of his profession shall annually, after the expiration of the first year of his registration, during the time he shall continue in such practice on such date as the Board may determine, pay to the said Board a registration fee to be fixed by the Board, but which shall not exceed $1 for a pharmacist or 50 cents for an assistant, for which he shall receive a renewal of said registration. Every person receiving a certificate under this act shall keep the same conspicuously exposed in his place of business. Every registered pharmacist or assistant shall, after changing his place of business or employment, as designated by his certificate, notify the secretary of the Board of his new place of business. If any pharmacist or registered assistant shall fail or neglect to procure his annual registration, or to comply with the other provisions of this section, his right to act as such pharmacist or assistant shall cease at the expiration of ten days from the time of notice of such failure to comply with the provisions of this section shall have been mailed to him by the secretary of said Board.

Sec. 7. Any registrations obtained through false representation shall be void, and the Board of pharmacy may hear complaints and evidence, and may revoke such certificates as it may deem improperly held.

Sec. 8. Any proprietor of a pharmacy who, not being a registered pharmacist, shall, ninety days after this act takes effect, fail or neglect to place in charge of such pharmacy a registered pharmacist, or any such proprietor who shall by himself, or any other person, permit the compounding or dispensing of prescriptions, or the vending of drugs, medicines or poisons, in his store or place of business, except, by, or in the presence, or in and under the supervision of a registered pharmacist or registered assistant; or any person, not being a registered pharmacist, who shall take charge of or act as manager of such pharmacy or store, or who, not being a registered pharmacist or registered assistant, shall retail, compound or dispense drugs, poisons or medicines of any kind, or any person violating any other provision of this act to which no other penalty is herein attached shall be deemed guilty of a misdemeanor, and for every such offense, upon conviction thereof, shall be punished by a fine of not less than $10, or or more than $100, and in default of payment thereof, shall be imprisoned not less than ten days, nor more than ninety days, or both such fine and imprisonment, in the discretion of the court.

Sec. 9. Nothing in this act shall apply to the busi-

ness of any retail dealer engaged in business at a distance of not less than five miles from the place of business of any registered pharmacist; nor with the exclusive wholesale business of any dealer, except as provided in section 10, nor with any resident registered physician dispensing his own medicines on his own prescriptions.

SEC. 10. No person shall add to or remove from any drug, medicine, chemical or pharmaceutical preparation, any ingredient or material for the purpose of adulteration or substitution, which shall deteriorate the quality, commercial value or medical effect, or which shall alter the nature or composition of such drug, medicine, chemical or pharmaceutical preparation, so that it will not correspond to the recognized tests of identity or purity. Any person who shall thus willfully adulterate or alter, or caused to be adulterated or altered, or shall sell or offer for sale any such drug, medicine, chemical or pharmaceutical preparation, or any person who shall substitute or cause to be substituted one material for another, with the intention to defraud or deceive the purchaser, shall be guilty of a misdemeanor and be liable to a prosecution under this act. If convicted he shall be liable to all the costs of the action and for the first offense be liable to a fine of not less than $10 or more than $100, and for each subsequent offense a fine of not less than $25 or more than $150. On complaint being entered, the Board of Pharmacy is hereby empowered to employ an analyst or chemist, whose duty it shall be to examine into the so-called adulteration, substitution or alteration, and report upon the result of his investigation, and if the said report shall be deemed to justify such action, the Board shall duly cause the prosecution of the offender, as provided in this act.

SEC. 11. All suits for the recovery of the penalties prescribed in this act shall be prosecuted in the name of the people of the State of Nebraska, in any court having jurisdiction, and it shall be the duty of the prosecuting attorney of the county where such offense has been committed to prosecute all persons violating the provisions of this act, upon proper complaint being made to them.

SEC. 12. The pharmacist of every house dispensing and compounding medicines, registered under this act, shall be exempt and free from all jury duty in the courts of this State.

SEC. 13. This act shall take effect and be in force from and after its passage and publication according to law.

DOMESTIC CORRESPONDENCE

RUMEX ACETOSA IN CANCER.

Dear Sir:—I have recently seen several communications in the journals in regard to the rumex acetosa or small-leafed sorrel. I have also had some experience with the herb that may be of some interest to the profession.

In 1849, directly after I began practicing medicine, an old gentleman, a very warm friend, proposed to give me a secret remedy for cancer, which he said he had obtained from a brother, who was a graduate of Jefferson Medical College, and then practising in one of the interior towns of Pennsylvania. He said it would cure every time without fail, and he brought out an old worn sheet of unruled foolscap paper, written over one-half of its surface, minutely detailing the season in which the broad-leafed, or horse-sorrel, was to be gathered and prepared. According to the recipe the directions must be followed out most scrupulously or the efficiency of the remedy would be impaired. The herb was to be gathered at a certain stage of development, bruised in a wedgewood or glass mortar, the juice expressed out on a pewter plate, dried in the shade to the consistence of honey, then spread on chamois skin or buck skin, and, after abrading slightly the surface of the diseased part, to be applied daily till the diseased tissue separated from the sound, when the dead mass could be easily removed. After this the best dressing is a weak solution of the medicine in water.

The different species of rumex have the same chemical constituents, and the broad-leafed sorrel not being easily obtained in the locality where I then was, I gathered a quantity of the small-leafed, or sheep-sorrel, at the proper time, to-wit: when the bloom began to drop, and bruised it in an iron mortar and expressed the juice out on a common delf-ware plate, as I was not the owner of a pewter one, and when evaporation had brought it to the proper consistence I put it up in a gallipot. In the first case of epithelioma that came under my care I used it, and was successful. I have used it frequently since, both successfully and unsuccessfully, and I feel safe in saying that the diagnosis, in some at least, of the successful cases, was correct, as it was confirmed by those high in authority and by the microscope. I think it is fair to admit that it is one of the best and safest escharotics we can use in such cases; and when our patients are not willing to submit to removal by the knife, when the glands are not involved, and the disease has not encroached too much on the underlying tissues, we can safely use this in preference to any other escharotic. Of course the use of any of this class of remedies cannot be compared to immediate removal by surgical procedure.

Very truly yours, JAMES LAMB, M.D.

Aurora, Ind., Feb. 21, 1887.

FUNGUS CEREBRI REDUCED BY PRESSURE.

Dear Sir:—An interesting case of cranial fracture, followed by fungus cerebri, removed by ligature, and reported in THE JOURNAL of February 5, prompts me to report a case somewhat like it, and with a like favorable result from different treatment.

F. M., aged 2½ years, was kicked by a horse, on the left superior posterior parietal bone, crushing the bone, and producing compression of the brain, without breaking the skin, but followed by a swelling the size of an egg. I saw the child about 4 o'clock in the afternoon of the same day, and immediately made an incision the whole length of the tumor; coagulated blood, and quite a considerable amount of brain,

following the knife. A conical incision enabled me to see that the bone was comminuted, and the brain investments very much torn. I removed eleven pieces of bone; trimmed off the jagged parts of the dura mater; brought the cut surfaces of the scalp together by sutures; and dressed with the water dressing. The case progressed favorably for nearly two weeks, when a fungus cerebri appeared and grew to the size of a hen's egg, which I proposed to excise, but as the mother refused her consent, I took an old leaden tea-caddy I found in the house—it was in the country, some fifteen or sixteen miles from my residence—folded the plate to a proper thickness, and, with a hammer made it concave. I then placed over the growth two thicknesses of lint, smeared over with cerate, a linen compress on that, then my lead compress, and retained all by moderate pressure with a bandage, which was drawn tighter from day to day, until the entire growth was absorbed. In due time the external wound healed, and the child grew to be as bright and intelligent as the other children of the family. Very truly yours,

F. Walton Todd, M.D.

Stockton, Cal., Feb. 14, 1887.

"THE ETIOLOGY AND CURE OF ASTHMA."

Dear Sir:—A paper under the above title recently appeared in The Journal which called out some comment to which the author has objected in the last issue (March 19). In this last note he seems to have gone quite as far as the reviewer in refuting his former claims.

From the comprehensiveness of the title and from the tenor of his paper one would naturally suppose he had some information to impart about asthma, but he now claims that he was not writing about asthma, but about "a rarer form of the disease." Every laryngologist, and probably nearly every general practitioner, knows that cauterization of the turbinated bodies will cure rare cases of asthma.

If the gentleman had entitled his paper "A Case of Asthma Benefited by Treatment," and had confined his subsequent remarks to a statement of facts as pointed out in the review, he would not have been troubled by the irritation into which he has wrought himself; but might have rested content with the knowledge that he had given a most excellent and interesting account of his own sufferings and the manner in which they were relieved. The charge which he makes of misrepresentation will be found wholly gratuitous by those who care to read the review. Very truly yours,

E. Fletcher Ingals.

64 State St., Chicago, March 20, 1887.

MISCELLANEOUS.

The Medicine and Hygiene of the Talmud.—Since the publication of my address on "Jewish Hygiene and Diet in the Talmud and various other Jewish Writings heretofore Untranslated," delivered before the American Medical Association in 1884, at Washington, D. C., I have been constantly urged by the profession to translate and publish the medical and hygienic portion of this "wonderful" compilation, the Talmud. I therefore beg to state to the profession at large that I have concluded to translate and publish from the Talmud everything relating to medicine, providing that, prior to the undertaking. I can receive one thousand subscribers for the book. Such subscription may be addressed to me in the following words:

I, the undersigned, agree to take one (or more) copy of the "Talmudic Medicine" of Dr. von Klein, which shall not exceed $5.00 in cost for 500 octavo pages, or at $1.00 for each 100 pages, payable on delivery. Under no other circumstances will I undertake this labor. No more copies will be published than the number subscribed, and fifty extra copies for distribution to the principal medical journals for review. Carl H. von Klein.

110 E. 2d St., Dayton, Ohio.

[Exchanges are requested to publish or notice as soon as possible.]

The Miami Medical College has, recently, become the Medical Department of the University of Cincinnati.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 12, 1887, TO MARCH 18, 1887.

Major C. H. Alden, Surgeon, ordered for duty at the U. S. Military Academy, West Point, N. Y., relieving Lieut.-Col. Andrew K. Smith, Surgeon, who will report by letter to the Surgeon-General. S. O. 52, A. G. O., March 5, 1887.

Capt. Wm. F. Carter, Asst. Surgeon, granted leave of absence for one month, on surgeon's certificate of disability. S. O. 25, Dept. Texas, Feb. 24, 1887.

Capt. Geo. McCrnry, Asst. Surgeon, leave of absence extended one month. S. O. 52, A. G. O., March 5, 1887.

Capt. R. W. Johnson, Asst. Surgeon, ordered for temporary duty at U. S. Military Academy, West Point, N. Y. S. O. 51, A. G. O., March 4, 1887.

First Lieut. Guy L. Edie, Asst. Surgeon, granted leave of absence for one month, to take effect about March 1, 1887. S. O. 27, Dept. Texas, Feb. 28, 1887.

Capt. Wm. F. Carter, Asst. Surgeon, leave of absence extended four months, on surgeon's certificate of disability. S. O. 57, A. G. O., March 15, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING MARCH 19, 1887.

Bradley, George B., Surgeon, detached from Marine Hospital Philadelphia, Pa., and granted six months' leave.

Steele, Jno. W., P. A. Surgeon, ordered to Marine Hospital, Philadelphia, Pa., without delay.

Parker, J. B., Surgeon, ordered to the U. S. S. "Ossipee."

Siegfried, C. A., Surgeon, ordered to Baltimore, Md., on special duty.

Hugg, Joseph, Surgeon, placed on retired list March 17, 1887.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE WEEK ENDED MARCH 12, 1887.

Banks, C. E., P. A. Surgeon, to proceed to Chicago, Ill. and assume temporary charge of the service. March 10, 1887.

ORIGINAL ARTICLES.

HYSTERO-NEURASTHENIA, OR NERVOUS EXHAUSTION OF WOMEN, TREATED BY THE S. WEIR MITCHELL METHOD.

Read before the Chicago Medical Society, March 7, 1887.

BY FRANKLIN H. MARTIN, M.D.,

PROFESSOR OF GYNECOLOGY IN THE CHICAGO POLICLINIC; FELLOW OF CHICAGO GYNECOLOGICAL SOCIETY.

Hystero-neurasthenia is a name that I will take the liberty of giving to an often recognized class of female difficulties which has not a well defined place in medical literature.

The symptoms of this class of cases are as difficult to enumerate and describe as the individual cases are difficult to manage to a successful issue. Under the term hystero-neurasthenia, I wish to include no symptoms which can be traced to a distinct pathological lesion of any one organ, but to a host of symptoms that can be accounted for in no other manner than by being the result of a partial or general nervous inefficiency, or perversion, of the nerves controlling the organs peculiar to women.

The first of these conditions, nervous inefficiency, may be congenital, or the result of excessive exercise of the functions of the organs of the pelvis, from a long and prolific child-bearing season, excessive cohabitation, or undue treatment of a local variety. The second condition, nervous perversion, will be found the result of excessive brain work, either as a consequence of early study, or from literary excess, teaching, and clerical work common to women of maturer life, the worries of motherhood, anxieties of impending or actual misfortune, prolonged lactation, nursing of the sick, excessive physical labor, and, rarely, masturbation.

The symptoms of this class of cases are too numerous to mention in detail, and inasmuch as each case has its own peculiarities, I will remain content to recite a few of the most prominent and common symptoms. General anæmia, or deficiency of red corpuscles, is a very common, but not universal symptom. The anæmic cases usually complain of loss of flesh, although it is well known some anæmic patients gain flesh; and where this state of affairs exists the functions of the generative organs usually suffer, as is often manifested by coincident amenorrhœa and sterility. Upon questioning these patients the key-note of a general outpouring of subjective symptoms is struck, when the womb is reached in the list of interrogations—bearing-down pains, backache, leucorrhœa, neuralgia in ovarian region, painful menstruation (pain before menstruation, during the flow, and for days following), frequent urination, constipation—"bowels never move without medicine"—painful defecation, neuralgia in all parts of pelvis at regular or irregular intervals, in the ovarian region, one or both sides, uterus, vagina, bladder, perineum, rectum, and even the urethra. Standing and walking is accomplished very seldom without fatigue, and scarcely less rarely without pain in the loins and lower pelvic region.

These sufferers usually have worn out the patience of one or two physicians; many times are pronounced hysterical incurables, who imagine many of their aches, and are therefore considered unworthy of more dignified attention than that required to prescribe an anodyne, a hypnotic or a blister. These cases are much too interesting, and the credit of effecting a permanent cure of too much gratification, to say nothing of duty, for us to be satisfied to listlessly alleviate symptoms, when it lies in our power to do more.

Upon physical examination this class of patients present few well-marked subjective symptoms. There is no evidence of hereditary taints. As this trouble is referred to the uterus, the first local examination is made of the pelvic organs. The vulva is often pale in color from general anæmia. The mucous membrane within the vagina presents a faded, lax appearance. The external genitals are sometimes bathed with mucus secretion from the relaxed vulvo vaginal glands. The vagina is often sensitive, bathed with mucus frequently; at other times abnormally free from secretion. The uterus is normal in size and location, with perhaps the exception of slight prolapsus from the general relaxation of all the surrounding parts. It is very movable, as a rule. The organ is very liable to be marked by hypersensitiveness on pressure. A slight mucus discharge from the cervix, of a milky character, is rarely absent. The cervix is usually pale in color. Pressure in the ovarian region causes pain, or at least a feeling of sensitiveness; the ovaries can be frequently engaged between the hand placed over the relaxed, thin abdominal walls, and the index finger in the vagina, and will often be found considerably enlarged. The *rectum* is rarely found in other than a relaxed condition. There is frequently much tenderness about the anus, with slight nodular enlargement of the external hæmor-

rhoidal veins. Fæces are often found in the lower bowel. The bladder is often sensitive to slight pressure, and not rarely, where the patient is anæmic, will there be a pouching of its neck. The urine is pale, and commonly filled with phosphates and mucus. Upon manipulating the abdominal wall there is scarcely a point that does not seem most sensitive, except, perhaps, the ovarian region. The muscles are flabby and relaxed upon the limbs, although occasionally covered with soft fat.

The heart action in these cases, while not strong, is usually regular. The exception to this is in very nervous patients where, through sympathy of a rebellious or weak stomach, palpitation and heart-burn will be a complication. The capillary circulation is frequently slow, as evidenced by the slow return of the circulation to a part deprived of its blood by pressure of the finger.

The digestion is often fair, but rarely very good. Attacks of nausea are frequently complained of, coming on without any warning and disappearing in the same way. Occasionally downright attacks of indigestion are experienced, which may not be confined to the stomach, but affect the whole digestive tract. These attacks may be accompanied with headache. Spinal tenderness in one or more regions is often present; this will frequently be found quite marked in the lower dorsal or first lumbar region.

Besides the symptoms enumerated, which can be said to rank under the head of hystero-neurasthenia, we may have, in addition, all the symptoms that are common to general neurasthenia, the special symptoms about the pelvis determining the disease, because of their greater prominence and severity. While we have found by general examination of these cases, both subjective and objective, not one organ in the pelvis or abdomen in vigorous health, and not one free from weakness and tenderness, we have not found an actually diseased member—that is, diseased from any pathological condition peculiar to itself, but rather from a general lack of balance between supply and demand in the nutrition of several. And while it is rare for a single case to present all the symptoms above noted, occasionally, as many of us can testify, *all* these and others will manifest themselves in their most aggravating form in one suffering individual.

Though no exact pathology of these cases has been definitely demonstrated, except through the deductions drawn from successful treatment, the fault is generally conceded to lie in a weakened or incomplete state of that part of the nervous system which presides over the nutrition of the organs involved. A general malnutrition, then, of the parts implicated is that towards which we must direct our treatment. As these patients always complain of being tired, the first indication for treatment is rest. As they are almost invariably anæmic, proper feeding is the second indication. As a case is rarely found in which nervous debility is not the rule, seclusion from annoying surroundings is a third indication. Sleeplessness, which is frequently a conspicuous symptom, gives us a fourth indication.

The prominent requirements, then, in these cases are: 1. Rest. 2. Proper Feeding. 3. Seclusion. 4. Sleep.

How can we obtain these four requisites without over-drugging our patients? We must introduce some means by which an irritable body, that is unable to assume the recumbent position without resting upon some painful spot, may lie down without pain. We must feed properly a patient whose appetite is capricious, whose stomach may be irritable and rebellious, whose bowels will not "agree" with anything that is suitable to sustain life. We must put into seclusion patients who imagine they require the sustaining sympathy of innumerable dear ones. We must produce sleep in a class of patients who have long ago worn out all the safe and efficient hypnotics.

I have had experience enough with these cases to satisfy myself that permanent cures can very often be effected by a line of treatment that has been practised so successfully in general neurasthenia by that eminent Philadelphian, S. Weir Mitchell. While Dr. Mitchell was the originator of this systematic line of treatment, of which I can only hope to give merely an outline this evening, it has been adopted with great success by others, and by none with greater success than Playfair, of London.

Dr. Mitchell seeks to meet the four requirements in the treatment of these cases by first getting full control and confidence of the patient. Without this first requisite, the case is a failure. After this is accomplished he makes the remaining part of the problem feasible by a combination of entire rest and of excessive feeding made possible by passive exercise obtained through the use of massage and electricity.

A physician, to treat these cases successfully, must have an eye to detail, possess at least the ordinary amount of tact, perseverance, firmness, and good executive ability. The nurses employed should be educated, intelligent, strong young persons, who are able and willing to work, and who can make themselves very agreeable; who possess tact and firmness, the latter without sternness. They should understand and be capable of performing thorough massage, administer a vaginal douche properly, and be adepts at preparing tempting sick-room delicacies.

In further describing this system of treatment I will give, for the sake of brevity, the details of treatment of a typical case of the kind that recently came under my observation:

The patient, a young married lady in the better class of society, without children, had been treated for "womb difficulties" for three years by at least two St. Louis physicians, from which city she had recently moved to Chicago. She had gradually become worn out from unsuccessful local treatment, and was about to give up in despair. She was in an extreme state of anæmia; had been gradually reduced in flesh from 120 to 100 lbs. Menstruation irregular and painful throughout. Bowels never moved without assistance. Appetite gone, and what little food she could be induced to take remained like a load on her stomach and gave her considerable pain. Besides the loss of appetite and indigestion, she had considerable ovarian neuralgia, general pelvic hyperæsthesia, and intense sacralgia. She was also troubled with persistent insomnia.

Physical examination elicited no localized patho-

logical condition. Uterus natural in size and location, and movable. Ovaries not enlarged, but very tender. While there was general hyperæsthesia in every direction from the vagina, there evidently was no cellulitis or peritoneal inflammation. The urine was normal.

The scheme of treatment mentioned above was explained to the patient, and she immediately acquiesced when advised to make a trial of it. Contrary to Dr. Mitchell's advice, she was not separated from her family, there being but her husband, and he at home but a small portion of the day. Be it remembered, she was unable to retain even a very little of the blandest food without distress.

She was immediately put upon an exclusive milk diet. The diet for the first day was laid down as three ounces of milk every three hours. She took at this rate, in the first twenty-four hours, twenty-one ounces of milk. The second day the amount was increased to twenty-eight ounces by increasing each allowance to four ounces.

The third day, as the patient was doing remarkably well and the stomach was free from pain, one ounce of thinly cut stale bread, well toasted, was given in addition to the milk that was due at the three regular meal times.

The fourth day six ounces of milk were taken every two hours, with double the amount of toast that was given the day before. All the dyspeptic symptoms had at this time disappeared, and the patient, notwithstanding the amount of milk taken, commenced to ask for her meals.

The fifth day she was allowed in addition to the milk, for breakfast, about one and one-half ounces of finely chopped steak of beef rarely broiled; this, with about one ounce of stale bread with butter, was taken with great relish, and without subsequent distress. At noon, on account of a little feeling of nausea, she had nothing except her regular milk diet. An afternoon sleep left her with an appetite for her supper. She was then given three or four raw oysters, with toast and a small cup of tea. This was taken with relish, and there was a disposition to take more.

The sixth day, on account of the patient exhibiting a slight disgust for the large doses of milk, the allowance was reduced to four ounces, it being rendered more nutritious by making it one-third cream. Besides the twenty-eight ounces of milk and cream, she was given this day the juice from one pound of beef in three doses, at 10 A.M. and 3 and 8 P.M. Besides this, the patient took part of a cup of coffee and an ounce of bread with butter for her breakfast, a lamb chop for her dinner, with bread and butter, and raw oysters with toasted crackers and butter for 6 o'clock supper.

From this time on while the patient remained under treatment with me, she had no trouble, with judicious care in its selection, in retaining and relishing an incredibly large amount of food. She would take, besides three large meals a day, a quart of milk and cream, and the juice from one-half to one pound of beef.

The digestion and assimilation of this large quantity of food by an irritable alimentary canal was made possible by systematic passive exercise. The routine of treatment for the day in this case was as follows: At 8:30 A.M., or as soon as the patient had awakened, she was given a light sponge bath, her hair was arranged, and her milk and breakfast taken. At 9:30 A.M., if the bowels had not moved spontaneously, a small rectal injection of soap and water was administered. This was not found necessary after a few days' treatment. At 11 A.M. or thereabouts the patient was given general faradization with an idea of reaching all the motor points of the superficial muscles. The region of the colon, especially of the transverse and descending colon, with special efforts at stimulating the rectum, was systematically sought. This treatment required from three-fourths to one hour's time. The patient usually took a short nap after this treatment. About 1 o'clock she was induced to take a light dinner, or, more properly, lunch.

In the afternoon, if necessary, the nurse would interest the patient by light reading for an hour, if she were not inclined to sleep, which was frequently the case. At 5 o'clock a light, rapid sponge bath was administered, followed by gentle rubbing of skin with a dry bath glove. This proceeding occupied thirty minutes, after which the patient was again allowed to rest for an hour. At 6:30 or 7 P.M. she was given her dinner. The milk, in the meantime, had been administered at regular intervals throughout the day. After the dinner or supper the patient was read to or amused in some way, or, if she was so inclined, allowed to sleep. Nothing, except the amount they eat, will astonish one more than the amount of sleep some of these patients seem to require.

At 8:30 or 9 P.M. the regular preparation for bed commenced. This began with a systematic massage which included all parts of the external muscular system, and occupied about one hour. The patient was then moved to a couch, given a large vaginal douche of hot water while in the recumbent position; her bed in the meantime was changed, and she was at last, after a hard day's work in which she had been but a passive laborer, deposited in it for the night.

This patient remained under this systematic treatment for about eighteen days only, at the end of which time it did not seem necessary that she should be kept under such close observation longer. She expressed a very strong desire to go with her husband, who was about to make a business trip South. Inasmuch as she was, to all appearances, now perfectly well, I gave my consent to this arrangement. She could take and digest more food than she had been able to for years, without a dyspeptic symptom; her menstrual period had passed without a pain; the pelvic hyperæsthesia, while not entirely subdued, was much improved; the vaginal leucorrhœa was entirely checked. The patient had gained ten pounds in weight. Her skin was now ruddy and healthy in appearance, and she felt strong, well, and in the best of spirits when she left the city. I have since seen the patient, and she assures me that she is in the best of health, and she certainly appears so.

All cases, however, in which the treatment described here seems applicable, will not give the brilliant results that twenty days' treatment accomplished

for me in the above case. Every symptom of importance here disappeared after four days' treatment, and subsequently there was nothing left to accomplish but to increase the flesh and strength of the patient. The getting-up was gradual; at the end of about the ninth day she was allowed to sit up in a large upholstered armchair for one hour in the forenoon. This was followed rapidly with greater liberty, and at the end of the fifteenth day she was about the room fully dressed; and at the end of the twentieth day was ready to travel.

Frequently grave complications are met in the treatment of these cases. Occasionally a patient has been thoroughly disgusted with milk on account of excessive use of it in previous treatments. Others have the impression that it "makes them bilious," and it is not taken on that account. By taking pains to explain that milk is one of the most perfect forms of food, and that it is an important factor in the successful treatment, most patients will be induced to try it in small, often repeated doses. There is occasionally a patient found, however, who cannot take milk in the raw state; the taste is objectionable, and the stomach rejects it. In such cases milk will often be well received if prepared with Fairchild Bros. & Foster's peptogenic milk powder. This is often also a valuable addition when the patient becomes tired of milk late in the treatment. Beef juice prepared after Weir Mitchell's formula, either raw or cooked, is sometimes a good substitute. Patients are frequently found who can take scalded milk who cannot bear it in the raw state; and, again, frequently if mixed with cream, when milk alone nauseates. Where this important article of diet is not tolerated under any disguise, other food must be adopted which will accomplish the same end. Here, in selecting a suitable substitute for milk from the long list of natural and artificial foods, is where the ingenuity and experience of the physician are heavily taxed.

Occasionally among these patients will be found one who requires an alcoholic stimulant. This is often indicated where there are sudden attacks of nausea. Hoff's fluid malt often arouses a desire for food, if given three or four times a day in small doses; the hop principle often acting, in addition, as a pleasant hypnotic in these cases.

Where the bowels are not sufficiently stimulated by the manipulation and faradization to cause an evacuation daily, a capsule containing ext. nux vomica ¼ gr., ox. gall. gr. ij, aloin ⅙ gr., or something similar, should be administered at bedtime.

In spite of feeding, rubbing, and faradization, patients are occasionally found whose insomnia will persist. These cases I endeavor to control by giving them a hypnotic in such a way that they are not aware of the fact, and are led to attribute the sleep to the treatment. A favorite method is to saturate a loose vaginal tampon with a solution of chloral in glycerine and insert it the last thing at night. Sufficient chloral is absorbed to produce sleep, and the local anodyne effect upon the surrounding organs is not unpleasant. This can gradually be reduced in strength as the effect of the general treatment is sufficient to make it unnecessary. I have found also the triple valerianate pill of quinine, zinc and iron, as manufactured by W. H. Schieffelin & Co., valuable in cases in this condition. Asafœtida pills are sometimes valuable at this point. The pills manufactured by Eli Lilli & Co., of Indiana, conceal the taste and odor of this drug perfectly.

The urine should be examined occasionally in these cases to guard against harm arising from the excessive feeding.

If iron is indicated it can be given in small doses advantageously, in the fluid malt, or, in case malt is not an article of diet, in a capsule. For administration in malt citrate of iron, quinia, and strychnine in 1-grain doses make an elegant preparation.

Success, however, depends much more upon the attendance the patient receives than upon the selection of drugs. Massage is given here with the idea of producing as much tissue change as possible, and the nurse who can accomplish the best results in this direction, as indicated by the amount of food taken and assimilated, is the greatest success. The faradization I do not usually intrust to a nurse, although an intelligent trained nurse can soon be taught to manipulate the faradic machine. The end sought here is simply to cause contraction of all the muscles of the body that can be brought under its influence, and to stimulate the circulation. For this purpose I place a large electrode under the two feet of the patient as she lies in bed with knees flexed; this electrode is attached to one pole of an ordinary interrupted faradic battery. At the other pole I attach a bifurcated cord terminating in two small hand electrodes, made to fit the palm of the hand in such a manner as not to interfere with the flexion of the fingers. A process of kneading or petrivage is performed over the surface of the body, dwelling particularly upon the motor points of the muscles, while the current is simply strong enough to produce an agreeable prickling sensation.

In this paper I have not been able to do more than to give the merest outline of a treatment of a condition which we all often meet in practice. In citing the particular case I have, I did so because of its being a typical one of the kind, and one in which the complete treatment in its most uncomplicated form could be demonstrated as a success. From this any intelligent physician can readily comprehend the scheme of treatment, and can as readily understand how many difficulties might arise that would complicate the treatment, at the same time not necessarily proving insurmountable barriers to its ultimate success.

163 State St.

WATER CLOSETS AND PRIVY VAULTS.

Abstract of a paper read before the Ohio State Sanitary Association, February 10, 1887.

BY JOHN McCURDY, M.D.,

OF YOUNGSTOWN, OHIO.

MEMBER OF OHIO STATE SANITARY ASSOCIATION, MEMBER OF THE YOUNGSTOWN BOARD OF HEALTH, ETC.

To those who have given study to the above subjects they rank them first in importance. They

know that to construct a perfect water closet or privy vault, the complete mastery of the laws governing gases and organic germs must first be made. What is any house, however elegant in appearance, or expensive in construction, without either one or both of these appliances of the most recent pattern, but a modified "Black Hole of Calcutta?" It is but a place of confinement where *malaise*, headache, debility, and low vitality dwell, and where the organic germs of fever, diphtheria, scarlatina, measles, cholera and small-pox find their habitat.

The sanitarian of to-day, to be at his best, should be familiar with all that chemistry can teach, mechanics demonstrate and engineering plan. So vast, intricate and numerous are the laws of sanitation, we can, at present, no more make them all subservient to our wills, than we can make a plain of the vast rock-ribbed mountain of our far west. But if we are incessant, earnest, and honest in our struggles for facts, we can pierce these laws as the mountain ranges are pierced, and utilize the materials found for the lengthening of life, and the perfecting of health.

First, then, what can be said regarding water closets? We can say that the three classes of men who prosecute both the science and art of sanitation, the physician, the plumber and the engineer, have attacked this problem together and singly, month after month, year after year, each marked by unremitting thought, and plan, and experiment, until a substantial, if not a triumphant victory has rewarded their perseverance. These workers have brought forth closets, numerous and various in style as leaves of autumn, that not only squarely meet all foul and fatal eminations from all forms of human excreta, but flank, surround and compel to surrender all the forms of bacteria, bacilli, micrococci and their vast progeny.

The essential parts of all these closets are the bowl, the container, the trap, with water seal or seals, supply soil and vent pipes. Some makes contain all the above parts in their construction, some only a portion. The thought that has filled the minds of all closet makers is how to control the gases—the odors—and especially the death laden germs. With every form of closet, save one, the trap is relied on in the soil pipe, whether leading from closet, bath tub or kitchen sink. Without this imperious necessity called a trap, the more sewers, soil pipes, waste pipes, and even ventilating pipes we put into our houses the more surely will they be dens for thieves to steal our health, and threaten, and eventually take our lives. Our houses are but expensively constructed receivers of foulness, and festering filth, containing "pestilence that walk in darkness and destructions that walketh at noonday." What then, is the nature of this seemingly imperative necessity? It is simply a bend in the pipe leading from the closet, a half "S," three-quarter "S," "S" or "D," a bag shape, a bottle shape or a bell shape. But they are all but different kinds of bends. As the art of plumbing is more and more advanced, the simple half or three-quarter "S" is preferred. I can say, then, the trap "is only that and nothing more." Behold then how great a matter a little trap preventeth. Of course these bends are placed there that the most depressed portion will at all times be filled with water. The water thus retained is called the water seal. And this little pool of water, often very impure, very offensive, and very foul, may be all that stands between us and death.

Now, a word about some of the closets in daily use with us. I cannot speak of all of them, or even of all the leading kinds, or perhaps, not even of the very best kinds. The first I shall notice is the "Hilliard Hopper." This is one of the most simple in construction, having but a bowl attached to a four inch soil pipe with a three-quarter "S" trap. A tank is used for the water supply, and is self acting, that is, pressure upon the seat causes a dash of water to wet the bowl, and upon removing the pressure an additional dash of water completes the action. The last gush is supposed to carry the deposit through the trap and also leave the trap full of pure water as a protection. For places where the closet is in almost constant use it answers fairly well; but for occasional use, I do not approve of it. In the first place, as now made, it does not use enough water. In the second place, while in use the gases from the deposit are constantly passing off into the room. And thirdly, the rush of water is not always sufficient to carry the deposit well through the trap and into the soil pipe. Indeed, in certain cases, quite a portion is left to decompose and poison continuously the atmosphere. The next is the "Zane Sanitary Closet." This is much more complicated and in some respects a better closet. It has a double protection in the form of two water seals; one in the pipe and one in the bowl, and it uses more water. Very similar in construction is the "Demorest." They are both plungers, and both leave flushing chambers.

These closets have many excellent qualities and are generally very satisfactory to those who use them. My objections to them are that nothing leaves the bowl when in use, and will not leave it except when the handle is pulled up, so that they are not well suited for children, imbeciles and careless people. But in the opinion of Dr. Tracy, of New York, and others, the most threatening defect is in the plunging chamber, which, in time, is coated with a very foul organic matter that is a favorable bed for the rapid culture of disease producers. In many of the most carefully plumbed houses of our town containing these closets, diphtheria has again and again visited different members of the family, and the supicions were centered on the foul flushing chamber as the cause. I only note this suspicion. My own knowledge does not verify it. While there is no trap closet I would recommend, that I know, I am very favorably impressed with a closet made by the Kelly Bros., of Chicago, and called the "Self-acting Water Closet." While not familiar with its actual working, it contains principles so often tested, that I would consider the time well spent, had I a house to furnish, in making myself thoroughly acquainted with it.

The question is often asked, can we get something better than the common "S," or at least something

which will assist in making the seal more perfect? Many efforts have been made and appliances adopted. Notably among them is the "Bowers Trap." This is a rubber ball that floats upon the water seal, and being made very carefully, as is also the trap, it fits accurately against the bottom of the pipe and so remains while the closet is at rest, and is intended to assist the seal in effectually preventing the escape of sewer gas. My experience with this trap is favorable, but those who perhaps know much more than I, object to it on the ground that gases form a stratum immediately under the ball, and when it is displaced by sewage, this stratum passes at once into the apartment. I have been much interested in the study of another ball trap on a wholly different plan. It is an invention of H. C. Lowrie, a member of the Denver Society of Civil Engineers. It is a rubber ball filled with shot, and for a four inch pipe, weight four and a half pounds, and so firmly is it seated that it takes twenty-five pounds of pressure to displace it. The trap used with this ball has a sort of elbow, or "race way" the inventor calls it, through which the ball rolls when displaced by the proper weight of sewage, only to at once take its place again when the pressure has passed, and firmly keep it, thus forming a perfect seal in all respects and doing away with vent pipes of all descriptions. Of course, in the construction of these balls and traps, everything must be of the most accurate make, and of the best materials, which must add considerably to the expense of furnishing a house. This is to me a great recommendation, as the most expensive materials of all kinds only should be chosen if they are of intrinsic value; for plumbing should be done regardless of cost.

In my opinion, there is not a more senseless practice than that of hawking a plan for plumbing from shop to shop, for the lowest bid. The builder of a house is as helpless in the hands of the plumber as he is, when sick, in the hands of the doctor. All kinds of frauds, experiments, and mal-practice can be heaped upon him, while he, all the time, is utterly unable to detect the impositions. If economy must be practiced, let it be done by doing without some of the multiplied gables, projections and oppressive ugliness of the so-called Queen Anne's and Mansard additions. In the midst of all these subtile agents, it is a comfort to know that experienced chemists like Pumpilly, Wernich, and many others, have found that a good water seal with the usual surroundings, will prevent all organic particles from passing back, and nearly all of the different sewer gases.

I close what I have to say on closets with a word for one with which I am familiar. The inventor is a resident of Youngstown, Ohio. So confident is he of its unequaled qualities, that he has placed them in some of the hotels and resorts, where they would get the most trying tests, agreeing to remove them at his expense if not fully approved. This inventor throws aside traps and vents of every kind, and places the closets upon a straight soil pipe. This closet consists of a seat, with air space in front between it and bowl, two supply pipes, one for the flushing rim and one for a spray seal near the bottom of the bowl, a copper cup, with or without a rubber ring that comes up and surrounds the lower end of the bowl and contains water on both sides of the end. The operation of this closet is as follows: Pressure being made upon the seat, the cup is at once carried to the side, the valves of both supply pipes open at the same moment, and two strong streams of water flow, one around the rim, and the other dashing in a thick sheet of spray across the lower end of the bowl before falling into the straight soil pipe. The action of these currents produces a rapid suction into the soil pipe carrying with them instantly all deposits and gases. These currents are continuous, and cease only when the weight is off the seat, at which instant the cup again takes its place and is rapidly filled by the last proportions of water of both supply pipes. Here we have an odorless closet, and one that neither allows gases nor deposits to remain an instant in the bowl, a quality no other closet has, of which I have ever read or seen. It was put to a crucial test in one of our plumbing shops. Three of the approved closets were placed in a row with it over the same soil pipe, a four inch, and filled for use. This soil pipe was heavily charged with illuminating gas, and although used repeatedly, not the slightest odor could be detected either during use or at rest. I have no hesitation in pronouncing it by far the best closet with which I am acquainted; and I say this in the exact language required by the Government Pension office, viz: I hereby vertify that I have no interest either direct or indirect in this closet. It is called "The McAndrews Spray Seal Trapless Closet."

Now, a word as to privy vaults. I have nothing to say in their favor. They are to-day, the most unmitigated, and unpardonable nuisance that infests the face of the earth. The idea of digging a hole in the ground for a permanent receptacle of human excreta, is the most depraved conception of civilization ever found in the desolate wilderness of man's brains. Sanitarians must face the subject squarely, for there is not a city, town, village, or country that is not honey-combed by them; and at this hour, the diggers with bended backs and sweating faces, are adding to the number by tens of thousands. It is but a quesion of time when all our surroundings will be fully saturated; the ground-air charged with virulent poisons, and the ground-water saturated with the germs of death. But the greed and disregard many have for the life, feelings and health of others, render it necessary for every health board to bow before their strength and compromise by mournfully saying, "dig, but the board will determine of what the bottom and sides will be." Brick. or stone and cement are chosen. Each brick will soak up at least one pint of liquid excrement; each stone absorbs the same as if a sponge.

Now with a vault walled with several hundreds of bricks, or many tons of porous stones, either or both of which are fully saturated with vault contents, which in turn, are surcharged with baccilli, micrococci, and all the other germs possible to convey or generate disease, and as these press into the air or ground, instantly the same pores are again filled, this time,

may be, with the discharges of cholera, typhoid, scarlet or yellow fever, diphtheria, dysentery, small pox or measles. How long can we be without epidemics while this order of things lasts?

The question now presents itself, is there any other good way of disposing of excreta save by closet and water carriage? I say most confidently, yes. In city, town, village and country, let every hole, vault and receptacle be cleaned, and filled with fresh and pure material, and having placed the privy upon a solid and well-aired foundation, convenient to the house, and somewhat secluded, and if this privy is six by four feet, place under it a box seven by four, this being kept off the ground by substantial stone corners, and this whole problem is solved, while purity, health, decency, and comfort are secured. This box can be furnished water-tight, thoroughly coated inside and out with hot coal tar and placed in position for $2.25. The projecting foot is covered with a neatly fitting plank, which is all that is displaced and set aside in the removal of contents. The scavengers of our town are anxious to contract for their proper care, removing contents without the knowledge or supervision of the owner, and dispos-of same, at the rate of $4 per annum. The ashes are saved and thrown into this box instead of upon the ash heap. Use lime, or earth or copperas if there is supposed to be occasion, but which, with my daily experience of ten years is, in my opinion, not necessary, the ashes alone from an ordinary house being amply sufficient. Another great advantage is, that the mass to be removed is so nearly odorless and dry, it can be removed at any time without giving offense.

To those unacquainted with the absorbing and deodorizing powers of earth, ashes or lime, I would say that they are marvelous. Those of us who study our Bibles as well as sanitation, find that this subject was dignified and emphasized by the direct command of God.

"Thou shalt have a place also without the Camp, whither thou shalt go forth abroad. And thou shalt have a paddle upon thy weapon: and it shalt be when thou wilt ease thyself abroad thou shalt dig therewith and shalt turn back and covereth that which cometh from thee. For the Lord thy God walketh in the midst of thy Camp to deliver thee and to give up thine enemies before thee, therefore shall thy Camp be holy: that he see no unclean thing in thee and turn away from thee."

The system I advocate so earnestly is not only suited to the isolated cottage, or elegant country house, but also to the mighty city, as year after year demonstrates in the case of Manchester, with her half million of people; or Glasgow, with her hundreds of thousands; or Rochdale or Heidelberg with their tens of thousands.

SPLENECTOMY FOR WANDERING SPLEEN.

BY WM. H. MYERS, M.D.,

OF FORT WAYNE, IND.

MEMBER OF THE BRITISH MEDICAL ASSOCIATION, OF THE LONDON PATHOLOGICAL SOCIETY, ETC.

In 1877 I was called to treat Mrs. H., æt. 32, living in the western part of Ohio, a malarial district. She was received into the St. Joseph's Hospital, at Fort Wayne, Ind., where I treated her for an enlarged spleen. In six weeks she left for her home, very much improved, the spleen being reduced almost to its normal size. In March, 1885, I was again called to visit her, in consultation. I found a large tumor occupying the lower portion of the abdominal cavity; it was believed to be an extra uterine fibroma. During the consultation I mentioned the previous history of the case, and the possibility of the tumor being a misplaced and enlarged spleen. She died July 20, 1885. I made the autopsy and discovered that the tumor was the spleen. It had gravitated downward until its lower portion occupied a portion of the pelvic cavity. The immediate cause of death was peritonitis.

After reviewing the history of this case and noting carefully the condition of the blood-vessels and the extent of the adhesions, I was strongly impressed with the idea that, in this case at least, the enlarged and displaced spleen could have been removed with success. So strongly impressed was I, that I determined, if in the future a similar case should present itself, I would attempt it.

In November, 1885, I was called to La Grange to visit Mrs. McKinley. She had a tumor in the left hypochondrium, and complained of pain and a sense of weight in the same region. Her symptoms and the history of the case pointed clearly to splenic disorder of malarial origin. Tertian intermittents filled an important chapter in the case. She had tenderness, nausea, and hæmorrhagic tendencies.

The tumor, at my first visit, occupied the umbilical region. The diagnosis being well defined, I prescribed quinine in large doses, with iodide of potassium occasionally; this treatment was to be pursued persistently. In February, 1886, I visited England, and knew nothing of the progress of the case until after my return in May, 1886. About this time I received a letter from her husband, in which he informed me that the tumor had increased in size, was much lower in the abdomen, and that she was pregnant.

On October 2, 1886, I received a telegram to "come at once." During this visit I met her attending physician, and from him I learned that she gave birth to a living child three weeks before. Upon making an examination I discovered that the tumor was then resting on the brim of the pelvis, and extending above the umbilicus. It had suppurated, and three sinuses existed, communicating with the abscess. The discharges were offensive, almost intolerable. She was emaciated, had chills with profuse perspiration at night, and great loss of appetite. She did not attempt to nurse the child. Her surroundings deterred me from venturing to relieve her by any surgical procedure at her home. By agreement she was brought to Fort Wayne and placed in the St. Joseph's Hospital.

Upon her arrival her condition was one of extreme exhaustion, and grave fears were expressed that she would not survive the operation. A consultation was held with Drs. B. S. Woodworth, H. McCul-

lough and H. S. Myers. The removal of the tumor was decided upon as the only expedient to be thought of.

The cleansing of the skin over the tumor and for some distance around was carried out by washing it with a carbolic acid solution, 1–20, after which stimulants were administered, when she was placed under the influence of ether and removed to the operating table. The line of incision was six inches in length, extending two inches above the umbilicus and made in the *linea alba*. During the progress of the operation the strictest antiseptic precautions were observed. Silk ligatures, previously carbolized, were applied to the bleeding vessels and then cut short; the hæmorrhage was thus arrested completely before dividing the peritoneum. The peritoneum was caught up with forceps and incised with a knife sufficiently to admit the completion of the incision with scissors. This was followed by a free discharge of sero-purulent fluid, received upon the towels and sponges conveniently placed for this purpose. The tumor was now freely exposed, and proved to be a displaced and wandering spleen, indurated and greatly enlarged lying in a peritoneal abscess. I succeeded in lifting the spleen from its resting place, the brim of the pelvis, and in securing the pedicle, composed of the vessels and fibrous tissue, much elongated. While the tumor was partially lifted from its bed, I succeeded in transfixing the pedicle with a needle, armed with a double thread of silk, and ligated it in two portions. The pedicle was then cut short and dropped back into the cavity occupied by the spleen; so also were the ligatures. Into the cavity occupied by the spleen carbolized sponges were introduced repeatedly until the hæmorrhage was entirely arrested. This was followed by the insertion into the lower angle of the wound of a large size glass drainage-tube, and I proceeded to close the wound with stitches of silk thread, including the peritoneum. After the edges of the wound were carefully approximated and the surface washed with carbolized water, protective gauze was placed over the line of incision and over it a layer of carbolized cotton and antiseptic gauze; and over these a firm snug-fitting flannel bandage; over the mouth of the glass tube, carbolized gauze. The spleen weighed 7 pounds.

The patient was now removed and placed in bed, wrapped in warm blankets and bottles of hot water placed about her. The evidence of shock disappeared in a few hours. The after-treatment consisted in the administration of tonics, stimulants and food, washing out the abscess cavity daily with carbolized water, 1–20, until the removal of the drainage-tube; this occurred on the twelfth day.

On the ninth day the first dressing was removed and union was found to be almost complete; the deep stitches were removed, and the superficial stitches allowed to remain until the fourteenth day.

Her pulse never exceeded 110, and her temperature never exceeded 102°. Her appetite improved rapidly, and her previous bad symptoms disappeared, so that in twenty-one days she was enabled to leave the hospital, and her recovery at the present time is complete.

While dislocations of the spleen are unusual, yet we find cases recorded by Haller, Dessault, Dunglison, Cragie, Riolanses, Wilks and Moxon, and Küchenmeister. Rokitansky, in his "Pathological Anatomy," describes three cases. In the first case he found the spleen upon the right ilium, attached to a twisted pedicle, containing the vessels. In the second it was in the left iliac region, being joined to a long pedicle. M. Kurns related a remarkable case, in which the spleen was mistaken for a strangulated hernia in the left inguinal region; the tumor was the size of the fist, and the splenic vessels formed a large cord leading to the left hypochondriac region.

The cause of these displacements is elongation of the ligaments, and in many of them the spleen has undergone great changes in form, being sometimes thick and round, with the edge ill-defined, increased in size and weight.

Conclusion.—While the weight of surgical authority is decidedly opposed to splenectomy, yet in a case in which the diagnosis is clearly made out, the spleen isolated and suppurating, or lying in a peritoneal abscess and death imminent, I believe, with John Knowlesly Thornton, that where it can be clearly shown that the condition is causing immediate danger to the life of the patient, the attempt to save life by the extirpation of the spleen is justifiable.

FIVE CASES OF LARGE VISIBLE PULSATING ARTERY ON THE POSTERIOR WALL OF THE PHARYNX, WITH REMARKS.

Read at the Meeting of the Section for Clinical Medicine, Pathology and Hygiene, of the Suffolk District Medical Society, February 9, 1887.

BY J. W. FARLOW, M.D.,
OF BOSTON.

Case 1.—E. N., a girl 13 years old, came to me at the Boston Dispensary, complaining of nasal catarrh and enlarged cervical glands; she had also an atrophic pharyngitis My attention was immediately drawn to two large, pulsating vessels on the back of the pharynx, about quarter of an inch inside the posterior pillar of the fauces, and lying directly beneath the mucous membrane. By slightly depressing the tongue the lowest point of the pulsation was easily seen, the upper limit was a little higher than the base of the uvula. The vessels were nearly vertical, and the left one had a more marked pulsation than the right. To the finger the impression was given of an artery fully as large as the radial. The patient knew nothing of this condition of her pharynx. Thinking that the large cervical glands might, by pressure, be the cause of this pulsation, I watched carefully to see if the vessels diminished in size as the glands grew smaller. But such was not the case. The glands entirely disappeared and the nose much improved, but the pulsation continued as before. I saw her the other day, eighteen months after her first visit, and found no change in the vessels.

Case 2.—Mary C., 18 years old, came to me complaining of nasal catarrh and some atrophic pharyngitis. There was a large, pulsating vessel on the

posterior wall of the pharynx on the left side, as in Case 1, but none was seen on the right. There were no large cervical glands.

Case 3.—Annie M., 23 years of age, came to me for post-nasal catarrh. On the back of her pharynx were two large, pulsating arteries, almost an exact counterpart of Case 1.

Case 4.—This was a woman about 30 years old, and was seen at the Massachusetts General Hospital, by Drs. F. I. Knight and F. H. Hooper. No notes of the case are at hand, but Dr. Hooper thinks the large vessel was on the back of the pharynx, about halfway between the uvula and the posterior pillar of the fauces on the right side.

Case 5.—A little girl, 4 years old, came to me for nasal catarrh. On the posterior wall of her pharynx on the right side was a large pulsating vessel, as in the other cases. The glands of the neck were slightly enlarged. A sister, 5½ years old, has beginning atrophic pharyngitis and rhinitis, but no artery visible.

All the other cases seen by me were women, and in all the pharynx was atrophic, in two markedly so, the mucous membrane being thin, dry and shining.

This condition must be very rare, for I find no mention of it in text-books or in the literature of the subject. In my service of five years in the throat-room of the Boston Dispensary, I had never met with a case, and yet my three cases were seen within a week or two of each other, as is often the case with rarities.

In regard to what vessels these are, let us look at the normal blood-supply of the pharynx. The pharynx receives its blood principally from the ascending pharyngeal, a branch of the external carotid, and the ascending palatine, a branch of the facial. Cruveilhier[1] says: "The ascending pharyngeal is the smallest branch of the external carotid. Its calibre is in inverse proportion to that of the palatine branch of the facial. I have seen it as large as the occipital. Its pharyngeal branch subdivides at the base of the skull into several branches which penetrate the very dense fibrous tissue at the insertion of the pharynx to the occiput. These then turn downward, and terminate in the walls of the Eustachian tube and the muscles of the pharynx. In a case of absence of the palatine branch of the facial I have seen the pharyngeal branch, very large, supply the tonsil and ramify and lose itself on the veil of the palate."

Sappey[2] says: "The ascending pharyngeal is distinguished from the other branches of the external carotid by its small size and vertical direction."

Gray[3] says: "The largest of the pharyngeal branches of the ascending pharyngeal passes inward, running upon the superior constrictor, and sends ramifications to the soft palate, Eustachian tube and tonsil, which take the place of the ascending branch of the palatine when that vessel is of small size." With regard to the ascending palatine Gray says:[4] "It passes up between the stylo-glossus and stylo-pharyngeus to the outer side of the pharynx. After supplying these muscles, the tonsils and Eustachian tube, it divides near the levator palati into two branches; one follows the course of the tensor palati and supplies the soft palate and palatine glands. The other passes to the tonsil which it supplies, anastomosing with the tonsillar artery. The tonsillar branch passes up alongside of the pharynx and, perforating the superior constrictor, ramifies in the substance of the tonsil and the root of the tongue."

According to the above descriptions it seems as if, in my cases, the vessels were the ascending pharyngeal arteries, from their situation on the superior constrictor and their vertical direction, and, inasmuch as mention is made of the increased size of the vessel when the ascending palatine is small, it is possible that the latter vessels in my cases were unusually small. The atrophy of the mucous membrane allowed the pulsating vessel to be seen more readily.

The surgical importance of these cases is sufficiently apparent. In case it were necessary to make an incision in the back of the pharynx, as in retro-pharyngeal abscess, we see how great the risk of an alarming hæmorrhage might be. In all cases, where possible, it is advisable to examine with the finger before operating, to see whether an artery of abnormal size or situation is present.

Dr. Porter[5] relates a case of recurrent hæmorrhage from behind the left tonsil, which he thought came from the tonsillar artery or from a branch of the ascending pharyngeal; also a case of hæmorrhage from an ulcer on the posterior part of the soft palate, probably from the same vessels.

Dr. E. Carroll Morgan, of Washington, D. C., who has recently written a paper on "Hæmorrhage following Uvulotomy," writes me as follows: "Obstinate bleeding following uvulotomy is, in my opinion, often due to the condition your cases so well illustrate. Literary research has surprised me, I confess, and I have now collected seventeen cases of dangerous hæmmorrhage after this simple operation. Twelve of these have never been published and were obtained by personal letters. Strange as it appears, the possibility of an anomalous artery being a factor in the dangerous hæmorrhages which have followed uvulotomy has never been mentioned in connection with reported instances."

These arteries must also be taken into consideration in cases of surgical treatment of the tonsils. Many cases of hæmorrhage following tonsillotomy are reported. In most of them no mention is made of the finding of an artery of unusual size, but it seems to me that a careful examination would have revealed this condition in some of the hitherto unexplained cases of hæmorrhage.

Downie,[6] speaking of tonsillotomy, says: "Of the vessels in the immediate neighborhood, the ascending pharyngeal is the only one which might be damaged, and this only in unwarrantably free incision into the tonsils, never in excision." Billroth[7] removed the left tonsil of an hysterical lady. The organ was

pulled toward the middle line, and a fold of the pharyngeal mucous membrane was probably drawn out and cut with the tonsil. A fearful hæmorrhage occurred, which Billroth thought came from some large branch of the ascending pharyngeal.

In Schmidt's "Jahrbücher," vol. 186, is related a case of severe hæmorrhage after cutting off the left tonsil. Various hæmostatics were tried unsuccessfully, and in three hours the common carotid was tied. In this case the cause of the hæmorrhage was thought to be some abnormal ramification of the vessels.

Other similar cases might be cited, but these will serve to show the importance of bearing in mind the possibility of having to do with a condition such as I have described, and also the need of making a thorough examination before operating on the throat.

A CASE OF EMBOLISM OF THE LEFT VERTEBRAL ARTERY, WITH AUTOPSY.

Read before the Section for Clinical Medicine, Pathology and Hygiene, of the Suffolk District Medical Society, February 9th, 1887.

BY F. W. STUART, M.D.,
OF BOSTON.

G. W., aged 62, came to the Carney Hospital on December 31, 1885, with the following history: His grandfather, father, two brothers and one sister had died of what he called "softening of the brain," and the account given of the disease, rendered it probable that they had had general paresis. In other respects the family history was negative. The patient considered himself well until three years ago, though he had for years been very corpulent, weighing at one time 250 pounds. In the fall of 1882, he fell and injured his knee, but attached no importance to the injury, though it obliged him to limp about for a time. Soon after he began to have trouble with his eyes and was operated on for cataract at the eye and ear infirmary, where he learned incidentally that he had fractured the patella of the left knee. For the last three years his health had been poor, loss of strength, weight, and appetite being the most prominent symptoms, added to which for the last few months there had been attacks of severe pain in the stomach, and vomiting, which lasted for from twenty four to forty-eight hours and always began at night, when they were also most severe. The patient was positive that the attacks began about midnight, and the ingestion of food seemed to bear no relation to them. The vomitus was as a rule, of a black or dark brown color, and once or twice was distinctly like coffee grounds in appearance. The patient admitted having used alcohol rather freely during his younger days, though for ten years past he had been a total abstainer. When at the hospital he was cachectic and some chronic affection was suspected. Physical examination failed to reveal anything except a decrease in the area of liver dulness. Careful examination of the urine, chemically and microscopically, showed nothing pathological. No diagnosis being made, an expectant treatment was entered upon, under which the patient improved, and ceased visiting the hospital.

On March 10, 1886, during the service of Dr. W. N. Bullard, he reappeared, and a diagnosis of probable cirrhosis of the liver was made. This was his last visit to the hospital, and nothing further was known of his condition until May 17, when I was called to attend him. I then learned that during the interval between March 10 and May 13, no evident change in the patient's condition had taken place, though he had been subject to attacks of dizziness and dyspnœa, so that he desired to have the windows opened, and these attacks had always been accompanied by profuse sweating. He had on that day, March 13, answered the door bell several times, but on returning the last time, he said that he had come near falling, and laid himself on the sofa. He answered several questions put to him by his wife, and nothing further was thought about his condition until an hour later, when it was noticed that he failed to recognize a friend who had entered the room. All attempts to rouse him were in vain, and finally he was put to bed, where after a few hours he became brighter, and it was not until May 17, four days later, that I was sent for. I found the patient lying apparently comatose, though he could be aroused to answer questions, which he did slowly but intelligently. He moved all of his extremities promptly as requested, and continued to repeat the motion, as it were automatically, not even ceasing always when requested to do so. None the less there was distinct paresis. The patient recognized all visitors, and conversed with them intelligently as far as they noticed. It is certain that he recognized them sufficiently to greet them by name, and properly according to their relationship, but a few minutes after they had gone he did not know of their visit, and often asked why they had not called. Difficulty in swallowing, indistinctness of articulation, and incontinence of urine completed the manifest symptoms. When asked if he wished to urinate he would pass considerable quantities of urine at a time, though repeated suggestions failed to relieve the dribbling. There was marked constipation. The patient himself complained only of weakness.

I then called Dr. W. N. Bullard in consultation. The patient's condition was noted to be as above. Physical examination showed the patient to be pale and cachectic in appearance, temperature normal, pulse 80. There was a cataract in the right eye, and iridectomy had been performed on the left, so that both pupils were dilated. The left reacted to light. The reflexes were normal, and no anomaly of sensation could be detected beyond that due to mental obtuseness. Further examination revealed nothing pathological except the small liver. Though the cause of the existing condition was recognized as distinctly cerebral, the exact nature of the lesion could not be determined upon, though a hæmorrhage was considered to be the probable cause of the trouble.

From this time, May 19, until his death, the patient lay in bed in a semicomatose condition, replying to questions intelligently, in spite of some aphasia, which appeared to be ataxic in character, but when

not addressed or otherwise roused, apparently unconscious of his surroundings. There was no aphasia, properly so called, that is he always used the proper word when he spoke at all, although his speech was hesitating and indistinct. The paresis, which nowhere amounted to absolute paralysis, continued unabated. There were no convulsions and the patient gradually sank away, becoming constantly weaker and weaker, and died May 27, ten days after I first saw him.

Autopsy was made May 29, thirty-six hours after death. The body was of medium development, somewhat emaciated. The relations of the cranium to the head, and of the head to the face, were normal. The cranium alone was opened. The bone was normal in thickness, the dura, everywhere strongly adherent, could not be removed except with great difficulty. The longitudinal and transverse sinuses were empty. The pia mater was much injected, the vessels being dark and swollen. There was no fluid in the meshes of or under the pia which was neither adherent nor thickened. The brain was of normal size and consistency, its bloodvessels everywhere dilated and very prominent. They all contained numerous atheromatous patches, yellow, hard, and not contracting on section of the vessel. These patches occupied one-third to one-quarter of the whole extent of the larger arteries from the vertebral upwards. Between these hardened yellow patches the arteries were dark blue and dilated, though little or no blood was found in them. There was no fluid in the lateral ventricles. Puncta cruenta were very few and not well-marked. The choroid plexuses were dilated and enlarged. No signs of hæmorrhage or softening were found in the substance of the cerebrum, cerebellum, pons or medulla oblongata. A grayish body the size of a pea was found at the anterior portion of the falx, there adherent. A small white thrombus was found occluding the left vertebral artery and extending into the basilar, which it partly occluded.

MEDICAL PROGRESS.

Uterine Dyspepsia.—In connection with a case lately observed by himself, Jaffé, of Frankfort-on-Main, calls attention to the affection which Kisch has named *dyspepsia uterina*, meaning thereby a dyspeptic condition that has its origin and cause in a diseased condition of the female sexual organs. Although it is well known to medical men, that during the course of diseases of the female sexual organs there may arise various dyspeptic symptoms, as disordered digestion, eructations and constipation, there has been no clear conception of the significance of these symptoms.

His case was the following: Miss S., æt. 23 years, had been affected two years before coming under Jaffè's observation, with a suspicious apex catarrh. She now sought relief for various nervous complaints, and more especially for an obstinate want of appetite. She had no fever, the color was remarkably pale, the courses were regular, quite painful. Excepting some dulness over the right apex, pointing to the remains of the former trouble, examination of the patient revealed nothing abnormal. Steel and easily digested food was prescribed. Her condition became worse from week to week; the want of appetite increased to a positive dislike for all food; she complained of pyrosis, frequent eructations; now and then she vomited shortly after eating; her bowels moved but once in eight to ten days, and then only after all kinds of purgations. Jaffè diagnosticated a chronic gastro enteric catarrh, as the age of the patient pointed against cancer, and the symptoms against round ulcer.

All treatment by muriatic acid, Carlsbad salts, cocaine, nux vomica and opium being useless, and the eructations and the vomiting continuing to increase, the question, if this was not a case of nervous dyspepsia, came up for consideration. To determine this point the stomach-tube was introduced seven hours after a meal had been taken, according to Leube's directions. The stomach was found empty and free from acid, and hence an organic disease of the gastro mucous membrane could be excluded. The patient now for the first time admitted that she had been troubled for a long time back with pain and heaviness in the lower part of the abdomen, and that she had leucorrhœa, which had grown much worse of late. Hip baths and vaginal injections of carbolic acid solution were added to the previous line of treatment. No improvement followed; on the contrary, the gastric symptoms increased greatly, and vomiting became so severe that no food at all could be retained, so that the patient emaciated to the last possible degree. The case now presented much similarity to obstinate vomiting of pregnancy. She now submitted to a vaginal examination. This was performed with patient under chloroform, and disclosed an enlarged womb, in anteflexion, with virginal cervix, and thick cream-like pus pouring from the os. The ovaries seemed to be normal. The uterus was dilated, and the mucous membrane of the body and neck thoroughly scraped, and then washed out with a three per cent. carbolic acid solution by means of a Fritsch-Bozeman uterine catheter. There was no hæmorrhage, and but slight febrile reaction; paresis of the bladder, however, developed, and necessitated the use of the catheter for several weeks. After this operation the gastric symptoms and the vomiting disappeared as if by magic, appetite and digestion became normal, and the patient gained rapidly in flesh. But with the appearance of the menses there was a partial relapse of the local symptoms, and with them there again came on dyspeptic signs, though of a very mild degree, and without any vomiting. Irrigation of the uterine cavity with carbolic solution always brought relief. There can be no question that the above was a case of uterine dyspepsia, in which the dyspeptic symptoms originated in the diseased condition of the sexual organs. Kisch cites a number of cases in which gastric and digestive complaints of many years standing would yield to energetic gynecological treatment. His two most marked cases are the following:

Mrs. N., æt. 25, was sent to Muricubad for a gas-

tric trouble of four years standing; she has been married six years, and is sterile. Her appetite is good, but after every meal intense gastric pain sets in, with pyrosis and acid eructations; she is obstinately costive, and much troubled with gaseous distension. She has never vomited blood. She has lost flesh and feels depressed in spirits. Neither the lungs nor the digestive organs presented any cause for these violent symptoms. The uterus was found retro-flexed. Kisch replaced the womb, and fortunately it retained its position without a pessary. The digestion, symptoms and the vomiting were at once relieved. Shortly afterwards the woman became pregnant, and carried her child to full term. Since then she has given birth to three children, and has never had any relapse of the old trouble.

The second case showed similar symptoms. An examination disclosed chronic metritis and endometritis, retroflexion, and a small perimetritic exudation on the left side. After proper gynecological treatment had been instituted, all the gastro-intestinal symptoms, for which the patient had for years visited various springs, disappeared completely, and patient gained six pounds in weight during her six weeks stay.

B. Schultze, in speaking of the treatment of chronic endometritis, expresses himself as follows: "Only the practitioner who, in a number of cases of catarrhal disease of the uterus, has washed out the cavity of the womb, after previous dilatation, and has observed how, in consequence of this treatment, long-lasting digestive disorders, dyspepsia of many years standing, are wont to disappear, can form an idea to what evil symptoms, beside the local ones, stagnation of the catarrhal secretions in the uterine cavity may give rise."

What is uterine dyspepsia? By dyspepsia we mean no disease, but only a complexus of symptoms common to many diseases of the stomach, and expressive of an abnormally conducted digestion in the stomach, and such symptoms are a change in appetite, eructations, nausea, vomiting, constipation, oppression and fullness, etc. In uterine dyspepsia this complexus of symptoms arises from an abnormal irritation of the gastric nerves, and this irritation is reflected from the diseased sexual apparatus. The principal effect of the reflected irritation consists in an alteration of the secretion of the stomach, increased acid secretion, in a checking of peristaltic action of the intestines, and in an irritation of the centre of vomiting. Diseases of the womb that are attended with increased size of this organ, and malposition of the uterus, give rise to these symptoms, according to Kisch, chronic metritis, endometritis, myoma, large pelvic exudations, follicular and carcinomatous ulcers and ovarian tumors. Retroflexion is the most common cause. Diseases of the vagina, erosions and ulcers of the os, if of small extent, small peri- and parametritic exudations, do not give rise to dyspeptic symptoms. Jaffè next describes at length the nerve-paths by which reflex irritations are conveyed from the sexual organs to the stomach, to the intestines, and to the centre of vomiting.

Not many physiological data that could throw light on this affection, are known, though Kretschy found, while experimenting with a girl with gastric fistule, that during menstruation the stomach was never free from acid, a neutral reaction was never present, and he had to wait until the cessation of the menses before the cause he had previously found for the acid secretion was resumed. This observation was confirmed by Fleischer, who could demonstrate by the frequent introduction of the stomach tube a distinct slowing of digestion during menstruation.

In Jaffè's own case the dyspeptic symptoms also suffered during menstruation. Though these observations and experiments are incomplete, they seem to show a correlation between the functions of the stomach and the generative organs in woman.

The diagnosis of uterine dyspepsia must often be very difficult, for though digestive disturbances may be present during disease of the sexual organs, still a diagnosis of uterine dyspepsia may not be admissible, as an organic disease of the stomach may be, at the same time, present. Only when an organic disease of the stomach can be positively excluded, would we be justified in making the diagnosis. Frequently it will have to be made *ex juvantibus*. The prognosis of this affection is very uncertain, and depends entirely on the fundamental disease. A non-adherent retroflexion will give a good prognosis, and a carcinomatous infiltration of the womb, a very unfavorable one. The treatment also depends upon the nature of the affection of the generative organs. An energetic local treatment frequently yields an immediate success, as it did in the above case.

In what relation does the affection stand to the nervous dyspepsia of Leube? Clinically they do not differ. Leube finds the nature of nervous dyspepsia in a perverted action of the gastric nerves, and of the entire nervous system, on the processes of digestion. Hence it may originate in all manner of causes of a central and peripheral nature. In this sense *dyspepsia uterine* is a particular form of *nervous dyspepsia*.—*Memorabilien*, 1886, Hft. 4.

Apocynum Cannabinum.—The apocynum cannabinum is a herbacious and perennial plant, belonging to the family of the apocynaceæ. The root contains tannin, resin, and two substances—apocynine and apocynum—having the same properties as digitalis. Dr. Rusch's attention was attracted to this plant by its valuable properties as a hydragogue in arresting serous effusion of the pleura and peritoneum. It is both tonic and diuretic, and is valuable in general anasarca. A decoction is made of 4 grams of the bark to 250 of water, and a dose of 30 grams is given every six hours.—*British Med. Jour.*, March 5, 1887.

Treatment of Blennorrhagia.—Dr. Awssitidjiski records forty cases treated as follows: For four or five days he prescribes a potion containing 5 grams of salicylate of soda in 180 of infusion of linseed. In case the sensation of ardor urinæ disappears, he orders injections of boric acid in two per cent. solution to the number of from 4 to 6 a day for 4 days, ending finally with an injection of bichloride, 1 to 6,000, until the cure is complete.—*União Medica*, October, 1886.

THE CONDITIONS FOR THE ADMINISTRATION OF NITROGLYCERINE.

In a most interesting paper in the *St. Petersburger Medicinische Wochenschrift*, No. 1, 1887, TRUSSEWITSCH recommends that in prescribing nitroglycerine the terms angioneurosin or aneurosin be substituted for the name which is so objectionable in some cases, since these terms clearly indicate the class of diseases in which the drug has been found most serviceable—diseases in which the vaso motor disturbances constitute the most important substratum.

A deviation of the arterial lumen from the normal vascular tone is a condition *sine qua non* to a successful employment of the drug, the dilating effect of which extends to the arterioles and the capillaries. But while the primary effect of the vaso constrictor nerves is the main indication, another of equal importance is found in the ischæmia, which secondarily follows upon an unequal distribution of the blood either from determination to or dilatation of certain vascular territories. A tonic vaso motor spasm seems to be added to the merely mechanical change in the calibre of the dilated vessels. It would be difficult to explain in any other way the therapeutic action of the drug in certain forms of local congestions to internal organs; for by dilating the remaining somewhat contracted vessels, it draws the blood from the dilated parts, relieves the congestion, and may thus possibly abort inflammatory processes. When, therefore, an irregular distribution of the blood in the vessels is present in disease nitroglycerine is indicated. By suddenly dilating extensive vascular territories it charges with blood parts whose vessels have been in a contracted condition, and relieves other parts in which they have been unduly dilated; thus performing, so to speak, transfusion of blood into an anæmic part, and abstraction of blood from an engorged part. In this way may be explained the action of the drug in megrim and sea-sickness: the contracted cerebral arterioles are dilated, and more blood flows to the brain, being abstracted from the over-distended abdominal vessels. In this way also it relieves the heart-work when contracted peripheral vessels retard the circulation by causing increased arterial pressure. The symptoms, therefore, that point to the selection of nitroglycerine in the treatment of diseases, belong to the sphere of the vaso-motor nerves.

Now, what are these symptoms? The paroxysmal nature of the attacks is characteristic of many of the diseases for which nitroglycerine is useful, this paroxysmal character indicating to a certain extent the absence of organic lesions and the frequent recurrence of exciting causes. Angina pectoris, megrim and neuralgia represent this class of diseases for which the drug is suited. Sea sickness, certain forms of anæmia, fainting fits, palpitatio cordis, etc., are some of the acute angioneuroses for which it may be employed. But nitroglycerine is also used successfully in diseases of a well-marked chronic character, as in Bright's disease, flabby and fatty heart, apoplexy, in which, of course, the treatment must be continued for a long time. In all suitable cases we may expect benefit from it if symptoms of unequal distribution of the blood be present, which are usually shown by pallor, especially of the face, and attended by a weak pulse in a contracted, rigid, deeply-placed radial artery. Trussewitsch makes it a rule to avoid the use of the drug in cases of headache or neuralgia in persons whose faces show the signs of chronic engorgement of the superficial veins; and in asthma, even if it is paroxysmal in character, this remedy is useless if the patient's face be more or less reddened from emphysema. On the other hand, a pale skin during an attack of angina pectoris, megrim, vertigo, shock, toothache, and most forms of sea-sickness, furnishes the best prognosis toward recovery. Dr. O. T. Schultz, of Mt. Vernon, Ind., says that in full-blooded girls of phlegmatic temperament, whose menstrual function has not yet been established, who suffer from constant and long-continued headache of a dull kind, greatly increased by mental or bodily exertion, from vertigo, and whose pulse the least excitement runs up 30 to 40, an alternate flushing and paling of the face does not form a contraindication, for vertigo, headache, and cardiac irritability will yield promptly to the remedy.

But Trussewitsch's observations have taught him

that the equalizing effect of nitroglycerine on the circulation can be utilized in congestive conditions of internal organs; it is in these conditions that the remedy seems to act as a direct abstracter of blood from the vascular system of the congested organ. He considers these observations of especial importance, because we have nothing similar to them in medical literature, and because they raise the hope that in future it may be possible, by means of this agent, to check the progress of acute hyperæmia of an organ, in diseases of this kind, into inflammation, extravasation and other processes. In this way retrogression of acute pulmonary hyperæmia from inhalation of cold air or irritating substances—variously styled acute congestion, engorgement, pulmonary apoplexy—may take place; extravasation of blood into the brain after apoplexy from circulatory disturbances may be prevented; overfilling of parenchymatous organs—especially the kidneys—may be dissipated; violent symptoms of congestion to the heart or brain in climacteric or hæmorrhoidal cases may be lessened; and profuse menstruation may be controlled. It is evident that in this class of cases the congestion must not be a permanent condition, for attention has already been called to the fact that nitroglycerine does not exert any influence when the arterial tone has been permanently lowered by long continued engorgement or passive hyperæmia. Trussewitsch remarks that in these cases of acute congestion he has found, coexistent with the congestion, a remarkably low and slow pulse—a condition which is generally recognized to be present in the non febrile period of acute pulmonary and renal hyperæmia. It is to be hoped that this new indication for the use of nitroglycerine will be confirmed by the further experience.

In the angioneurotic as well as in the congestive forms of disease, good results can be expected from nitroglycerine only if the vaso-motor system of nerves is normally developed, *i. e.*, with normal function of its presiding centre in the medulla and its terminal apparatus in the arterial walls. Before prescribing Trussewitsch examines the pulse, as he considers its character the best guide to the use of the drug and the size of the initial dose. His experience is that the more contracted the radial artery the more rapidly will it become dilated, and the less pronounced will be the secondary effects of the drug; the fuller the pulse with a tense artery the less will nitroglycerine act upon it; and the softer the artery with a weak pulse the greater will be the secondary effects, and the more readily will excessive general symptoms appear. For this reason he dispenses in cases of the first class only the normal dose—1 drop of a 1 per cent. solution, in those of the second two drops after a trial dose of 1 drop, while in those of the third class he begins with a subnormal dose, ¼ to ½ of a drop, so as to avoid the severe drug-symptoms. It is advisable to give women, children, and aged persons smaller doses, and he has made it a rule to give anæmic, weak, nervous, fatigued and frightened persons an initial dose of $\frac{1}{200}$, and to advance to the normal dose only after three to seven days. Organic heart disease is no contraindication. He has given it in cases of angina pectoris with insufficiency of the aortic valves, and dilated aorta, and with flabby, dilated heart without bad effect. Those addicted to the abuse of alcohol seem to suffer more severely from violent and long-lasting headache. In persons who seem not easily impressed by the drug, and to whom, on this account, large doses have been given, this violent headache may not make its appearance for several hours. Caution must be exercised in general atheromatosis of the arteries.

By his trial dose Trussewitsch attempts to find the capacity of the patient for the remedy, and it serves to acquaint the patient with the manner of taking it. In his opinion, the good action of a dose of nitroglycerine is in proportion to the subjective symptoms to which it gives rise. These subjective symptoms are cerebral congestion, dulness, moderate pain, and pulsation, and their onset is an indication that a favorable effect will follow the given dose. The objective sign that the drug will act favorably is a change in the pulse, consisting in an increased frequency, increased duration, and increased softness of the radial artery. If no cerebral symptoms are complained of, and if the pulse does not weaken and become excessively soft, the dose is increased to 2 drops of a 1 per cent. solution. Usually the treatment may be begun with a single drop, and the peculiar physiological effect is experienced even if the medicine be continued for several weeks. In a purely neurotic attack—the symptoms completely disappearing before and after the paroxysms—it is advisable to give 2 drops at once, or else to repeat 1-drop doses every five, fifteen or twenty minutes. To prevent a new attack and to cure the affection the dose is repeated three or four times a day, and an extra dose is given when the premonitory symptoms of the paroxysm are manifested. The fulness, oppression, and pulsation in the head disappear more rapidly if the patient remains seated in a chair, in a well-aired room, and avoids everything that could give rise to a flow of blood to the brain. When the physiological effects of a dose cease to appear, the

time has come when its good effect on the disease has also ceased, and the dose must be increased; only by a single drop, however. Now both objective and subjective drug-symptoms are again promptly manifested, and the disease symptoms again vanish, the patient in a short time learning what to look for, if it should do him good. In diseases of long duration, as in angina pectoris due to organic causes, in which nitroglycerine can only serve as a palliative, great care must be taken in increasing the original dose. It is better in such cases to give an extra drop only just before a paroxysm, and the smaller doses in the intervals, or else to stop the medicine entirely during the latter and only give a full dose before and during an attack. For patients who have become accustomed to nitroglycerine, the dose may be gradually raised even to 10 drops. Trussewitsch has found that if the use of the drug be interrupted for ten or fourteen days, on recommencing the treatment the original, smaller dose will again give rise to pronounced physiological symptoms with their coincident prompt controlling action on the paroxysms; and this peculiarity of the drug makes it unnecessary to unduly increase the dose simply on account of the patient's having become accustomed to the dose.

The best method of administering nitroglycerine, says Trussewitsch, is to drop the dose on the tongue, or to dissolve a chocolate tablet of nitroglycerine in the mouth, so as to bring the medicine into most intimate contact with the mucous membrane of the upper digestive tract. Other methods are unsatisfactory, and that of introducing it into the stomach diluted with water gives the poorest therapeutic results; as little water as possible should be given with it. He is certain that, if given by the stomach, an augmentation of the dose will be much sooner called for and far larger doses will be necessary; and he is not at all surprised that Murrell should have been compelled to rapidly advance to enormous doses in angina pectoris, and that Cantilena, after rapidly raising the dose to 40 drops, should have thrown the drug aside as useless. He can recall no cases in which in a beginner more than 2 or 3 drops, and in one habituated to the medicine more than 5 to 10 drops were necessary to relieve the paroxysm. Dr. Schultz reports that in a case lately under observation 1 drop of a 1 per cent. solution, given with a few drops of water and retained in the mouth, gave rise almost instantaneously to the usual drug-symptoms with violent lightning-like twitches of pain through the brain; while, when the dose was given with water and swallowed, the sharp twitches of pain were absent, and the fulness and throbbing in the head were much milder and appeared much later. When he finds that nitroglycerine does its work, dilates the vessels, and reduces their tension and the blood-pressure in chronic diseases, Trussewitsch is accustomed to gradually advance to the maximum dose, say 10 doses, and then as gradually go back to the original dose. He then interrupts the use of the drug, or drops it altogether. This plan has been found of especial advantage in Bright's disease. He sometimes find it advisable in chronic diseases to combine with the nitroglycerine treatment the use of other drugs, as digitalis in weak, irregular heart-action, cocaine or morphine in neuralgia, and amyl nitrite in violent attacks of angina pectoris, when it is not desirable to augment the dose of the leading remedy. It is of course very necessary to combat any constipation present, and for this purpose uses an aloes and podophyllin pill, or an emulsion of castor-oil with glycerine. A strict dietetic regime is to be insisted on in the treatment of diseases with nitroglycerine; bodily and mental quiet is necessary; change of temperature, excessive exercise, long-continued brain work, mental worry and care must be avoided.

Care must be taken that the preparation of the drug used is a reliable one. The dose should be applied to the tongue by means of a pipette that drops uniformly. The preparation should be kept in a glass-stoppered vial. Many patients always carry a vial of nitroglycerine and a pipette with them, so as to be able to take their dose at a moment's warning. There is no danger of carrying a 1 per cent. or even a 10 per cent. solution, as Trussewitsch has proved by numerous experiments. The preparation does not deteriorate with time, for he has carried the same supply around with him for over four years without noticing any change.

THE DUTY ON FOREIGN BOOKS.

Those members of the medical profession who attempt to keep themselves posted in the advances made outside of our own country, and who are able to read some of the European languages, fully appreciate the injustice (apparent certainly, if not real) of the present high duty on all foreign works. As medical men we are not interested particularly in knowing how such duty protects any home interest; though as a matter of fact the keeping of books in foreign languages out of the country can protect no home interest. Further than this, we must regard at least 95 per cent. of such books purchased by medical men in this country as necessities, not as luxuries. These books are necessities in the same way that agricultural implements are necessities to the

farmer; but all good agricultural implements may be made in this country, while the works of which we speak cannot be made here.

Suppose, for example, a medical man in this country wishes to buy a English, French or German work which costs $1; he must pay 25 cents duty, or at this rate, on a book which costs $20 he must pay $5 duty. How many reading, studying medical men can afford to pay one-fourth more for an article than it is worth? This tax falls exclusively on the reading, studying members of the profession; it does not affect those who do not attempt to make progress after leaving the medical colleges; it does not affect the drones in the profession. We think it will be agreed that such works are as much a necessity for the State at large as for the profession, since it is now well recognized that the highest aim of the profession is preventive medicine. Would it not be well for the American Medical Association to take some action in regard to this matter at its next meeting, and memorialize the General Government, setting forth the injustice of this tax.

COLLECTIVE INVESTIGATION OF DISEASE.

Only a very limited number of the blanks prepared and distributed to members of the profession in this country by the American members of the International Committee for Collective Investigation, organized at Copenhagen, 1884, have been returned as requested, on or before January 1, 1887. The blanks related to rickets, acute rheumatism, chorea, cancer, and urinary calculus. As the time is near when the several members of the Committee are expected to make their returns to the Secretary-General of the International Committee, it is very much desired that all who have received copies of the blanks alluded to and have filled any of them, would return the same without further delay to Dr. N. S. Davis, 65 Randolph Street, Chicago, Ill.

Cholera in South America.—From the Weekly Abstract of Sanitary Reports, from the office of the Supervising Surgeon-General of Marine Hospital Service, dated March 24, we learn that the latest dates from Buenos Ayres, Feb. 5, represent the prevalence of the cholera as decidedly diminishing throughout the Argentine Republic, with a prospect of its early disappearance from that country. But in Santiago and the departments of Aconcagua, Andes and Quillota of Chili the disease continues active and fatal, particularly among the poorer classes of the people.

Died, at Mt. Vernon, Ohio, March 22, 1887, John W. Russell, M.D., one of the oldest and most highly respected physicians of that part of the State. He had been an honored member of the American Medical Association since 1860, and was one of those who crossed the mountains to attend the annual meeting of the Association in San Francisco in 1871. He was born in Caanan, Litchfield Co., Conn., June 28, 1804, acquired a good general education, commenced the study of medicine in 1823, and graduated in the Jefferson Medical Collge in 1827.

Died, at Atlanta, Ill., March 25, 1887, William T. Kirk, M.D., from disease of the heart. Dr. Kirk was well known as an active and honorable member of the profession, and was President of the Illinois State Medical Society at the time of his death. He had been a member of the American Medical Association since 1882; and commanded the respect and esteem of a large circle of friends.

Sir B. Walter Foster, of Birmingham, Eng., President of the Council of the British Medical Association, has been recently elected to the House of Commons for the Western division of Derbyshire. Dr. Foster has previously done good service in Parliament, and we congratulate him on again being honored with a seat in that most important legislative body.

The death of Arthur Farre, M.D., F.R.S., of London, Eng., a celebrated surgeon and writer, and physician extraordinary to the Queen, has just been announced as having taken place in the seventy-seventh year of his age.

The Sanitary Record, London, Eng., for Dec. 15, 1886, contained two important communications concerning the health of London, alluded to by our regular London correspondent in this journal for Feb. 26, 1887.

Professor Borodin, of St. Petersburg, known as a warm supporter of female medical students in Russia, died suddenly of heart disease in February. He was an eminent chemist, and worked out a valuable process for the estimation of nitrogen.

Professor Hirschberg, of the Berlin University, has accepted the Vice-Presidency of the Ophthalmological Section of the Ninth International Medical Congress, to be held in September at Washington.

SOCIETY PROCEEDINGS.

CHICAGO GYNÆCOLOGICAL SOCIETY.

Regular Meeting, Friday, January 21, 1887.

THE PRESIDENT, CHAS. WARRINGTON EARLE, M.D., IN THE CHAIR.

W. W. JAGGARD, M.D., EDITOR.

DR. CHARLES T. PARKES reported a case of

INTERSTITIAL PREGNANCY, WITH REMOVAL OF THE PRODUCT OF CONCEPTION THROUGH THE UTERINE CAVITY,

with the exhibition of the specimen.

The specimen, which I exhibit to-night, comes from a case, which has been of extreme interest to me, and is, I think, the remains of a conception, which was certainly outside of the uterine cavity, and which I succeeded finally in delivering through the womb. It was taken from a lady, 33 years of age, who, seven years ago, was delivered of a child at full term. The child is now living. A year after that, she was taken with hæmorrhage and had quite a severe bleeding, every month or second month, for two years. Some time after her pregnancy she was operated upon for laceration of the cervix, but the operation had little effect upon the hæmorrhage. Two years ago she again became pregnant, and was delivered at the proper time. This child is still living. The lady came under my charge last September for hæmorrhage from the uterus. On examination, I found a globular mass in the lower portion of the abdomen, as large as two fists, very hard and tense. When I felt it through the abdominal walls, my impression was that it was a fibroid growth. Upon digital examination, I found the cervix dilated sufficiently to admit the finger very readily, which went over the surface of a smooth mass in the uterine cavity. This led me to think that it was a fibroid tumor with a broad base, probably a submucous tumor, which gave rise to the hæmorrhage. On that supposition I placed her on the ergot treatment and kept it up for a week, 20 drops of the fluid extract every six hours. This gave rise to such severe attacks of pain that the patient could not bear the treatment any longer, but it had the effect of diminishing the flow of blood and increasing the dilatation of the cervix. I took pity upon her on account of the pain and gave two hypodermic injections of morphine, when the pain ceased, the cervix began to contract again and soon reached its normal size, and the patient recovered from the acuteness of the disturbance; but the hæmorrhage still continued, accompanied with a flow of muco-pus. I attended her from the 16th of September until the 14th of October; as she was getting along pretty well, I supposed the action of the ergot would gradually force this mass down so that it could be removed.

My visits ceased and I heard nothing more from the patient, except an occasional report that she was getting along in the same way, until the 10th of December, when her husband came into my office and showed me a little piece of bone, or a piece of hard substance that looked like bone, which he said his wife had picked off the napkin. It had the appearance of fetal cranial bone. He asked me what it meant, and I told him I could not say but would see his wife. On inquiry, I found that the flow of blood had ceased, but the flow of pus had increased, and occasionally there was extruded a piece of this bony substance. On digital examination, I discovered the os and cervix filled with particles of this bony substance, and after removing them I found it impossible to introduce my finger into the cervix. The external tumor was reduced considerably in size, and was low down in the pelvis, and could be felt projecting through the anterior vaginal wall. I then decided to dilate the cervix. I introduced as many tupelo tents as I could get into the cervix—at first but two of fair size—to their full length, and allowed them to remain there over night, when I removed them and introduced four more. That evening I removed them, and the cervix was dilated so that I could easily introduce my finger. As I had examined the uterus with the sound at my first visit, and it went around this mass to its full length, I supposed I had nothing but a fibroid to deal with. When I had dilated the cervix with these tupelo tents, I found I could not get at the mass of the growth, my finger going into the cavity of the uterus. At the distance of one joint and a half inside the cervix, I found a little opening, and projecting through this opening—about as large as the end of a pencil—were some of these particles of bone. Then the query arose, how was I to get into this cavity, and what was it? a double uterus, with multiple pregnancy at the last conception—one delivered and the other retained? I was at a loss to know what it was. (But finally concluded it to be an intra-mural pregnancy.) I had the particles examined under the microscope, and they showed the structure of a fetal bone. Then I thought of using the tents, to increase the dilatation, but was troubled with the fear that I should have a severe scepticemia come on as soon as this outside cavity was opened to air. But I was convinced that unless I tried to do something, the patient would pass out of my hands; so I decided to keep on with dilatation. On the 20th of December, I began introducing the tents, and within two or three days after their removal, the cervix was again contracted so that it would not admit the finger. I introduced the tents again, and met the same difficulty in exposing the mass. The thought struck me that if I could not get the large body out of the small opening, I could diminish the size of the mass; so I introduced small forceps into this opening, and took it away piecemeal. All this time I had the entire uterus under my command, because it was an easy matter to bring the cervix down to the vulvar orifice. On the 24th I introduced tents and dilated it, so that I could introduce two fingers very readily, and finally got one of my fingers into the opening in which this body (indicating the specimen) was found. I then began to separate it and pull it away, getting hold of it with strong forceps. Sometimes I succeeded in bringing away a large mass of flesh, which

looked exactly like that from a macerated fœtus, the skin macerated and parchment like. This was continued up to the 30th. Passing over the New Year, and allowing the patient to rest without interference, on January 9, I introduced four tupelo tents, a little longer than the ordinary, and fortunately succeeded in getting one or two into the opening in which the body was found; so when I removed them that evening, I was enabled to bring away the entire mass and pass the finger into the cavity afterwards. It was very irregular, as though the uterine tissues had been forced into the irregularities of the foreign body. Since that time the patient has improved, the bleeding has ceased, the uterus has diminished in size, and she is up and about the house. I have had all parts of this specimen examined under the microscope. The fleshy mass shows connective tissue, muscular fibres, blood-vessels and hairs. The osseous material shows all the characteristics of fœtal bone.

The President, asked if there was a history that would lead one to suppose that at any time during her invalidism there was a pregnancy, or a pelvic hematocele, or anything of that kind?

Dr. Parkes said, that at the time of her last pregnancy, she was very large and yet was delivered of a child that weighed but six pounds. Her abdomen was very large for some time after the delivery of this child. Again, there is a history several years back, of a period when menstruation ceased, and she supposed she was pregnant, but nothing came of it.

Dr. W. W. Jaggard said that the interesting specimen presented by Dr. Parkes was a typical lithopædion—a calcareous capsule, containing the fœtal structures infiltrated with lime salts. He thought the diagnosis of interstitial pregnancy highly probable. It was impossible to make a positive diagnosis without a post-mortem examination of the maternal organs. Carl Braun (*Lehrb. d. g. Gynäk*, 1881, p. 128) was responsible for the statement that the formation of a lithopædion occurred only in case of extra uterine pregnancy. Spiegelberg (*Lehrb. d. Geburtshülfe*, 1882, p. 342) however, indicates that this proposition is too general. The formation of a *uterine lithopædion* occurs infrequently in the human female, but is not unusual in ewes. Kœberlé (*Gaz. Hebd.*, No. 34, 1866) extracted by abdominal section a lithopædion from the rudimentary horn of a *uterus bicornis*. The formation of a lithopædion, therefore, was not a reliable sign in the differential diagnosis between uterine and extra-uterine pregnancy.

Dr. John Bartlett read a paper on

DYSTOCIA; A CASE OF MALPOSITION OF CORD.

Recently I was requested to assist a younger physician in a case of midwifery. Dr. H. had been called some hours before my coming. He found a healthy, well-built woman in labor with her eighth child, hitherto she had had no difficulty in her confinements. She had been in labor some hours, and, although the pains were very strong, the os fully dilated, and the head presenting, no progress had been made. A midwife had been in attendance. The doctor attempted to use Elliot's forceps, but, because of the high and abnormal position of the head above the pelvic brim, he had desisted from his purpose. Upon examination, I found the os widely dilated, the crown of the head presenting. By introducing the hand into the vagina, my fingers directed toward the left sacro-iliac synchondrosis, encountered and passed slightly beyond an extremity of the head ovoid which I supposed to be the occipital protuberance, but near it was so distinct a fontanelle as to lead me to examine the opposite extremity of the head. Passing the hand deeply behind the left foramen ovale and well above the pubes, the fingers embraced the occiput; sweeping well backward again over the side of the head they traversed the temporal region till the ear was reached and carefully outlined. Still further backward the fingers passed over the frontal eminences which had at first been mistaken for the occipital protuberance. The head was floating above the pelvic brim; the frontal region sinking somewhat below the plane of the superior strait. The crown of the head rested gently upon the pubes, while the occiput rested so far forward over the pubic bones as to be distinctly appreciable to sight and touch from without. Having determined the position of the head, I proceeded to inquire the cause of its detention; for it did not impinge with force upon any portion of the circumference of the brim. Passing the fingers along the side of the head I felt for the cord around the neck. A coil of cord was immediately encountered, and pressing a little farther upward a second, third and fourth coil were detected. I felt authorized to announce to Dr. H., as the cause of the dystocia, the suspension of the head above the brim by the cord shortened by four coils about the neck. The fingers were passed about the occiput and it was pressed downward and backward, throwing the forehead backward and upward above the brim and bringing the occiput slightly into the pelvis, the pains meanwhile having a decided effect in assisting the manœuvre. I now intended to seize the occiput with the vectis, and so deliver. Upon trial with the fingers, however, I appreciated that, as the occiput had descended into the pelvis, the forehead had risen above it, so that the power of the vectis as a tractor would not be available, seeing that the forehead, the opposite end of the lever I proposed to move, was not fixed but floating, the fœtus yet resting with the equators of the head well above the brim. As a lever to keep the occiput in proper relation to the inlet, the "Roonhuysen" would have served admirably; but in order to make available traction upon the head it would be necessary to lay hold of it with the forceps. Accordingly, with very little trouble, though locking was effected within the vagina, the head was seized with a well-curved Simpson's forceps, and readily brought down. The expectation was, as soon as the head was delivered, to place quickly two clamp forceps on the cord and cut it between these, in order to escape the embarrassment which the several coils about the neck might occasion. The first loop, however, was easily drawn over the head, the other coils were then readily released. The child which weighed eleven pounds

breathed at once, seeming but little affected by the unnatural position of the funis. The length of the cord was forty-six inches.

In connection with this case, I propose to make some comments upon the mode of determining the position of the head in labor. From time immemorial, it has been the custom of teachers to describe with particularity how the position of the head may be determined by the tips of the fingers by means of the sutures and fontanelles. Whatever skill or tact others may be endowed with, or may have acquired in such methods, for myself I wish emphatically to declare that such examinations are often entirely insufficient to furnish me with the desired formation; and that now, after years of careful observation, I am not unfrequently at a loss to determine the position of the head after the usual examination *per vaginam*, and that I am occasionally led into an error in this regard only to be dissipated by the birth of the head. Nor am I alone in this want of capacity; a number of experienced obstetricians, with whom I have conversed on this subject, have expressed like uncertainty in determining the position of the head by the means mentioned.

How, in cases requiring a knowledge of the head's position, is such information to be obtained? I know no better way of answering this question than by making reference to the practice of Smellie. Please note the thorough methods by which he satisfied himself of the size or position of the head in the several cases here cited. "I knew the child was small because I passed my finger all around the head." And, "I perceived that the head was not large, because I could easily introduce my finger all around the lower part of it." Desiring to ascertain the position he says, "I scooped up the head above the brim of the pelvis, and as I slipped my hand flattened between the sacrum and the child's head, I felt with my fingers on the back part of the neck" (determining the position of the occiput). And again, "I turned the back of my hand down towards the sacrum and raised or scooped the head gently to the upper part of the pelvis; and now with my fingers I felt the posterior part of the neck, and distinguished that the pelvis was not distorted. Thus informed, I introduced the blade of the forceps, etc. In reference to another case he says, "Being foiled in delivering the head, which was not large, after having properly applied the forceps I disengaged the instrument, and raising the head again (out of the pelvis) and found the difficulty was owing to the left shoulder being over the pubes. I got hold of the arm, brought it down, and again fixed the forceps and delivered, pulling gently at the hand." From these extracts it will be seen that Dr. Smellie did not content himself with vaguely touching such portions of the presenting part as might be reached by the introduction of one or two fingers, but that he introduced deeply the half-hand, or the whole hand, and passed the fingers into every available space; not hesitating, when necessary and practicable to lift the head above the brim that he might get his fingers about its salient points as the ear, the face, the back of the neck. It is noteworthy that it is only when circumstances prevent the head being thus "traced," that Smellie recommends that "the observation" be taken from the fontanelles and sutures. In the case which is the basis of this paper, the vaginal examination was made after Smellie's method. The steps of the procedure have been given in detail with the purpose of illustrating his teachings.

Dr. Philip Adolphus said: The diagnosis of the position of the child in head presentations by means of sutures and fontanelles is not as difficult to the physician, who has been in attendance during a case of labor as has been stated this evening. The gradual descent of the head into the pelvis will permit the recognition of the landmarks by *repeated* examination with the finger. In diagnostic obstetric investigations, palpation of the abdomen, the examination of the child's head and the pelvis of the mother by bi-manual palpation, should be conducted on the same principles as in gynecological cases. An empty bladder is also essential to a successful diagnosis. Such an examination will insure the recognition of the position of the child's head, and other necessary information. The consulting physician, who encounters a tender abdomen, tumified soft parts and a swelled scalp in an exhausted patient, has a far more difficult task. The same rules, together with the introduction of the hand as far up as is required, under anæsthesia, will give him the necessary information.

A refinement of diagnosis is not absolutely essential. Many cases of labor are completed, in which the diagnosis of the position of the head has not been ascertained by its sutures and fontanelles. Moreover, cases which require delivery by forceps are frequently skilfully handled when the operator has not been enabled to ascertain the position of the head. We explain this by stating that the mechanical adaptation of the child's head to the bones of the pelvis is perfect; sooner or later the child's head, if *not disproportionate in size to the pelvis*, will accommodate itself to its configuration, provided other obstacles in its path have been removed by the attendant. We state, also, that the position of the head does not determine the position of the blades of the forceps, but the position of the blades is always determined by the anatomy of the mother. Therefore, the forceps should be applied along the sides of the pelvis, and its pelvic cures should correspond to the curved axis of the pelvis. Its introduction is governed by the direction of the obstetric canal, the globular head of the child, and the cranial and pelvic curves of the instrument. The direction of the obstetric canal in a woman in labor is not the osseous pelvis merely; but the pelvis covered with soft parts, whose terminal outlet is not at the point of the coccyx, but at the anterior commissure of a greatly distended perineum, a distance of ten to twelve inches during labor. The blade of a long doubled curved forceps—having both the cephalic and the pelvic curves—is guided into the pelvis by the fingers and insinuates itself between the head and the soft parts of the mother. To facilitate the introduction of the second blade the first blade is

gently elevated and rotated as much in a lateral direction as possible. The same manipulation is repeated with the second blade. In many cases the elevation of the blades and their gradual rotations for the purpose of locking them, adjust the blades of the forceps to the head of the fœtus, as they have already adjusted themselves to the mother's pelvis; and now traction, some compression, and slight leverage (if necessary) complete the delivery of the child, *which will rotate spontaneously within its blades* during traction, owing to the anterior and posterior planes on either side of the cavity, and the resistance of the floor of the pelvis.

It is best that the exact position of the head should be known, but such knowledge is not essential to its safe extraction; on the contrary, it is not correct to apply the forceps to the sides of the fœtal head when its position is oblique or transverse, for if its pelvic curves are twisted, injury must be inflicted on the mother.

Dr. W. W. Jaggard wished to make one or two criticisms. The diagnosis of dystocia, by reason of a short cord, is not adequately established by the clinical history of the case. The ease with which the vertex engaged, after manipulation, and descended, after application of the forceps, the absolute length of the cord, forty-six inches—even with four loose coils around the neck, not relatively short—the condition of the child when born, these are facts which do not indicate that the length of the cord constituted a mechanical hindrance to the progress of labor. The author has quoted Spiegelberg, who is of the opinion that shortness of the cord constitutes a mechanical hindrance only where the presenting part reaches the lower portion of the parturient canal. The only method of determining with certainty, in the concrete case, that shortness of the cord is acting as a mechanical obstacle, consists in the introduction of the fingers, direct contact with the cord, and the detection of the abnormal tension. If the case related by Bartlett was one of dystocia, and if the "occiput projected so far forward over the pubic bones as to be distinctly appreciable to sight and touch from without," does it not seem a plausible hypothesis that the child was presenting slightly obliquely, and that the operator performed cephalic version? "The fingers were passed about the occiput and it was pressed downward and backward, throwing the forehead backward and upward above the brim, and bringing the occiput slightly into the pelvis, the pains meanwhile having a decided effect in assisting the manœuvre."

In treating of obstetrical diagnosis, in general, Dr. Bartlett does not mention the signs derived from inspection, auscultation, and particularly *abdominal palpation*. I am induced to call attention to this topic for the reason that, notwithstanding the writings of Kucher, Mundé, Richardson, the recognition of the value of abdominal palpation in obstetrical diagnosis in the best recent text books, and the translation of Pinard's Treatise, by Dr. L. E. Neal, of Baltimore, still many practitioners affect to disregard the paramount importance of the method. Litzmann (1865), Halbertsma (1870), Winckel (1878), Credé (*Gesunde und kranke Wöchnerinnen*, Leipsig, 1886, p. 80. *et seq.*, in order to prevent the infection of parturient women in their respective lying-in hospitals, having omitted all examinations *per vaginam* for months at a time, with most gratifying results. Under these conditions, external examinations has proved perfectly adequate in the diagnosis of presentation and position.

I confess to a feeling of decided surprise upon hearing that a medical man, with the average degree of tactile sensibility and even moderate experience, should necessarily have difficulty in the diagnosis of position, by indagation, in normal, vertex presentations, after engagement, before the formation of the *caput succedaneum*—the *os externum* being dilated or dilatable, the bags of water, intact or ruptured. I am under the impression that failure to make an accurate diagnosis, by examination *per vaginam*, under the conditions specified, is due in very many cases to inattention. It is an obstetrical maxim of importance that both fontanelles and their sutures should be felt before making a diagnosis, when vaginal touch is exclusively employed. When an extensive *caput succedaneum* has formed, or ossification of the fœtal skull is advanced, or in case of subnormal tactile sensibility on the part of the accoucheur, no absolute contra-indication to the introduction of the half-hand exists. In forceps cases, a correct diagnosis of the position of the vertex must be made, since that instrument ought to be applied first with reference to the pelvic walls, and then adapted to the child's head, before the exercise of its most important—and as I believe, exclusive—function of traction.

Dr. Edward Warren Sawyer: I wish to speak of an interesting experience. A gentleman who had carefully translated the book alluded to called me in consultation to assist him. He had, by means of bimanual palpation, diagnosticated a presentation of the vertex, but on my examination I found the buttocks were presenting. I think in most cases abdominal palpation is of no service whatever to the majority of practitioners. I have experienced the same difficulty that Bartlett has so graphically described in recognizing the position of the head by the introduction of the finger into the vagina. And after a long practice, so uncertain am I concerning the position that I never think of applying forceps until I have introduced enough of my hand to recognize some part of the face or head, in order to determine the exact position of the head.

Dr. J. Suydam Knox said: In regard to making an exact diagnosis of vertex positions, I must often confess failure if I rely only on digital touch. I have no doubt if the practitioner is called early to a case of labor before the uterus has become contracted, and the bag of waters has been ruptured, that it is possible by abdominal palpation to make out the position of the fœtus. When, however, labor has gone on for several hours the uterus becomes irritable, contraction and retraction taken place, and the liquor amnii to some extent discharged, I am satisfied that it is often impossible to make out a diagnosis of the position of the fœtus by digital

examination. Even if you can determine that the vertex is presenting, you cannot then make out the position exactly. I have no doubt that Dr. Jaggard is correct about those large obstetrical hospitals in Europe. The diagnosis is made because the patient is under observation from the time labor begins. But the busy practitioner is called after labor has progressed some hours, and the uterus is so irritable that as soon as he begins to make any abdominal examination it contracts, and it is impossible easily to make a diagnosis. I do not introduce the hand into the vagina in many cases, but when the labor is protracted, and I think the use of forceps necessary, and I cannot make out the exact position of the head, I give the patient an anæsthetic, and introduce the hand sufficiently to find out how the head lies. I cannot see how sepsis can occur by the introduction of that portion of the hand necessary to make a diagnosis, and I think the diagnosis should be made before instruments are applied. I have several times tried the oblique introduction of the long forceps, but doubt the wisdom of introducing them obliquely without reference to the shape of the mother's pelvis and attempting traction. It is much better to apply the forceps to bring down the head, with reference only to the maternal passages, and when the head has been brought through the superior strait, to unlock the forceps and allow rotation before effecting delivery. At times it is better to remove the forceps entirely, and to re-apply them after rotation has occurred.

Dr. De Laskie Miller was much interested in the paper. It is true that there were many statements that seemed strange. The paper was on the treatment of complications resulting from short cord, and the illustration was a case in which the cord was forty-seven inches long with only four coils around the neck. This should not, it seems to me, be a cause of dystocia; but admitting that it was, we come to cases of actually short cord causing dystocia. Take a cord that measures only four inches in length, or a case of labor which has occurred in which there is no cord, of course there must be a placenta, and the fœtus is attached through this directly to the wall of the uterus. In such a case how can delivery take place without applying traction force sufficient to sever the placenta? Physiologically the contraction of the uterus, especially after dilation is completed, is attended with a muscular retraction of the fibers of the body and fundus, which diminishes the cavity of the uterus and has the effect of severing its relation with the placenta. It is therefore possible for the placenta to be severed from its attachment to the uterus, by this retraction, and moreover there can be no injury to the uterus from the short cord if the contractions are normal, for while the organ is contracted the relation between the attachment of the cord and the uterus, or the placenta and its attachment to the fœtus, is not extended, rather shortened, so that the advance of the child can take place and delivery result.

A case is recalled which occurred in my own practice, of a primipara who was perfectly healthy, with nothing abnormal until about the time labor commenced. When I saw the patient in the first stage of labor, she remarked that she had felt no movement of the child for a considerable time, but this produced no impression on my mind, for it is a common thing for patients to say, and I paid no attention to it. The labor proceeded, and as the head was expelled from the vulva, I did as I always do, pass the finger instantly to the neck with the view of searching for the cord, and if it is found there liberate it. I found two or three coils of the cord around the neck, and they were so tightly drawn that it was impossible to disengage them. In order to deliver the child readily, I severed the cord. I noticed there was no circulation, and the child was still-born, past all possibility of resuscitation, and it had been dead a long time, for I found a knot in the cord drawn so tightly that the circulation was entirely cut off. In addition to the coils around the neck the cord passed over the shoulder, under the opposite arm, around the body and under the knee, possibly there were other coils. It appeared very much like the statue we see of Laócoön. I infer that the movements of fœtus at the time labor commenced or shortly before had tightened the cord, causing its death. This is the only case I have met in my practice in which I could satisfactorily trace the death to the closing of the knot. In regard to diagnosis of position, I was not aware that it is so difficult to make the diagnosis of position. I believe the practitioner should make out a diagnosis by abdominal palpation, which can be done with great facility if he is accustomed to the practice; but I also believe that the diagnosis can be made with one fontanelle and the sutures. We can certainly discriminate between the anterior and posterior fontanelles.

Dr. Bartlett said: A fellow has expressed surprise that as a means of diagnosis I have not made reference to abdominal palpation. I purposely limited my remarks to the ordinary methods of vaginal examination. I may, however, give it as my opinion that the method of determining the position of the head by abdominal palpation will probably prove available to those only who are capable of diagnosing head positions by the ordinary examinations per vaginam.

Drs. Jaggard and Miller have called in question the assigned cause of dystocia. To them it does not seem probable that the shortened cord was the cause of delay. Their objections are well taken. In this case there are two facts which give rise to the question whether the cause of the dystocia was really the shortening of the cord, the one in itself offering at first glance a sufficient cause for delayed labor, viz., that the head was projecting decidedly forward over the pubic bones; the other seeming to guarantee freedom from restraining tension on the part of the cord, namely, its unusual length; so that after delivery of the head the funis, though shortened, was not too tense to admit of its coils being released in the usual way. It must be considered, in reference to the abnormal position of the head at the superior strait, that while its attitude presented an impediment to the descent of the occiput, it invited a facile descent of the forehead; and yet this descent did not occur.

Besides, the head could be swayed to and fro in the median plane of the occipito frontal diameter so easily and freely as to give the impression that it swung on a pivot at the neck. In fact, it was this sensation imparted to the hand that suggested the probable suspension of the child by the cord; and this suggestion was strengthened by the apparent absence of any natural tendency of the head to settle into the excavation, either in the first instance as a brow and face presentation, or subsequently, as a right occipito-anterior position.

In regard to absence of great tension of the cord after the birth of the head, it is to be considered that without calling in question the possible detachment of the after-birth, surging of the coils about the neck, etc., the well-known mechanical principles by which the attached placenta in such cases in some measure keeps pace, so to speak, with the descending head, so clearly described by Dr. Miller just now, may themselves offer an answer to the objection that the cord was not found more tense after the head was delivered.' No argument, however, can place the case certainly within the category of those which dystocia is due to shortening of the cord. It will be perceived that I have regarded the case as interesting rather than because of the unusual diagnosis of the malposition of the funis than as one in which this abnormity produced dystocia; and that I have availed myself of the free exploration of the presenting part by which the diagnosis was made an opportunity to present what I regard as the more important part of this paper. I refer to my views as to the insufficiency of ordinary vaginal examinations as means of determining presentations and positions in labor. Upon the discovery of the four coils of cord about the neck, in association with other circumstances and conditions mentioned, I conceived the circling of the funis to be the cause of the dystocia, and conducted the delivery in accordance with that idea.

Criticisms on the plan adopted should be made in this case, as in others, from the ante-partum standpoint of information. They should not be based, for instance, upon the knowledge that the cord was of very unusual length. This surplus in the cord's length threw a new and unexpected light upon the case, casting difficulties, before prominent in the foreground, into shade, and causing possibilities not before visible distinctly to appear. In this new light an opinion might be formed that the case left to nature would have terminated well, and that all interference was unnecessary. And yet I incline to the opinion that the ante-partum view of the case through the dark glass of the clinical obstetrician was the correct one.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

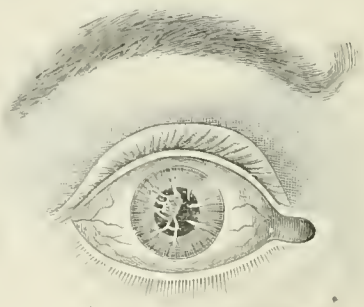
Stated Meeting, February 23, 1887.

The President, J. Solis-Cohen, M.D., in the Chair.

Dr. Charles S. Turnbull exhibited a patient presenting a

PERSISTENT PUPILLARY MEMBRANE.

I have brought before you to night a case of unusual interest to ophthalmologists and to medical men in general. The patient has in his right eye what is known as a "persistent pupillary membrane." This is a remnant of fœtal life, but its exact structure has not been ascertained. Some consider it to be made up of atrophied blood vessels, which have served their purpose. Other authorities hold that it consists of the remains of connective tissue through which blood-vessels pass. In this man's right eye there is a network of hair-like fibres occupying the outer half of the pupil. These fibres originate from the anterior surface of the iris, and interfere in no way with the constrictor muscle of the pupil. This form of congenital anomaly was first observed about 1735, and on an average about one case has been reported every five years since that time. I am indebted to Dr. P. H. Bailhache, of the U. S. Marine Hospital Service, for the opportunity of exhibiting this patient.



Dr. E. Jackson said: This case is notable for the clearness with which it shows the relation between the membrane and the iris. In all the cases I have seen heretofore, as in this, the pupillary membrane has seemed to arise from the anterior surface of the iris; but in no other instance has the connection been so obvious, the membrane here appearing to be simply an extension of the anterior layer of the iris; and similar to it in structure.

Dr. Turnbull said that the point referred to by Dr. Jackson is well illustrated in this case, and it settles the disputed question as regards the origin of these fibres. It is distinctly seen that the sphincter muscle is in no way involved. The membrane has no connection with the muscle nor with the inner pupillary margin.

Stated Meeting, March 9, 1887.

The President in the Chair.

Dr. J. Solis-Cohen read a paper on

ADMINISTRATION OF GASEOUS ENEMATA.

He desired to exhibit Morel's apparatus for administering gaseous rectal injections, according to the method of Professor Bergeon,[1] in diseases of the

[1] For details, see Nouveau Traitment des affections des Voies respiratoires et des intoxications du sang par les injections rectales gazeuses, d'apres la méthode du Dr. L. Bergeon. Par V. Morel. Paris, 1886.

respiratory passages, and in blood-poisoning; but as it had not been forwarded from the Custom House, he exhibited a substitute made in imitation. The object in view is to supply to the venous circulation an antiseptic, such as sulphuretted hydrogen, in sufficient doses to be effective; a result impossible when supplied directly to the arterial current, a plan which would poison the patient. Sulphuretted hydrogen inhaled in far less than sufficient doses would suffocate the patient; taken by the stomach, it would produce other serious results. Administered by the bowels, however, and entering the venous current already deteriorated by organic refuse, it is quickly eliminated by the respiratory tract, which thus becomes subjected to its beneficial local antiseptic effects without subjecting the system at large to injury, as when thrown into the arterial current. In other words, the parasite is killed, without killing the individual.

Its beneficial effects in phthisis are explained by the action of the gas on the suppurative and septic surfaces, and not by any influence on the bacillus tuberculosis; the consumption proper, the exhaustion, being due to the suppuration and to the consequent septicæmia, and not immediately to the bacillus, which, while it produces the destruction of tissue, does not produce the morbid phenomena. The method of administration utilizes the discovery announced by Bernard in 1857, that toxic materials introduced into the economy through an organ at a distance from the arterial system could not penetrate into the arterial system because it is eliminated before that system can be reached. Volatile sub stances are eliminated by the pulmonary alveoli.

The antiseptic substance employed is preferably sulphuretted hydrogen. This is propelled by means of a current of carbonic acid. It is important that the carbonic acid be freshly made, and that the injection be made without any admixture of atmospheric air, the presence of which will cause griping. The carbonic acid gas as evolved from the action of the dilute sulphuric acid upon sodium carbonate is collected in a rubber bag previously emptied of air by rolling it. This bag is then connected with a hand-ball compresser, by means of which the gas is propelled through natural sulphurous water in a sort of Wolfe bottle, driving off the sulphurous gas with it through a tube, the terminal extremity of which has been passed into the rectum. Within less than a minute the escape of the gas by the lungs can be detected in the breath.

The beneficial results obtained in pulmonary phthisis by Dr. Bergèon, and reported last July to the Académie des Sciences, have been confirmed by Professor Cornil, in a communication last October, to the Académie de Médecine, by numbers of French physicians, and by Dr. Hughes Bennett, of Mentone. Bergeon stated that the patients he considered practically cured, had no more expectoration, and only dry auscultatory signs of cicatrizing cavities, or other cicatricial results of old lesions. Some of them had become able to resume tolerable laborious employment, with full maintenance of the amelioration they had acquired. In most patients, it is said, there is a marked diminution of cough, expectoration and night sweats within two or three days. Nevertheless, the trifling expectorations of those apparently practically cured, continued to contain bacilli. This fact may be taken both for an indication that the immediate danger in phthisis is less from the bacilli than from the septicæmia which they set up, and as an indication that this protective treatment, when successful, should not be discontinued until the general healthiness of the tissues is sufficiently restored to resist the further development and sustenance of the bacillus tuberculosis.

Dr. William Osler said, that recently at the University Hospital, a patient very nearly expired after an injection of a mixture of carbon dioxide and sulphuretted hydrogen. He was not aware at the time that sulphuretted hydrogen, if given in sufficient quantities, is capable of producing poisonous effects even when taken by the rectum. This accident was mentioned lest similar mistakes may arise. Evidently the amount of sulphuretted hydrogen which is given must be small. At the Biological Society, at Paris, some experiments were related, which showed that even a few cubic centimetres are sufficient to poison a good-sized dog. In the experiences which are related in French journals, the odor of sulphuretted hydrogen is readily observed in the breath, but this has not been noticed in any of the Blockley patients. This is an exceedingly interesting, not to say comical, method of treating phthisis, but it is too early to say what the results are likely to be. Certainly, however, in Dr. Bruen's hands, at the Philadelphia Hospital, they have been extremely good.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, March 7, 1887.

The President, Edmund J. Doering, M.D., in the Chair.

Dr. Franklin H. Martin read a paper entitled

HYSTERO NEURASTHENIA, OR NERVOUS EXHAUSTION OF WOMEN.

(See page 365.)

Dr. J. G. Kiernan said: I might quarrel a little with the name adopted, as a somewhat useless addition to disease nomenclature; for it seems to me that most of the symptoms given are not characteristic of any particular disease other than the common form of nervous prostration occurring in women. Most of the symptoms given as regards the vagina, uterus, etc., are such as we would expect to find secondary to nervous exhaustion in females. Dr. Martin has not outlined the difference between a condition of neurasthenia, which occurs in a female of previously sound constitution both from heredity and other standpoints, and the condition of the woman whose ancestors have been the victims of neurosis or hereditary disease, or who has acquired a neurotic constitution. In the first of these forms a great deal can be done by combating the exhaustion, and no better system can be given than that which has been

outlined by Dr. Martin. In the last type this treatment is worse than useless. I remember that a number of patients whom S. Weir Mitchell had treated afterwards came to the private insane hospital to which I was at one time physician. With this class of patients the trouble is with the brain, and in most it is congenital. In them the *ego* is of superlative development; they are perfectly willing to be petted and fussed over, but that simply tends to develop the egotism in certain directions. In this class of cases massage is peculiarly noxious, since in many of them there is a sexual element which is likely to be increased by massage, as has been pointed out by Murrell and others. In regard to medicinal treatment, Dr. Martin has not indicated the danger of inducing habits in some of these cases by the prescription of morphine and alcohol, as Dr. Mary H. Thompson some years ago pointed out in this Society. Many a neurasthenic person has become the regular inmate of an inebriate asylum or home for opium habitues, because some physician has prescribed opium or alcohol for the treatment of insomnia.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, February 9, 1887.

The President, Jos. Taber Johnson, M.D., in the Chair.

Dr. H. D. Fry read a paper entitled,

THE VALUE OF THE ANTISEPTIC METHOD IN OBSTETRIC PRACTICE AND ITS APPLICATION TO THE FORCEPS OPERATION,

and exhibited Breus' modification of Tarnier's forceps. He spoke of the advances which had been made in recent years in the practice of obstetrics, and of the reduction of childbed mortality that had followed these improvements. He directed attention more particularly to the germ theory of disease in relation to the pathogenesis of puerperal fever, and to the adoption of antiseptic precautions for the prevention of the affection. The brilliant result that had followed the application of this line of treatment in maternity institutions was mentioned, and the antiseptic precautions demanded in the forceps operation were then dwelt upon. These precautions differ but little in detail for the various obstetrical operations, and those applicable to this one may be employed for others when modified by changes to meet the exigencies of particular cases.

The objects sought are three fold:

1. Preventing the transport of germs to the genital canal of the woman.

2. Killing those which elude our vigilance, and

3. Limiting the production of traumatic injuries as much as possible.

Dr. Fry then applied these principles to the forceps operation, and stated the rules to be observed in such practice.

Dr. S. C. Busey asked Dr. Fry if he had any statistics showing the relative proportion of cases of puerperal fever following the use of forceps and without their use.

Dr. L. Mackall asked how long Dr. Fry had been using antiseptics, and with what result?

Dr. Fry replied to Dr. Busey, that he had no such statistics, and to Dr. Mackall, that he had been using them two and one-half years and with the most gratifying results. During the first year he used antiseptics only on every other case of midwifery. He, however, visited all his obstetric cases once, sometimes twice a day, and took the temperature and other notes at each visit. At the end of the year he compared notes, and found that the average temperature in the cases in which antiseptics had been used, was lower than in the others; in fact, the cases had not had the usual rise, the so-called "milk fever," and they had in every way a much better "getting up." In forceps cases, even with a lacerated perineum, there was usually no rise of temperature above 100°. In but a single case has he seen, in two years, "milk fever," and that was when he had forgotten to bring his tablets with him. He did what he could in the way of washing his hands, but the temperature reached 102 on the second day.

In reply to Dr. T. C. Smith as to what he thought the mortality of private obstetric practice ought to be, Dr. Fry replied, about 25 per cent.

Dr. T. C. Smith, quoting from the Health Report of Washington, for the year ending June 30, 1885, said that twenty-nine deaths were put down to puerperal fever. There were also 3334 births reported, which makes the mortality less than .9 per cent. The births probably reached 4,000, as all of them are never reported, which makes the per cent. even lower. The twenty-nine deaths were from various causes, all being put down under the general term "puerperal fever." When we recollect that a large majority of the births are in charge of midwives and in colored women in the worst possible hygienic surroundings, is there any wonder that there should be twenty-nine fatal cases? Moreover there were 393 illegitimate children and 391 stillbirths, both conditions bearing directly upon maternal mortality. Are there not sufficient causes to indicate that something besides "germs" kill? He said that he never had a serious case of puerperal fever after the use of forceps. He recalled one case of a primipara whom he delivered with forceps, and in ten days she was well.

At her next labor, he arrived too late to be of assistance and she was six weeks in getting up. Another woman he had delivered three times with forceps, but on the fourth he used neither ether nor forceps, and both he and she were sorry for it. He mentioned two other cases in which he had used the forceps, in spite of torn perineums, both made a rapid recovery.

He thought that douches during labor remove the mucus, the natural lubricant of the vagina, and that after labor they are worse than useless, for if nature had intended the parts to be antiseptic she would have made them so. In his opinion the lochia are antiseptic, for they plug the open absorbents, and if they are removed by douches there is an increased chance of infection. If we expect to keep out germs, we must go back of the vagina into the uterus,

where there is a large surface of open mouthed veins ready to absorb them. Yet he ventures to assert that there are not a half-dozen doctors in Washington, who wash out the uterus in all cases, or even three who use intra-uterine injections after the forceps. He thought that in a population where there was so much bad hygiene, illegitimate pregnancies and abortions, that it was surprising that there were "only" twenty-nine deaths from puerperal fever.

Dr. A. Y. P. Garnett said, that now-a-days when any man opposed antiseptics, he laid himself open to criticism. He thought that individual experience was worth more than all the hospital statistics put together. He has a pair of forceps with which he has delivered sixty-two women; he has never used antiseptics, and has never had a case of puerperal fever in these sixty-two cases. He thought that the great value of Listerism was in the systematic cleanliness which it introduced into medicine and surgery; this, with better hygienic surroundings, was more potent for good than the killing of germs by antiseptics. He expressed little faith in the germ theory.

Dr. S. C. Busey has more than once committed himself to antiseptic obstetrics. He may not follow the details of some of its most enthusiastic followers, but he always, to a greater or less degree, follows the antiseptic treatment in puerperal cases. Dr. Smith was wrong if he thought that those who adopted this method of treatment believed it would or ought to save every puerperal woman. They claimed, and it had been proven, that antisepsis had greatly reduced the mortality of the lying-in. The statistics Dr. Smith had quoted were only accurate in showing the number of deaths, but were valueless in regard to the causes of death. Maternity hospitals supplied the most reliable statistics, and they exhibited a greatly diminished mortality since the introduction of antiseptic midwifery. In his opinion, absolute cleanliness was the essential part of antisepsis. He frequently relied upon cleanliness and hot water vaginal injections. In all cases of post partum hæmorrhage and adherent placenta, and in some cases of instrumental labor, he employed intra-uterine hot water irrigation with the most satisfactory results. He would not advise intra-uterine irrigation as a routine practice, but whenever he had employed this method he had a rapid and complete convalescence. He believed the lochial discharge was a pathological rather than a physiological discharge. The statement that one may have had 100 cases of obstetrics without a single death, though not using antiseptics proves nothing. The next 100 cases may show a very different result. It is only in dealing with larger numbers that the value of antisepsis can be shown. The results in large maternity hospitals where it has been employed demonstrate its value. In private practice and in the country where the cases are isolated its value is not so apparent. He did not consider all the minute details of the antiseptic method essential to success in every case. They may be sometimes overdone, but we cannot tell in which they may be safely dispensed with. We do know there is vastly less serious illness and fewer deaths since their introduction.

Dr. C. W. Johnston said that Dr. Smith mentioned with surprise the fact that only twenty-nine women a year died of puerperal fever, when we consider the fact that a great number are "colored" women with the worst hygienic surroundings, etc. So far as his observation goes, and he believes the experience of the President agrees with his, he finds the colored race peculiarly insusceptible to certain inflammatory diseases which are destructive to the whites. In his service at the Central Dispensary, in about 500 colored and white women, equally exposed to disease, he found relatively fewer colored women suffering from pelvic inflammation than he did white women. Among the colored there are frequent cases of venereal disease, but even in those with the so-called "latent gonorrhœa" he has been able to find but one case of pyosalpinx.

Dr. Mackall said the statements made by Dr. Fry had made more impression upon him than all the statistics. It is true that he thought he had seen but one fatal case of puerperal fever, and that in consultation, he had always considered himself lucky to get off without trouble after forceps delivery. In his experience there has usually been more or less offensive discharge in these cases. He does not believe that there is a specific germ for puerperal fever, but some malign influence conveyed to the woman, from either a cadaver, a case of erysipelas, or something of that sort. Formerly we were unable to stop the epidemics of what was then called "metritis," with calomel, etc., but lately he has seen severe cases checked by bromo chloralum, which was the form of antiseptic he used. He contends that if such a result can be obtained from antiseptics in an infected system they must be infinitely more valuable as a preventive of the ingress of the poison.

Dr. Smith said that the hospitals of the present day were not as they were—say sixty years ago. In those days there was faulty drainage, and as likely as not cess-pools were just under the windows. One could not expect such results as we get now a days, under those conditions. Dr. Busey had referred to the use of antiseptics in post-mortem hæmorrhage. In one of the cases he had just alluded to there had been tremendous hæmorrhage which he had stopped by packing with ice. No antiseptic had been used, and still there was a good recovery. In another case in which he had applied the forceps to the after-coming head, there had been no fever, though without the use of antiseptics. Dr. Busey says that he may have septicæmia at any time unless he uses antiseptics. He would say to Dr. Busey that *he* may at any time meet a case which antiseptics would not save. He did not believe that a germicide strong enough to kill the germ would be tolerated in the uterus. One of the most poisonous of gases, sulphuretted hydrogen, is common enough in the intestine, and yet nearly every child has had intestinal worms of some sort, upon which the poisonous gas failed to act.

Dr. Mackall asked Dr. Fry if he has had any cases of mammary abscess since using antiseptics. He has had several cases, all following fissures of or about the nipples. He understands it is claimed that the use of antiseptics is preventive of abscess. The

need of forceps is increasing. One supposes that he is going to have a short labor, but the pains gradually diminish in intensity and the head stops in its descent. Ergot has no effect or is dangerous; it may be successful in starting up pains or it may fail, chloral has failed; and finally resort to the forceps is necessary. If, as seems probable, the danger to the mother is increased by their use, we must find some means to lessen the mortality, and this we seem to have in antiseptics.

Dr. Fry, in closing, said that puerperal fever does not occur often in the practice of midwives and in the class of patients which Drs. Smith and Gleeson speak of as being attended by these women. It was this fact, among others, that led Semmelweiss to make the investigations that subsequently laid the foundation for antiseptic treatment. The disease is far more prevalent among the patients attended by practicing physicians, and the infection is probably conveyed by the examining finger of the obstetrician. Parvin relates the case of a French surgeon who, after having visited a patient suffering with phlegmonous inflammation of the thigh, made a vaginal examination of his wife. The lady had been delivered seventeen days before, and up to that time was doing well. She contracted septicæmia and died. Dr. Smith says he has never had a serious case of any nature after the use of forceps; without them he has had four cases of puerperal fever and two deaths. He goes on to argue the question in such manner as to make one believe that the universal application of forceps would be desirable. In the case which Dr. Smith relates where forceps was used in three labors but not in the fourth, and the patient did well after all the labors except the last. Dr. Fry supposes that the same indications for the use of instruments existed in the last labor as in the others, and they should have been used.

Dr. Smith's objection to the use of vaginal douches during labor, and his theoretical ideas regarding the value of the vaginal mucus, cannot have much weight when opposed to the combined experience of obstetricians who have all the opportunities of perfecting antiseptic precautions by observation in maternity institutions. As a matter of fact Dr. Fry does not himself employ vaginal injections during labor unless it is protracted. He does, however, without exception, employ them before and after the use of forceps or any instrumental interference. He does not approve of antiseptic vaginal injections during the puerperium unless demanded by some complication—fetid lochia, fever, etc. He quoted from an article by Dr. Baruch, of New York, the results of a number of maternity hospitals, all of which employed antiseptic precautions. These precautions were much the same in all of the hospitals except one class used vaginal douches during the lying-in, while the other only made use of them when specially indicated. The advantage, as demonstrated by percentage of recoveries, was strongly in favor of the latter.

According to Dr. Smith, if prophylactic douches be given at all, they should be applied into the uterine cavity. This is directly contrary to the chief rule of antiseptic treatment, which teaches that everything is dangerous that is not absolutely necessary. The dangers of prophylactic intra uterine injections have been demonstrated by Hoffmeier. In a series of cases, over 200 in number, he administered an intra uterine injection as soon as labor was completed, and in another series of about the same number of cases, he omitted the injections. The morbidity was fifty per cent. greater in the cases that were treated by the injections. Even when fever exists, intra-uterine injections should not be used until vaginal douches have failed to give relief. Delay, however, must not be permitted many hours.

Dr. Garnett attributed to cleanliness the success of the antiseptic system. It is, indeed, the basis of that system, but epidemics of childbed fever were not arrested until antiseptics were employed. When Semmelweiss began his labors at the Vienna Obstetric Clinic, he found a maternal mortality of more than 5 per cent. cleanliness, ventilation, and isolation were brought to bear against the disease, and it went up in spite of all to a 10 per cent. death rate. A solution of chloride of lime was employed to wash the hands, instruments, etc.,-and the performance of operations prohibited, and the mortality immediately dropped to 1.25 per cent. Dr. Smith asserted that an antiseptic solution strong enough to kill germs cannot be used for intra-uterine injection without injury to the woman. A solution of bichloride of mercury 1 to 20,000 is strong enough to destroy the vitality of micro-organisms, and yet it is used for intra-uterine injection in the proportion of 1 to 2000. The excellent results that follow antiseptic treatment are not attributable, as Dr. Smith suggests, to the use of modern and well-built hospitals. The success is equally great in the older institutions, which formerly were scourged by puerperal fever. The Paris Maternity and the Vienna Hospital illustrate this fact.

Dr. Fry had met with but two cases of mammary abscesses in his practice, and suppuration had occurred in these before they came under observation. Dr. Alloway, of Montreal, says he has not had a case of suppurative mastitis since he has been employing antiseptic vaginal douches during and after labor, while before that practice was adopted it was not uncommon. According to the observations of Behm, the staphylococcus and streptococcus are found in the pus of mammary abscesses, and he offers the more plausible theory that they gain access to the gland lobules through fissures of the nipple.

DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Diabetes—Large Ventral Hernia—The Aneurismal Diathesis—Glycozone.

At the last meeting of the County Medical Association Dr. Austin Flint made some very interesting remarks concerning diabetes, of which, as is well

known, he has of late years been making a special study. The case which suggested them was one which was related by Dr. Gouley. The patient was a lady 72 years of age, who suffered from ventral hernia for more than twenty years, and Dr. Gouley said it was the largest ventral hernia that he had ever seen. She had also been diabetic for at least thirteen years, and the form of glycosuria with which she was affected was that which the French term intermittent glycosuria. She finally died of exhaustion in an attack of acute bronchitis, and at the autopsy the hernial sac was found to consist of nothing but skin, and that very thin. Dr. Gouley said he had always advised against operative interference in the case, and the condition of affairs found after death showed how unavailing any operation would have been. The sac contained the entire intestinal canal, with the exception of the duodenum, the caput coli, and the rectum; so that it could not possibly have become any larger than it was. The diameter of the neck of the sac was no less than nine inches. There was marked sclerosis of both the kidneys and of the spleen, and this condition was no doubt attributable to an old mitral stenosis which was found to be present.

In commenting upon the case, which he had seen in consultation with Dr. Gouley, Dr. Flint remarked that it presented some points of extreme interest to him. This intermittent diabetes was a variety of the disease which he had seldom observed, and in regard to which he said he had formerly been somewhat skeptical. There could be no doubt, however, that this was an instance of true intermittent diabetes, and not one of those cases, of which he had seen quite a number, in which the sugar disappears from the urine for a time after the patient undergoes a moderate restriction of diet. The case was of great interest, again, as regards the matter of diabetic coma. This patient had at no time exhibited the slightest tendency to coma, but retained consciousness perfectly up to the last. In her enfeebled condition she was unable to dislodge the mucus accumulated in the bronchial tubes, and died simply of exhaustion.

Dr. Flint then referred to another case of diabetes which he had recently seen in consultation with Dr. Frederic Dennis. The patient was a lady 70 years of age, who for seven or eight years had had diabetes which was by no means of an intermittent character. On the contrary, it was persistent in character, and was attended with nearly all the typical symptoms of the disease. For some time the case had been under the care of Dr. Lusk, but on account of the fact that gangrene attacked one of the patient's feet it was transferred by him to Dr. Dennis. She had been taking very large quantities of milk daily, and this was stopped by Drs. Dennis and Flint, who also placed her upon a very strict anti-diabetic diet and gave her Clemens' solution of arsenite of bromine in 3-drop doses. Under this treatment the improvement in her condition was very marked. The quantity of urine passed *per diem* was reduced from 110 to 50 ounces, and sugar was entirely eliminated from it. The condition of the foot also improved for a time, but the gangrene afterwards extended, and the patient finally died of exhaustion. In this case, also, the patient's mind remained perfectly clear to the last, and there was not the slightest approach to anything like diabetic coma.

Dr. Flint went on to say that during the last two or three years he had accumulated records of almost ninety cases of diabetes, and that he had taken unusual care to follow them up. Some of the patients had died under his observation, but he had never yet met with a single instance of diabetic coma. He had, however, records of cases, seen by him at one time or another, which had terminated fatally under other physicians, and in which the patients were reported by them to have been the subjects of diabetic coma. In this connection he related the case of a very wealthy lady to whom the restraint of the restricted anti-diabetic diet became intolerable and who, on leaving for the country, announced her intention of trying the effect of a return to general diet for a time. He afterwards learned that she had died in a state of coma. He also knew of another case in which the patient died of diabetic coma after indulging in a protracted "sugar debauch." In still another case the patient had died in the same way after travelling to Carlsbad. During the journey to that resort she had lived upon an unrestricted diet, and he had been informed by her physician that by the time she arrived there she was in a practically hopeless condition.

The idea had been expressed in certain quarters that the restriction to anti-diabetic diet tended to produce diabetic coma; but Dr. Flint's experience was directly opposed to any such theory. So far from its leading to this condition, he was convinced that it was extremely rare for patient's to die of diabetic coma while they were living on a strict anti-diabetic diet, and he believed that this restricted diet actually prevented, or tended to prevent, diabetic coma. This condition was apparently due to the presence in the blood of some obscure poison which the kidneys were unable to throw off, and it was noticeable that when the coma came on, the sugar disappeared from the urine. He was at present engaged in a series of investigations upon this important subject, and hoped that at no distant date he should be able to ascertain certain facts which might perhaps throw some light upon it. In conclusion, he made some remarks upon the neglect of patients to faithfully carry out the anti-diabetic regimen. It was this which had brought the method into bad repute, and he thought that physicians, as a rule, did not pay sufficient personal attention to the diet of their cases. It was very important that this should be made as pleasant as possible for the patient, and that no efforts should be spared to constantly tempt his appetite with novel articles and dishes belonging to the allowable class.

The paper of the evening was by the President of the Association, Dr. John Shrady, and was on the subject of *The Aneurismal Diathesis*. He said that he was not sufficiently settled in his convictions to formulate any law comprehensive enough to embrace all cases, but thought he was warranted in making the

statement that a tendency to aneurism might be recognized in the following instances:

1. In individuals possessing a large, not necessarily hypertrophied, heart, the pulsations of which are quick and forcible; this condition generally being present in the long-bodied and short-limbed. These individuals are necessarily muscular, to compensate for a relatively poorly developed osseous system.

2. There are certain racial configurations in which fatty degenerations are prominent, as, for example, among the Teutons, and exceptionally among the Celts, in which the aneurismal tendency is a marked feature.

3. There may be an induced or cultivated diathesis, as among those addicted to athletic sports, who primarily over-tax the heart, and secondarily the circulation.

4. Obesity, as presenting an enfeebled resistance to forces which have been adjusted to a different condition of things.

5. The diathesis may be latent from lack of circumstances awakening it into existence, as in the case of those leading lives of luxury and ease.

In conclusion, he remarked that the absence or suppression of the emotional temperament may retard or altogether avert the final catastrophe.

On this occasion he introduced to the notice of the Association two new antiseptics and disinfectants, which he had tested with very satisfactory results in his own practice. These are glycozone, consisting of chemically pure glycerine with four volumes of ozone, and solution of peroxide of hydrogen, and they both possess the advantages of being colorless fluids.

As Mayor Hewitt was prohibited by the law from appointing a physician successor to General Shaler, as President of the Board of Health, he did the next best thing by giving the position to an expert in sanitary science outside the profession. Mr. James C. Bayles, the Mayor's selection, for the past sixteen years has been editor of the *Iron Age and Metal Worker*, and has long been considered an authority on drainage and sanitary engineering. In addition, he is a gentleman of much public spirit, and while his appointment has been a source of chagrin to the politicians, the community in general has every reason to be satisfied with it.

At the commencement of the University Medical School this year there were 151 graduates; at that of the Bellevue School 134; and that of the Long Island College Hospital, in Brooklyn, 30. The thirtieth annual commencement of the New York College of Veterinary Surgeons and School of Comparative Medicine, was held at the Carnegie Laboratory March 16th when the address to the graduates was made by Prof. Joseph H. Raymond, of Brooklyn, and the diplomas were presented by the President, Dr. Wm. T. White. This is the oldest veterinary school in the country, having been chartered in 1857, and its friends have of late been interesting themselves greatly in its behalf; so that it is now provided with a most excellent Faculty, and with every needed facility for the successful scientific and practical study of this department of medicine. ASSOCIATION ITEMS.

AMERICAN MEDICAL ASSOCIATION.

SECTION OF OBSTETRICS AND DISEASES OF WOMAN.

The following papers, in addition to those mentioned in The Journal, January 15, 1887, are announced for the June meeting in Chicago:

1. Ely Van de Warker, Syracuse, N. Y., "Laparotomy as a Cure for Tuberculosis of the Peritoneum."

2. John A Miller, San Francisco, Cal., "Erosions *vice* Ulcerations of the Vaginal Portion and their Relation to Lacerations of the Cervix, with Practical Hints when not to Perform Emmet's Operation."

3. John Morris, Baltimore, Md., "Treatment of Placenta Prævia."

4. Wm. M. Findley, Altoona, Pa., "Ante-partum Hæmorrhage."

The following gentlemen have signified their intention of contributing papers, but have not yet announced the topics:

H. F. Campbell, Augusta, Ga.
L. Ch. Boislinière, St. Louis, Mo.
S. S. Todd, Kansas City, Mo.
E. H. Trenholme, Montreal, Can.

[Signed] F. M. Johnson, M.D., *Chairman*,
Kansas City, Mo.
W. W. Jaggard, M.D., *Secretary*,
2330 Indiana Ave., Chicago.

MISCELLANEOUS.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 19, 1887, TO MARCH 25, 1887.

Capt. Wm. W. Gray, Asst. Surgeon, leave of absence further extended two months. S. O. 62, A. G. O., March 17, 1887.

First Lieut. Guy L. Edie, Asst. Surgeon, leave of absence extended three months. S. O. 67, A. G. O., March 23, 1887.

First Lieut. Jefferson D. Poindexter, Asst. Surgeon (recently appointed), ordered for temporary duty at U. S. Military Academy, West Point, N. Y., relieving Capt. Richard W. Johnson, Asst. Surgeon, who will return to his proper station (Ft. Adams, R. I.). S. O. 62; A. G. O., March 17, 1887.

Capt. Frank Reynolds, Asst. Surgeon (retired), died March 4, 1887, at Oakland, Cal.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING MARCH 26, 1887.

Cordeiro, F. J. B., Asst. Surgeon, detached from the Navy Yard, Boston, and placed on waiting orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE TWO WEEKS ENDED MARCH 26, 1887

Bailhache, P. H., Surgeon, to proceed to Mobile, Ala., Pensacola, Fla., Ship Island, Miss., and New Orleans, La., as inspector. March 14, 1887.

Long, W. H., Surgeon, granted leave of absence for seven days. March 16, 1887.

Goldsborough, C. B., Surgeon, granted leave of absence for thirty days. March 14, 1887.

Devan, S. C., P. A. Surgeon, to proceed to Tacoma, Washington Territory, as inspector. March 19, 1887.

Long, W. H., Surgeon, leave of absence extended five days. March 23, 1887.

Urquhart, F. M., P. A. Surgeon, relieved from duty at Norfolk, Va; ordered to Washington, D. C., on special duty. March 22, 1887.

Pettus, W. J., Asst. Surgeon, when relieved by P. A. Surgeon Guitéras, to remain at Charleston, S. C., "waiting orders." March 24, 1887.

ORIGINAL ARTICLES.

OPERATIONS FOR PHIMOSIS AS A MEANS OF CURE OR RELIEF OF SOME NERVOUS AND OTHER SYMPTOMS.

Read before the Washington Obstetrical and Gynecological Society, June 15, 1883.

BY G. L. MAGRUDER, M.D.,

OF WASHINGTON, D. C.

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, MEDICAL DEPARTMENT GEORGETOWN COLLEGE; IN CHARGE OF DISEASES OF CHILDREN, CENTRAL DISPENSARY, ETC.

Recent continued success in the relief of nervous and other troubles by the operation of circumcision and breaking down of the adhesions sometimes found existing between the prepuce and the glans penis, has induced me to submit the report of some cases, with a few remarks thereon. Since the date of the publication of Dr. Sayre's operations in 1870—upon reflex nervous disturbances—much has been written both *pro* and *con*. The mass of testimony derived from actual experience has been steadily accumulating to prove the value and truth of his announcement. But notwithstanding this, there are some persons who still seem either to ignore or, at least, to overlook the value of the statements that have been published.

I shall not attempt to enter deeply into the pathology of the troubles attending congenital phimosis, with or without elongation and adhesion of the prepuce, but will be content with a bare narration of facts as they have appeared to me. Research into pathological conditions can never be very satisfactory, for the want of opportunity to investigate the same, since the relief of symptoms almost always ensues upon the removal of the exciting cause, and, should death occur from other causes whilst one was suffering from these troubles, the immediate cause of death would probably mask the condition derived from preputial irritation.

This subject has interested me greatly. My experience has been derived from largely over a hundred cases. In nearly all there was either phimosis, elongated prepuce or adhesions, sometimes both. Amelioration, and more frequently perfect success, rapidly followed the removal of the abnormal conditions—occasionally no relief was obtained. The improvement, more often than not, was obtained without the assistance of any medication. In some cases tonics or sedatives were required for awhile. At times the relief given has been beyond expectation.

Case 1.—F., from the day of his birth, had to have a catheter passed night and morning to empty the bladder. All other means failed to give relief. The orifice of the prepuce was so small that it was with difficulty I could force the instrument. Upon the fifth day I circumcised the child. Relief was immediate and permanent.

Case 2.—W. L., aged 2 years, was very backward in walking. After he did commence to walk, his gait was very uncertain, and he stumbled at the slightest irregularity in the floor. Slight talipes valgus was appearing in both feet. Examination showed adhesions of prepuce extending almost to orifice of urethra. These were broken down and a large amount of smegma was removed from around the corona glandis. This accumulated rapidly, and was daily removed by the mother. Gaiffe's battery was used on the muscles of the leg twice a week for four weeks; by the end of this time the improvement was very marked. Recovery was perfect.

Case 3.—P., aged 2, had not walked; was able to stand for a brief while by the side of a chair. Locomotion was accomplished upon his buttocks by thrusting his feet first on one side and then on the other. Adhesions were broken down. Very soon the child was able to use his legs.

Case 4.—Willie G., aged 4, had suffered continually with incontinence of urine. The mother informed me that this was a nightly occurrence. Circumcision was performed. During the process of healing urine was passed involuntarily once or twice. In this case, the cicatrization caused the glans to be compressed. The trouble returned occasionally. A pair of dressing forceps inserted under the prepuce and forcibly opened broke up the adhesions and relieved the contraction. There was no return of the incontinence.

Case 5.—Francis McN., aged 11, was brought to my service at the Central Dispensary complaining of pain in the left hip joint, outer side of thigh and knee joint. These pains continued at night when in bed, and frequently were more severe at this time. There was decided atrophy of the muscles of the back and of the inside of the thigh. The left leg was much weaker than the right; frequently it would give way under him, thereby causing him to fall. The least unevenness in the roadway would cause him to stumble. He had been under the care of two physicians at different times during the preceding two years. One pronounced the patient as suffering from hip-joint disease and so treated him for awhile. I did

not hear the other diagnosis. Circumcision gave perfect relief both from the pain and the impaired locomotion. Recovery was complete. This case might readily have been mistaken for one of hip-joint disease. A number of months have now elapsed since the date of the operation, and there has been no return of the unpleasant symptoms.

Case 6.—Wm. D., aged 10, has always suffered greatly when he urinated. The father tells me that the agony is terrible and that it requires some time for him to empty the bladder. Examination disclosed an irritated prepuce. Adhesions existed almost to the orifice of urethra. Upon breaking these down marked relief was obtained, and entire relief was given as soon as the laceration of the ruptured adhesions was healed.

I have found this abnormal condition of the genitals in all my cases of hernia in children. I have only seen one case of talipes in girls. In all of those in boys, I have noticed phimosis, adherent or elongated prepuce. In November, 1881, this subject was discussed by the Neurological Society of New York. Having been requested by Dr. Seguin, through my friend Dr. Burnett, to send him a summary of my experience, I forwarded him the following account of some of my cases. This was printed in the report of the proceedings in the *Medical Record* of November 19, 1881. Through some mistake they were credited to Dr. McGuire, of Washington, instead of myself. I will here give them:

Case 1.—J. M., aged 18 months, had been troubled with incontinence of urine for several months. Prepuce much elongated. Performed circumcision January 15, 1876. No medicine was given. Perfect relief obtained. No return of trouble to this date.

Case 2.—J. W., aged 8 years. This boy had continual incontinence of urine for several years; drawers were always wet. Prepuce much elongated and adherent. Performed circumcision April 16, 1880. May 13, 1880, the dribbling during the day had almost ceased. He has passed water in bed four times at night since the operation. Small doses of strychnia were given. There was marked improvement, but not perfect success. Medication was continued. At present he is well.

Case 3.—G. T., aged 10 years, April 15, 1880, complained of constant pain in popliteal space of left leg; great weakness of the legs, headache, palpitation on the least exertion. Broke down adhesions which extended to orifice of urethra; gave no medicine. June 22, 1880, perfect relief; no return of symptoms.

Case 4.—January 15, 1880, John D., aged 19 months, cannot walk, stands with difficulty, head is thrown back; is peevish, restless and bow-legged; whines continually. Ordered malt, cod-liver oil and hypophosphites. May 6. the child is stronger, but the above symptoms still persist. Examined penis. Adhesions broken down and smegma removed; medicine continued. May 20, marked improvement. Adhesions had reunited; again broke them down. August 16, child walks readily.

Case 5.—John B., aged 2 years, has great muscular debility of the lower extremities; locomotion difficult. Prepuce elongated. Circumcised June 21, 1880. On 28th much stronger, walks better. August 16, improvement continues. There is slight inclination to talipes valgus. This case has required constant care up to the present time. His condition now is very favorable.

Case 6.—July 29, 1880, W., aged 3 years, cannot walk readily. Has incontinence of urine. Broke down adhesions and removed a large amount of smegma. October 18, no return of incontinence; walks much better.

Case 7.—Charles H., aged 6 years. This child was very backward in walking; is now weak in lower extremities, has incontinence of urine and inguinal hernia. August 5, 1880, broke down adhesions and removed a quantity of smegma. August 19, marked improvement. September 6, much stronger; no return of incontinence.

Case 8.—C. R., September 23, aged 2½ years, is unable to stand; very little power in legs, muscles of thigh loose and flabby. Circumcised and broke down adhesions. Ordered malt and hypophosphites. October 31, 1881. To day the child runs around readily.

Case 9.—Jos. W., aged 2 years, August 16, 1880, walks with great difficulty, drags his legs and is easily pushed down. Adhesions were broken down August 23. Walks without dragging his legs. September 27 circumcised him. October 4, marked improvement. The progress in this case was not so decided as in others. Gaiffe's battery was applied. This seemed to be beneficial.

Case 10.—Pierce W., aged 2 years, stumbles on coming in contact with the least elevation; walks very awkwardly. Slight talipes valgus. Circumcised and broke down adhesions. Marked improvement.

Case 11.—Wm. F., aged 2 years, is unable to stand, has laryngismus stridulus. Muscles of thighs and legs very poorly developed. The laryngismus was treated for one week without any improvement, then he was circumcised and the treatment continued. One week later he was better and could stand by a chair. Improvement was continuous and rapid.

Case 12.—Willie B., aged 1 year, is very weak throughout the whole left side. This side is not so well developed as the right. He drags the left foot when he crawls, and has had frequent convulsions. Circumcised and broke down adhesions. Three weeks later the child had much better use of his extremities. The improvement continued. Electricity was used in this case.

Case 13.—E. L., aged 11 years. Incontinence of urine. Broke down adhesions. No improvement.

Case 14.—W. E., aged 4 years. This child had a severe case of talipes equino-varus. The tendo-Achilles was cut and the foot brought into position. About four months afterward I noticed the prepuce much elongated. Circumcised and broke down adhesions. Brace was applied and electricity used. The improvement was rapid and excellent.

Case 15.—Richard G., aged 4 years. Incontinence of urine. Circumcised and broke down adhesions. Perfect relief.

Case 16.—W. B., aged 13 years. This boy had convulsive seizures almost continually, sometimes

forty or fifty in the twenty-four hours; would awake and scream out during the night. Easily excited, and would at times be almost uncontrollable. Prepuce elongated and adherent. Broke down adhesions December 15, 1880. Ordered no medicine. I saw him again January 11, 1881. He had not taken any medicine since I broke down the adhesions one month ago. The attacks during the day had recurred very rarely and the nights were very much less severe. Circumcised him October 23, 1881. The improvement has been decided and continuous. For awhile after the circumcision there was immunity from the convulsive seizures for a week or more at a time. Then they would return occasionally at night. To control this I gave bromide of potassium. Now he goes to school regularly. His teacher gives excellent reports of his behavior and progress in his studies.

Case 17.—Joseph L., aged 6 weeks. This was one of the most interesting and pronounced cases that have ever come under my observation. He had never had a good night's rest since his birth, and had to be drugged to have the least rest. He cried almost incessantly night and day. The legs were in constant motion, sometimes striking the abdomen. The penis was in a state of priapism. As soon as it was touched the convulsive movements were augmented in severity and rapidity. In each inguinal region small tumors appeared when the child cried. I circumcised him March 28, 1881. As there had been such severe muscular action, I ordered ½-grain doses of chloral every hour until quieted. During the ensuing four days he took 8 grains of chloral, then medicine was discontinued. All the nervous symptoms have disappeared. The child slept readily. Three months after the operation, the mother told me that from the second day thereafter, she had not had a particle of trouble with her boy.

Case 18.—B. P., aged 10 weeks. Had not had a good night's rest since his birth. Cried and fretted almost continually. Was in constant jactitation. The urine would accumulate under the prepuce and dribble out through a very small orifice. The head was thrown back on the spinal column. The mother said that she used to pass a handkerchief around the head and fasten the ends of it to the belly band to keep it erect. Performed circumcision—did not order any medicine. Every symptom of irritation disappeared. Three months later there had not been the least evidence of return.

Case 19.—A. F., aged 13 years. Had shown great muscular debility in the lower extremities from birth, especially in the left leg. This leg would give way under him. He would fall on the street and around the house. He complained of dizziness and pain in the lumbar region, also had nocturnal incontinence of urine. Prepuce firmly adherent, almost to the orifice of urethra. I broke these down Jan. 19, 1880. No medicine was employed. There was no return of a single symptom except upon one occasion, there was incontinence of urine. He has continued to grow stronger, and is to-day, Oct. 15, 1881, brighter than ever before.

To better understand this subject it will be well to hurriedly consider the nervous supply and connections of this region.

The nervous supply to the genital organs is derived from the pudic nerve of the cerebro-spinal system and the pelvic plexus of the sympathetic system. The pudic nerve is a large branch of the sacral plexus and gives off in its course, the inferior hemorrhoidal nerve which supplies the external sphincter, integument around the anus and terminates in the perineal and the dorsal nerve of the penis. The perineal nerve is distributed by the cutaneous and muscular branches to the integument in front of the anus, the sphincter-ani, the scrotum and under part of the penis, the levator ani, transversus perinei, accelerator urinæ erector penis, and compressor urethræ. The dorsal nerve of the penis accompanies the dorsal artery of the penis, and is distributed to the glans, prepuce, the upper surface and sides of the organ, and sends off branches to communicate with the sympathetic.

In the female, the pudic nerve terminates in the clitoris, labia majora and perineum. The other branches of the sacral plexus are the muscular, the superior gluteal, and the great and small sciatic. These supply the integument of the perineum and the back part of the thigh and the whole of the leg, the pyriformis, obturator internus, the two gemelli, the quadratus femoris, the glutei, the tensor vaginæ femoris and the adductor magnus muscles. Branches from this plexus supply the hip joint, perforating the capsule, and also the knee joint. Connection with the sympathetic nerve is had immediately through the large cavernous nerve, which after joining with the dorsal branch of the pudic nerve passes forward to supply the corpus cavernosum and spongiosum. This larger cavernous nerve is derived from the inferior hypogastric or pelvic plexus. This plexus distributes branches to all the pelvic viscera, viz., rectum, bladder, and the vagina in the female. Filaments pass to the vas deferens, vesiculæ seminales and prostate gland in the male. The connection with the rest of the cerebro-spinal and sympathetic systems is intimate.

Reflex spasm and paralysis from diseases of the digestive canal, the ovaries, uterus and urinary organs have been frequently observed. Why cannot the same phenomena arise from genital irritations? A. McL. Hamilton, in his "Diseases of the Nervous System" assigns phimosis as one of the causes of spasm. Henoch, in his lectures on "Diseases of Children" attributes incontinence of urine to a spasm of the detrusor urinæ which acts more vigorously because the action of the will on the sphincter vesicæ is diminished during sleep. He says that the urine is always passed in a stream during sleep or in a half waking condition. Amongst various causes for this reflex irritation he mentions first congenital phimosis. The removal of this condition has cured the enuresis. The same author, in speaking of spasm of the glottis, calls attention to the fact that it occurs more frequently in boys than in girls and almost exclusively between the sixth and twenty-fourth month. I think that every case that I have seen of this trouble, except one, has occurred in boys. In all that I have examined I have found either congenital phimosis or

adherent prepuce. Removal of these brought relief. Might we not consider that there was some connection between the two conditions?

Erichsen, after stating that Bryant had shown that various affections of the genito-urinary organs of children, such as incontinence of urine, intermittent flow, hæmaturia, priapism, etc., were due to phimosis, and that Sayre had pointed out the important fact that reflex paralysis in various forms of spastic contractions, chiefly of the lower limbs are due to the same cause, being readily curable by circumcision, says: "In addition to these I have seen general spasmodic affections in children resembling chorea, resulting from congenital phimosis." He also states that he has known it to be a cause of impotence in the adult. Further on he says: "Every child who has congenital phimosis ought to be circumcised, and even those who, without having phimosis, have an abnormally long and lax prepuce would be improved greatly in cleanliness, health and morals by being subjected to the same operation; and it would be well if the custom of Eastern nations, whether it be regarded as a religious rite or only a time-honored custom were introduced amongst us."

Reflex paralysis is due, according to Romberg, Stanley, and Graves to a suspension of the sensory influence of the fibres of the sympathetic system and are motor spinal paralyses. Brown-Séquard attributes the origin to chronic irritation of the genito-urinary organs with secondary contraction of the vessels of the cord and atrophy of the corresponding parts. Levisson experimented by compressing the uterus, kidneys, intestine, or bladder of rabbits, and found reflex excitability abolished and a paralysis of the posterior limbs lasting until the irritation was removed. The paralysis was considered due to excessive irritation of the sensory fibres, thereby causing an arrest of the function of the motor-nerve centres.

Feinberg has observed in animals, after a coat of varnish, tremor, hyperæthesia, partial anæsthesia, increased reflex action, spasms and paralysis. Examination disclosed a dilatation of the cutaneous vessels, of the capillaries of the lung and the ramifications of the vena porta, hyperæmia of the meninges and a dusky redness of the cervical cord. If the animals survive a certain length of time, proliferation of the neuroglia occurs with atrophy of the nerve tubes from compression. Rosenthal, quoting these observations, says: "Thus the irritation of the cutaneous nerves produces a reflex paralysis of the centres of vascular innervation in the cord." Now, if this follows from irritation of the cutaneous nerves, can we not expect as much from irritation of the nerves about the head of the penis. The same author mentions the fact, that several cases had been referred to him by Prof. Dittel, which upon exploration of the bladder had given negative results, whilst a careful examination of motion and sensation showed a diminution of the various forms of sensibility in the legs; in the trunk there was abnormal excitability of the nerve trunks or of the genital organs. He cites a case of a girl, aged 23 years, who was relieved of a paresis of three week's standing, by the removal of a needle deeply imbedded in the vagina.

Leyden reported three cases of paraplegia following diseases of the bladder, which commenced by symptoms of motor and sensory irritation. He found diffuse softening of the cord in two cases. He thinks that a sacro-lumbar neuritis may be progagated to the cord in diseases of the bladder.

Dr. Otis has seen many nervous disturbances relieved immediately after the removal of genital irritation and believed that this was more than coincident; moreover, he was firmly convinced that reflex paralysis was possible. Dr. Hammond also admits the possibility of preputial irritation giving rise to paraplegia. Dr. Seguin has never seen reflex paralysis from irritation of the genitals of the male, but had seen reflex nervous troubles, and believed that the genital irritation should be relieved. He had met with paralysis from irritation of the deep urethra and uterine disease. Cure of the uterine disease was followed by rapid recovery from the paralytic symptoms. Dr. Campbell Black has seen hæmaturia, dysuria, incontinence, retention of urine, reflex paralysis, epilepsy, chorea, as well as spermatorrhœa, prolapsus ani, and other troubles from genital irritation. He, as well as Barwell give the priority of calling attention to these troubles to Dr. Sayre. Black attaches immense importance to genital irritation as a source of infantile paralysis and many other indications of nervous disturbance in childhood.

Barwell, ("Diseases of the Joints." Wood's Library, pp. 289 and 290) says: "A good many years ago I was struck with the fact that nearly all the boys admitted for hip disease into Charing Cross hospital had congenital phimosis. In a short time this coincidence was found to be nearly, if not quite constant. At last, in the beginning of 1873, I began to note, in a hundred male cases of hip disease occurring in my private practice or admitted into hospitals, the presence or absence of this condition; for the sake of better classification they were divided into classes:

1st Degree.	2d Degree.	3d Degree.	Elongation.	Normal.
39.	27.	17.	11.	6.

The same divided in ages—

	1st Degree.	2d Degree.	3d Degree.	Elongation.	Normal.
2 to 4,	3.	2.	0.	1.	1.
4 to 6,	7.	5.	2.	3.	3.
6 to 8,	16.	11.	9.	4.	1.
8 to 10,	13.	9.	6.	3.	1.

First degree: The opening in the prepuce, a mere pin hole, so that on retraction no part of the glans or only a minute portion of the urethral lips could be seen. Second degree, in which all or a considerable part of, but nothing beyond the utheral orifice could be uncovered. Third degree, in which the prepuce, when retracted, uncovered some portion, but only a portion of the glans. Fourth degree, elongated prepuce, projecting more than a quarter of an inch beyond the glans, but capable of entire retraction. Fifth degree, normal. It will be observed that of these cases eighty-three have phimosis; that only six have normally formed prepuces, and that from complete or the first degree of phimosis to which class more than one-third of the cases belong, the number steadily declines to normal. I would

also point out that these are not fortuitous coincidences, because for two years at least before commencing tabulation, this association was remarked. Furthermore, I asked my friend, Mr. Morant Baker, to inquire for me about the prevalence of hip disease at the Evelina Hospital, which is largely used by Jews. He tells me that few children are there admitted for hip disease, and that most of those so received belong not to Jewish, but to the Christian community. The important fact, however, is simply, coincidence of phimosis and hip disease—a coincidence which I should never have dreamed of or imagined, had it not been forced upon my observation. Upon the mode in which the one influences the other I would rather not speculate further than to point out that phimosed children have facile, frequent and often long continued priapism; that this condition, unnatural in the infant, must produce after a time a certain irritability or irritation of the lumbar spinal cord; that from this part the various nerves of the pelvis and lower limbs are given off; that the influence of spinal irritation on the trophic nerves is well known; and that just at this particular period large trophic changes are in progress about the hip joint." During the time that he was collecting these 100 cases in boys, he met with 74 cases among girls. In a large proportion of them he found vulvitis, vaginitis, protruding nymphæ or nymphæ covered by a cuticular surface.

Dr. Sayre noticed this same coincidence, and connected the condition with hip joint disease by the supposition that the majority of cases of this affection start from a fall or injury. The increased muscular debility from reflex irritation readily contributes to these falls.

Charcot, speaking of urinary paraplegia, says: "The very number of the cases in which we see paraplegia appear in the course of disease of the urinary passages is of itself enough to show that the phenomenon is no chance coincidence."

From the foregoing I think that we are justified in the conclusion that phimosis and adherent prepuce give rise to varied troubles of more or less gravity, manifesting themselves either in the muscular, osseous or nervous systems; and that the removal of these abnormal conditions of the penis frequently affords marked relief, and at times perfect and permanent cure.

THE IMPORTANCE FOR INSTRUCTION IN FIRST AID TO THE INJURED.

BY W. THORNTON PARKER, M.D. (Munich).
OF NEWPORT, R. I.
LATE A. A. SURGEON U. S. ARMY.

In 1884, while acting Post Surgeon at a lonely frontier station, I became very much interested in the work of the New York State Charities Association. I had been in correspondence with this organization for some time, before it occurred to me that some useful practical work in this direction might be accomplished in the United States military forces. I accordingly prepared the following letter, and as I have been informed that it was *probably* one of the first on the subject sent to our military medical authorities since the War, I will reproduce it here, merely to introduce the remarks I am about to make on military first aid to the injured. I have never received any reply to the letter, not even an acknowledgment of its receipt, and it was probably ignominiously pigeonholed:

To the Medical Director Dep't of the Missouri:

Sir:—I beg leave to call attention to the great success of the New York State Charities Association in organizing societies in various sections of the country for the purpose of affording instruction by lectures, illustrations, etc., in "First Aid to the Injured." The efforts have met with much general encouragement from the public, and their good effects have been recognized. It has occurred to me that it might be advisable to have something of this kind attempted at our military posts, providing suitable instruction in "first aid to the injured" to both officers and men. It undoubtedly frequently happens that officers in command of small detachments, deprived of the services of a surgeon, are called upon to extend aid to the sick and wounded, and although on more than one occasion officers have been found who were not only ready, but able to offer valuable assistance, yet a careful instruction in the course suggested would enable them to more fully afford relief and save considerable suffering. At all of our larger posts, and especially at Fort Leavenworth, this course of instruction could be very easily carried out, and suitable appliances being already on hand, little if any expense would be incurred to illustrate the lectures. It is reasonable to believe that many officers and men would be interested in these lectures, and only good would result to the Army by a general distribution of the knowledge which may be able not only to alleviate suffering, but even to save life. Very respectfully, your obedient servant, W. Thornton Parker,
Act. Asst. Surgeon U. S. A.

Ft. Gibson, Indian Ter., June 6, 1884.

It is possible, however, that the letter was referred from one office to another until at last it attracted some official notice in the War Department, and may have indirectly resulted in the promulgation of the following order, which must prove of considerable value to the Army in the near future:

General Orders, No. 86. Adjutant-General's Office, *Washington, Nov. 20, 1886.*

The Secretary of War being of opinion that instruction by lecture or demonstration in the simpler practice of medicine and surgery may with advantage to all concerned be given by officers of the Medical Department stationed at military posts to other officers and the enlisted men serving thereat, directs that, whenever practicable and where voluntary attendance in sufficient numbers can be secured, arrangements be made for a series of such lectures on the practical treatment of the unhidden diseases, early aid to the injured, the most expeditious and proper manner of treating temporarily gunshot wounds, poisoned wounds, frost-bite, bruises, dislocations, hæmorrhage, and fractures of bones; application of the tourniquet; the most approved method for resuscitation from drowning; and other kindred subjects.

Medical officers delivering these lectures will forward, not later than June 30, 1887, through the regular military channels, to this office, a report of the results, beneficial or otherwise, which may have attended them up to that date.

By command of Lieutenant-General Sheridan:

R. C. Drum, *Adjutant-General.*

Whatever the fate of my communication to the Medical Director may have been, it is very gratifying for me to see that our military authorities are gradually awakening to what has been proven an absolute necessity in foreign armies. Probably in no other country has this matter secured the attention and won the success which has attended this humane and practical movement in England.

One of the best appliances for ready use in first aid to the injured is the Esmarch triangular bandage. This is a strip of cloth fifty inches long, triangular in shape, its greatest width being 24 inches. Upon the bandage are six pictures illustrating its use, and with the bandage is a little book describing its use. For the benefit of those who do not read French or German I have translated the directions and given the foreign address of the manufacturers, although I presume that Messrs. Geo. Tiemann & Co. can furnish the packet with English directions in any needed quantity.

Translation.

FIRST AID TO THE INJURED.

Under this title the undersigned Society offers to persons in every state and condition—in the workshops, manufactories, mines, and railroad organizations, engineering undertakings, to all travelers and emigrants, and to any thoughtful family—an emergency packet for wound dressing, which, thanks to its small, compact form, its convenient arrangement and facility of packing, will give it a place everywhere; it can be carried under all circumstances. Each one of these packets is sold for one franc (fifty centimes) postpaid, and contains: First, a compress composed of cotton charpie of Dr. Bruns, and an antiseptic bandage. These two kinds of bandage have the property of absorbing the fluids, blood and pus, and protect the wound against hurtful influences. 2. Two bands of linen, one wide, the other straight, with pins for fastening them. 3. Some "ping-hawar-yambi," as a hæmostatic application. 4. A triangular piece of linen prescribed by Dr. von Esmarch. With the aid of this apparatus the majority of bandaging operations may be accomplished without any special skill. The method is as follows: The compress, which is folded in four, unfolds in such a manner that the cotton lint will be covered entirely by the bandage (antiseptic), which gives a surface similar in form to a sheet of letter-paper. We cut off each time the requisite quantity for covering the wound. After having washed the latter, and controlled the hæmorrhage by means of the application of the ping-hawar-yambi, it is covered with a piece of the compress, which is fastened by means of the linen bandages, which, should the wound be upon the head, neck, trunk, or main parts of the extremities by the use of the triangular bandage (Esmarch's). If it be a case of an open or deep wound, you form with the compress a pad proportioned to the size of the wound, which is introduced therein after previously saturating it with good olive oil, if this be within reach. According to the abundance of the secretions from the wound, it will be necessary to change the bandage once or oftener during the day; in this case, the same bandage and the same linen can be employed—but it is important to renew the compress or the pad. As to the employment of the Esmarch's bandage, we will quote the words of Professor Esmarch, who, in his celebrated work entitled "The First Aid in Bandaging on the Field of Battle," expresses himself as follows:

"According to the part of the body wounded, the triangular bandage is used as follows: It is folded in the form of a cravat by rolling the point several times in the direction of the lower edge; the oftener it is folded the narrower the bandage becomes. Under this form a practical bandage is made, not only for wounds upon the neck, but also for those on many other portions of the body; for example, the eye, the forehead, the ears, the cheeks, the chin, and the lower jaw. It is employed in the same manner for the simple muscular wounds of the extremities, and for fixing the splints and other protective apparatus in the case of fractured bones; besides making all of it, as a sling for supporting the wounded arm. The manner of employing the bandage under this form is so simple that no particular description is necessary. The ends are well fastened by means of strong pins, or well knotted one with the other. For dressing a wound on the head, or a simple scalp wound, the bandage is placed upon the head in such a manner that the lower border will be brought directly across the forehead, the point hanging towards the neck. Then the two ends are passed backwards, behind the ears, turned again and tied in front. The point hanging in front is pulled down firmly, returned upon the head, and fastened on the top of the head with a pin (head bandage or cap).

"To bandage a wounded hand a small bandage is necessary. The hand is placed upon the opened bandage in such a manner that the wrist covers the middle of the lower edge, and the points of the fingers are directed to the pointed end of the bandage. The point is then turned backward over the hand in the direction of the forearm. The two remaining ends are crossed over the point of the bandage and tied on the other side of the wrist.

"For the foot the sole is placed on the middle of the bandage, so that the toes are directed towards the point. The point is then brought forward over the top of the foot and the two ends are passed around the malleolar processes, crossed on top of the foot and tied under the sole.

"We can also bandage the stump after amputation in the same manner. The superior border or biased edge is placed around the limb above the extremity of the stump, turned around the wound, the hanging point is brought up over the wound, and the two free ends are adjusted over these and tied.

"To comfortably sling or suspend a wounded arm the ends must be placed over the uninjured shoulder and upon the neck sufficiently in front so that it will readily pass around the neck to the other side, and it is there fastened, while the other end hangs in front of the body. We carefully place the bended arm upon the middle of the linen, advancing the point below the elbow several inches. Then the end which hangs before the arm is brought back to the side of the shoulder of the wounded arm and tied with the other end upon the back. Then the point is brought around the elbow and fastened with a pin. This bandage is called the large scarf or big sling bandage.

"For bandaging wounds upon the chest the middle of the linen is placed upon the chest, the point raised and turned backward, passing over one shoulder, and the inferior border adjusted (at the waist) in the region where the chest and abdomen unite; then bring-

ing the two ends backward and tying them together upon the back. The pointed end passed over the shoulder is then drawn down and made to pass under the knotted end, and adjusted by means of a pin or knot. For wounds on the back one proceeds in the same manner, but inversely. For wounds upon the shoulder the bandage is cut into two equal parts, of which one is folded in cravat form and is used as a little scarf for the forearm, whilst the other is placed upon the wounded shoulder in such a manner that the point shall be upon the side of the neck and the superior border upon the middle of the forearm. The ends are then passed around the under side of the arm, crossed beneath the point of the elbow, and tied together on the exterior surface of the forearm. The point of the bandage is then slipped under the scarf at the neck, plaited back upon itself and fastened with a pin at the top of the shoulder.

"In the same manner the bandage is placed upon the hip; and here we often need the entire bandage, because the upper part of the thigh is much larger than that of the arm. The inferior border of the bandage is passed around the largest part of the thigh, and the ends fastened with a double knot, but in the cases where the thigh is too large it is pinned. The point of the bandage is adjusted in the same manner as for the shoulder, by passing under the leather belt of the soldier, returned upon themselves and fastened with a pin. When there is no leather belt it will be necessary to use a second bandage folded in cravat form."

Everyone can be assured that in the manner detailed above our bandage outfit for wounds will prove satisfactory for first usage in the majority of cases of wounds. The essential thing, which is self-evident, is to have it constantly available, which is now easily accomplished, thanks to its available form. Consequently we recommend "our first aids" to all persons, as already mentioned. We recommend, also, to all large establishments, the packet containing the articles indicated as necessary to complete the outfit, which will be found invaluable when one has become accustomed to their use.

The International Manufactory of Bandaging Articles, at Schaffhausen, Switzerland. Articles to complete our bandage packet: cotton-charpie of Dr. Braus in packages three-fourth, one-half and one-eighth lb.; hydrophile bandage in packages of a yard and one-half to ten yards; triangular bandage with illustrations of wounded soldiers.

The two best works at present obtainable on this subject of ambulance corps organization are: first, "Manual for the Medical Staff Corps (British), War Office, 1885. Official Copy." This is a most valuable little work, is very suitable for our own Army, and should be reproduced here. The second is "Ambulance Handbook for Volunteers and Others," by J. A. Raye, Surgeon, and is published by Churchill, London.

These books are very important, and their completeness and admirable arrangement make them invaluable additions to the surgical library. During the War (1863), Dr. Ordronaux published a valuable little work entitled "Hints on Health in Armies." It is for sale at present by Van Nostrand, 192 Broadway, New York, and contains very valuable recommendations on military hygiene. Surgeon Woodhull's (U. S. A.) able article on "Military Hygiene," in the "Reference Handbook of the Medical Sciences," vol. iii, just published, contains the latest military medical science. I mention these writings on military hygiene because it is essential that they should be studied by all military surgeons, and because they contain valuable information for all medical men who are likely to have anything to do with military medical matters.

Three other works are in process of preparation or have been already published: Surgeon-General Langmore's work on "Transport, etc., of Sick and Wounded;" Surgeon Moore's "Manual of Drill for the Army Hospital Corps;" and Surgeon-Major Evatt's "Ambulance Organization Equipment and Transport." Another very important work in this connection, by Dr. Paul J. Möbius, Surgeon in the Saxon Army, entitled "Grundriss des Deutschen Militair-Sanitätswesens," has been translated, and will soon be published in this country, but in an abridged form.

This important subject has received comparatively little attention from the medical press, but the *Boston Medical and Surgical Journal* has done much to awaken interest in the matter, and from time to time valuable editorials and items have appeared in its columns. This has come about, no doubt, in consequence of the enterprise shown by the Surgeon-General's Office of Massachusetts, which has, without doubt, led in this matter, and has accomplished more in ambulance drill than all the organizations in the country.

The following editorial, in the *Boston Medical and Surgical Journal* of September 23, 1884, is well worth reproducing, and should strongly appeal to any officers interested in this important branch of the military service:

"It is generally understood that a militia should be a school of instruction for the men, and the public expect the development of a nucleus from which can grow, in case of necessity, an effective body of soldiers. Now, it is a well-known axiom that familiarity and experience with any work are necessary for its best accomplishment; therefore the training of an ambulance bearer corps should form part of the duty of the volunteer militia. Properly instructed and drilled, this body would form a unit from which might spring in time of need a service of the greatest importance."

Volunteer ambulance bearer corps have recently been instituted at the various military camps in England, and great success and popularity have attended the efforts of those who have had charge of this important undertaking. This has been attempted in our own country, especially in Massachusetts, but has so far been considered a failure. It must be expected that great difficulties will be encountered at first, but each trial faithfully made makes success in the end more certain. Development goes on slowly in healthy action—the militia system itself demon-

strates this fact. During the War, when one would have supposed that the plan would have secured prompt encouragement, efforts to establish an ambulance corps failed, and a bill for this purpose perished in the Senate, having received the discouraging and utterly unsound endorsement of the Committee as "*an impracticable measure at this time.*"

I quote again from the same journal: "Modern warfare has reached a stage of perfection in which results are rapidly accomplished, and this is undoubtedly due to the development of arms which can be used with rapidity and precision, the mobilization of troops, and their rapid and machine-like movements. Modern warfare has brought into use the railroads, telegraphs, massive steel cruisers, and new explosives. When we consider that with the improved Gatling and Nordenfelt ten barrel guns a thousand shots can be fired in each minute, as was actually done in the Soudan, we see that a large number of combatants can be rapidly disabled. This increase in destructive power creates an increased necessity for means of caring for the injured. Unfortunately, however, military commanders have generally considered the care of the wounded as a minor consideration, and only in recent years has it dawned upon such officers that the certainty of good care in the event of misfortune develops in men an *ésprit de corps* second only to the accomplishment of victories. Again, the certainty of good care and attention, in case of injury, softens the anxiety of those who part with their loved ones for the national defense. This home feeling forms the foundation of the moral support on which commanders at times lean so heavily, and without which supplies of men and materials to carry on their campaigns would be wanting. The lamentable failure of men to receive proper medical care in the Crimea early drew attention to the defects of the old system of caring for the disabled. It was only when Letterman, in our Civil War, developed gradually an ambulance system (which at the close of the War was quite effective), that the necessity for sure, rapid, and effective treatment and transportation of injured combatants was properly appreciated. Many will remember the heart-rending tales of the needless suffering in transportation inflicted on our soldiers in the early part of the Civil War. Needless, because this exigency of warfare should have been foreseen and provided for.

"At Aldershot, a few weeks since, a detail of a hundred men, acting as wounded soldiers, were searched for at night, after a supposed battle, by the aid of an electric light carried by a bearer company of the army hospital corps, with all the paraphernalia of transports complete. The application of the electric light was a distinct success, the necessary dressings of the wounded being performed with accuracy and dispatch.

"An attempt was made at one of the recent annual encampments of the Massachusetts militia to instruct the men in the treatment of emergencies; owing, however, to a variety of causes the trial was a failure. This was due, in a great measure, to the amount of tactical instruction and drill required of the men. The topics considered were of general interest, but the men showed a lack of appreciation because of these conflicting duties. It was also found impossible after "retreat," the men requiring amusement at that time rather than instruction and hard work. Now, while a general knowledge of the principles of sanitary science, as taught German officers, is of importance, we feel that in time of war the rapid treatment of wounded combatants demands the training of brave and intelligent men for this important work. We hope that there will soon be an ambulance bearer corps connected with the various State militias, under the control of the Surgeon-General of the State. A company should be connected with each brigade, under the direction of the medical director, and this company should be composed of enlisted men, having the proper number of sergeants, corporals, and privates. A number of such a bearer corps should be medical students, as it is self-evident that by the discipline of such a service they would be better fitted to act after graduation as medical officers of the volunteer militia.

"Major-General George B. McClellan appreciated the necessity for an ambulance corps. In a letter dated February 21, 1863, addressed to Henry I. Bowditch, M.D., in answer to the question, 'Should the men in the ambulance corps be detailed soldiers, taken from time to time from the ranks, or should they be men enlisted for the purpose and taught their especial duties?' General McClellan answered as follows: 'There are many self-evident objections to the system of taking men temporarily from the ranks for this duty; they need instructions in their peculiar functions as well as the ordinary discipline, and should have distinctive uniforms. I am of the opinion that men should be enlisted especially for duty in the ambulance corps.' Dr. Bowditch asked also the following question: 'Do you think the establishment of such a corps would increase the the number of non-combatants?' McClellan's answer is: 'I think it would decrease the number of non-combatants, especially during battles.'"

Besides the evident value of preparing soldiers to administer intelligently first aid to the injured, some effort should be made to instruct train hands in this necessary work. "Every guard's van of every passenger train should carry a stretcher and a basket of bandages and restoratives. Every railway station should have a stretcher as part of its equipment; and every 'break-down' train sent to aid at accidents should include a regular sick transport wagon, containing dressings, restoratives and stretchers." Our recent frightful railway accidents prove this clearly.

It has been the purpose of this paper merely to act as a skirmisher in the great battle which must sooner or later take place, to decide what is useful and practical for the soldier's welfare, and what should be discarded. Prominent army officers are very apt to be conservative, and really important inventions are often put aside because they interfere with the old romantic ideas of generations past.

The object of this paper has been attained if I have emphasized the importance of "First Aid to the Injured," which in military life must develop into organized ambulance and stretcher corps.

The books I have mentioned will give more information on the subject than any others yet seen by me. The English books especially are of the greatest value, and for those medical officers of our regular and volunteer army who are about to carry out the provisions of the general order referred to will be found of remarkable assistance and practical usefulness. The subject is of national importance, and unites with the highest humanity practical economy of human lives. There should be no delay in organizing for such an important movement in the history of the U. S. Army.

Newport, R. I., February 22, 1887.

REMARKS ON CATARACT EXTRACTION.

Read before the Medical Society of the District of Columbia, Feb. 23, 1887.

BY SWAN M. BURNETT, M.D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN THE UNIVERSITY OF GEORGETOWN; OPHTHALMIC AND AURAL SURGEON TO THE GARFIELD HOSPITAL; DIRECTOR OF THE OPHTHALMIC AND AURAL CLINIC AT THE CENTRAL DISPENSARY AND EMERGENCY HOSPITAL, WASHINGTON, D. C.

Since the opening of the Garfield Memorial Hospital about two years ago, I have made twenty-five extractions of senile cataract. The number is not large, but the cases have been of such a character as will very properly serve as a basis for a few remarks on some of the mooted questions concerning this most important surgical operation.

The extraction in every case was effected through an upward incision in the cornea, made in accordance with the plan of De Wecker; that is, the upper third of the cornea was detached from the sclerotic, the incision lying wholly in the transparent tissue. Sometimes a flap of less magnitude was formed by the apex of the incision lying farther from the scleral border than the base, but this was only exceptional, and experience shows that it has no essential advantages over the incision as perfected by De Wecker and now very largely adopted by operators who have not originated some special plan of their own. In no case was the incision placed so peripherally as in the method introduced by Von Gräfe.

This incision of De Wecker seems to steer us as safely through the straits between the Scylla of corneal suppuration, and the Charybdis of iritis and cyclitis as could be reasonably hoped for. It gives an opening sufficiently large for the easy delivery of even the largest nucleus, and the lips of the wound adapt themselves as perfectly and with as little danger of gaping as in the so-called linear incision of Gräfe. This incision offers yet additional advantages over the Gräfe linear, in that it enables us to make the extraction without an iridectomy. It seems therefore, that as far as the form and position of the incision are concerned, it is hardly possible for us to go farther towards perfection.

In ten of the cases the *extraction was made without an iridectomy.* This method, practiced largely, indeed almost without exception by the French, is struggling for a foothold in this country, with however, I believe but only a moderate chance for immediate adoption. Certainly an eye with a central movable pupil is on all accounts to be preferred to one with a large coloboma in the iris, but it is equally certain that even in the hands of the most skillful this is not to be attained in all cases in operating without an iridectomy. In a rather large minority there will be prolapse of the iris. It is an operation demanding rather more skill in its performance and requiring more quiet and repose on the part of the patient for the first forty-eight hours after the operation than with an iridectomy. And yet it is an operation that I think should be cultivated, because I believe we shall in time be able to master most of its disadvantages. I attempt it in every case in which there is no marked increase in the tension of the eye-ball, and when the anterior chamber is reasonably deep. Under these conditions, with a moderately docile patient, I do not greatly fear a prolapsus of the iris. And, moreover, should the iris refuse to return after the delivery of the lens, with a moderate amount of coaxing, it is as easy to make excision of the iris after as before the exit of the lens, thus converting it into an ordinary extraction with an iridectomy. I do not find that delivery of the lens is any more difficult than with iridectomy, and I believe the danger of prolapse of the vitreous is less, since there is not so great a liability to rupture of the zonula.

The possibility, however, of prolapse of the iris after it has been once returned cannot always be guarded against, even by the use of eserine. Here everything depends upon the accurate coöperation of the wound, and an early and persistent adhesion of its lips. A perfectly proper incision is therefore one of the first requisites for success in this method. This comes of skill and experience; but the second requisite—perfect rest of the eye for forty-eight hours—can never be counted on; for even the quietest patient, during sleep may make a sudden movement of the eye which will open the wound, when the aqueous humor will gush out, carrying with it the iris which remains thereafter fixed in the wound.

In *two cases* extraction was made *with the lens in its capsule.* In these cases an iridectomy was first made, since extraction in the capsule is much easier thus than with the iris entire. In both cases the result was perfect, and there was no escape of vitreous following the exit of the lens. In one instance it was done on account of a thickened and tough capsule; the other case was one of "black" cataract and it was desirable, for the purposes of investigation, to remove the lens in the capsule.[1]

[1] A detailed history of this case and a consideration of the subject of black cataracts and their diagnosis is to be found in a clinical lecture published in the Medical News, Jan 29 1887.

In one instance only was a *preliminary iridectomy* made. This method, which has been brought again to the notice of the profession of late years, principally through Förster, of Breslau, has something to recommend it in a certain class of cases of which ours is typical. It was in an old man of near 80 years, the cataract was maturing slowly, the anterior chamber was very shallow, the pupil responded but feebly to light and mydriatics, and there was a chronic conjunctivitis due to an epiphora caused by a falling away of the puncta from the globe as a consequence of general laxity of the lid tissues. Such a case is not adapted for extraction without an iridectomy. I therefore made an iridectomy and rubbed the cornea against the capsule with the round corner of a strabismus hook according to Förster's recommendation. The result was a rapid maturing of the cataract which was successfully extracted three weeks later without any unusual complications. The making of such a preliminary iridectomy very much diminishes the danger of an operation in suspicious cases, since it divides the risk between the two operations, though it has happened to me to lose an eye from such a preliminary operation some years ago.

The ideal operation for cataract is without an iridectomy, and with the lens in its capsule—and some operators have confined themselves quite closely to such methods. Prof. Roosa, of New York, is at present, I believe, practicing an operation of that kind, and his statistics certainly recommend it to the further trial, but the conservative spirit of ophthalmic surgeons is very adverse to making any such radical departures from methods which give only about 6 per cent. or 7 per cent. of losses in ordinarily skillful hands. And yet I think it can be safely predicted that in the probably near future more tentative efforts will be made in that direction. In a progressive art like ophthalmic surgery no stop will be made short of as nearly absolute perfection as positive science and the greatest operative skill will allow us to attain.

In twenty-one of the cases *cocaine* applied locally *was the anæsthetic used.* The strength of the solution was 4 per cent., and no evil effects that could be referred to its employment were noted. A concurrence of testimony, however, seems to point to a possible danger from its too long employment in strong solutions. Cocaine undoubtedly has a tendency to cause a loosening of the epithelium of the cornea, thus furnishing a nidus for any pyogenic germs that may gain access. That it is, of itself, in any way deleterious I do not believe. After every instillation of the drops I cause the patient to close the eyelids, and in this manner it is believed the peculiar effect on the corneal epithelium is avoided.

In all the cases a certain amount of *antiseptic precaution* was used, but in the last eleven those of the strictest nature were adhered to. The conjunctival sac was thoroughly washed out with a solution of mercury, 1 to 25,000. made according to the formula of Panas, of Paris; the instruments were laid in absolute alcohol; the lids, brow and neighboring parts of the face were washed with a carbolic acid solution, and the dressing applied next the eye after the operation was saturated with the mercuric solution.

In the cases in which an iridectomy was not made, it was attempted to *return the prolapsed iris* by rubbing the upper lid gently over the incision, but where that was not sufficient a small Bowman's probe, dipped in the antiseptic solution was used to reposit the membrane. A solution of *eserine* was then instilled into the conjunctival sac, and in the latest cases even into the anterior chamber, thus bringing the drug in direct contact with the iris-tissue and ensuring the strongest possible contraction of the pupil. In some instances where there were remains of corticalis, the anterior chamber was even washed out with the biniodide solution. This going directly into the anterior chamber is an innovation of quite recent origin. Confidence in antisepsis has made us bold, and we now handle tissues fearlessly which before we touched only with trembling.

So far as my experience goes, this treatment of the iris and anterior chamber is not followed by any evil results, and it gives us two important factors necessary for a perfect healing—a well contracted pupil, and a clean aqueous chamber.

Within the last twelve months a great deal has been said about the "new" and "rational" *after treatment* of cataract operations—the method being claimed as "original" by several parties. The method consists in abolishing dark rooms and doing away with cumbersome bandages. For eight years I have not confined an operated case in a room in which it was too dark for the nurse to read the directions given by the surgeon. That relic of barbarism I discarded because it seemed to me both irrational and pernicious; irrational, because in only exceptional cases is light in moderation hurtful, while on the contrary, in most instances, it is of a decided advantage in keeping up the normal relation between the internal eye and its natural stimulus; pernicious, because I believe light, whether felt by the eye or not, to be as important to the well-being of man as good air, and I am myself too keenly alive to the blessed, vivifying influence of light to exclude it from persons who from age or decrepitude need all the sustaining power they can get. To enter the rooms of some ophthalmic institutions is like going into a dungeon. All these cases were treated in the open wards of a general hospital with abundant supply of light.

In regard to the matter of bandages, I do not go to the length of some in discarding them altogether, nor do I think such a course advisable. I do not use the flannel roller generally employed, for it is exceedingly hot and uncomfortable in summer, is easily disarranged, and the ordinary nurse cannot replace it when it becomes so. It seems to me also that an adhesive plaster applied over the lids would be very stiff and uncomfortable and would not afford as much protection against the accidental rubbing of the eye by the hands during sleep as the more elastic absorbent cotton. The bandage I use is a band of elastic flannel 2½ by 6½ inches, with a tape secured to each of the four corners, sufficiently long to pass around the head and come again to the front to be tied on the forehead.

After the operation is completed and the eye is disinfected, a thin linen or cotton cloth, saturated

with an antiseptic solution, is placed over the closed lid, the orbital cavity filled out to the brow with absorbent cotton and the bandage applied, and the tapes, passing above and below the ears, are brought around to the front and tied in the centre of the forehead. This bandage is easily removed and the lids can be inspected and washed—which is often very grateful to the patient—without opening the eye. The lids are always thus inspected at the end of the first twenty-four hours, or earlier, if there were symptoms demanding it, but the eye is not opened if there is no marked swelling of the lids. It takes at least forty-eight hours for the union of the lips of the wound to be firm enough to bear any considerable movement of the ball without danger of reöpening. At the end of the second day the lower lid is pulled down, and if there is no marked chemosis of the conjunctiva the bandage is replaced. At the end of the third day the corneal wound is inspected, and atropine drops applied.

The *operation* was not *complicated* in a single case, if we except a slight prolapse of vitreous in two cases, and a falling of the iris before the knife in one, necessitating the making of an iridectomy where none had been intended. The *healing* was smooth and uninterrupted in all but eight cases. In two there was reöpening of the corneal wound one week after the operation; in four severe iritis supervened; in one there was hæmorrhage into the vitreous, and in one there was suppuration of the cornea. In one of the cases the patient, a colored woman of 70 years, was seized with *mania* on the third day, and tore the bandage from her eyes and was with difficulty controlled for the next four days. Similar cases have been reported before, and it is a question as to whether it is due to the bandaging and confinement, or to the atropine which had been used. This patient had had atropine applied but once, and the mania continued though the drug was not applied again. So far as we could learn the woman had never before manifested any symptoms of this character. The corneal wound healed nicely, but a plastic iritis obstructed the pupil to such an extent as to render a secondary operation necessary. With that, however, her vision will be good.

As to *results*. There was complete primary success in twenty-one cases; in two good vision can be obtained by a secondary operation, and two eyes were lost. One of the eyes was lost by hæmorrhage into the vitreous caused by vomiting six hours after the operation. The vomiting was caused by the anæsthetic (A. C. E. mixture), it being in the præ-cocaine days. I have lost two eyes from this same cause, the other being some four years ago, and embodied in my last statistics.[2] Had I had the invaluable cocaine then, I believe those eyes could have been saved.

Of the ten cases without an iridectomy, there were only four in which there was an adhesion of the iris to the corneal wound, and in one of these, the patient—a mentally debilitated man—tore the bandage from his eyes and walked about the ward within the first twenty-four hours. When discovered by the nurse, the corneal wound was gaping wide and filled with prolapsed iris. The prolapsed portion of the iris was cut off, but inflammation of the iris set in leaving closure of the pupil as the result. With a secondary operation, however, his vision will be fair.

The loss of the eye from suppuration is of interest, as the operation was done under the most approved antiseptic method, and because the operation on the other eye, done some eight months previously but without such strict precautions, was perfectly successful, there not having been even a single unpleasant symptom after the operation. The first operation was done with an iridectomy, the last without. The operation itself was as smooth as it is possible for an operation to be. The incision was accurately placed, the lens delivered without any difficulty, and the iris returned with only a slight rubbing of the upper lid; and when the eye was closed for bandaging the pupil was central and round, and the wound was coäpted. And yet, at the end of twenty-four hours the lips of the wound were thickened and yellow, and there was a small quantity of pus on the cloth dressing next the eye. The infiltration rapidly increased, and by the next day the whole of the upper half of the cornea was involved. The bandage was removed on the first appearance of signs of suppuration, and it was vigorously combated by atropine, frequent washings of the eye with the mercuric solution, and dusting the cornea with powdered iodoform. To this prompt treatment we believe is due the arrest of the suppurative process at the end of the fifth day, though not before the upper third of the cornea had been lost. The remaining portion of the cornea is so opaque as to render any operation for restoration of vision futile.

This case is somewhat discouraging to the enthusiast for antisepsis, and advocate for the microbic theory of suppuration. I, of course, will not deny positively the absence of pyogenic microbes, but I do affirm that I used all the precautions that the most ardent antiseptist recommends; and though the majority of facts, clinical and experimental, seems to support the microbe theory, the final word yet remains to be said in regard to the cause and origin of suppuration. It seems to me that the cause cannot be altogether external. The general condition of the patient must not be excluded in settling the question of etiology. It is, I think, an important fact in this connection that this patient, on the tenth day after the operation, was attacked with facial erysipelas on the side of the operated eye, and nine days later a milder attack occurred on the other side. I will also state, as bearing on the same point, that in the thirty-four extractions recorded in my last statistics (l. c.), there were two suppurations of the cornea, both in women broken down in health and with little vitality, one having been bed-ridden for years, and the other dying in less than a week after the operation.

[2] Comparative Frequency of Eye Diseases in the White and Colored Races in the United States. Archiv. of Oph., vol. xiii, No. 2, 1884.

THE SEASONAL RELATIONS OF CHOREA, RHEUMATISM AND NEURALGIA.

Read before the Philadelphia County Medical Society, on March 23, 1887.

BY MORRIS J. LEWIS, M.D.,

OF PHILADELPHIA.

I have been requested by your committee on meteorology and epidemics to read a paper on the influence of different conditions of weather on rheumatism and nervous affections, and take pleasure in doing so, but must state that the paper read by me before the Philadelphia Neurological Society, in October, 1886, which appeared in the *Medical News*, of November 13, 1886, embodies nearly all the facts that I have to bring before you to-night. The salient points, however, I think I can bring forward in a clearer manner than then, having changed the method of tabulation so as to make the subject more easily comprehended.

A *daily* comparison between the states of the weather and disease could not be made, as the *days of onset* of the two affections, chorea and rheumatism could not be obtained. The *months of onset* were, therefore, taken and compared with the *monthly* average of the weather, this, although rendering the result less accurate will, however, show many points of interest, the study extending over the decade 1876–1885 inclusive.

The months of onset of 437 separate attacks of chorea were taken from the books of the Orthopædic Hospital and Infirmary for Nervous Diseases during this decade; and attention is drawn to the fact that it is the time of onset of the disease that is noted and not the time of application for treatment; any conclusion drawn from the latter method of notation must necessarily be inaccurate. As it is a well-recognized fact that a relationship exists between chorea and rheumatism, which it is needless to say, is as yet imperfectly understood, I thought it would be of interest to compare with the cases of chorea the months of onset of attacks of acute and inflammatory rheumatism, and for this purpose studied the notes taken at the Pennsylvania Hospital, which were placed at my disposal; from these were collected 467 separate attacks of acute rheumatism which occurred during the years in question, all cases being excluded that were at all doubtful, together with those that did not originate in this city: this, of necessity, excludes nearly all the cases occurring among sailors.

To compare neuralgia with these two affections, I have extracted from the article by Captain Catlin, on "The Relation of Pain to Weather" (read before the College of Physicians in June, 1883, by Dr. S. Weir Mitchell), the hours of pain per month for the period of his study, of his own case, from 1875 to 1882 inclusive; but, unfortunately, Captain Catlin was situated at West Point, and the years of study do not coincide, and, therefore, for a better comparison I have prepared a table in which the first year of the neuralgia record (viz., 1875) and the last three of my records of chorea and rheumatism (viz., 1883–84–85) have been expunged, this then includes a period of seven years, 1876–82 inclusive, in which the two studies coincide, except for locality.

The weather statistics were compiled from the records kept at the Signal office in this city, and consist of a study of the temperature, range of the thermometer, barometer, relative humidity, amount of rain and snow in inches, number of cloudy and rainy days, and the number of storm centres (centres of low barometer) passing within circles of varying radii drawn around Philadelphia as a centre.

The monthly average of the weather being thus studied for ten years was then taken and compared with the monthly average of disease; but the peculiarities about to be spoken of, are best seen when a table is made which shows the mean of the ten years in question, month by month.

It must be borne in mind that while the records of the weather are complete so far as they go, the cases of disease here reported are but a small portion of those that must have occurred in this city during that decade; the neuralgia record is an exception, as it is a complete record at least of the sufferings of one person. The 437 attacks of chorea are distributed among the twelve months of the year as follows:

January,	36 attacks	= 8.2	per cent.
February,	33 "	= 7.5	"
March,	67 "	= 15.3	"
April,	38 "	= 8.6	"
May,	47 "	= 10.7	"
June,	40 "	= 9.1	"
July,	46 "	= 10.5	"
August,	34 "	= 7.7	"
September,	27 "	= 6.1	"
October,	18 "	= 4.1	"
November,	19 "	= 4.3	"
December,	32 "	= 7.3	"

The 467 attacks of rheumatism are distributed as follows:

January,	50 attacks	= 10.7	per cent.
February,	44 "	= 9.4	"
March,	45 "	= 9.5	"
April,	81 "	= 17.3	"
May,	48 "	= 10.2	"
June,	32 "	= 6.6	"
July,	28 "	= 5 9	"
August,	26 "	= 5.5	"
September,	29 "	= 6.2	"
October,	28 "	= 5.9	"
November,	24 "	= 5.1	"
December,	32 "	= 6.6	"

To compare the relative frequency of neuralgia per month with these records, I have had recourse to the unique study of the relation of pain to weather by Captain Catlin, previously mentioned.

The total amount of pain for the eight years ending January 1, 1883, was 12,994 hours, or nearly one-fifth of the time.

The winter months hold the advantage as pain producers, and for this period, while the sun was north of the equator, there were 6783 hours, against 6161 hours while it was south of the equator.

The hours of pain were distributed among the twelve months as follows:

January,	1220	hours	= 9.4	per cent.
February,	1084	"	= 8.3	"
March,	1234	"	= 9.4	"
April,	1062	"	= 8.1	"
May,	1089	"	= 8.3	"
June,	947	"	= 7.2	"
July,	997	"	= 7.6	"
August,	1060	"	= 8.2	"
September,	1006	"	= 7.7	"
October,	1038	"	= 7.9	"
November,	1104	"	= 8.4	"
December,	1153	"	= 8.8	"

In glancing over these figures, great variation in the number per month is seen; the two highest months for chorea being May and March respectively, and the two lowest being October and November; while for rheumatism, the two highest are January and April, and the two lowest November and August.

The highest month for rheumatism follows the highest month for chorea, instead of preceding it, as we might have been led to suppose from our knowledge of the relationship between these two affections, although a considerable rise is seen in the number of attacks of rheumatism in January, two months before the greatest rise in the number of chorea cases.

The greatest suffering from neuralgia occurred in March, and the least in June. An attempt to explain these variations, naturally brings us to a study of the varying conditions of the weather.

Nothing especial is seen in comparing with the chorea tracing (tabulated from the foregoing figures) that of the *mean relative humidity*, (and by this is meant, not the *mean actual amount* of moisture contained in the air, but the *mean per cent.* of the moisture that could he held in suspension at the mean temperature of each month) or that of the mean barometer, except that there appears to be an increase in the number of attacks of chorea with a fall in these two tracings; the reason for this will appear later; neither is much learned by comparing the chorea tracing with that of the mean daily range of the thermometer, which shows the variableness of the different months; this is greatest in May, and least in December. The mean temperature tracing which is highest in July and lowest in January, does not throw much light upon the subject. When, however, the tracings of the number of the cloudy days, and the days on which rain or snow fell, and the amount of rain, or melted snow in inches, are studied, a slight resemblance to the chorea tracing begins to be apparent, and the probable cause of this becomes more evident when the storm tracings are studied, because these meteorological factors may be considered as component parts of a storm. The cause of the relationship previously noted as existing between the chorea, and the mean relative humidity and mean barometer tracings, now becomes clearer, the storm centres being centres of low barometer.

In studying the storms, circles of varying radii were drawn around Philadelphia as a centre, and the number of storms, as marked on the weather bureau maps, counted in each.

The storms passing within the 400- and the 700-mile circles are the only ones I will discuss; the former because it shows the nearest resemblance to the chorea tracing, and the latter, because the average distance over which a storm can influence neuralgia has been found by Captain Catlin to be about 700 miles. A very strong resemblance exists between these two storm tracings.

The smallest number of storms passing within the 400 mile circle occurs in August; a rapid rise of the tracing then takes place, until December and January are reached, then there is a slight fall in February, immediately followed by a rise to the highest point in March, after which there is an irregular fall until the low point in August is reached. The total number of storms passing within this circle for the ten years in question, is 520, and they are distributed as follows:

January,	60	storms	= 11.5	per cent.
February,	54	"	= 10.3	"
March,	75	"	= 14 0	"
April,	46	"	= 8.8	"
May,	41	"	= 7.8	"
June,	28	"	= 5.3	"
July,	34	"	= 6.5	"
August,	19	"	= 3.6	"
September,	24	"	= 4.6	"
October,	32	"	= 6.1	"
November,	47	"	= 9.0	"
December,	60	"	= 11.5	"

Any one comparing a tracing made from these figures with that of chorea, must be struck by the resemblance between the two, which is more than accidental.

While the chorea tracing shows a strong tendency to keep pace, month by month, with the irregularities of the storm tracing, that of rheumatism, while also strongly resembling the latter in its general characteristics, may be seen to be almost exactly *one month later*, looking as if the effect of the meteorological changes was immediate in the case of chorea (as will be seen later to be the case with neuralgia), and preparatory only in the case of rheumatism. A marked resemblance exists between a tracing made from the hours of pain per month previously mentioned, and the storm tracings, even when the years of study do not coincide; when, however, a table is prepared for the years 1876–82 inclusive, during which the studies do coincide, the great resemblance becomes manifest; this is most marked with the 700 mile, and less marked with the 400-mile tracing, although still pronounced.

It would be interesting to know how many nervous disorders are thus immediately influenced by the weather, and in how many others are the meteorological changes to be looked upon as preparatory to the outbreak of the disorder. The hot weather of July has been shown to precede the month of onset of the greatest number of attacks of infantile palsy.

A similar study in the case of epilepsy, hemiplegia, and many other affections might open up much that is new.

TABLE SHOWING THE FIGURES FOR CHOREA, RHEUMATISM, NEURALGIA AND THE 400- AND 700 MILE TRACINGS FOR THE YEARS 1876-82, INCLUSIVE.

MONTH.	No. of attacks of chorea.	No. of attacks of rheumatis a.	Hours of pain.	Storms passing within 400-mile circle.	Storms passing within 700-mile circle.
January	32	44	1018	44	76
February	16	27	918	38	67

MEDICAL PROGRESS.

SALICYLIC ACID IN CHANCROID.—The use of salicylic acid in the therapeutics of soft chancre has been recommended by various authors. Dr. Giuseppe di Bella, in a report of cases treated in the clinics of Drs Monteforte and Santi-Sirena, says that this agent has acted promptly and efficaciously in a large number of cases. Hebra has seen a number of cases of chancroid cicatrize in a very few days under treatment by salicylic acid. Dr. Ping y Falco has also obtained most satisfactory results with this same agent in similar cases. DR. A. FARRIOLS ANGLADA reports in the *Gaceta Médica Catalana*, of October 15, 1886, thirty-two cases of soft chancre in which salicylic acid was used with the happiest results. This method, he says, possesses many advantages over the others hitherto used, and especially over the abortive plan. It is very simple, and the patient himself can carry it out; it is only necessary to wash the chancroid with some antiseptic fluid, and then to dust it with finely pulverized salicylic acid. In the great majority of cases, no more than two applications in the twenty-four hours are required, and in a few days (four or five, according to the author's experience) the ulcer loses entirely its specific characteristics. When this result has been obtained, that is, when the lesion has been converted into a simple ulcer, the applications of salicylic acid should be suspended, and a carbolic acid lotion or boracic acid ointment employed. Under this treatment, the ulcer becomes covered with healthy granulations, and cicatrization proceeds with great rapidity. Finally, Dr. Anglada urges, if we bear in mind that salicylic acid causes hardly any pain or inconvenience of any sort, in this way differing so greatly from the caustics ordinarily employed, we are forced to admit that it is a most valuable therapeutic agent in the management of soft chancres.—*Journ. Cutan. and Genito-Urin Diseases.*, February, 1887.

EFFECTUAL DISINFECTION OF UTERINE TENTS.—DR. DIRNER, of Buda-Pesth, has recently written in the *Centralblatt für Gynäkologie* on the effectual disinfection of tents used for gynæcological purposes. He observes how, after the greatest precautions, serious pelvic inflammation may follow the introduction of sponge or laminaria tents. This accident is clearly due, not to the mere ulceration of the dilated structures, but to the introduction of septic material through the wounded mucous surface. The preparation of tents by soaking or coating in antiseptic media is insufficient. Septic matter may be introduced with the aseptic tent; surgeons handle and throw about samples at the shops, nor is the process of manufacture always properly superintended. Fritsch's method of coating tents with wax requires warm water to be at hand when the wax has to be melted, and that water may be septic. Dr. Dirner has detected cracks in the wax, allowing the admission of dust. The most carefully prepared dry tents can convey septic germs on their surfaces. For a year Dr. Dirner has employed in Professor Tauffer's wards a special system of disinfecting laminaria tents. He immerses them in a 1 per cent. solution of corrosive sublimate in absolute alcohol contained in a wide-mouthed bottle, When required, a tent is taken straight out of the solution and passed into the canal of the cervix, the patient being previously placed in the semiprone position, and the vagina disinfected. He takes care to inspect hollow stems before introduction, and should any crystals of sublimate be detected in the channel of a stem, it is dissolved with pure water. The results of this practice have been admirable, and he has seen no bad effects follow the introduction of the disinfected tents; provided that absolute alcohol be employed, the expansive power of the laminaria is in no way damaged.—*British Medical Journal*, March 5, 1787.

PERIOD OF INCUBATION OF HYDROPHOBIA.—BAUER, in a careful study of 510 cases of hydrophobia in man, in which the length of the period of incubation was positively and reliably known, arrived at the following conclusions:

The average duration of the period of incubation was in men eighty days, in women sixty-five days, in children fifty-seven to, in the strongest, seventy to seventy-five days.

The location of the wound influenced much the length of the period of incubation. Bites on the head or neck, or numerous teeth wounds about the body, produced an average period of fifty-five days; wounds of the lower extremities, a period of seventy-four, and of the upper, 81.5 days.

The period of incubation from wolf bites averaged thirty-nine days; from dogs, 73.5, from cats, eighty days.—*Centralblatt für klinische Medicine*, January 8, 1887.

PASTEUR states that the average period of incubation is from forty to sixty days when the bite is by a dog; and when by a wolf, thirty to sixty days, or less.—*Bullet. de l'Acad. de Méd.*, March 2 and May 4, 1886.

BACTERIA IN ICE.

At the last stated meeting of the New York Academy of Medicine, in March, DR. T. MITCHELL PRUDDEN read a paper of great interest, denoting more original research than any contribution to the Academy for some time past, on "Bacteria in Ice, and their Relations to the Ice Supply of New York City—an Experimental Study." His object in the series of investigations was to give by experimental means definiteness and precision both to the problem in general, and to the detailed questions which arise in connection with the ice supply of one particular town. His valuable studies enable us to know now with tolerable certainty just what series of questions are to be answered, and what investigations are to be made, in order to decide upon the safety of any given source of ice supply. These detailed investigations, however, as he said, can only be made under the sanction and direction of the public authorities. In the clear light which new methods of science throw upon the whole subject of ice impurities, it seems necessary that a sweeping reform, in some respects, should speedily be brought about.

Even after we have determined the number of bacteria present in water or ice, a careful consideration of other conditions is still imperative, in order to determine whether the water or ice is fit for use. The popular impression that water purifies itself in freezing is only partly true, so far as the bacteria are concerned. The partial purification from bacteria is accomplished, not by their expulsion from the water, but by the death of a certain proportion of their number, so that, if the bacterial contamination of the water be extensive, or even largely made up by the more hardy species, the ice formed from it, even though quite transparent, may still contain large numbers of the living germs. The experiments showed that bacteria of different species possess different degrees of vulnerability to the action of low temperatures. Certain species which are capable of producing serious and even fatal diseases in man—the bacillus of typhoid fever and the common bacillus of suppuration, for example—are capable of resisting a prolonged low temperature, with the destruction of only a part of the individuals thus exposed. In the case of the typhoid fever germ the exposure was for seventy-seven days. The resisting capacity of the different species was found to vary with the vitality of the individuals, the degree of temperature, and the time of exposure; while alternate freezings and thawings sufficed to entirely exterminate in a short time all species experimented on, even those which can endure for long periods a sustained low temperature. The data gathered seem to justify Dr. Prudden in the conclusion that in the freezing of natural waters there may be a precipitation amounting to as much as 90 per cent. The effect of freezing on water containing bacteria was comparable, he said, to that of filtration, but with this vital difference, that whereas by filtration all forms of bacteria are removed in approximately equal ratio, by freezing, which acts as a sort of selective filtration, some of the most dangerous forms may be retained while others are destroyed.

The ice supply of New York City is principally derived from a series of naturally excellent lakes and tanks and from the Hudson River; the latter being by far the most important source. The Hudson River ice is obtained between Troy and Poughkeepsie, and in the upper portion of this region the stream receives the entire sewage of Troy and Albany, to say nothing of that of many smaller places, and the contaminations brought from the west by the Mohawk River. Here, then, is a great tidal river rich in sewage pollution; but, while the conditions in the upper Hudson during the ice-forming season scarcely seem to be such as would favor purification from organic matter by oxidation, they do seem to be theoretically, and are shown to be practically, favorable to a considerable degree of spontaneous purification from bacteria by sedimentation.

In regard to the actual analysis of the ice brought from the Hudson, and from the lakes and ponds referred to, it was found that there is a much greater number of bacteria in the snow ice than in clear ice, or that moderately full of bubbles. The species of bacteria are much more varied and abundant in the river ice than in that from the other sources, while in

both there is a considerable proportion of the relatively harmless water bacteria. While the number of living bacteria varies greatly, not only in different parts of the same block of ice, but also in ice from different parts of the river and from different lakes and ponds, the average number is considerably greater in ice from the river than from the lakes and ponds; even when Albany ice, which is the worst of all, was excluded from the estimate. It was found, also, that the average number of bacteria in ice from all sources taken together was far beyond the general standards which even a moderate degree of purity would allow. As regards the lakes and ponds we may conclude that, although the ice from some of them contains a larger number of living bacteria than is consistent with the highest hygienic standards, the conditions can be readily changed so as to render this ice unimpeachable. With Hudson River ice, however. the case is very different; and it is a pertinent question as to what actual danger is to be feared from its use for drinking purposes. A considerable number of the bacteria which it contains are undoubtedly the relatively or absolutely harmless species, which may exist in any natural river or spring water; but a large number may, with equal certainty, be assumed to originate from animal excreta. Here, again, it is scarcely to be doubted that a considerable proportion of the bacteria existing in sewage and coming from human and other excreta, and the various putrefying fluids which form a prominent ingredient in the water of populous towns, may not be positively dangerous if taken into the body in moderate quantities.

There are some varieties of diarrhœal disturbance, severe or mild, which often seem to depend upon impure water or ice; but whether they are occasioned by sewage or other bacteria, or by organic matter, or by both, is not yet certain; and this class of cases may be left out of view. Cholera and anthrax, both bacterial diseases, transmissible by drinking-water, are not ordinarily present in the sewage of the region under consideration; and these diseases, though they cannot be ignored by those having the public health in charge, may also be left out of view. But there are many common and very important bacterial affections, almost constantly present in large towns, like Albany, and frequent enough in the smaller ones, viz.: typhoid fever and the trouble associated with acute suppuration and the so-called blood-poisoning from wounds, and pyæmia. As to the probable danger from typhoid fever to which persons using Hudson River ice are exposed, it is impossible to determine at present. The typhoid bacillus was not detected in Hudson River ice; but to do this, even though it were present in considerable numbers, in its mixture with other species and in the large dilution which exists, is a matter attended with very great practical difficulties. As is well known, it has been found in water suspected to be the cause of certain local outbreaks of typhoid; but here the conditions for its discovery in such instances are much more favorable. It is certain that this ice is not so important a factor in the transmission of the disease as to render the typhoid fever statistics worse than those of other places whose residents use cleaner ice; but, at the same time, there are many cases of typhoid fever in which the most rigid examination of the sanitary surroundings of the patients and their personal contacts entirely fails to account for the origin of the disease; and some of them may well be cases of ice-poisoning from the typhoid bacillus. With the bacteria of suppuration and pyæmia the case seems much less serious, because of the very general antiseptic treatment of wounds now in vogue; but the fact that the *staphylococcus pyogones* may be in ice in a living condition is one that should not be lost sight of.

The measures which may be adopted to guard against this not only possible, but very probable, source of danger are of two kinds: *first*, such as come under the supervision of health officers; and *second*, those belonging to the province of the consumer. In the first place, it would seem necessary that the State Board of Health. or some other authorized body, should be placed in charge of the ice-harvesting fields, and, by a system of inspection not less strict than that which should exist in the case of the ordinary water supply, determine which, if any, of the sources of ice supply are so situated as to imperil the health of ice consumers. In view of Dr. Prudden's investigations, this appears to be comparatively simple in all cases except that of the Hudson or other large rivers. Here it would be necessary to establish, by a most thorough scientific examination, the distances from all sources of sewage pollution at which it might be safely assumed that the water had sufficiently freed itself from the bacterial and other impurities to form safe ice. It might in this way be possible to remove any chance of danger by permitting the questionable or bad ice to be sold only for cooking purposes, if such a classification were practicable, and thus not materially interfere with the interests of the ice companies. A compulsory system of disinfection of excreta in infectious diseases should be instituted, as has been done in other countries in which the purity of the water supply is under constant supervision.

THE PATHOLOGY OF PUERPERAL CONVULSIONS.

In regard to our editorial article on the "Treatment of Puerperal Convulsions," in THE JOURNAL of March 12, DR. F. WALTON TODD, of Stockton, Cal., writes:

"I do dot think that a misleading expression (*me judice*) in your editorial of the March 12th number, on the "Treatment of Puerperal Convulsions" should go unchallenged. You say: 'We need not stop here to discuss the pathology of puerperal convulsions.' In that lies the success or failure of our treatment of this frightful disease. That some cases are apoplectic while others are epileptic is clearly manifest from treatment, and abundantly attested by leading obstetricians of our own and foreign countries; and he who relies upon the hypodermic injection of morphine, on chloroform, chloral, veratrum viride, or the bromides in the apoplectic form will be doomed to disappointment; and he who relies upon the lancet in the epileptic will equally fail of a happy result.

"I will give two typical cases: Mrs. Dr. P. was delivered of a child, her first, at midnight. A few minutes afterwards she became convulsed, the paroxysms returning every half hour, and continuing all night and all the next day until 8 P.M. During this time eight of the leading physicians of our city had seen her, and upon the suggestions of one and another she had taken morphia by the mouth and hypodermically, chloroform, chloral and bromides, but the convulsions were unchecked, either in frequency or violence. I saw her at 8 P.M.; she was unconscious, lips and fingernails livid, breathing stertorous, extremities cold, but the pulse full and hard. My proposition to bleed was objected to as she had already lost much blood, but the objections being overruled I opened a vein freely, and before the operation was half finished the stertor was gone, she became calm, and had no further convulsions. 2. Mrs. McL. within two weeks of her confinement at full term gave evidence of albuminuria. She had taken pulv. jalap com., digitalis, and such other remedies as seemed called for. She was safely delivered, and went into convulsions in fifteen minutes. Anticipating them she had chloroform during the latter part of labor, and as soon as they appeared I gave her a hypodermic injection of morphia and atropia, and repeated it several times, together with chloroform and the bromides, with the same results as in the former case. The first case was apoplectic, and in the opinion of every one of the medical men present would have died without the bleeding; the second was epileptiform, and would, I think, have been injured by venesection."

We must take issue with our correspondent on several points. We are aware that Dewees taught that puerperal convulsions were epileptic, apoplectic, or hysterical, and Meigs and Hodge respectively referred the convulsions to the determination of blood to the head, and to a congestion of the cerebral vessels or an actual effusion of blood or serum into the substance or cavities of the brain; but to show how these theories are regarded by "leading obstetricians of our own and foreign countries" it is sufficient to say that they are not mentioned by Barnes, Galabin, Zweifel (whose work has just appeared), or Lusk; Parvin mentions them as a part of the history of the pathology of puerperal convulsions. Indeed, when the editorial article in question was written those theories did not once occur to us. Again, admitting such pathology of the affection, a discussion of it would be futile if it "is clearly manifest from treatment." If it is not manifest before treatment is begun it is certainly of no particular value as regards treatment. A differential diagnosis based on treatment in such a case is very much like that once given between acute yellow atrophy of the liver and yellow fever: if the patient gets well it is yellow fever; if he dies it is probably acute yellow atrophy of the liver. Still again, admitting some cases as apoplectic, there is a great deal of mystery surrounding the sudden recovery after venesection. Apoplexy does occur sometimes during labor, but the symptoms are not those of puerperal convulsions, nor is the recovery similar to that seen after venesection for such convulsions. In the fourth place, our correspondent thinks that his second case would have been injured by bleeding; as nothing is said as to the state of the pulse, or of the vascular symptoms, we are justified in saying that this case may have recovered under venesection as promptly as did the first case.

What we really meant by the sentence objected to was, that a discussion of the *pathology* of puerperal convulsions would have taken us beyond the limits (as to space) of our article. To us Breus' success with hot baths in this affection is, of itself, sufficient proof that these cases are neither apoplectic nor epileptic.

WHAT IS A BANQUET?

"A banquet without wine would be a hollow mockery." Such is the apparently serious exclamation in a recent editorial in one of our valuable exchanges.

The author of it was very properly deprecating the evil influence of the example of providing wine or alcoholic drink for banquets at annual meetings of State or other Medical Societies, and yet claiming that some kind of entertainment or social reunion is desirable on such occasions.

The same mental embarrassment that troubles our editorial confrère, has troubled in times past, and is still troubling the minds of many thousands of good people, who dread the terrible dangers of the luring wine-cup in the family, in the social circle, and on the banqueting table; and yet they seem puzzled to know how to be social or hospitable without it; or more correctly speaking, they are greatly oppressed with the fear that if the *wine* is omitted, some, at least, of those they desire to entertain will regard their "banquet a hollow mockery." But is there really any truth in the assertion that, "A banquet without *wine* would be a hollow mockery?" Is it true that banqueting simply means wine drinking, or that a banquet and a debauch are necessarily synonymous? The most authoritative lexicographer, using the English language, gives no less than six definitions or uses of the word banquet. Three of them make it indicate a bench, a three-legged stool, or a bridge or sidewalk, and the other three define it to be "a feast, a rich entertainment," etc., and illustrate it by quoting lines from Dryden, Coleridge, Milton, and the following from Evelyn: "There were all the dainties, not only of the season, but of what art could add, venison, plain solid meat, fowl, baked and boiled meat, *banquet* in exceeding plenty, and exquisitely dressed." But in none of them is there a single mention of wine or any other alcoholic drink. Poor indeed would be the civilized community that could not furnish from the dainties of the season, the varieties of fish, fowl, and solid meats, etc., exquisitely dressed and decorated by art sufficient for a "banquet of exceeding plenty," without wine. And still poorer must be the human mind that cannot rise to the higher plane of social and intellectual enjoyment without the prompting of the wine-cup.

We are not now alluding either to temperance or intemperance, but to the absurdity of claiming that a *banquet* cannot be abundantly rich, varied, and luxurious, and accompanied by the most brilliant display of wit, social repartee and eloquence, without either wine or other alcoholic beverage. Some of the richest and most enjoyable banquets we have ever attended, had neither a wine-glass nor a bottle in the room. The Temperance Breakfast, spread in the banqueting room of the Royal Pavilion during the last meeting of the British Medical Association in Brighton, was one of the most enjoyable feasts of the week. At the regular Annual Banquet of the Association during the same week, every member taking his ticket for the banquet exercised full liberty to choose *wine* or *no wine* and paid the price accordingly. The richest and most enjoyable banquet ever partaken of by the members of the Illinois State Medical Society was during the last meeting in this city, only a few years since, in the spacious dining room of the Grand Pacific Hotel, without so much as a cup of either fermented or distilled drinks. The time has fully come when every man and woman who desires neither to drink wine themselves nor to furnish it to others, should exercise the right of choice with just as much freedom, as those who desire to drink, whether in the family, the social circle, around the banqueting table, or in any other relation of life.

THEISM—THE NEW NERVOUS DISEASE.

Attention has recently been drawn to a new nervous disorder said to be especially prevalent in England and America; it is called "Theism" or tea-drinker's disease. It is said to exist in three stages —the acute, subacute, and chronic. At first the symptoms are congestion of the cephalic vessels, cerebral excitement, and animation of the face. These physiological effects being constantly provoked, give rise, after a while, to reaction marked by mental and bodily depression. The tea-drinker becomes impressionable and nervous, pale, subject to cardiac troubles, and seeks relief from these symptoms in a further indulgence in the favorite beverage, which for a time restores to a sense of well-being. These symptoms characterize the first two stages. In chronic cases theism is characterized by a grave alteration of the functions of the heart, and of the vasomotors, and by a disturbance of nutrition. The patient becomes subject to hallucinations, "nightmares" and nervous trembling. With those who take plenty of exercise, an habitual consumption often may be indulged in with impunity, but with women and young people who follow sedentary occupations this is not the case. The best treatment for theism is said to be indulgence in free exercise, such as walking and open air life.

ILLINOIS BOARD OF MEDICAL EXAMINERS.—The annual meeting for examination of candidates for licenses to practice medicine, will be held by the Illinois State Board of Health, at the Grand Pacific Hotel, Chicago, on Thursday, April 21.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, February 16, 1887.

THE PRESIDENT, JOS. TABER JOHNSON, M.D., IN THE CHAIR.

THE PRESIDENT presented

AN OVARIAN TUMOR

with the following history of the case:

Miss B., single, age 29, white, was sent to me by Dr. H. E. Leach, of South Washington, last December, on account of an enlargement in her abdomen recognized by Dr. Leach as an ovarian tumor. Upon examination I at once agreed with his diagnosis, and, although the tumor was no longer than an adult head, and gave her scarcely any trouble, I recommended its removal as soon as she could arrange for it.

I performed the operation on February 5, in a private room in the Providence Hospital, in the presence of Dr. Cutts, Bayne, Cuthbert, McArdle, Smith, Cook, and others. The tumor grew from the right ovary, was unattached except to a narrow pedicle and was removed after the evacuation of its contents through a two and one half inch incision. The tumor was multilocular. The contents of its numerous compartments differs in color, consistency and quantity. One small lobe was delivered through the abdominal opening—unbroken—and is preserved for inspection. The entire tumor weighed about six pounds. The left ovary was found to be at least four times its normal size, and cystic. In drawing it up for inspection one cyst ruptured. On this account and by its abnormal condition it, with its Fallopian tube, was unmoved also. The patient is now in her thirteenth day since the operation, perfectly comfortable, with normal pulse and temperature, and so far as I can see an unclouded prospect for perfect recovery.

A section of the unbroken cyst reveals it full of blonde hair in a sebaceous material, and the hard lump felt through the walls proves to be two rudimentary teeth.

Stated Meeting, February 23, 1887.

THE PRESIDENT IN THE CHAIR.

DR. J. FORD THOMPSON presented a specimen of

OSTEO-SARCOMA OF THE FEMUR.

The following is the history of the case: Mrs. X., aged 60, white, fell August, 1886, and fractured the right thigh about the middle. She was treated in the usual way by Dr. Sothoron. About seven weeks ago Dr. Thompson first saw her. He found non-union of the femur and stated that the only way to cure her was by an operation. After seeing her once or twice subsequently, however, he concluded that there was probably malignant disease of the bone. The woman was beginning to have pain and she was obliged to give up the use of crutches with which she had been going about. The thigh increased in size. Amputation seemed the only recourse, but upon consultation with Dr. Lincoln it was decided to delay a little longer, and the leg was put up with a slight amount of extension in order to keep it quiet. The pain, however, increased to such an extent that it was impossible to afford relief, and upon further consultation with Dr. Lincoln amputation was decided upon. Dr. Thompson stated that he fully appreciated the gravity of the operation, and while he felt himself justified in performing it, he was not by any means sure that the patient would not die on the table. This morning, (February 23,) with the assistance of Drs. Sothoron, S. W. Bogan, G. W. Johnson, Sprigg and Cutts, the operation was performed, the full consent of the patient and her friends having been obtained.

Dr. Thompson said that while he was certain that the best hope of permanent relief was in removing the leg at the hip, he had determined to make the flaps so that he might save as much of the femur as he possibly could, if he found that advisable. Having applied the Esmarch's elastic bandage from the toes to about where he expected the ends of the flaps would be, he put on an elastic ligature at this point. A second elastic ligature was applied just behind the tuberosity of the ischium, brought upwards and passed inside the crest of the ilium. He had seen this method of compression suggested, and some years ago he had used it with success in the case of a boy under similar circumstances. In this case, however, owing to the amount of fat, the large vessels in the anterior flap were not controlled, so that digital pressure had to be kept up upon the femoral artery until it could be tied. The posterior flap was kept perfectly dry. An anterior and a posterior flap were made, both by cutting from outside inwards. The femur having been reached it was sawn through just below the lesser trochanter. At the first cut of the saw it broke into fragments. Finding that the bone was diseased, the head of the femur was dissected out from the acetabulum. Owing to the great thickness of the flaps, free drainage became necessary, and with this end in view he inserted a large drainage tube into the acetabulum and a smaller one externally at the most dependent portion of the wound. The flaps were then united by four concealed catgut sutures into the mass of the muscles, several interrupted silk sutures in the usual way, and finally an uninterrupted catgut suture the whole length of the wound, thus closely and securely fixing the parts in apposition. The wound was then washed out with a warm, weak solution of carbolic acid, and the drainage tubes were found to communicate. Irrigation with hot water was kept up during the operation. The patient stood the operation very well, and when she was put to bed showed but little evidence of shock.

The dressing was of iodoform gauze followed by many thicknesses of bichloride of mercury gauze, kept in place by a spica of the groin. The thigh of the amputated leg is about twice as large as the

other. Below the knee the legs are of the same size. About the middle third of the thigh, can be plainly felt a tumor as large as an infant's head. The incision which is seen through this tumor shows it to be an encapsulated mass in appearance, and of a consistency but little harder than the brain. Several nodules, also encapsulated, project from it. The tumor appears to be nearly spherical in shape and about five and one-half inches in diameter. It has pushed forward from the femur to just under the skin, causing the muscles in contact with it almost entirely to disappear, while the other muscles have undergone fatty degeneration. At its centre the whole of the femur, except a few rough particles, has been absorbed for about four inches, while the rest of it, both above and below is practically a "sequestrum" in soft tissues, for it is completely dead. There has been an enormous increase of subcutaneous adipose tissue. The capsule strips readily from the tumor and shows no sign of ossification as might be expected if it were the periosteum.[1]

The specimen consists of the lower three-fourths of the left femur, the lower half of which, excepting the epiphysal portion has been destroyed by a spherical, lobulated, encapsuled, medullary tumor, five inches in diameter; the portion of bone remaining above the tumor as well as its medulla, is very vascular; and the muscles adjacent to the tumor, pale from fatty degeneration. The tumor probable originated in the medulla and in growing, produced the fracture mentioned in the history of the case.

The committee on Microscopy report as follows: This tumor is a spindle celled sarcoma with some giant cells. The softness of the growth is due to granular and fatty degeneration and the scarcity of connective tissue.

Dr. Swan M. Burnett read a paper entitled

REMARKS ON CATARACT EXTRACTION.

(See page 401.)

Dr. J. Ford Thompson said that he was a firm believer in antiseptic surgery, and he did not think that any good would accrue to that system if it had to rest upon the results obtained in ophthalmic or abdominal surgery. Dr. Burnett deserved credit for his effort to carry out antisepsis in his work on the eye, but it is probable that he can only approximately reach a perfect antiseptic dressing in that region. Distilled water might just as well be used as a weak solution of some antiseptic used merely to wash over the surface of a part. The same obtains in regard to abdominal surgery. Men who do not employ antiseptics in this field use their successes against Listerism. The peritoneum will not permit a very useful solution to be used upon it, and at any rate, that is only one branch of the wide domain of antiseptics. Lister himself says that the results obtained in abdominal surgery are not a criterion by which to judge of the value of antiseptics.

Dr. Burnett said that he was interested in the discussion of the value of antiseptics both as a pathologist and a physician, for it opens up the question of the etiology of suppuration. Is there a microbe of suppuration? If so and we can find something with which to throttle it, then we have accomplished a great end. He cannot agree with Dr. Thompson that the eye is not a good field for the use of antiseptics. We have here more or less control of the parts. We can make it a closed cavity by shutting the lids, and this is most favorable to healing without suppuration. It is also, constantly bathed by a bland if not strictly an antiseptic fluid. We cannot, however, foretell the cases in which suppuration will take place. Even the most perfect operations will be followed by this complication. He uses the biniodide of mercury 1 25,000 for which he has the highest authority. It seems that we have not reached the final cause of suppuration. Either there is some other external factor beside the microbe or we have not yet got the agent which will kill the germ.

There must be some condition of health or idiosyncrasy of the patient which makes them susceptible to this process. In all his cases in which suppuration occurred, the patients were in a low state of health. In one case a most perfect operation was done and there was every prospect of a typical union. Suppuration followed without any apparent reason. Six months previously the same patient who was in better health was operated upon with complete success.

Dr. Thompson thought that Dr. Burnett expects too much from the use of antiseptics. The surgeons who use antiseptics have about abandoned the idea that antiseptic dressings will prevent suppuration. Union without suppuration is obtained even where no antiseptics have been used.

The microbe of suppuration is not the important element, but the microbe of putrefaction. This last we do not yet know enough about. A deep seated abscess is not accompanied by a microbe of suppuration. It is a death of cells, and nature takes this way to rid herself of effete material. The pus is either absorbed or finds an exit for itself. When the pus reaches the surface of the body the trouble begins, for then it is that the air is admitted and with it the germ of putrefaction. The object of the antiseptic dressing is to shut out this germ, to keep the wound aseptic. In the cases referred to by Dr. Burnett, the patients were in bad health, which, as he says, probably had much to do with the complication. Moreover, in the eye, suppuration is a much more serious process than in other parts, and is of itself sufficient to destroy the organ without the complication of putrescence. Suppuration in the abdominal cavity is also as harmful as it is in the eye, so from the results in these two classes of cases the value of antiseptics in general surgery cannot be obtained. Of course, it is desirable to prevent suppuration if we can, but he does not believe that this end will ever be attained.

Dr. C. E. Hagner thought that Dr. Burnett struck the keynote when he spoke of the condition or idiosyncrasy of the patient as an etiological factor of the process of suppuration. Persons with a scrofulous diathesis, and so far as his observation goes, light haired and fair skinned persons are especially liable to suppuration. Laudable pus, however, is

[1] Patient died of exhaustion on the sixteenth day after operation.

not especially harmful. This we see in cases of obstetrics. For a few days after labor there is a bloody discharge *per vaginam*. This changes into a yellowish discharge, which is in fact, pus, but harmless pus until germs of putrefaction reach it.

In reply to Dr. J. T. Sothoron as to the percentage of failures in the cases reported, Dr. Burnett replied, but two cases in the thirty-four.

The President asked if the mania developed in one of the cases might not have been due to the anæsthetic used? Mania with this for a cause has been reported in abdominal surgery.

Dr. Burnett replied that the anæsthetic used in this case was cocaine.

(*To be concluded.*).

ST. LOUIS MEDICAL SOCIETY.

Stated Meeting, March 5, 1887.

The President, S. Pollak, M.D., in the Chair.

Dr. E. H. Gregory presented

A FIBROID TUMOR,

removed a week before, including the uterus. He first saw the woman from whom it was taken about one year ago. She had then been a sufferer for three years. It was a tumor that reached nearly to the umbilicus, and he was satisfied that it involved the uterus. She lost a good deal of blood and was treated with ergot. For two months before its removal she had not lost much blood, but there was almost a constant reddish leucorrhœa, and she was very pale. She suffered very little, nor was any function especially encroached upon. She was advised to let it alone, and the advice was repeated when she came again to have it operated upon. He told her that she was within a few years of a period when certain natural changes take place in the organ in the direction of atrophy. She was 35 years of age, and, feeling that there was much danger and uncertainty, he advised her to let it alone. But he felt sure that some younger, more enterprising surgeon might advise her to have it removed, and she seemed determined to have it done. It was therefore removed last Saturday. On opening the abdomen, carrying the incision beyond the umbilicus, he easily tilted this tumor out, put a clamp opposite the internal os, was very careful to exclude the intestines and more particularly the bladder, because in these cases it sometimes reaches high up, and it was excluded with some difficulty. Tait's clamp was used. After making the clamp fast on the bladder side, he was equally careful in making it fast on the hinder portion, and the uterus was then cut off and shelled out. The woman died. The rule is that they get well, and without a bad symptom. His patient died without a good symptom. He thought it well to have this sort of a thing placed opposite the numerous recoveries. She lived until Thursday. On Tuesday it was thought she was about to get well, but there was never a reaction from the operation, and he thought that she died from shock after hysterectomy. She had a temperature of 100° on Monday, but there was no peritonitis and no hæmorrhage, and he could not say positively what she died of.

Dr. Chas. Stevens wished to know whether, as a general thing, one would expect recovery after a uterus like this was removed.

Dr. Gregory said that in the large majority of cases, one would expect recovery. He removed one a year ago, and the woman recovered—"without a bad symptom." He did not use any drainage, because there was nothing to drain.

Dr. F. Lutz said that those who had paid attention to this subject think there is a well-founded opinion concerning the natural growth of a fibroma of the uterus; and in many instances, the question is, whether the patient ought to be operated on at a certain period of life; whether the nourishment of the fibroma does not cease at the time of the climacteric period. Keith lays special stress on the fact that in many cases a tumor which heretofore has been troublesome, when the climacteric is reached ceases both to be troublesome and to grow, on account of the diminished nutrition, on account of the change going on in the genital organs. Dr. Lutz has now under observation a woman whom he has been treating for more than a year, with a fibroma of the uterus. At first the hæmorrhages which occurred seemed to be due to the fact that she was in the climacteric period, occurring every two or three weeks. He thought she had an intra mural fibroid, and the question of interference came up. He succeeded in converting the gentleman who attended with him to the opinion that possibly this fibroid would be less troublesome after the period had passed, and that the symptoms were not sufficiently urgent to demand immediate operative interference, so he put off the operation, and he believes, rightly, as for the last four months there has been but little hæmorrhage, and the tumor has given her but little trouble. The patient is 43 years of age.

Stated Meeting, March 12, 1887.

The President, S. Pollak, M.D., in the Chair.

Dr. H. H. Mudd made some remarks on

COLLES' FRACTURE.

Last fall he presented a patient who had a Colles' fracture; accompanying the fracture there was an extensive teno-synovitis with stiffening of the parts around the joint. His reasons for again bringing up this subject may be found in a portion of the report of the discussion of the meeting held June 12, 1886, as follows: Dr. Gregory had not abandoned the old pistol-shaped splint and had heard no good argument to prove that such a splint invited subsequent deformity. He thought deformity almost absolutely certain in every fracture,—sometimes, of course, so slight as not to be apparent. Bones did not unite without scarring at the side of fracture, and there is no such thing as scar tissue without departure from the original. He had never seen a Colles' fracture treated with a perfect result. The almost universal rule is deformity. The displacement of the ulna

incident to the injury is perhaps the most frequent cause of deformity. The wrist is extremely seldom left so that the skillful eye and hand cannot detect that some accident has happened to it. As to the straight splint, cut off at the metacarpal joints, Percival Pott had once said justly, that a splint that does not control neighboring articulations was a mischievous splint. Dr. Lutz, at the same time, intimated that such perfect results were not to be expected. At the meeting of October 16, Dr. Lutz presented a specimen of fracture of lower end of radius, and in speaking of the results of Colles' fracture he thought it was very seldom that results could be obtained with no deformity. When Dr. Mudd presented this subject and patient last fall, he thought we ought to get good results in this fracture; better than the text books declared we could obtain; that for a number of years he had obtained better results, a percentage of good results that approached 90. He knew very well that tissue which is regenerated, which is renewed, is never quite so perfect as original tissue, and yet he is satisfied that many of the fractures we see should be treated so that the result would be good and that deformity could not be observed. He had an opportunity of presenting the results of some cases this evening, and asked the President to appoint a committee, of which Dr. Gregory and Dr. Lutz should be members, to inspect some of the cases and determine which arms were broken. He wished to call attention also to a recent fracture that is now under treatment, not so much because it illustrates the particular method that he has employed, as it indicates the condition of the arm after it has been confined for weeks. This fracture he did not see until forty-eight hours after the injury, and the deformity was marked, and it had been dressed imperfectly. He wished simply to show the freedom of motion given to the fingers without disturbance to the end of the bones by the short palmar splint. At the time mentioned, there was some discussion on that point. He believed it was of importance that the fingers should be free at the end of the third or fourth week, and especially in older patients.

Drs. F. Lutz, W. H. Ford, and LeGrand Atwood were appointed a committee to examine Dr. Mudd's cases, and report as follows: Concerning No. 1, Drs. Lutz and Ford say the left is fractured; Dr. Atwood says the right is fractured. The left one is correct. No. 2, all these doctors say it is the right one; correct. No. 3, Dr. Atwood says it is the left, Drs. Lutz and Ford say the right; the right was broken.

Dr. F. J. Lutz said that the cases were wonderfully perfect results. An examination of this kind must be very imperfect. The first thing any one does is to make a comparison between the two wrists, the distance between the extreme lower ends of the ulna and radius. Next, one would expect to find thickening, if not displacements of the lower end of the radius. Ordinarily there is some difference between the transverse diameter of the wrists, dependent on whether the man is right or left handed. Perhaps it would be equal if he were ambidextrous. In most cases of Colles' fracture there is displacement. In one of the cases, No. 3, there is thickening at the ulnar side of the radius, if not displacement of the lower fragment. In No. 2, in which he guessed right, the lower portion of the radius is thickened. In No. 1, the difference between the radius and ulna of the left arm he thought was markedly greater than that of the right one. They were better results than we have a right to expect, but he added that the fourth case will be the usual result of a Colles' fracture. The exhibition of the cases proved this, that in three cases a better result than is ordinarly gotten was obtained. In the fourth, the usual result was obtained.

Dr. A. Green said he had treated three or four cases a month from the Turner gymnasium with the pistol-shaped splint, and that so far as the appearance and use of the arms of fourteen cases he had were concerned, the results were perfect. The fifteenth case was that of a boy who was always running about; a few days after injury, on opening dressing and trying to get passive motion, he found that the fracture was united but not hardened, but the radius was leaning too much towards the ulna. He was afraid that supination would be lost, but introduced between the bones a pad, and a perfect result is the consequence.

Dr. Gregory agreed with Dr. Lutz exactly, and supposed that everybody who knew him would say that he has held that position for many years; for he has been telling people for many years to "let it alone." In reply to Dr. Dudley, if he ever knew a tumor of that size to be recovered from after operation? Dr. Gregory said he had seen cases recover of a tumor that size. He determined that if he could not remove the tumor, he could remove the ovaries. If he had another case, and could look into the woman and see just what was seen after it was exposed, he should advise an operation, because he is satisfied that that tumor would have grown worse.

Dr. Le Grand Atwood was surprised and delighted with the result of these three cases. He always used the pistol-shaped splint, and to his sorrow. He was careful to remove it to make passive motion, but invariably with bad results. An outline of his future plan of treatment is, that he will not use the pistol-shaped splint, and will make the patient use the fingers from day to day to prevent the anchylosis which is made with the pistol-shaped splint.

Dr. Lutz did not consider Dr. Mudd's cases deformed in the sense that he considered the ordinary result obtained from a Colles' fracture deformities.

Dr. Mudd said that no one will contend that we can have repair to a broken bone without some thickening after the injury. He believed there was no deformity in the three cases, nor that there will be deformity in the other case, notwithstanding the difficulties. He had asked, to-day, Dr. Moore to go and see an old gentleman 67 years of age, whom he treated, who suffered from Colles' fracture in January, 1873, and so perfect was the result that the man, as also his wife, was unable to tell which arm was broken. He did not advocate any special method of treatment. There are methods, the plaster, the dorsal or palmar splint, etc., with which we will get

good results. The dorsal is not as comfortable as the palmar splint. The plaster will make a very perfect dressing if the swelling is not great. He feels safer when he has a splint which he can remove to see if there is any irritation or swelling of the tissues. Patients differ in their complaints of pain. If we watch the amount of irritation expressed by the tissues, by the infiltration, we can very readily change the points of pressure, and remove very often the conditions which develop irritation. He thinks that if there is any splint which is a source of irritation to the patient, it is the pistol-shaped splint, and the Dupuytren splint in Pott's fracture. They are dangerous splints. If there is much swelling and infiltration around the tendons and ligaments, when the ankle is turned inward in Pott's fracture, we put it in an uncomfortable and dangerous position by using the Dupuytren splint, because it increases the amount of engorgement and deposit about the bones. Prof. Dennis, of New York, had developed a point in fractures about ankle joints that had been impressed upon his mind for ten years—first by a patient, Dr. Gregory—the fact that the irritation about such a fracture is diminished very much if the muscles are put at rest. He put them at rest by making an excision. He had seen Pott's fracture, where there was simply turning out of the bone, treated by putting it back with the muscles on a stretch, and the result was a long-continued inflammation. Dennis says divide the tendons when the muscles are excited to action by the irritation about the joint. A Colles' fracture is not put at rest on a pistol shaped splint, but the ligaments are put upon the stretch. The fingers should rest on the splint until the third or fourth week. Then they can be released without disturbance, and in that way mobility can be maintained. In addition to the straight palmar splint padded at the hand, he puts a pad above the end of the radius; it does not press on the sharp end of the radius, but is above. He never uses a second or dorsal splint, one being sufficient.

Dr. D. V. Dean used the straight palmar splint, or the plaster or other molded splint, usually not the plaster until after a few days, when the swelling has subsided. If one holds his hand voluntarily, or by dressings, in the position of the pistol splint, it will soon be tiresome and painful. He has never had a case under his care conducted through to the end with a pistol splint, because he has been better satisfied with other methods. In using the plaster or molded splint, he always slits it after the third or fourth day, so as to see the position. He rarely allows the palmar splint to extend further than the base of the first row of the phalanges, at least after the first week or so.

Dr. A. H. Meissenbach said the case he had treated by Dr. Mudd's method had given the best results. He had a case which occurred this week; the patient came to the office when he was busy, and having a pistol-shaped splint at hand he put it on, temporarily; the man complained of pain that night. He changed the splint the next day, and after that the arm felt perfectly comfortable. It was natural, because the idea of the pistol splint is to extend and bring into line over riding fragments, and in order to do this there must be a great amount of pressure. He has adopted a little different plan. A greater amount of freedom can be allowed without detriment to the part, not abridging the motion even at first. He thinks it can be done, because a certain amount of motion is not detrimental to the healing of fractures, for instance in position, and also in fractures of the humerus, and in some of the thigh. He thought Dr. Mudd made a very good point in stating that special attention should be given to this point in cases over 40 years of age, because he knew of several cases that had at first temporary anchylosis, and at last permanent anchylosis of the part.

Dr. W. H. Ford said Dr. Mudd's results in cases are in the highest degree satisfactory; so much so that he would not be inclined to consider either of the wrists as deformed at present. They are almost normal, and in the course of time will become more so. They are decidedly better than those it has been his lot to see in the limited results he has had. He has used the straight palmar and dorsal in all his cases. He found the other method to produce so much discomfort that he removed it and substituted the other splint. He obtained good results, but as all the cases were hard working people, they were not absolutely perfect. But it stands to reason that if we quiet the parts with a palmar and dorsal splint and leave the motion of the fingers with good supination, we will get pretty good results. He thinks the action of the supinator longus, and to some extent of the square pronator, is preventive of good results. The remark of Dr. Mudd concerning the muscular action in Pott's fracture, he thought correct. He had seen very great distortion after that treatment. In 1867 he advocated the plan of tenotomy for the the three perinei and possibly for the tibialis anticus; but he had never done it. He supposed the plan would be applicable only where there is a great deal of muscular action. It must be done early or not at all, before the œdema sets in. But of late years he has fallen on a different plan, which has been very satisfactory. If the fracture is not compound, he generally places the foot back in position. He takes a broad band of adhesive rubber plaster, 1¾ inch wide, and long enough to go from foot to knee. One point of it is applied to the dorsum of the foot, carried outwards, brought around against the sole, then up, drawing down the tissues, fastening it to the skin, turning in the remainder and securing it. He places it, besides, in a splint, and if necessary elevates it. The results have been so good that it is almost impossible to know that anything had ever happened to the foot, and there is no tendency for the foot to splay out. So that may possibly supplant the measure of tenotomy in cases where there is no spasm of the muscles, which is more apt to occur in compound fractures.

Dr. H. C. Fairbrother asked Dr. Mudd how early after the dressing he removes it, and at how late a period he removes it finally in the average age of patients.

Dr. Mudd said that if the fragments are well adjusted there is not much tendency to displacement.

He inspects such fractures on the fourth day after the injury; the worse the case the earlier he inspects. He removes these splints in the fourth or sixth week. The age does not govern very materially.

GYNÆCOLOGICAL SOCIETY OF BOSTON.

Stated Meeting, December 19, 1886.

The President, H. O. Marcy, M.D., in the Chair.

H. J. Harriman, M.D., Secretary.

Dr. E. C. Keller exhibited an

OVARIAN CYST,

removed by her at the New England Hospital for Women, with the following history: Patient 32 years old; widow. Tumor of two years' growth. Had been tapped some months since, and again about three weeks prior to the operation. Had always had much pain and had not been able to lie down since February, 1886; heart displaced and pulse 120; weight before operation 126 pounds. At the operation the tumor was found bound down by adhesions to the omentum, stomach and intestines. The adhesions were not recent. The opening into the cyst resulting from the last tapping had not closed, and the ovarian fluid had leaked into the peritoneal cavity. The tumor was multilocular, and one of the sacs contained a very dark fluid, almost black. Bleeding from small vessels torn while breaking down the adhesions was so troublesome that twenty ligatures were applied, and as they did not check the hæmorrhage, two gallons of water at a temperature of 118° F. were poured into the abdominal cavity. Even this was not entirely successful, and Monsell's solution, diluted one-half with water, was used to touch the bleeding surfaces. The pedicle was tied with the shoemaker's stitch as recommended by Dr. Marcy. A glass drainage tube was left in the wound, and on the day following the operation one half ounce of black fluid was washed out of the pelvic cavity. Stitches were removed on the eleventh day, and on the day when the case was reported the patient was doing well.

Dr. E. W. Cushing read a paper on

THE USE OF IRRIGATION IN GYNÆCOLOGY.

In 1845 Semmelweiss propounded the theory and proved the fact that, as a rule, puerperal fever is simply an infection of the genital tract at the hand of the physician or midwife. Since then the genius of Pasteur and the labors of Lister have made clear the nature of the infection, and the teachings of Semmelweiss have been generally accepted. Now it is proposed to broaden the application of this principle of infection and to show that pelvic inflammations of other than puerperal origin are due to septic infection. "Catching cold," with subsequent inflammation in the pelvis following gynecological operation or manipulation, means either that septic material has been introduced into the lymphatics from the surface laid bare by operation, thus producing a cellulitis, or that the endometrium has been infected, and that the infection has spread up the tubes and set up a peritonitis. The immediate cause of such inflammation is an infection with living bacteria or germs; the more or less favorable nature of the soil into which they fall determining whether the symptoms will be slight, with moderate fever and local hardness, or a violent explosion of peritonitis or septicæmia resulting in death.

In some cases collections of bacteria may lie dormant for long periods in the tubes or in circumscribed abscesses, ready to start into activity when released. Self-infection from such sources explains many mysterious cases of puerperal fever and cellulitis. It should be remembered that the vagina is a veritable hot-bed for the development of bacteria, and that an old gleet in the husband may have set up a mild gonorrhœa in the wife, so that gonococci or other germs abound, ready to be carried into the uterus on a sound, or to infect any wound which a surgeon may make.

The writer expressed the opinion that endometritis, erosion, ectropion, etc., may be due to bacterial irritation.

In view of the fact that these septic processes cannot be controlled by treatment after they have been thoroughly inaugurated, it is the duty of the physician, first, to prevent such troubles by killing off the bacteria in the vagina and uterus; and second, to avoid operations or harsh manipulations when he has reason to believe that the tubes contain pus.

For the first purpose there is nothing so sure, speedy and convenient as bichloride of mercury. In hospitals it ought to be a part of every vaginal examination or operation to douche the vagina well with 1:1000 or 1:2000 sublimate solution, and to carry some of an even stronger solution or strong carbolic acid into the uterus on a probe. When the cavity of the wound is to be invaded by operation it should be thoroughly washed out with a disinfecting solution. In cystitis, after operation, a sublimate solution of 1:5000 should be run through the bladder, washing it out thoroughly and repeatedly, and be followed by an iodoform emulsion.

Before, during and after all operations upon the cervix, and between packings of the vagina for hæmorrhage, the vagina should be irrigated. For long operations, or where much raw surface is exposed, the solution should be 1:5000 and should be hot. In hospitals it is comparatively easy to introduce the systematic use of irrigation, but in office practice the surgeon is tempted to neglect it. In office practice a good swabbing of the vagina with sublimate solution on cotton may answer the purpose, or one of the springes may be used which irrigate the vagina without spilling the fluid externally. A sublimate solution in water does not keep well, and must be prepared every day. By using the sublimate lozenges prepared by Grosvenor & Richards, each of which contains 7⅓ grains, a quart of solution can be quickly made by using one lozenge. For hospital use a solution of sublimate in glycerine is convenient. If 1 drachm of a solution containing ℥ij of sublimate to ℥i of glycerine be added to two quarts of water, a solution 1:2000 will be gained.

Dr. W. Symington Brown said that his principal objection to corrosive sublimate was its poisonous character, which renders it a dangerous agent in the hands of inexperienced or careless physicians. Cases of poisoning from the use of the sublimate douche have been reported, and a 1:4000 solution is the only safe one. Iodoform is also a source of danger, as it contains 90 per cent. of iodine. Antiseptic irrigation in all cases is a fallacy, and cleanliness from plain water is equally efficient. The three essentials of Listerism are absolute cleanliness, rest and drainage—germicides are not necessary.

Dr. H. L. Betts said that she used the antiseptic douche as much to protect herself from infection during examinations, etc., as to protect the patient.

Dr. E. C. Keller is partial to antiseptics, and uses sublimate, iodoform and carbolic acid freely in both surgery and obstetrics. The effect of the mercury upon instruments is bad, and to avoid this she uses a sublimate solution for irrigation and a carbolized solution in operations. Dr. Keller has always used iodoform freely and has never seen any bad effect. She does not use the douche after a normal labor unless the lochia are foul.

Dr. H. C. White regarded the use of antiseptic irrigation as essential in hospitals, but as unnecessary in private practice. In applying such measures a distinction should be made between physiological and pathological processes, and antiseptics which may be of value in morbid conditions are not essential when the process is normal, as in parturition.

Dr. Cushing, in closing the discussion, said that he had not intended to open the whole question of antiseptics in his paper, but only to present one method in which they can be profitably used. He regarded the use of antiseptic precautions as necessary for the general practitioner as for the hospital surgeon, on account of the variety of infections to which the former is exposed. He also thought that the dangers arising from absorption of the sublimate solution had been overestimated, and that no trouble would arise if ordinary precautions were used.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, March 23, 1887.

The Vice-President, W. W. Keen, M.D., in the Chair.

Dr. Morris J. Lewis read a paper on

THE SEASONAL RELATIONS OF CHOREA, RHEUMATISM, AND NEURALGIA.

(See page 404.)

Dr. W. Osler said: This is a very important and valuable (as well as seasonable) contribution to the interesting and obscure question of the relations of chorea and rheumatism. As Dr. Lewis remarked, it is not a little curious that, in his tables, rheumatism has followed chorea, while the common experience is that chorea follows rheumatism. It is the more usual sequence for a child who already has rheumatism to develop chorea, though they frequently come on so closely that it is sometimes difficult to say which came first.

I would ask Dr. Lewis whether or not his statistics in this matter gave any clew as to the relationship of these two diseases? In what way chorea is related to rheumatism, or in what way the rheumatism to the chorea? The recent statistics of the Committee of the Collective Investigation of Disease in Great Britain, show that some 32 per cent. of all the cases of chorea (430 in number) were associated with rheumatism. These affections have, in common, extreme liability of endocardial complications. It is not improbable that all cases of chorea have endocarditis. So far as the morbid anatomy goes, I do not know of an instance in which the mitral valve did not present vegetations. In the three instances that I have examined, this has not been the case. In the cases occurring at Guy's Hospital over a number of years the same has been true. So far as my reading goes, the experience of German observers confirms this view. It might be interesting to ask whether the blustering, stormy weather of the past two months has brought out an unusual number of cases of chorea. It has not brought them to my clinics.

Dr. W. B. Atkinson said: I have had within the last four weeks, at my clinic, three severe cases of chorea. During the month of January I did not see a single case. I cannot say that I have ever seen a case in which an attack of chorea antedated rheumatism, but I have seen many cases in which rheumatism has been followed by chorea.

Dr. Lewis said: I am unable to explain the relation between chorea and rheumatism. With reference to the statistics, I will state that those of chorea were obtained from the Orthopædic Hospital, the patients, as a rule, being children, while those of rheumatism were from the Pennsylvania Hospital, and the patients mainly adults.

Dr. Osler mentions that he has not seen an increased number of cases of chorea at recent clinics. I think that he will find that many cases that have occurred will arrive or be heard from later, It is not the month of application that I have taken, but the month of onset.

DOMESTIC CORRESPONDENCE

TRANSFUSION OF BLOOD.

Dear Sir:—Your synopsis of Dr. Hunter's paper, on transfusion, published in The Journal of March 5, is very interesting, and presents some new ideas on this almost obsolete operation. If I interpret them correctly the conclusions Dr. Hunter arrives at are in brief, as follows:

In a transfusion upon man of 6 ounces of blood, the excess of corpuscles would, under normal circumstances, be got rid of in a period of from one to two days.

2. That the condition of the blood as regards the number of corpuscles, does not in itself, in cases of anæmia constitute the disease, but is mainly a result.

3. Transfusion can only act by modifying the nutrition of the body, and this it can do only: 1. By the corpuscles continuing to live for a certain time within the circulation and performing their functions. 2. By the introduction of oxygen and the increased supply of oxygen brought to the tissues while the corpuscles remain in the blood; or, 3. By the introduction of the hæmoglobin contained in the blood.

As to the first possible benefit, Dr. Hunter concludes that the corpuscles transfused into an organism whose own corpuscles were being destroyed with undue rapidity, would themselves be rapidly destroyed and of not the slightest value. This reasoning also disposes of the second supposed benefit; and as to the third, "only a small proportion of the hæmoglobin so introduced can be utilized for purposes of blood formation, etc."

Now, allow me to say, that Dr. Hunter's theory is based entirely on suppositions and premises which are in dispute and doubtful of demonstration. The life of the blood corpuscle in sickness and in health; the cause of pernicious prognosive anæmia; the disposition which the organism makes of the hæmoglobin after the corpuscle is destroyed; the office of the liver in blood destruction, etc. All these functions are difficult and unsettled. But one thing is certain: "In many cases of anæmia the first important requirement is to make blood." (S. Weir Mitchell in his work "Fat and Blood.")

All cases of anæmia are not alike; some are beyond the reach of science. After transfusion, in some cases there is hæmaturia owing to the rapid destruction of the excess of blood corpuscles, in many cases there is no hæmaturia. In some cases there is no perceptible benefit, in many cases transfusion has resulted in a cure. Facts are better than theories, and displace and dispel them. Professor Immerman, in Vol. 18, of the "Cyclopædia of the Practice of Medicine," gives a table of 243 cases; 114 complete recoveries, thirty-four temporary benefit, ninety-five no benefit. Roussel reports that from 1820 to 1875 transfusion saved life in at least eighty cases of confinement, in thirty cases of wounds in war or of surgical wounds, in fifty cases of diseases of the blood or *anæmic* consumption, and twenty cases of typhus, chorea, etc. Professor Brunton, of Philadelphia, says: "It is not the number of *failures* but the number of *successes* in transfusion which surprise us, when we consider the desperate circumstances for which the operation has been reserved." (*Medical Record*, 1878. p. 20).

I am in receipt of a letter from Dr. Frank W. Epley, of New Richmond, Wis., in which he says: "I have transfused four times for anæmia, twice with brilliant success, and once it was a total failure, owing to some internal ulcer in the pelvic region, which I diagnosed malignant. The fourth operation was in a case of phthisis. The only benefit I could see was a cessation of the sweating which had previously baffled all our efforts. After the transfusion there was never a particle of sweating. . . I am convinced that anæmia may always be benefited, and many cases cured by transfusion." In one case Dr. Epley sent a specimen of the patient's blood before transfusion and three days afterwards to Professor Danforth for microscopical examination. In the first specimen Professor Danforth reported the corpuscles shriveled and serated; in the second case he reported a marked improvement. This tends to show that if the excess of corpuscles are disposed of it is not necessarily those transfused. Rokitansky's opinion was based on the fact, that the corpuscles of the defibrinated blood were not destroyed by the process, but would live when transplanted.

It is now known that in addition to the red blood corpuscle which, with the white, Rokitansky supposed to be all there were, there are, in the adult, about 500,000 blood placques per ccm. which are entirely destroyed by the process of extracting the fibrin, and of which Rokitansky knew nothing. These are, according to the weight of reasoning (if not the weight of authority) elementary corpuscles, and a very important and useful element of the blood.

I do not wish to be understood as claiming that transfusion is a specific in any class of cases. Doubtless there are a multitude of anæmic diseases in which patients have inherited a predisposition to consumption in some form, for whom there is no cure; but there are other cases which may be called accidental. They began with a cold, or are the result of ignorant disregard of the laws of health, or follow other diseases, such as typhus or diphtheria or surgical wounds, or pyæmia. In these cases I believe direct transfusion to be the best known curative agent. It is in the direct line of modern medication, tonics, fresh air, sunlight, cleanliness, etc., for it is a tonic, it is air, it is sunlight. "The blood is the natural and healthful stimulant of the heart." "Oxygen is the most important nutritive element." (Prof. Henry, "Lecture on Anæmia," August *Polyclinic.*)

I believe transfusion to-day occupies the insecure place which it has for two reasons: *First*, it is a difficult operation to perform.

"No safe and simple instrument has yet been devised with which the operation can be safely performed." (Immermann.)

Second; The medical profession have, for years insisted that defibrinated blood is fully as good as the unchanged blood (and some say better) for transfusion. So the operation has been almost wholly confined to that class, but my own experiments have been sufficient to satisfy me that blood exposed to the air and which has been subjected to the process of whipping, although not worthless, "will never," as Roussel says, "give those satisfactory results which follow a direct transfusion."

Respectfully yours, E. E. Allen, M.D.

Grand Rapids, Mich., March 15, 1887.

ASSOCIATION ITEMS.

AMERICAN MEDICAL ASSOCIATION.

The Thirty-eighth Annual Session will be held in Chicago, Ill., on Tuesday, Wednesday, Thursday and Friday, June 7, 8, 9 and 10, commencing on Tuesday, at 11 A.M.

"The delegates shall receive their appointment from permanently organized State Medical Societies, and such County and District Medical Societies *as are recognized by representation in their respective State Societies*, and from the Medical Department of the Army and Navy, and the Marine Hospital Service of the United States.

"Each State, County, and District Medical Society entitled to representation shall have the privilege of sending to the Association one delegate for every ten of its regular resident members, and one for every additional fraction of more than half that number: *Provided*, however, that the number of delegates for any particular State, territory, county, city or town shall not exceed the ratio of one in ten of the resident physicians who may have signed the Code of Ethics of the Association."

Secretaries of Medical Societies, as above designated, are earnestly requested to forward, *at once*, lists of their delegates.

Also, that the Permanent Secretary may be enabled to erase from the roll the names of those who have forfeited their membership, the Secretaries *are, by special resolution*, requested to send to him, annually, a corrected list of the membership of their respective Societies.

SECTIONS.

"The Chairmen of the several Sections shall prepare and read, in the general sessions of the Association, papers on the advances and discoveries of the past year in the branches of science included in their respective Sections. . . ." *By-Laws*, Art. II, Sec. 4.

Practice of Medicine, Materia Medica and Physiology.—Dr. J. S. Lynch, Baltimore, Md., Chairman; Dr. J. B. Marvin, Louisville, Ky., Secretary.

Obstetrics and Diseases of Women and Children.—Dr. F. M. Johnson, Kansas City, Mo., Chairman; Dr. W. W. Jaggard, Chicago, Ill., Secretary.

Surgery and Anatomy.—Dr. H. H. Mudd, St. Louis, Mo., Chairman; Dr. A. M. Pollock, Pittsburg, Pa., Secretary.

State Medicine.—Dr. George H. Rohé, Baltimore, Md., Chairman; Dr. Walter Wyman, U. S. M. Hospital, New York, Secretary.

Ophthalmology, Otology and Laryngology.—Dr. X. C. Scott, Cleveland, O., Chairman; Dr. J. H. Thompson, Kansas City, Mo., Secretary.

Diseases of Children.—Dr. DeLaskie Miller, Chicago, Ill., Chairman; Dr. W. B. Lawrence, Batesville, Ark., Secretary.

Oral and Dental Surgery.—Dr. John S. Marshall, Chicago, Ill., Chairman; Dr. E. S. Talbot, Chicago, Ill., Secretary.

Medical Jurisprudence.—Dr. I. N. Quimby, Jersey City, N. J., Chairman; Dr. H. H. Kimball, Minneapolis, Minn., Secretary.

A member desiring to read a paper before a Section should forward the paper, or its *title* and *length* (not exceeding twenty minutes in reading), to the Chairman of the Committee of Arrangements at least one month before the meeting.—*By-Laws.*

Committee of Arrangements.—Dr. Charles Gilman Smith, Chicago, Ill., Chairman.

Amendment to By-Laws.—Create a new Section, to be known as the Section on Dermatology and Venereal Diseases. WM. B. ATKINSON, M.D.,
Permanent Secretary.
Philadelphia, 1400 Pine St., S. W. cor. Broad.

MISCELLANEOUS.

DR. JOHN W. RUSSELL.—At a called meeting of the Knox County Medical Society, held March 23, 1887, the following preamble and resolutions were adopted:

WHEREAS, It has pleased Almighty God to remove from among us Dr. John W. Russell, it seems fitting for us who have been favored with the acquaintance and instruction of one whose intellectual attainments have commanded the highest admiration, whose name will stand among the foremost of his profession and whose memory will be cherished by all who had the honor to be his students and associates, to in some manner express our deep sorrow. Therefore, be it

Resolved, That this society and the medical profession have sustained the loss of a most active, earnest, and useful member.

Resolved, That the community in which he lived has thus been deprived of a Christian gentleman, and society of one of its truest and noblest safeguards—an active and learned physician, skillful and beloved, who devoted the best efforts of a well-balanced mind to the alleviation of suffering humanity.

Resolved, That we extend to the bereaved family our sincere sympathy in their affliction.

Resolved, That the medical fraternity attend the funeral in a body.

Resolved, That a copy of these resolutions be presented to the family, to each of the county papers, and to the *Medical and Surgical Reporter*, *Medical Record*, and JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION. (Signed)

F. C. HARIMORE, M.D.,
P. PICKARD, M.D.,
R. W. COLVILLE, M.D.,
Committee.

FRENCH SURGICAL CONGRESS.—The next meeting of the French Surgical Congress, the third since the foundation, will be held in Paris, in April, 1888, under the Presidency of Professor Verneuil; the precise date will be subsequently announced. The following questions are proposed for debate at the Congress: 1. On the treatment of gunshot wounds of the visceral cavities. 2. On the value of the radical treatment of hernia as a permanent cure. 3. Chronic suppuration of the pleura, and its operative treatment. 4. Recurrence of tumors after operation (causes and prevention).

The object of the French Surgical Congress is to establish scientific relations amongst surgeons and practioners of France and foreign countries. All qualified men become members of the Congress on duly entering their names and on payment of the snbscription of 20 francs. Members of the Congress

who desire to make a communication to the meeting are requested to communicate their intention to the Secretary-General three months before the opening of the Congress. A summary of the conclusions of their paper must also be forwarded. All communications should be addressed to Dr. S. Pozzi, Secretaire-Général, Congrés de Chirurgie Française, 10 Place Vendome, Paris.

Birth and Death-rate in England and Wales.—The report of the Registrar General for 1885, just issued, shows that the births of the year were 32.5 to the 1,000 persons living; the lowest number recorded since 1848. With the exception of an insignificant rise in 1884, the rate has fallen continuously year by year since 1876. The male births were 455,809, the female 438,461. It is satisfactory to learn that the long-continued fall in the marriage rate has led, for 1885 at least, to no increase in the number of illegitimate births. On the contrary, the decline under this latter heading has beaten the record in the most encouraging way. The deaths of the year lag behind the births in a way that precludes all anxiety for the immediate future of the race. They were in proportion of 19.0 to the 1,000—with one solitary exception, the lowest yet recorded. Among the deaths were 63 of reputed centenarians, 19 of whom were males and 44 females. The death-rate in the urban population was 20.0 per 1,000, and the lowest on record, while that of the rural population was 17.5, a slight increase.

Dr. R. E. Carrington, one of the most promising physicians on the junior staff of Guy's Hospital, has just died of pleuro-pneumonia, after a two days' illness.

A Loyal Dentist.—A dentist in a small provincial town in England, will celebrate Her Majesty's Jubilee by extracting teeth and supplying false ones free of charge on the morning of the celebration.

Surgical Laboratories.—The surgeons of the London Hospitals have signed a memorial asking the Royal College of Surgeons of England to build a suitable laboratory for the study of morbid anatomy, including histology, experimental pathology, including bacteriology, and of experimental operative surgery. They say that in view of the power and wealth of the college any Fellow or Member who is competent to carry out scientific investigations should be able to do so without inconvenience or expense.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 26, 1887, TO APRIL 1, 1887

Capt. Harry O. Perley, Asst. Surgeon, ordered for temporary duty at Ft. Maginnis, M. T. S. O. 23, Dept. Dak., March 18, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING APRIL 2, 1887.

Waggener, J. R., P. A. Surgeon, commissioned a Surgeon on March 18.

Fitts, H. B., P. A. Surgeon, ordered to the receiving ship "Vermont."

Tracy, E. C., Asst. Surgeon, detached from the "Vermont" and ordered to the "Atlanta."

Heffinger, A. C., P. A. Surgeon, detached from the "Atlanta" and ordered on special duty in connection with construction of hospital at Widows Island, Me.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE WEEK ENDED APRIL 2, 1887.

Urquhart, F. M., P. A. Surgeon, to assume charge of Cape Charles Quarantine. March 29, 1887.

Norman, Seaton, Asst. Surgeon, to report for duty at Cape Charles Quarantine. April 2, 1887.

NOTES AND QUERIES.

ARMY SURGEONS ON SICK LEAVE.

Dear Sir:—Referring to "Inquirer's" question in The Journal of March 19, it would seem that he has found a prototype of the famous "Pooh Bah," in a physician who is:—1st, an Assistant Surgeon U. S. Army; 2d, a local practitioner of medicine; 3d, a holder of a State appointment; 4th, a proprietor of a drug store, as the inquirer states, "all at the same time."

Now, it would seem that a solution is very easy. If an Assistant Surgeon is on sick leave, undoubtedly his only official duty is to get well; and presumably the Medical Department of the Army is the judge of this matter, though undoubtedly "Inquirer" might take the Surgeon-General into his confidence if he thinks the officer is not recovering quickly enough, or his recovery is hampered by the duties of offices 2, 3, and 4. If he is not attending to his duty under the second heading, it might be inferred he would have no patients, *ergo*, nothing to practice on. If he is not fulfilling the requisites of the third office, presumably the State Governor or legislature is open to complaint. And, fourthly, if the drug store is a poor one, it will be a victim to inanition. So, therefore, it seems that the question answers itself, and an Assistant Surgeon U. S. A. can do all of these things.

By section 94, Rev. Reg. U. S. A., 1881, "Whenever an officer has been absent on account of sickness for one year, he may be examined by a Medical Board, and the case specially reported to the President." As the retired list is limited to 400, he may have to wait an opportunity therefor.

Section 106 of the Regulations states: "Retired officers may engage in private business or hold civil offices not contrary to law."

Very respectfully,

S. T. Armstrong.

Memphis, Tenn., March 22, 1887.

PRIVATE REGISTRATION AT THE CONGRESS.

Dear Sir:—In view of the large number of gentlemen who will undoubtedly attend the International Congress, and who will hope and expect to meet old friends, classmates, etc., would it not be possible for the Committee of Arrangements to request each State Secretary to provide and forward a large register—plainly printed on the cover the name of the State—that every attendant might register his name, residence and stopping place. To the large majority it will be a pleasure trip; they will rely on published transactions for the work of the Congress. The finding of friends is to many one of the chief pleasures; yet we cannot hope to "meet by chance" all those we want to see most. A line of registers, for separate, States will in many ways facilitate the work, and accommodate individuals immensely. If it is thought advisable I will submit my plan in detail to the committee.

Hippolapius.

Terre Haute, Ind., March 20, 1887.

CORRIGENDA.

In the discussion on the Cæsarean operation, Journal of March 19, p. 325, 1st column, 17th line from bottom, for Heyner read *Keyser*.

In the issue of April 2, p. 388, 2d col., line 27, for about 25 per cent., read *one-half of 1 per cent.*

ORIGINAL ARTICLES.

A CONTRIBUTION TO THE THERAPEUTICS OF WATER, AND THE PHYSIOLOGICAL ACTION OF HEAT AND COLD.

Read before the Chicago Pathological Society, January 11, 1887.

BY G. FRANK LYDSTON, M.D.,

LECTURER ON GENITO-URINARY AND VENEREAL DISEASES IN THE CHICAGO COLLEGE OF PHYSICIANS AND SURGEONS; SURGEON TO THE WEST SIDE DISPENSARY.

In view of the fact that modern medicine is chiefly occupied in bacteriological investigations of a more or less practical nature, it is perhaps too much for one to expect a subject as old and apparently well-worn as that selected for discussion in the present paper, to attract much attention, or excite a great deal of interest. I am convinced, however, that there are those present who, if they so choose, can express views upon the action of heat and cold, and upon hydrotherapy in general, which will be both interesting and profitable. A desire to hear such expressions of opinion upon a subject in which I am greatly interested, rather than the hope of adding greatly to our general fund of information, must be my apology for presenting this paper.

The usefulness of water in its various forms in the prevention and treatment of disease is very great, and its applications to pathological conditions are so manifold, that there are few subjects of a therapeutical character so worthy of the attention of the physician. Simple as the subject may at first appear, the important part which water may be made to play in the management of various diseases is but little understood by the mass of the profession. The application of water as a panacea for all our ills, and the extravagant claims of the system of exclusivism known as "hydrotherapy," are of course fallacious, and are so often obscured by absurdities and dogmatic sophistry, that we are naturally inclined to condemn its claims to efficiency *in toto*. Strange as it may seem, the first shaft of ridicule aimed at this system of exclusivism was hurled, not by a medical man, but by that "prince of satirists," René Le Sage. Nearly two centuries ago, this author immortalized the hot-water craze in his "Dr. Sangrado." Tradition tells us that this was not an aimless thrust, for the object assailed was no less a personage than the lean and lank Dr. Hecquet, Dean of the Parisian Faculty.

It would be impossible for me to discuss in detail so comprehensive a subject as the therapeutic action of water within the limits of this paper, and it will be impracticable to avoid touching upon points which are already more or less familiar.

The therapeutic use of water is of quite ancient origin, and inasmuch as primitive man must necessarily have familiarized himself with the properties of the more common substances with which he was surrounded, it would be strange indeed if he had not discovered the value of water in disease at a very early period. Admitting that he did appreciate its value, it is certainly remarkable that nothing was written upon the subject until 1702, when Sir John Floyer, stimulated by his observations upon the popular application of certain mineral springs in his vicinity, wrote his noted work, "The History of Cold Bathing, both Ancient and Modern." Following him, Hahn, of Silesia (1738), and the renowned Currie (1797), wrote treatises upon the subject. In 1804 no less a man than Prof. Oertel, of Ansbach, became a convert to the teachings of Hahn. It was not until 1829 that any attempt was made to construct a distinct system. In that year, however, Vincenz Priessnitz, who was an untutored farmer of Gräfenberg, Austria, formulated a system of hydrotherapy which, however glaring its faults from a scientific standpoint, was marvellously clear and accurate in its details. It was not long after the promulgation of the views of Priessnitz before hydrotherapy, as an exclusive system of therapeutics, became very popular, and "water-cures" and bathing establishments sprang up rapidly in Germany, England, France and America. This was due to the ardent disciples of Priessnitz, and not to him, as he himself never wrote a line upon the subject.

The comparatively recent date of our recorded knowledge of the uses of water is especially surprising when we note the sagacity of the lower animals. M. Delaunay, in a recent memoir to the Biographical Society of London, has dwelt at some length upon the therapeutic intelligence of animals, and makes special mention of their knowledge of cold water dressings for wounds, and of cold baths in fever. When a dog is suffering with a fever, he will not only drink large quantities of water, but will often plunge into a running stream and remain submerged for a considerable time. Wounded cats, dogs and horses have been known to remain in a pool or stream of water until their hurts were healed. Graves selected as his epitaph "I fed fevers;" Currie should have

selected one reading, "I cooled fevers." A judicious avoidance of drugging, and a combination of cooling and feeding, saves fever patients to day who less than a century ago would have been bled, blanketed, starved and purged into untimely graves.

It is impossible to present, even in a general way, the therapeutical action of water, without dwelling upon the influence of heat and cold upon the animal tissues. This is especially true of its external uses, in which its action mainly depends, not upon its own physical properties, but upon the temperature at which it is applied. It is obviously illogical to arrange the phenomena resulting from the use of the hot bath and the spinal ice-bag under the common head of "hydrotherapy," but it would be impracticable to separate the effects of a mere variation in temperature from those of the bath *per se*. In a less degree this statement will also apply to the ingestion of hot water, it being difficult to say what proportion of the benefit thereby derived is due to the water *per se*, and how much to the heat. The heat imparted to the viscera, and the increased amount of fluid in the gastro-intestinal tract, and in the blood after its absorption, being alike powerful therapeutic results, it is difficult to differentiate them. In a general way it may be said that there is no difference between the effects of a local hot bath, and those of a hot poultice, so that in speaking of the action of moist heat in any form, we must relegate the matter to the domain of hydrotherapy, although it is hardly fairer than to classify the action of a hot brick or a hot water bottle under the same head.

In discussing the therapeutic uses of any remedy, it is customary to consider its various local and general effects in health and disease, and to attempt the explanation of its action upon purely physiological grounds. This plan may be most fittingly applied to the remedy at present under consideration. The explanations usually given of the action of hot and cold water when applied to the animal tissues, are based entirely upon practical observations and theoretical reasoning upon those resultant phenomena involving vascular changes, and the hypothetical tissue changes which are brought about by nervous influences, vaso-motor or inhibitory. Indeed, we are inclined to attempt the explanation of many physiological and pathological processes, and the action of many remedies, by the nervous influences, sympathetic or spinal, involved in the various phenomena, or by the vascular and gross tissue changes produced by these nervous influences. Inasmuch as these changes are all that can be determined by actual observation, it remains to be considered whether theoretical and analogical reasoning will enable us to determine upon the ultimate physiological basis of such phenomena. Now, if we analyze these phenomena, and the tissues involved in their production, we will find something behind all, the reaction of which will explain the various changes most satisfactorily. I refer to the protoplasm or basic substance of the tissues.

The rôle of protoplasm as an entity, independent of vascular and nervous influences appears to me to be a most important one, and too little thought of in our studies of nutrition, and the action of remedies. We are taught that protoplasm, even before it has been differentiated sufficiently to arrive at the dignity of a cell, has properties and functions which are but the prototypes of those possessed by the animal body as a whole. It is contractile, irritable, and automatic; receptive, assimilative, metabolic, secretory, respiratory, reproductive, and excretory.[1] Such are the properties of the amœba, which is but formless protoplasm; and of how much greater importance these functions become when, through differentiation, the protoplasm is exalted to the dignity of a cell, is illustrated by the experiments of Cohnheim and Waller, who, in 1867, so clearly demonstrated the properties of the leucocyte. If, then, we consider the matter, we may conclude: 1, that every living tissue has certain vital properties by virtue of its component cells; 2, that the cells of a tissue or organ have certain special properties and functions, few in number, by virtue of their differentiation; 3, that the essential or main vital properties of the cells are not due to their differentiation, but are possessed by them simply by virtue of the protoplasm of which they are composed. Bichat conveys a somewhat similar idea, although not so literally expressed, when he speaks of "the vital properties of tissues."

In attempting the explanation of the physiological action of heat and cold, we will consider, not the tissues as a whole, but the protoplasm or basic substance as an entity; and as a warrant for this, the following proposition may be advanced, viz.: *Tissues are endowed with certain properties which we term vital, because the cells composing them have vital properties, and these cells are possessed of vital properties, because the material of which they are composed has vital properties and functions independent of those qualities acquired through its differentiation into cells, just as the latter have certain properties and distinguishing characteristics independent of their aggregation into formed elements of tissue.* Their higher functional evolution, of course, depends upon their aggregation and organization into tissues and organs, but apart from this, their elementary properties prevail. It is upon modifications or perversions of the vital properties of tissue (*i. e.*, its protoplasm), that pathological phenomena depend, and the science of therapeutics depends upon the correction of such perversions, by the action of remedies.

There is a class of diseases which, in the absence of perceptible change in the tissues, macroscopical or microscopical, we have been compelled to term "functional" in lieu of a better name. The number of these diseases has steadily grown smaller, *pari passu* with the discoveries of chemistry and microscopy; but there are still remaining ailments which medicine confesses itself unable to account for, although loth to accept them as "functional." May not the morbid condition in many such cases consist of a perversion of the life properties and functions of the protoplasm of the affected part, too obscure to be demonstrated by any known method of research, and involving certain occult derangements of

[1] Text-book of Physiology. By Michael Foster.

tissue metabolism? The development of medical science in this direction will probably be through a more perfect knowledge of physiological chemistry. Judging from the results of the experiments of Gautier and Selmi, we are already beginning to get glimpses of light. Certain it is that the discovery of ptomaines and leucomaines is destined to be of great pathological as well as physiological importance.

Among the modern writers who appreciate and forcibly present the importance of protoplasm as an entity in biology, may be mentioned Huxley and Martin,[2] and Clevenger.[3] These eminent authorities, in describing the life history and properties of the amœba, have practically presented the independent vital properties of protoplasm, as the basis of all the phenomena of organic life, and in a most striking manner. Based upon deductions from the writings of these authors alone, we might venture to advance the following as an excellent proposition, and one which is apt to prove serviceable in the study of all physiological and pathological processes, viz.: As are the properties of its protoplasm, so are the properties of the cell, and the latter are always subservient to the former. A cell without protoplasm is impossible, but the protoplasm, unorganized, has still its distinctive properties and functions, albeit they may be intensified by differentiation.

We are not lacking in other authorities who are convinced of the independent importance of protoplasm in the phenomena of life, for some of our most noted biologists dispute the dictum of the great master, Virchow, in his doctrine of "*omnis cellula e cellula.*" Heitzmann,[4] and following him, Stricker, claim that the tissues are built up of small masses of a homogeneous undifferentiated basement substance (protoplasm, "bioplasm"[5] or "bioplasson"[6]) bound together by a delicate reticulum of fibrillary structure. Elsberg, in his studies of hyaline cartilage, demonstrates the importance of the same substance. There are, then, many excellent authorities for the position assumed in the present paper, although I am not prepared to accept the views of the biologists last mentioned as to the unimportance or non-existence of the cell in organized tissues.

To apply the theory advanced to the explanation of the action of heat and cold, or of any other agent capable of making a definite impression upon living tissue, we may accept the proposition that the changes which are induced by such agents are but a manifestation of the aggregate activity of the various cells involved, they being the primal factors in the various physiological or pathological phenomena. In this, they act simply as differentiated protoplasm. The nervous currents may be said to be merely special manifestations of protoplasmic activity, resulting in an alteration of the molecular arrangement of the cells and fibres constituting the nervous cord, and of the special collection of cells termed a nervous centre, which presides over the nerve and is responsible for its special functions. How many and what vascular effects may result from simple protoplasmic changes in the venous and arterial walls, would be difficult to demonstrate or even conjecture, but that definite effects do result from such changes is quite probable. Could they be discovered, we would undoubtedly be greatly enlightened upon the phenomena of inflammation. It may be assumed, then, that perturbations of bioplasmic activity are the basis of many pathological conditions, and especially those of an inflammatory character, and as a corollary we may accept the theory that a stimulation on the one hand, or a depression on the other, of bioplasmic activity, will explain the effects of the application of heat and cold under certain conditions of disease.[7]

It is always essential in assuming a definite position regarding a therapeutical problem, to attempt the reconciliation of conflicting elements in the form of apparently contradictory facts. This is especially necessary in the present instance, inasmuch as the profession generally accept the view that there is no essential difference in the action of heat and cold in inflammation. From a clinical standpoint, this appears to be true in acute sthenic inflammations, but that the beneficial effects are produced in the same way, is negatived by the difference in their action upon healthy tissues, when applied at a temperature short of that required to completely destroy vitality. The surgeon who believes implicitly in the theory of the similar action of heat and cold, would be apt to find himself in trouble if he applied his theory indiscriminately. Surely, the same line of treatment would not be equally beneficial in a robust patient with a traumatic arthritis, and a broken-down hospital patient with phlegmonous erysipelas.

Again, it would hardly be proper to treat a chronic synovitis upon the same principle as an acute joint inflammation. In fact, the more carefully we study the subject, the narrower the range of the indifferent application of heat or cold becomes. Life, as defined by De Blainville, "is a double internal movement of composition and decomposition; at the same time general and continuous." One of the principal elements of life, therefore, is tissue metabolism. Heat favors chemical changes in Nature's laboratory, as well as in that of the chemist, and it consequently favors physio-chemical as well as inorganic chemical processes, and interchange of ele-

[7] As an illustration of the powerful influence which changes of temperature exert upon living protoplasm, I would direct attention to the phenomena attendant upon the incubation of the chick. The protoplasm of the egg contains the inherent energy, or potential vitality, necessary to develop a chick, but it requires the influence of steady and continuous heat to develop the dynamic vitality requisite for the formation of a living animal. This illustration is in itself sufficient evidence of the important influence of warmth over physio-chemical and strictly physiological changes. The disastrous effect of chilling is obvious, and even the instinct of the mother fowl teaches her how long she may safely absent herself from the nest. It is well known that the conditions under which the human ovum develops are essentially the same as in the incubation of the chick. As an apt illustration of the disastrous effects of cold upon the vitality of cells, the effects of cold water upon living spermatozoa may be cited.

There is a strong analogy between the process of repair in wounds and inflammations, and the development of the ovum, and the moderate and continuous application of heat favors this process. In preparing a protection for the child, Nature has surrounded it during intra-uterine life by a warm, fluid environment.

mentary molecules. If, as has been claimed, inflammation depends primarily upon retarded tissue metabolism, it is quite easy to understand how moist heat will act beneficially, from a purely chemical standpoint. This fact would also explain the apparent paradox of an acute inflammation being benefited either by cold or heat, the former affecting chiefly the attendant vascular phenomena and hypernutrition, while the latter, aside from its merely emollient effect, tends to remove the original cause. The balance of benefit, even in acute inflammations, is in favor of moist heat. The prolonged application of cold is apt to prove injurious, and to induce pus formation by depressing the vitality of the exuded cells. The prolonged application of heat is rarely productive of injury, and if pus forms it is in spite of, and *not* because of it.

With reference to retarded metabolism giving rise to hypernutrition, the latter appears to be the result of a vicarious strain upon the tissues surrounding the original focus of irritation, and is itself followed, after a time, by retarded chemical change, hence the inadvisability of prolonging cold applications. It is as a result of these changes and of the pressure of inflammatory exudate that necrosis of various tissues occurs in certain inflammations.

An interesting theory of inflammation has been recently propounded by Lauderer, of Leipsic.[8] This is termed by the author "the mechanical theory of inflammation." It implies that there exists a normal balance or equilibrium between the pressure of the circulating fluid and the elastic tissue cushion surrounding the blood-vessels. A diminution of the tissue pressure without, by wasting of tissue from traumatism, or blood infection with secondary perversion of nutrition, gives rise to hyperæmia and the special phenomena of inflammation. Thus it may be observed that this theory, like that which is based entirely upon vascular and nervous phenomena, implies that inflammation is a definite effort at repair; in the theory in question, an effort at restoration of equilibrium. In presenting his theory, Lauderer claims, and with reason, that, as inflammation is merely a reparative process, it is not well to antagonize it, hence he recommends warm or hot applications, and deprecates the use of cold, save as an anæsthetic. The theory of this author is logical enough, but we cannot say as much of his deductions, for even a natural attempt at repair may be misdirected and perhaps destructive, and thus require limitation, and where cold will accomplish this, it should be used. It will be observed that with Lauderer, the balance of benefit has appeared to be in favor of heat in inflammation.

It would occupy entirely too much time were I to attempt to enumerate the various conditions which I believe to severally indicate the application of heat or cold as remedies for inflammation, but I will venture to formulate a few general considerations in their use, reserving a few of their more interesting and special applications for the conclusion of my paper.

1. Acute sthenic inflammation will be likely to be benefited by either hot or cold applications, if properly used.

2. Caution is necessary in the use of cold, and, as a rule, it should not be continued after the violence of the inflammatory process has sensibly abated.

3. Warm or hot applications are, on the average, productive of better results than cold, and they rarely, if ever, are productive of injury.

4. In the use of either agent, the temperature should be kept as equable as possible, for nothing is so injurious as alternations of heat and cold in acute inflammation.

5. In all chronic inflammations and hyperplasias, heat is the most efficient agent, by virtue of its stimulating properties. By alternating with cold, this stimulating effect upon the absorbents and the walls of the blood-vessels becomes still more marked.

6. In all inflammations characterized by general depression and local inhibition of tissue vitality, cold should never be used. In such diseases as erysipelas, gangrene, phagedæna, etc., heat is a most valuable agent. As a matter of personal experience, I can certify to the great benefit to be derived from hot applications in phlegmonous erysipelas. The improvement in the results obtained by hot applications in such cases was most marked in my hospital experience, as contrasted with those obtained by cold, which had been used almost as a matter of routine for a considerable time.

7. In all cases in which the prevention of suppuration is a desideratum, moist heat is indicated. This is contrary to the prevailing notion that a hot poultice forms "matter." Heat will not cause pus formation, but cold may do so, if its application be too prolonged.

8. In cases in which the prolonged use of hot poultices or fomentations causes a sodden and baggy condition of the part, this result is due, not to the heat *per se*, but to the moisture.

But the use of heat and cold is not restricted to the treatment of local conditions of inflammation, for they are prescribed in various general conditions. Since the time of Currie, cold has been especially useful in the treatment of fever. There is probably, in febrile conditions, excessive activity of the tissue protoplasm. Whether this is a result of an attempt to eliminate the *materies morbi* of the disease, or occurs as a consequence of a morbid impression upon the nervous system, is a matter of but little moment; the result is the same, and consists of an excessive production of heat, which is immediately dangerous to life, and which depends on an exaggeration of the special function of protoplasm known as metabolism. Now, we find that the temperature will be lowered and irritability lessened by cold sponging, and it is hardly probable that the benefits are due directly to refrigeration, for the abstraction of heat must necessarily be slight, and we find that a moderately warm or tepid bath will accomplish the same, and often more effectually.

It seems probable, therefore, that the benefit is due to a temporary inhibition of protoplasmic activity, both in the tissues generally, and in the nervous centers. In health, this is followed by a beneficial

[8] Volkmann's Sammlung klinischer Vorträge, No. 259.

reaction if the bath be not too prolonged, but in fever, the reaction must be very slight, for were it not so, cold baths would be fatal in every case of pyrexia of high degree. That the vital depression may be carried to extremes, has been demonstrated by all who have tried Liebermeister's system of cold baths in typhoid, and it is well to remember that reaction is much slower in fever than under normal conditions. There is one method of applying cold in fevers which is extremely beneficial and productive of refrigeration with little or no danger of depression. This method is that of Stephan, and will receive attention later on.

In all conditions in which stimulation is indicated the general hot bath is of value. Thus it is of service in conditions of shock, and in such diathetic and cachectic affections as gout, rheumatism, malaria and hospitalism. In conditions of nervous depression the hot bath should not be prolonged, for while its primary action is stimulating, it produces secondarily systematic depression and relaxation. Over stimulation produces necessarily exhaustion of cell vitality. In convulsive affections it will be found that the hot bath produces primarily exaltation, and it is not unusual for a child with convulsive symptoms to develop a paroxysm the instant it is placed in the hot bath. The temperature of the water under such circumstances should not be extreme, or more harm than good will be accomplished. In the diathetic affections mentioned the hot bath not only stimulates tissue metabolism and waste, but also stimulates the various eliminative areas, notably the skin.

Much more might be said upon the important subject of hot and cold bathing, but our time is limited, and I will therefore briefly formulate a few general considerations.

1. Hot and cold baths in health and disease act by virtue of their effect upon tissue protoplasm.

2. The general application of heat to the animal body produces primarily an increase of tissue metabolism, an exaltation of the nervous system, and an increase of elimination. Secondarily it produces as a consequence of over stimulation, an exhaustion of vital power which persists until the tissue protoplasm has had time to restore itself. These effects vary considerably according to the degree of heat and the duration of its application. The indications for the use of heat therefore are: 1. Nervous depression. 2. Convulsive and spasmodic affections. 3. Diathetic or cachetic conditions in which peccant materials are present in the blood and tissues. Caution is necessary in applying it in the condition of plethora.

3. The general application of cold is productive of effects for the most part diametrically opposite to those produced by heat. If the patient be robust and healthy, and the application of short duration, there occurs a temporary depression of vitality, superficial in character, almost inappreciable in amount, and almost immediately followed by a healthful reaction and increase of tissue metabolism. As a consequence, all the vital functions are exalted.

As applied in pyrexia, this depression is more prolonged, and is not followed by a proportionate degree of reaction. It is an inhibition of tissue metabolism and heat production, rather than a direct abstraction of heat, that is productive of benefit. This inhibition of vital power is modified by the degree of cold, the duration of its application, and last, but not least, the inherent vitality or resisting power of the patient. It will be seen, therefore, that the cold bath is a two-edged weapon, and is to be handled with caution.

It is well to remember, that the sudden application of cold to the surface of the body, is liable to produce marked internal hyperæmia and congestion, which may prove disastrous in diseased conditions of the viscera and vascular system. The indications for the cold bath are: 1. Conditions of debility, not too pronounced. In these conditions, its use should consist only in its transitory application, the reactionary effect being that from which benefit is to be expected. 2. Febrile conditions: In these conditions its use must be prolonged, in order that direct cooling of the tissues should be produced. These effects are modified by circumstances already indicated, and a careful selection of patients and measures is necessary.

The theory of the independent importance of protoplasm in the phenomena of life, is not only of importance as bearing upon the external application of moist heat and cold, but it is serviceable in explaining the effects of hot and cold water when ingested in greater or less amount.

It is a well known fact that cold water taken internally is capable of retarding the digestive processes under certain circumstances, especially if the patient be weakly. A glass of ice-water taken before or during a meal, especially if one be warm and fatigued from exercise, will often cause a sharp fit of indigestion due to a diminution of gastric secretion and perhaps reflexly, of intestinal secretion. That the latter results from direct chilling of the intestinal surface, is hardly probable, for the fluid must almost necessarily be warmed sufficiently to obviate any directly evil effect, by the time it passes the pylorus. That simple dilution of the gastric juices cause the indigestion is very doubtful, for a glass of hot water has a directly opposite effect.

It is generally held that a direct blanching of the mucous surface is caused by the application of the cold water, but in an organ so vascular as the stomach, the temperature of which is always above the average blood heat, such an effect is of comparatively minor importance, unless successive doses of cold water are taken. If we assume that the effects noted are the result of a direct inhibition of the vitality of the protoplasm of the secretory cells, we have certainly a logical explanation. If the condition was merely one of vascular spasm reaction would speedily come on, and the digestive process would be more energetic than ever. We notice that in the case of the cold douche applied to the skin, reaction is very beneficial and the activity of its secretory apparatus is improved. That the application of cold to the skin is not productive of depression of secretory activity unless it be continuous, is due to the comparative density of the cuticle, which protects the more

sensitive protoplasm of the secretory cells. The depressing effect of the continuous application of cold, has already been alluded to.

The beneficial effects of hot water, in certain digestive disturbances, may be explained by the stimulating effect which it exerts upon the secretory cells and muscle fibres of the digestive tract. Caution is necessary in its use, as over-stimulation may result injuriously, and enhance the disturbance already existing.

The effects of hot and cold water when taken internally are first exerted locally upon the gastro-intestinal mucuous membrane, but in common with all absorbable substances, etc., has certain effects after absorption into the blood. These effects are of two kinds. 1st, those upon the tissues, and 2d, those upon the emunctories from a functional standpoint. While these effects are usually beneficial, and the fluid practically flushes out the tissues, sewers and drains of the body, thus carrying off effete material, they may be injurious. The hyper-investigation of water or fluids containing it, is apt to prove deleterious in a general sense, for the system, so to speak, becomes supersaturated with fluid, and the loculi of the connective tissue distended and sodden. Under these circumstances, there is exclusive imbibition of fluid, by the basement substance or protoplasm of the various cells, and it might be inferred *a priori*, that a consequent sluggishness of function would ensue. This explains in part, the manifest perversion of the nutritive functions in those who consume large quantities of fluids, whether spiritous (providing the alcohol be not in excess) or otherwise. When oxidation is thus interfered with, we have an excessive accumulation of fat, or what often passes for such, a thickened, soggy condition of the areolar membrane.

Richardson says: "The signs of laxity of muscular fibre, of thinness of the blood, of pallor of the face, and of nervous excitability with deficiency of power which mark so many of our women, are often due to the consumption of an excess of liquid food." He dwells with especial emphasis upon the evil effects of beer and other watery alcoholic beverages, upon habitual drinkers. The explanation which he gives of the evils resulting from this excessive tippling, is a purely mechanical one, and implies merely a mechanical obstruction to nutrition from distension of the interstices of the areolar membrane. I believe, however, that this is hardly comprehensive enough. It is probable that the essential morbid condition is an inhibition of protoplasmic activity.

We are all familiar with the manner in which the basis substance of living cells will imbibe water through the limiting membrane, by endosmosis[6]

Undifferentiated protoplasm will do the same, although we could scarcely term the process, osmosis. There are doubtless lost at the same time, certain saline and other principles, which are of the utmost importance to the vitality of the cell. Necessarily, inhibition of function must result, and in direct proportion to the inhibition of protoplasmic activity, general vitality is impaired, for as Maudsley aptly defines it, "vitality is but the aggregate manifestation of independent existence of individual cells."[7] The effects upon the cell which I have mentioned, consist really, in mechanical hydration, but it is possible that chemical hydration occurs in a greater or less proportion of cells, and this is most disastrous. According to Hoppe-Seyler, "living protoplasm consists of anhydrous molecules in a hydrated medium." The instant the protoplasmic molecule is hydrated (*i.e.* the instant its chemical composition is modified by the addition of the elements of water) it dies, and consequently the cell of which it is an integral part, dies. It is evident that a certain equilibrium of the amount of water contained in the molecules of living tissues is necessary to their integrity, and that either marked increase or depreciation is detrimental.

This view of the physiological action of water may be applied to the internal treatment of fever, and will explain the instinctive demand for cooling drinks experienced by all animals under such conditions.

We have in febrile conditions: 1. The existence of a materies morbi in the blood and tissues, whether primarily as a specific cause of disease, or secondarily as a result of tissue metamorphosis (*e. g.*, in inflammations). 2. Excessive tissue waste due essentially to hyper-metabolic activity of the protoplasm. 3. A high grade of temperature resulting from this excessive metabolism. 4. A rapid loss of water consequent upon the high temperature. 5. Sluggishness of function of the emunctories. By the administration of large quantities of water we answer all the indications presented by these essential elements of fever, viz.: 1. Dilution and removal of the specific poison, or the products of oxidation, as the case may be, and prevention of toxæmia, both hetero and auto-genetic. 2. Inhibition of protoplasmic activity and consequent diminution of heat production, these results being due mainly to hydration. 3. Actual refrigeration of the tissues and consequent diminution of the immediately disastrous effects of heat upon the heart muscle. 4. A restoration of fluid to the tissues. 5. A stimulation of the various eliminative areas.

It is well, then, in our modern practice of refrigeration in fever, to remember certain indications which even the instinct of the dog fulfills, and which are much more direct and urgent than those for the external application of water. Too often the patient's thirst is ignored, while his heat of skin is magnified in importance.

It is well to bear in mind that concentrated alcoholic beverages when given in fever should be well diluted, for the affinity of alcohol for the water of the tissues is apt to neutralize its possible benefits in other directions. The morning thirst of the toper is an every day illustration of this action of the stronger alcoholics. It will be found that alcoholics may be best administered to fever patients in soda or seltzer water, and it is safe to say that the moderate drinker may attain the maximum of safety by a similar dilution of his daily beverage.

While it would be impracticable to discuss in de-

[6] Diseases of Modern Life.

[7] The Theory of Vitality, by Henry Maudsley, F.R.S.

tail the various applications of water, hot and cold, there are a few of the more recent uses of these agents in therapeutics that I desire to mention.

A few months ago Stephan, of St. Petersburg, published an article upon the use of the ice-bag in fever. His method consists of the application of ice-bags to the neck upon each side, just above the clavicles. The theory advanced is that the large volume of blood coursing through the carotids and internal and external jugulars is directly refrigerated, and the blood thus cooled enters the heart almost immediately to be redistributed throughout the body.[11] Since the publication of Stephan's article I have tried the method repeatedly, and have to look upon it as one of our most valuable resources for controlling fever. I have usually applied an additional ice-bag to the epigastrium, thus taking advantage of the relatively large amount of blood in the peritoneum and intestines. The directly sedative effect upon the cervical ganglia and the solar plexus obtained by this method is also an element in its favor, for the intimate relation of the sympathetic centers to the trophic changes of fever or perhaps heat production is generally admitted. In my opinion this method if generally adopted, will supersede the general cold bath. It is easy of application, not likely to be injurious if used with even a moderate amount of caution, is rational in theory, and better than all, it can be applied more or less continuously as occasion may require. The bags may safely be left in charge of any intelligent person, which cannot be said of the general cold water bath.

In substantiation of the claims advanced I take the liberty of presenting the following brief clinical notes:

Case 1.—Typhoid with complicating croupous pneumonia.—The patient was delirious at night from the first day of her illness. The stools were characteristic. The temperature upon the fourth day was 105.5° F. Quinine and cold sponging reduced it but 1° at any time, and these remedies were faithfully tried. Antipyrin in 10 grain doses was no more effective, and produced marked depression and was discontinued as unsafe, general prostration being profound. On the fifth night the temperature was 105.8° F., and the patient was wildly delirious. Bromides and opium within the limits of safety were of no service. Ice-bags were applied to the neck and abdomen, and for about two hours it was necessary to hold the patient by main force to prevent their displacement. At the end of that time she fell into a quiet sleep and slept for about four hours, the temperature having meanwhile fallen to 101° F. The ice-bags were now removed and ordered reapplied whenever the temperature rose to 102° F., and to be removed whenever the patient complained of discomfort. There was no more delirium and the patient slept a great deal. At the end of the second week convalescence was established, the temperature having been no higher than 102° F. since the first application of the ice-bags. In this case the treatment appeared to change the entire course of the disease from a severe to a mild one.

Case 2.—Typhoid, seen in consultation on the evening of the thirteenth day of the disease: The temperature was 104° F., and had stood at this point for some days. Antipyrin and quinine had not been of any service. Ice bags were applied to the neck and abdomen, and by morning the temperature had fallen to 101°. It afterwards rose, but never above 103° F., and the case was apparently hopeful, when fatal perforation and peritonitis occurred.

Case 3.—Puerperal Septicæmia.—Patient was taken with a violent chill on the fifth day after a tedious and difficult instrumental delivery. The temperature rose at once to 104° F., and in spite of intra-uterine irrigation persisted with but slight remission, and on the third day rose to 106° F. At this time she was seen in consultation by Dr. A. Reeves Jackson. Ice-bags were applied as in the previous cases, intra-uterine injections being meanwhile persisted in. In less than ten hours the temperature fell to normal, and never again rose above 102° F., and that only during the second night after the bags were used. They were at once reapplied and the temperature again fell, the thermometer registering 98° F. There was no further rise of temperature, and in a few days the patient was convalescent.

Among the more recent applications of hot water, is its use in gonorrhœa. As usually applied by continuous irrigation through the double current catheter, this method of treatment is likely to prove too stimulating in acute gonorrhœa, and the passage of the tube is likely to cause serious complications. I have used in preference ordinary urethral injections of hot water with a large syringe. The injections are to be given repeatedly for at least thirty minutes and used as hot as can be borne. It has been my experience that this method of treatment is adapted only to the more chronic forms of urethritis.

Inflammation of the prostate and vesical neck is benefited by hot enemata frequently repeated.

The recently revived hot water craze has directed attention to the internal uses of hot water, and although a great deal of rubbish has been written upon the subject, there is much of good in the hot-water system. In cases of atonic and flatulent dyspepsia, and in such functional perturbations of the kidney as Sir Andrew Clark describes under the head of "renal inadequacy," the free use of water is to be commended. Hot water taken internally is an excellent stimulant and diaphoretic, and will aid one in performing muscular labor to a remakable extent. This I know from personal experience, and some of my friends who have tried it at my suggestion while working in the gymnasium, admit that they can do more work and obtain more benefit while drinking freely of hot water. Unlike other stimulants, hot water is not followed by disagreeable effects. It is my belief that hot instead of cold water, should be drunk while in the Turkish bath. By taking hot water those individuals who complain that they do not perspire will be greatly benefited.

[11] Jour. of the Am. Med. Association, Sept. 25, 1885.

CLOSURE OF THE JAWS AND ITS TREATMENT.

Read before the College of Physicians of Philadelphia, February 2, 1887.

BY J. EWING MEARS, M.D.,

PROFESSOR OF ANATOMY AND CLINICAL SURGERY, PENNSYLVANIA COLLEGE OF DENTAL SURGERY, SURGEON TO ST. MARY'S HOSPITAL.

At the meeting of the American Surgical Association, June 1, 1883, I read a paper on "Closure of the Jaws and its Treatment." In this paper, which was published in the first volume of the *Transactions of the Association*, I described the two forms of permanent occlusion of the jaws—one due to the formation of osseous or cicatricial bands between the alveolar processes, and the other dependent upon ankylosis of the temporo-maxillary articulation, either fibrous or osseous in character. I gave also a *résumé* of the methods of operation which had been suggested and practised for the relief of these conditions, reported the almost universal failures of these methods in obtaining successful results, as gathered from the reports of cases, and stated the objections to their employment. That a better understanding may be had of the subject, I give, at this time, this *résumé*.

A *résumé* of the methods of operation which have been suggested for the relief and cure of permanent closure of the jaws shows that they have been as follows:

1. Division of the cicatricial tissues. Section of the masseter and temporal muscles, as originally suggested by Carnochan, when division of the cicatricial bands is insufficient.

2. Excision, more or less complete, of the cicatricial bands or osseous formations, and the subsequent employment in case of the former, for a long period of time, of wedges and levers to maintain the separation of the jaws. Transplantation of mucous membrane to cover the surface of the wound, as suggested by Dieffenbach, or transplantation of skin, as practised by Jaesche.

3. Division of the cicatricial tissues, and the adaptation of metal shields, not only to prevent recontraction, but to re-establish the sulcus of mucous membrane at the base of the alveolus.

4. Dieffenbach's method of simple division of the ramus of the jaw—and the formation of a false joint *behind* the point of contraction.

5. Esmarch's suggestion that the joint be formed in front of the contraction, and that a segment of bone be removed for this purpose—by external incision.

6. The formation of a false joint *in front* of the contraction by simple division of the bone, made by forceps applied within the mouth—Rizzoli's method.

In closure due to ankylosis of the temporo-maxillary articulation, the methods practised are:

1. Formation of a false joint by exsection of the jaw, by external incision (Carnochan's suggestion), or the division of the ramus from within the mouth, either by saw, forceps, or chisel.

2. Exsection of the condyle with a portion of the neck, the incision being external, as practised by Professor S. D. Gross.

The objections stated were as follows:

1. To incision and excision. The reformation of the cicatrix and the great pain to which the patient is subjected in the use of wedges, levers, and screws—the difficulties of securing flaps of mucous membrane and skin from adjacent parts and their successful transplantation. The almost universal failures.

2. Division of the Cicatricial Bands and Use of Shields. The pain and inconvenience experienced by the patient in the use of the shields, and difficulty of obtaining the full coöperation of the patient in carrying out the necessary manipulations within the mouth.

3. Section of the Ramus *behind* the Contraction—Dieffenbach's Method. The difficulty of obtaining a permanent false joint after simple section of the bone.

4. Esmarch's Method. The loss of one-half of the jaw for the purposes of mastication, where excision is made in front of the contraction. Its inapplicability when both sides are affected, and the deformity which results.

5. Rizzoli's Method. The difficulty in accomplishing the formation of a false joint by simple division of the bone—the tendency to reunion being much greater than when a segment is removed.

Having given this *résumé* of the different methods of operation and the objections which I believed to exist against the accomplishment of entirely successful results by their employment, I described a method which I had practised in a case of jaw closure due to the formation of osseous and cicatricial bands, involving the left side, the result of a gunshot wound. The injury was received when the patient was 2 years of age, and the operation for her relief was performed on January 26, 1883, eighteen years later. The plan of operation practised, and which differed from those which had been employed, consisted in the exposure of the temporo-maxillary articulation by an incision along and below the zygomatic arch, the excision of nearly the entire ramus of the jaw with the coronoide and condyloid processes, section of the masseter, temporal, and external pterygoid muscles. The osseous plate which had formed between the alveolar processes on the palatal surface was sawn through, the saw having been introduced between the teeth to accomplish this purpose. The jaws were now separated to the extent of an inch. The subsequent treatment consisted in the daily use, for a period of four weeks, of my mouth-gag, during the formation of the artificial articulation, with the result of securing a separation of one and a quarter inches. About the middle of January, 1887, four years after the operation, the patient called upon me, and I found the separation of the jaws to be over *one and a quarter inches*, and the movements in every respect normal. The patient is unable to recognize any difference, in motion or in sensation, between the natural joint on the right side and that formed upon the left.

Since the time of this operation I have had six cases of jaw-closure, in four of which I have operated by methods somewhat different from that above described. Of the six cases five were due to bony ankylosis occurring in the temporo-maxillary joint.

In one, the buccal cavities on both sides were entirely obliterated by the formation of masses of dense cicatricial tissue, which bound the jaws firmly together and permitted the separation of the lips only. This condition followed an attack of noma, in which the tissues of the cheeks, except the integument, were entirely destroyed by the inflammatory action, the tongue and lower jaw on the right side being likewise involved, causing a loss of a portion of the former and necrosis in the latter. In the report of the first case, made to the Surgical Association, I stated that I had not divided the cicatricial band which existed, but had utilized it as a ligament; and I stated my belief at the time that such use could be made of these bands. In this case, however, the cicatricial bands were so extensive, reaching from the ramus of the jaw to the angle of the mouth, and were so unyielding that it became necessary to modify the plan of operation. The condition of necrosis demanded that the mouth should be opened at once, in order that treatment could be adopted. The bands were therefore divided by incision in the mouth, the cavity opened wide, and several spicula of dead bone were removed. Use was made of the mouth-gag to maintain separation of the jaws. Despite daily use of the instrument, reunion of the bands occurred at the end of six weeks, and almost complete closure was again effected. Division of the cicatricial tissue was a second time performed, and with the same result as in the first operation. At the expiration of two months the cicatricial bands were dissected out *en masse*, leaving the buccal spaces free. Reformation of the tissues followed, and, with their recurrence, closure, not, however, to the full extent.

The difficulties experienced in this case, and the failures which accompanied the methods employed, induced me to make an effort to effect division of the dense tissue by means of a ligature, believing that reunion could thus be partially, if not completely, prevented. In this expectation I was not altogether disappointed.

Having armed a strong-handled needle with double-twisted carbolized silk ligature, I passed it from the angle of the mouth backward between the integument and the outer surface of the cicatricial mass, and caused the point to immerge just behind the last molar tooth of the lower jaw. In this manner I surrounded the cicatricial tissue with the ligature, which was tied loosely and moved each day for a week, so as to establish a canal which would not readily close. At the expiration of a week I tightened the ligature slightly, and every third day for the next two weeks made slight torsion, passing a probe meanwhile along the track of the ligature. In this way the dense tissue was slowly divided, union not taking place at the bottom of the wound, and the jaws were separated *three-quarters of an inch*, sufficient for all practical purposes. The patient went to his home in the country. At some future time the remaining tissue may be divided by the ligature and separation of the jaws to a greater extent accomplished. The result obtained in this case, an example of occlusion by the formation of most extensive cicatricial bands, induces me to offer the method of slow division by ligature as possessing advantages over the methods heretofore suggested and employed.

Modifications in the method of depositing the ligature may be required in different cases. When the jaws are firmly locked by broad bands it may be necessary to pass the ligature from behind, introducing the needle externally just behind the posterior border of the cicatricial band, and carrying it forward to the angle of the mouth; then reintroducing the needle, it may be carried along the inner surface of the mass, and brought out at the wound made on the external surface. It may be deemed expedient in certain cases to divide the bands in portions rather than *en masse*. Care should always be taken to avoid implication of the duct of Steno.

Of the cases of synostosis of the lower jaw, two were due to traumatism. In one there were evidences of fracture of the neck of the condyle of the jaw, caused by a fall upon the chin; in the other, a kick by a horse had fractured the body and ramus of the jaw, and inflammation had attacked the articulation. The articulation upon the right side was affected in both of these cases; the injuries were received when the patients were 10 and 11 years of age respectively, and the operations for their relief were performed fourteen and seventeen years later, securing in each case a separation of the jaws to the extent of *one and a quarter inches*. In the one injured by a fall upon the chin there was marked recession of the lower jaw and an absence of full development.

In the third case, a boy 10 years of age, the bony ankylosis upon the left side had followed necrosis of the body and ramus consequent upon an attack of scarlet fever. Closure of the jaws had existed for four years. In this case *one and a half inches* separation was permanently secured.

In all of these I modified the operation employed in my first case, by effecting excision of the upper portion of the ramus, the coronoid, and the condyloid processes through the mouth, avoiding in this way an external cicatrix.

The method of operation is as follows: A straight sharp-pointed bistoury is introduced beneath the masseter muscle on a level with the last molar tooth of the lower jaw. Into the wound thus made the blade of an Adams' saw is passed, and the ramus sawn through. The periosteum, with the overlying masseter muscle, is raised by the periosteal elevator, and the wound thus enlarged. The insertion of the temporal muscle is now divided by a probe-pointed bistoury. The tissues on the inner surface are separated by the elevator, the bone seized by the lion-jawed forceps, and an effort made to dislodge it by forcibly twisting it outward. If it yields at the neck of the condyle, the process is afterward chisseled out. If sufficient space is acquired without removal of the firmly ankylosed process, it is permitted to remain, the object being to provide ample space for the formation of an artificial joint. Section of the masseter muscle is made if its tense condition demands it. Hæmorrhage which arises from the di-

vision of muscular arterial branches, and possibly of the inferior dental artery, is controlled by pressure effected by packing the wound-cavity with sponges. Wounding of the internal maxillary artery is to be avoided by careful use of the instrument in close contact with the bone in the upper and inner portions.

Section of the inferior dental nerve is likely to occur, producing anæsthesia in the teeth, and regions of the chin supplied by its mental branch. In one case in which this has occurred, I have observed a gradual restoration of the function. In another, anæsthesia still exists, although nearly a year has elapsed since the operation. The wound cavity is packed with iodoform gauze, 7½ per cent., and renewed every third day. Manipulation with the mouth gag is instituted at the expiration of a week, and maintained for a varying period—from six to eight weeks or longer, according to the requirements of the case. This manipulation gives no pain in the newly formed joint. In two instances the renewal of motion has caused pain in the sound articulation. In one of the patients exhibited this evening an attack of subacute inflammation occurred in the sound joint which required the application of three blisters to remove. The use of the ordinary chewing-gum, I have found, assists materially in maintaining the movements of the jaw during the formation of the false articulation. In one of the cases the restoration of the motions of the jaw stimulated the hair follicles, and gave rise to a marked growth of the beard.

EXOPHTHALMIC GOITRE: WITH REPORT OF A CASE.

Read before the Illinois and Iowa Central District Medical Association, October 14, 1886.

BY STELLA B. NICHOLS, M.D.,

OF DAVENPORT, IOWA.

This affection is characterized by three prominent symptoms: protuberance of the eyeballs, enlargement of the thyroid body, and palpitation of the heart. The name, exophthalmic goitre, relates to the first two of these symptoms. That it is defective, is proven by its failure to include the increased frequency of the heart's action, which is almost invariably the initial symptom, and is the only one of the so-called symptomatic triad which is never absent. Although ophthalmologists, like Demours, Mackenzie, Sichel and Desmarres, had already made mention of this affection, it remained for Graves to describe it as an individual complaint, which he did in 1835. Afterwards, from Basedow giving a fuller description of it, it was known as Basedow's disease, which is the name now given to the affection by German writers. American, English and French writers have adopted the name Graves' disease, as proposed by Trousseau. Cardiogmus strumosus, and exophthalmic cachexia are other titles by which it has been known.

There are cases in which one of these cardinal symptoms is absent. The exophthalmia is the event most often wanting; the palpitation, the goitre and the associated phenomena being the same as if coexistent with the exophthalmus. In other cases the goitre alone is absent. It occurs more frequently in women than in men, though it is by no means confined to the former sex. Niemeyer thinks that menstrual disorder, or perhaps the lack of red corpuscles in the blood, which so often accompanies such disorder, also seems to have some part in its production; but it is altogether inadmissible to regard such disease of the vaso-motor nerves as a mere part of that widespread disorder of innervation which occurs in hysteria, and to attribute the relaxed state of the vessels, or of their nerves, proceeding from the want of red corpuscles in the blood. Indeed, Basedow's disease is not especially prevalent in cases of severe hysteria or intense chlorosis, and in some cases even appears in persons free from both menstrual disturbance and impoverishment of the blood. Graves and his colleague, Stokes, took the view that the goitre and exophthalmus were dependent on the cardiac disorder. In some particular cases the disease has been attributed to fright or other mental excitement, or traumatic causes. Austin Flint believes that, "in view of the fact of the exophthalmia and the goitre being, in the vast majority of cases, bilateral, it seems rational to suppose the pathological nervous condition to be central rather than peripheral." Aitken believes that "the normal nutrition of the nerve-centres is impaired," and says "palsy of the vaso-motor nerves connected with the carotids, thyroid gland, and heart, is the explanation given of this disease;" that it coexists with wasting diseases, or supervenes upon them; such as leucorrhœa and menorrhagia in females, and hæmorrhoids in males. Amenorrhœa, long continued hæmorrhages, want of rest, and many other similar causes, have been assigned in different cases. Dr. Stokes says: "In young women, mental anxiety and the effect of terror may produce it."

Hammond does not accept the opinion that the disease is an affection primarily of the heart and the blood-forming organs, and thinks that we have no evidence to show that chlorosis or anæmia ever produce in their entirety the remarkable phenomena characteristic of Graves' disease. On the contrary, he thinks that we are justified in regarding it as an affection of the brain and medulla oblongata, and bases his opinion on the fact that the disturbance of cardiac action, the cough, nausea, and protrusion of the eyeballs, indicate the pneumogastric nerves as the organs through which the phenomena are manifested; and cites the absence of pupillary disturbance as one of the strongest circumstances against the hypothesis of sympathetic disorder. In the four cases which have come under my observation there has been uterine disease, and the sequel has seemed to prove that it was the primary cause of the disorder.

The first symptoms are usually palpitation of the heart and habitually rapid pulse, with other signs of nervous debility. The next symptom in order is generally an enlargement of the thyroid gland with violent beatings of the carotid arteries. Exophthalmus makes its appearance either at the same time, or a little sooner or later. The palpebral fissure is widely opened, closure of the lids is infrequent and

incomplete, while the upper eyelid takes but little part in the movements of elevation and depression of the eyeballs. Although these three phenomena may be said to constitute the pathological trinity of which the disease consists, there are cases in which the goitre may be almost if not entirely wanting, while in other cases the exophthalmus may be slight or absent.

The severity of each of these symptoms is variable. In addition to these cardinal symptoms, we may find minor manifestations such as cough, nausea, increase of temperature, profuse sweating, hæmorrhages from the lungs, nose or bowels, and sometimes œdema of the extremities. Emotional excitability is also increased. There are insomnia and various disturbances of sleep, headache, vertigo, neuralgia, mental irritability, and often depression of spirits. There may be disorder of digestion with constipation or diarrhœa. Anæmia and emaciation are usually present, and may be coexistent with more or less mental weakness. In women, menstruation is almost always either entirely absent or greatly diminished. There are rarely any marked disturbances of vision, and the movements of the eyeballs are usually normal.

The diagnosis of exophthalmic goitre is rendered comparatively easy by the usual prominence of the three characteristic phenomena. The heart is seldom organically affected; the protrusion of the eyeballs, although sometimes so great as to interfere materially with the closure of the lids, is not productive of pain, disorder of the globes, or impairment of vision. The enlargement of the thyroid rarely attains any great bulk, as in common goitre. Loud, and often musical murmurs, both arterial and venous, may be distinguished upon applying the ear to the enlarged gland.

The clinical history is an important factor in the diagnosis of the disease. Cohen tells us that the prognosis in those cases—the most frequent—in which there exists no sign of organic disease in the heart or other organs, is very favorable, though a long time often passes before the characteristic features of the disease entirely disappear. Aitken says "the result may be unfavorable, by reason of dilatation of the heart, with diminished functional power. The patient becomes cyanotic and dropsical, with dyspnœa. Death takes place also, but more rarely, by cerebral symptoms." Cases due to uterine disorders in which the functional derangement has not already induced organic disease of the heart, improve promptly upon removal of the cause. Of course, as a rule, recent cases yield more readily to treatment than cases of longer duration.

The causes and symptoms of the disease point very definitely to the proper treatment. Rest of mind and body, and the removal of those conditions which seem to have been important elements in the first production of the disease; generous diet, change of air and scene, and in short whatever has a tendency to invigorate the system. The excessive irritability of the heart and nervous system demand digitalis, the bromides, and other remedies of this class. Tonics, especially iron, should be used to improve the impoverished condition of the blood. Iodine has been quite generally used in the treatment of the enlarged thyroid gland, but whether used internally or applied to the swollen gland, it appears by itself to be of little use. Carpenter has found iodoform internally to be peculiarly efficacious in the treatment of this form of goitre. He ascribes the excellent results obtained, to some influence of the nervous system, rather than by its resolvent properties.

Trousseau relates a case of suffocation, caused by pressure of the enlarged thyroid body on the trachea, which was relieved by the application of ice to the neck, and the administration internally of digitalis.

Hammond relies upon the primary galvanic current as the principal agent for the cure of the disease. His rule is to make the intensity of the current as great as the patient can bear with comfort. He says: "One pole—a wet sponge—should be placed on the nape of the neck, and the other should be stroked down the skin over the pneumogastric—or sympathetic if the physician regards this nerve as the seat of the disease; it is impossible to act on one without at the same time affecting the other to an equal extent. This should be done daily, for five or ten minutes."

Pepper has effected a complete reduction of the thyroid enlargement, by the injection into the gland of a solution of ergotine, in addition to ergot, given internally. Some of our latest writers regard ergotine as being almost a specific in this disease.

Uterine troubles are to be removed, as they are believed to bear a special causative relation to the affection.

Four cases of exophthalmic goitre have come under my observation. All occurred in women; all presented the cardinal symptoms, distinctly marked; all suffered from uterine lesions, and all improved more or less promptly upon instituting appropriate gynecological treatment. Of course, internal remedies were used to control nervous excitability and other annoying symptoms, during the course of treatment. One of these cases has been particularly interesting to me, from the fact that it has been, throughout a typical case.

The patient, an unmarried woman, 23 years of age, consulted me because of amenorrhœa of seven months' duration. Upon inquiry I learned that shortly after the cessation of menstruation, she suffered greatly with palpitation of the heart, and extreme nervous sensibility. A little later exophthalmus gradually made its appearance. At about the same period she began to experience some difficulty in the deglutition of solid food, and by this symptom her attention was directed to the slightly enlarged thyroid gland. A little more than a month after the onset of the disease she became confined to her bed, by reason of nervous prostration and palpitation of the heart. In the meantime, all of the symptoms were greatly aggravated. At the end of six weeks she recovered her strength in a sufficient degree to admit of her being up and about the house. The exophthalmus and goitre were still very noticeable, and she was much emaciated. At this time, digestive disturbances be-

came prominent, and for the space of one month she vomited a large portion of her food. When this symptom was under control, there still remained constipation, alternating with diarrhœa. From this time until she came under my care, her condition remained practically unchanged.

When I saw her, there was violent palpitation of the heart, pulse 120. The arterial excitement was not confined to the vessels in the neck, there was also increased action of the abdominal aorta. The prominence of the eyeballs was well marked, though the lids could be closed without difficulty. The eyes were suffused and red. I cannot better describe the condition of the thyroid gland than by quoting from Holmes' "Surgery": "It was soft, smooth and elastic, and of equal character throughout, presenting the form of hypertrophied gland, and had rapidly developed itself to its present size—that of three or four times the magnitude of the gland in health; but it was subject to remarkable variations in this respect, according to the state of mind, rest or palpitation. It appeared to be highly vascular, and conveyed to the touch the sensation of an erectile tumor. There was also a purring thrill to be felt by the fingers, and a loud and sometimes musical bruit to be heard through the stethoscope." The lower extremities were œdematous. There was at times, profuse sweating. Examination showed the uterus to be about two-thirds the usual adult size. The posterior lip of the cervix was elongated, and soft and flabby to the touch. There was slight erosion of the cervical mucous membrane. No discoverable ovarian difficulty.

The general treatment consisted of tonics and sedatives, such as pyrophosphate of iron, digitalis, and bromide of zinc. Good results were obtained from the use of ergot. The galvanic current was applied daily, as suggested by Hammond. The gynecological treatment was directed to the relief of the uterine disorder, independently of the associated phenomena improvement followed rapidly.

At the end of two months the exophthalmus and goitre were much less noticeable; the palpitation of rare occurrence, the symptoms which usually precede menstruation made their appearance, and with the exception of slight dyspnœa on exertion, the patient said that she felt perfectly well, and discontinued further medical treatment.

212 Brady St., October, 1886.

PERINEORRHAPHY AS PERFORMED BY DR. W. GILL WYLIE.

Abstract of a paper read before the Obstetrical Society of Philadelphia, March 3, 1887.

BY HOWARD A. PARDEE, M.D.,
OF PHILADELPHIA.

The interest shown in the paper describing Dr. Emmett's operation for the restoration of the perineum, read at the February meeting, leads me to think that a brief description of the operation devised by Dr. Wylie might also be acceptable to the Society.

According to a paper by Dr. Wylie, contributed to the *N. Y. Medical Record*, March, 1885, he had devised the operation about five years previously. It was first performed before a class, so far as I know, in a ward in Bellevue Hospital, in the winter of 1882–83. It is the operation as I then became acquainted with it that I shall describe, for it is the one I have since used and am most familiar with. A letter, received from Dr. Wylie a few days ago, tells me that he still uses the same operation with little if any modification. It is performed as follows:

The usual preparation by laxatives, hot douches and glycerine tampons having been carried out, the bowels are cleansed by enema an hour or two before the time for operation. Just before the patient is etherized, a hot vaginal douche of corrosive sublimate, 1 to 5000, or carbolic acid, 1 to 40, is given. Patient is placed on her back, the buttocks as near edge of table as possible, with the thighs strongly flexed and knees held apart by an assistant on either side. The labia are drawn apart as fully as possible without straining, and are held by the assistants. The caruncles marking the posterior border of the vaginal orifice are found and mark the limit of the denudation upwards or towards the pubes. A tenaculum is hooked into the crest of the rectocele, which is drawn down and an examination is made with the finger to find at what point the tissues on either side of it are put on the stretch by the traction. This point or one a very little above it is made the limit of denudation backwards into the vagina. It is well to mark it by snipping of a particle of the mucous membrane on either side. For the denudation a pair of moderately sharp pointed scissors, curved on the flat is the most convenient instrument. Following Dr. Wylie's example, I have always used a pair of good dissecting forceps to catch the tissues, instead of the tenaculum.

Commencing from below, a strip of mucous membrane as wide as can be conveniently cut is snipped off, following the line of junction of the skin and mucous membrane from the level of the inferior caruncle on one side to the same level on the other. We then denude all the posterior surface of the vagina up to this level till we reach the beginning of the sulci running on either side of the rectocele. The part of the operation requiring the greatest judgment has now come. Our object is to unite the vaginal walls above the sulcus on one side with the corresponding portion of the vaginal wall on the other side, so obliterating the sulci and forcing back the rectocele. If we carry denudation too high we shall find it difficult to bring the two sides together without undue tension. If we are too timid our support will be insufficient and the operation will be but a partial success. The proper level having been determined, we continue the denudation upwards till we reach the points in the vagina which we marked out as the limits of tension from the apex of the rectocele. This will usually be about one and a half or two inches from the orifice. In denuding this portion of the vagina we still work from side to side carrying the strip of mucous membrane down into the sulcus, up over the rectocele, down into the other sulcus and up to the level we have marked on

the other side. In doing this we should not cut very deeply, and preserve as much as possible of the muscular substance of the wall of the vagina over the rectocele, but afterward we should go over our work in the sulci removing all tissue till we come to the fibrous external sheath of the vagina. In this way we hope to preserve a firm muscular coat over the rectocele. When we are through, the denuded surface will be nearly square, or if the rectocele be very large a paralelogram, the greatest length being transverse to the axis of the vagina. All bleeding should be controlled perfectly by pressure and torsion, but if necessary catgut ligatures may be used and the parts washed thoroughly with some efficient antiseptic.

The suture should now be introduced. The first three or four are placed as in the old "butterfly" operation, entering about a quarter of an inch outside the line of junction of the skin and mucous membrane, passing backward and downward and then upward and forward emerging on the other side at a point corresponding to the point at which they entered. The last one of these external sutures should be entered a little above the level of the caruncle which marked the limit of denudation upward. The remaining sutures, four or five in number, are usually entered in the mucous membrane a little above the line of denudation, passed down below the angle formed by the sulcus and up to the crest of the rectocele. It is best to bring the needle through at this point and reintroduce it at the same point, it then goes down the other side of the rectocele, round the angle of the sulcus and up the opposite vaginal wall till it emerges above the line of denudation opposite the point where it entered on the other side. This may seem to be a difficult stitch, but with a straight needle, a good needle holder, and the index finger of the left hand in the rectum while the thumb is in the vagina, it is made without much trouble. The greatest care should be taken that the needle is buried when it passes under the angle of the sulcus.

When the sutures are placed and before they are tightened, the sphincter ani should be thoroughly stretched. This, to a certain extent, relieves the tension on the sutures, and at least adds largely to the comfort of the patient by preventing straining at stool. Another thorough cleansing of the parts should be done, and the sutures should be tightened from below upward. The urine is not drawn unless the patient is unable to pass it. The parts are washed after urination.

MEDICAL PROGRESS.

Condurango in Cancer of the Stomach.—Fifteen years ago there was introduced from Brazil a remedy which was claimed to be a specific for cancer. Since then, as before, other remedies have been similarly vaunted, and none have stood the test of experience. The remedy in question was condurango bark, of which a trial was made at the Middlesex Hospital, the negative results being read before the Clinical Society by Messrs. Hulke and De Morgan (Clin. Soc. Trans., vol. 5). In Germany almost the only favorable report came from Professor Friedreich, who related instances of its value in gastric cancer. Since then it has fallen much into disrepute, having been regarded as little better than a stomachic, and prescribed thus with advantage (Wilhelm: Year-Book of Treatment, 1886, p. 49) in cases of carcinoma and ulcer. But Dr. Riess, of Berlin, has just published (*Berl. Klin. Wochensch.*, March 7), some striking testimony to the value of the drug in gastric carcinoma, more conclusive than any that has hitherto appeared. It is noteworthy that he doubts whether its qualities as a stomachic are better than those of other drugs of that class, and that he has not found it efficacious in cases of cancer where the stomach is not primarily involved. (Messrs. Hulke and De Morgan's reports did not deal with gastric cancer.) It was in cases presenting the symptoms of cancer of the stomach (many with a tumor) that the best effects were noticed. In 105 cases—*i. e.*, where gastric cancer was diagnosed—treated at the General Hospital from 1878 to 1886, condurango was prescribed, and in no case, even in those in the last stage, without some effect. The drug was often given every hour—the total amount per diem reaching 10 grammes of the decoction—and continued for long periods without ill effect. The appetite improved in a few days, vomiting and pain diminished, and eventually ceased, and the patient gained in weight. Whether life is actually prolonged is, of course, difficult to prove; but Riess quotes statistics which show that the cases treated with condurango, both the fatal ones and those discharged in improved health, remained much longer in hospital than those not treated by the drug. He even states that of sixty four cases in which a palpable tumor was present, in seventeen it diminished in size, and in eight quite disappeared; and he details three cases of such disappearance of obvious tumor, which, subsequently dying, presented only cicatricial structure, with no trace of malignant disease. Obviously, before we can accept such cases as examples of the *cure* of cancer we must be certain that the original diagnosis was correct, and the same skepticism may be allowed respecting the whole series of cases. For cancer of the stomach may not only be latent, but may be simulated by non malignant ulceration, as every physician knows. Dr. Riess fairly discusses this point, being quite alive to the objection. He claims, at least, that condurango has some local effect upon a diseased stomach, and considers that in all suspected cases it should be prescribed. It need hardly be pointed out that a local action as here claimed is a very different thing from a specific action in cancer generally, which was sufficiently disproved by the observations at the Middlesex Hospital.—*Lancet*, March 12, 1887.

The Cure of Large Ulcers of the Leg by the Carbolized Spray.—Gilles de la Tourette, of Paris, presents in detail three cases of stubborn ulcers of the leg in inmates of the *Infirmerie des In-*

curables connected with the service of Charcot. The general condition of the patients was of the worst description. The first was an extremely debilitated and emaciated subject of asthma conjoined with chronic bronchitis, 69 years old, presenting an enormous ulcer covering the whole right leg, from the malleoli to within an inch of the tuberosity of the tibia. The carbolic spray for an hour and a half morning and evening, with intermediate dressing with borated vaseline, caused a complete cure in less than a month. The second was an ulcer, eighteen centimeters high, covering the lower half of the leg in a patient 82 years of age, feeble and senile, and the subject of chronic bronchitis. Carbolized spray for two hours twice a day with borated vaseline dressing in the intervals, secured a complete cure in about six weeks. The third case occurred in a syphilitic subject, with mitral insufficiency, tertiary syphilis and chronic bronchitis, aged 59, with a vast ulcer, twenty-two centimeters long, enveloping the whole leg. Carbolic spray applied during the next six months had brought the ulcer down to about the size of a six sous piece when the patient died by his own hand. As the result of his observations, the author concludes: *a*. The method of carbolic spray repeated daily for an hour and a half, morning and evening, beter than any other method leads to a rapid cure of large varicose ulcers. *b*. In the early part of the treatment, the pains seated in the ulcer disappear. In the three cases observed, no erythema ever appeared at the margin of the wound, nor did the patient ever void the black urine indicating carbolic poisoning. *c*. A state of debility or senility of the patient does not in any way contra-indicate the employment of the method, which, on the contrary, by the local stimulation, which it determines, seems formally indicated in this particular case. *d*. The solutions used are the stronger, as the ulcer is the more atonic; solutions less than 1 to 50 should be rejected and even the greater strength, $\frac{1}{30}$, $\frac{1}{20}$, or even $\frac{1}{10}$ could be used. In the interval between the applications of the spray, the dressing of borate of soda and vaseline, 1 to 10 will be found useful.—*Revue de Chirurgie*, July, 1886.—*Annals of Surgery*, March, 1887.

Scopoline.—Mr. H. Percy Dunn says: This new mydriatic, introduced by Pierd'houy, is, as far as my experience of it goes, a useful drug. Since the beginning of the current year I have employed it almost continuously amongst my out-patients at the West London hospital, not for the purpose of testing its qualities as a mydriatic, but as a drug to supersede atropine in the treatment of keratitis, corneal ulcers, and iritis. I have found that in the case of troublesome corneal ulcers which had been treated respectively with both atropine and eserine without success, rapid improvement followed the installation of scopoline. And especially was this good effect shown in cases of severe interstitial keratitis, in which atropine had been previously employed. Again, in rheumatic iritis the use of scopoline was obviously effective in reducing the pain and injection of the globe. Upon no occasion have I seen any conjunctival or other irritation set up by its use, and I have found one grain to the ounce a sufficiently strong solution for my purposes.

I am disposed to believe that, in addition to its mydriatic power, scopoline is able to effect some control upon the vascular supply of the eye; the drug may be, indeed, the physiological antithesis of eserine; at present, I am engaged upon an inquiry with Dr. P. S. Abraham, into the physiology and chemistry of the drug, and we hope before long to publish the results.—*British Medical Journal*, Jan. 8, 1887.

Peroxide of Hydrogen in Whooping-Cough.—Dr. Benjamin Ward Richardson, states that he has treated nine cases of whooping cough with peroxide of hydrogen exclusively, in six males and three females, all children. The solution was given in doses of a fluid-drachm five or six times a day. The remedy in this affection has a decided value. Commencing with it in the acute stages of the disease, and trusting to it alone, he has never seen pertussis cut short so quickly and determinately by any mode of treatment except change of air. He had previously used dilute nitric acid in whooping-cough, as advised by the late Dr. Gibb, and with satisfactory results. The peroxide appears to him to act in a manner very similar, but, he thinks, with more effect. It subdues the spasmodic paroxysm, checks the secretion in the throat, and shortens the period of the malady, lessening, thereby, the dangers of after-effects. The mode of prescribing it is:

Hydrogen peroxide (10 vols. strength)....	ʒvj.	
Glycerine pure.....	ʒiv.	
Water distilled to.....	ʒiij.	ɱ.

To make a solution of three fluid-ounces, of which let half a fluid-ounce be taken in a wineglassful of water as directed.

When there is a stridulous spasm with the cough he substitutes ozonic ether ʒij for the solution of the peroxide, or adds it to the mixture.—*The Asclepiad*, No. 13, 1887.

Antifebrin.—Eisenhart, in the clinic of Ziemssen in Munich, has used antifebrin, and reports as follows: The number of cases observed was 30. The doses given were from 4 to 8 gr., in powder and solution, by rectal and anal use. In a case of erysipelas a dose of 8 grains was vomited when given by the mouth; when given by injection it was retained. In general the drug was well borne; half the patients had profuse perspiration following, and an exanthem occurred in one case. Cases of typhoid, treated with antifebrin, had an easy course. The influence of the drug was generally manifested two hours after it had been taken. After a dose of .4 gr. the temperature sank six times from .1° to 1°, thirteen times from 1° to 2°, fifteen times from 2° to 3°, six times from 3° to 4°, and three times more than 4°. After a dose of 8 gr. a depression of temperature of .1° to 1° occurred three times; from 2° to 3° seven times; from 3° to 4° twice; from 3° to more than 4° twice.

In doses of 4 to 8 gr. antifebrin is a very valuable febrifuge, reasonably certain of success.—*Deutsche Medizinal Zeitung*, No. 51, 1886.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

The Editor of this Journal would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SATURDAY, APRIL 16, 1887.

BERGEON'S TREATMENT OF CONSUMPTION.

If experience justifies the claims of M. Bergeon for his method of dealing with this deadly foe to mankind, he will have illustrated the saying of Horace:

Exegi monumentum aere perennius.

There is another name which should be associated with his in honor: that of Claud Bernard, since his experiments thirty years ago laid the foundation for this present discovery.

It is not likely that in this or any other form of treatment will be found a cure for all cases of pulmonary phthisis. Yet such are the results already gained in numerous cases by the rectal administration of carbon dioxide charged with sulphuretted hydrogen as to expose the physician, who does not try it in any given case of consumption, to the charge of culpable negligence. Therefore although the majority of our readers are probably familiar with this novel treatment through descriptions published in this and other journals, we propose to state a few points for the sake of any one who may chance to desire enlightenment. Full descriptions of the apparatus and the method of its employment are to be found in the *British Medical Journal* of Dec. 18, 1886, and the *Medical News* of April 2, 1887, besides various French journals, and a pamphlet published by M. Morel, Bergeon's assistant.

The results claimed by the inaugurator of the method and his colaborers, by Cornil, Chantemesse, De La Roche, physicians in Geneva, Marseilles, Philadelphia, this city and elsewhere, all competent observers, are strikingly in accord; viz., a lowering of the temperature, lessening of the sweating, cough and expectoration, a feeling of well being, improvement of appetite and consequent gain in strength and weight. This improvement of symptoms is manifested, moreover, so soon, that Bergeon says the patients may be considered convalescent oftentimes in from fifteen to twenty days. Is it strange then that the laity and profession alike are being carried away by enthusiasm! What other line of treatment is there that will accomplish as much and in so short a time, if at all! Moreover, Bergeon, Cornil and others cite cases in which all symptoms of disease have disappeared and only signs remain indicative of once active, but now quiescent pulmonic lesions. Furthermore, M. Chantemesse has reported this treatment as strikingly efficient in allaying paroxysms of asthma. It is said to mitigate the severity of whooping cough, as well as to abbreviate the duration of the disease. Chronic bronchitis is also favorably influenced; while septicæmia and other blood diseases dependent upon the presence of germs, are likewise amenable to this method of therapeutics. Enemata of carbonic acid gas charged with hydrogen sulphide are said to be tolerated without ill effects to the patient, if properly given.

Such, in brief, are the glowing accounts of M. Bergeon's method, which is exciting such lively hopes. Such are the effects in which optimists see the long sought cure for consumption. We frankly own they are flattering, and repeat our assertion above, that they are such as to render every practitioner guilty of negligence toward his patients if he does not try the method in suitable cases.

Is there, however, no other side of the picture? Are there no considerations which render the treatment inadmissible in certain cases? Assuredly; and the conservative element in the profession is beginning to direct attention to these. It is not denied that almost miraculous amelioration of symptoms has followed the treatment in numerous instances. Nevertheless, since bacilli are still found in the scanty expectoration of patients in whom disease appears to have been arrested, it is claimed quite justly that a cure cannot be said to exist. Again, cases are on record in which the treatment was not well borne. Indeed, M. Wiss, of Geneva, cites three cases in which it was not at all well tolerated, the patients dying inside of two months from the beginning of the treatment. One of them was a man aged 40, in whom it produced such severe colic and diarrhœa that it had to be abandoned at the end of a month. In this instance Bergeon himself superintended the treatments. Dr. Osler, of Philadelphia, in some comments upon this method before the Philadelphia County Medical Society, mentions one case in the

Philadelphia Hospital who nearly expired after the first administration of the gas charged with a mixture of carbon bisulphide and sulphuretted hydrogen. M. De La Roche, of Lyons, has also reported a case in which the treatment produced intense colicky pains, but in this there were hæmorrhoids and fissure of the anus. These are sufficient to render caution necessary. De La Roche furthermore thinks the treatment inadmissible when both lungs are extensively destroyed. The reason is clear; the lungs would be able to eliminate the gas but slowly, and unless the injections were made very gradually, a degree of distension of the bowel would be produced which might seriously, perhaps fatally embarrass the limited respiratory capacity remaining to the patient. Finally, in cases of intestinal ulceration, a rash degree of distension might cause rupture of the weakened bowel.

Such are the considerations which dispel the glamour thrown about this new method by optimistic supporters, and make its indiscriminate application by advertising charlatans dangerous. This view of the case also should be set before the press of the country lest enthusiastic, unscientific and exaggerated reports of the success of the method arouse hopes never to be realized, if indeed nothing more serious should result. It is too soon for this treatment to be characterized as a cure for consumption, as it is being heralded by the quacks and the press. It must first be tested critically and established upon a scientific basis. To this end M. Cornil has instituted a series of careful experiments upon tuberculanized animals, to ascertain if this treatment possesses microbicidal virtues, or whether its effects are due solely to the power of disinfecting the products of suppuration within the lungs. The profession awaits with interest the results of these experiments. It is to be hoped that Bergeon's method may not share the fate of so many other vaunted weapons against this dire disease. Meanwhile a word of caution to the wise is sufficient.

ESBACH ON DIABETES.

Dr. Esbach, Chef of the Laboratory of Clinical Medicine at the Necker Hospital, has lately written an interesting Thèse on diabetes or glycosuria, which he describes to be a disorder of the assimilating functions, by virtue of which certain aliments which ought to be destroyed in the organism to be transformed into force and heat, pass through it without being utilized and are eliminated by the urine in the form of sugar. The author reserves the name of glycosuria (symptomatic diabetes) for cases in which the diabetes has not a special existence. Essential diabetes is, on the contrary, glycosuria which cannot be connected with a lesion, or with an anterior or existing malady.

Dr. Esbach describes diabetes as being composed of four principal elements in the static period, or, in other words, in a paroxysm of diabetes mellitus: 1. A nervous disorder, of divers origin, most frequently from some mental cause, which deranges the assimilating function of the liver. 2. Glycosuria, the richness of which varies according to the degree of the malady, in proportion to the bread and to the sugar and starchy substances ingested. 3. Exaggeration in defective assimilation, or increasing fatigue of the assimilating function, in proportion to the exaggerated consumption of sugar and starch, and to the overtaxing of the function of the intestines. 4. "Physiological misery" (anæmia), the result of improper alimentation, and tending to exaggerate the assimilating powerlessness of the diabetic neurosis. The author draws the distinction between fat and lean diabetics, and gives as important rational signs of diabetes, polyphagia, polydipsia, and polyuria. Isolated polyuria (diabetes insipidus) is not rare in women.

Esbach has made persevering researches on the chemistry of glucose, and recognizes only two certain means of discovering its presence in the urine: Fehling's liquid and the polarimeter. The measure of the density is not always significative; however, it is rare that beyond 1030 there is not glucose. As to treatment, he recommends diabetics to drink largely according to their thirst, in order to diminish glycæmia as much as possible, water being the accelerator of all the secretions, of all the nutritive processes—the medicament *par excellence*. The treatment by drugs, he says, is almost *nil*. With the exception of the alkalies the general treatment is founded almost exclusively on alimentary hygiene. Two methods are vaunted as being capable of combating the glycosuria: The first is by the complete suppression of all farinaceous and saccharine substances until the entire disappearance of glucose in the urine takes place, the exclusive use of gluten bread being at the same time prescribed. After six months' absence of the glycosuria, the treatment consists in the method of strict surveillance. In the latter case, the patient may be allowed a small quantity of ordinary bread, as long as the glucose does not augment or reappear in the urine. This method is specially applicable to old and confirmed diabetics. In his *menu*, the author allows his diabetics the use of coffee without sugar, or it may be sweetened with glycerine, without, however, attaching to the latter any curative action on the

diabetes. It is rather disagreeable to the taste, but it does not produce sugar in the urine. Finally, a good deal of muscular exercise should be insisted upon, particularly walking. The mind should be kept perfectly quiet, and the patient should avoid politics and the reading of medical works.

THE DUTIES OF SECRETARIES OF SECTIONS.

In view of the approach of the annual meeting of the American Medical Association, we would again call attention to some defects in the practical working of the Sections of the Association, and chiefly to the fact that the discussions on papers are not fully reported. The discussions as sent with papers to this office are usually entirely valueless, and in not a single case for two years have they been at all full. It is of no interest to a reader to know that a certain paper "was discussed by Drs. Brown, Jones, Smith, Johnson and several others." We gain no valuable information by reading that "Dr. —— asked a question about the dose of croton oil, and Dr. —— answered it." It is of no value to know that "Dr. ——'s paper was ably discussed by several gentlemen." We must presuppose that all papers read before the Association are discussed by gentlemen when discussed at all, but it is for the readers of the discussions to say whether the discussions were able or not. Our curiosity is excited by reading in a Secretary's report that "The discussion was closed by Dr. ——," but our stock of information is not increased.

Those who take part in the discussions can lighten the labors of the Secretaries, and have their remarks appear in a much more readable and valuable shape by writing out their remarks, wholly or in part, as far as possible, before going to the meeting of the Association. This can be made more practicable by having the author of a paper indicate to the Secretary of his Section those who would be likely to take part in the discussion, and have the essential points sent to them before the meeting. It is done in other scientific bodies. And should any matter come up which has not been embodied in the written discussion, it can be easily added to what has been written. And should no new point come up the discussion is ready to be handed over to the Secretary. To say the least, those who discuss papers should do all that they can to assist the Secretaries in making out a useful report of the Sectional meetings. If a paper is worth discussion it is worth while for those who discuss it to make a little self-sacrifice in having their remarks appear in proper form, and accurately. In some cases last year we had to write to different parts of the country to find out what certain men had said in the discussions.

The position of Secretary of a Section is a purely honorary one, but he who accepts it should feel it a duty to do his work properly and carefully. It is regarded as an honor to be elected to such a position, but it should not be regarded as an honor which entails no duty or work on the recipient. No one should accept the position who is unwilling to do the work devolving upon him. It is entirely useless for a Secretary to report in full the business transactions of his Section to the Editor of THE JOURNAL. This properly belongs to the business of the Association, and as such should be sent to the Permanent Secretary to be incorporated in his report. THE JOURNAL does not publish separate reports of the Sectional meetings of the Association, and when they come to this office they are only so much waste paper. What is wanted of the Secretaries of Sections is an accurate and full report of the *discussions on papers* read in the Sections, giving simply the name of the author and the title of his paper, and the *date on which* a paper is read, so that it may be published in its proper order. Abstracts of papers read in the Sections are of no value whatever, as the papers are published in full in THE JOURNAL. It will be noticed that in THE JOURNAL the discussions, such as are sent, are placed immediately after the papers. The reason for this is obvious: the papers are published at different times, not in a lump, and it would be annoying to have to refer back possibly eight or ten numbers to read the discussion on a certain paper. In reporting discussions, and giving names of authors of papers and of those who take part in discussions the Secretaries will prevent much confusion by giving the full, or usually known names, postoffice, and State of each person.

We know that absolute attention to all details may deprive some of much of the social enjoyment of the meetings, but neglect of these details and duties may subsequently deprive the members and readers of THE JOURNAL of much valuable material.

MEDICAL GRADUATES FROM CHICAGO COLLEGES.—The number of students receiving the degree of Doctor of Medicine at the several recent annual Commencement exercises in the regular colleges was, Rush Medical College, 134; College of Physicians and Surgeons, 53; Chicago Medical College, Medical Department of Northwestern University, 44; Woman's Hospital Medical College, 25. Making the total 256, representing about 750 matriculants.

Illinois State Medical Society.—In another column will be found the usual notice for the annual meeting of the Illinois State Medical Society, to be held on the 17th, 18th and 19th of May, in this city. It is very desirable that the profession in every part of the State should be represented in the coming meeting. The recent death of Dr. Wm. T. Kirk, of Atlanta, devolves the duties of President upon the first Vice-President, Dr. Elias Wenger, of Gilman. Members of the Society will meet a cordial reception from the profession in this city.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, February 23, 1887.

The President, Jos. Taber Johnson, M.D., in the Chair.

(*Concluded from page 413.*)

Dr. J. Ford Thompson gave the history of a case of

LAPAROTOMY FOR INTESTINAL RUPTURE.

Called in June, 1885, by Dr. Henderson, to see A. B., a young man of 18, who was suffering with symptoms of obstruction of the bowels. He found a large, hard tumor in the right iliac region, which was very tender on pressure.

The patient had been treated with purgatives and enemata, but without relief. The long rectal tube and copious injections, however, relieved him.

Was called again in April, 1886, to see the same boy whom he found much more ill than at his first visit. There was vomiting, and a tumor in the right iliac region was rapidly increasing in size. The same means as before failed to give relief.

On May 4, he explored the tumor with a needle and found pus and fæces. It being impossible, owing to other important engagements, to operate that day, the next morning (May 5,) he made a long incision over the tumor and evacuated an immense amount of fæces. He seized a fistula in the colon just below the ileo-cæcal valve and drew it into the wound. As far as he could see the abdominal cavity was filled with fæces. The cavity was washed out with hot water, but the fæces seemed still to be escaping into it.

On the anterior aspect of the colon he found an opening about 1.25 inches in diameter. The condition of the tissues around the opening would not permit him to close it in the usual way, so he stitched it at each end to the incision, thus making an artificial anus. A drainage tube was inserted beside it, into the abdominal cavity to allow of the escape of water and fæces.

The patient rapidly improved and in a few days all the fæces were being discharged through the artificial opening.

The wound in the parietes closed so rapidly that it had to be occasionally dilated to admit of the exit of the fæces.

The gut, however, did not unite, and the epiron could be seen between the two openings in the intestine.

About two months after this, having slightly enlarged the parietal wound, he carefully applied Gross' enterotome to the epiron. In six days the instrument came away but the fistula still remained patent.

The patient was now in a good state of health, but was very much troubled by the continuous discharge of fæces through the artificial anus. In fact, his life was made unbearable, and both he and his parents were very desirous that some curative operation should be done.

Dr. Thompson having fully explained the uncertainties and dangers, as well as the possibilities, of a radical operation, readily obtained consent to the trial.

On December 11, therefore, assisted by Drs. Henderson, G. W. Johnston, Spigg, Leach and Cutts, he once more opened the cicatrix of the old incision. Having broken down the adhesions of the gut to the parietes he had no difficulty in finding the opening into the intestine. This was of considerable extent, and to his surprise in the "small" intestine, while it had been the "colon" which he had previously stitched to the wall. He, however, pared the ragged edges of the fistula and joined them by the Czerney-Lembert method with three layers of fine silk sutures. This fistula was about six inches above the ileo-cæcal valve.

He was just about to close the wound in the abdomen, when he discovered a second and larger fistula in the "colon" about opposite the ileo-cæcal valve. Had he known in advance of the existence of "two" fistulæ, he would probably have resected the gut between and joined the two ends together.

As it was, having closed the first opening, and judging from the appearance of the intestine between the openings that it was healthy, he closed the second fistula as he had the first.

The abdominal wound was closed, and on the fourth day an enema brought away fæces *per rectum*. On the eighth day, however, fæces appeared at the artificial anus, and they have been discharging from there ever since, although there is an occasional movement from the regular passage. This proves that his estimation of the condition of the ileo-cæcal valve was correct.

Dr. Thompson went on to say, that his diagnosis of the cause of this inflammation and sloughing of the caput coli, had been perityphlitis, but that now he was not certain whether perityphlitis or typhlitis had come first. It makes, however, very little difference, as one almost always leads to the other.

Laparotomy, in these cases, is nearly always a late operation, for it is very difficult to tell the proper moment for its performance. If we wait until fluctuation appears in the region above the inflammation, suppuration has done all the harm it can. He is in

favor of treating it as any other abscess, by cutting down upon the gut at the first signs of suppuration without waiting for fluctuation. If only pus be found this incision is sufficient, but if there are fæces in the cavity they must be washed out and the wound in the intestine closed, provided it is a recent one. If the edges of the fistula are congested and there is much inflammation, the only thing to do is to make an artificial anus, with the intention of closing it when the patient has somewhat regained in health.

On the other hand, severe symptoms of perityphlitis or typhlitis suddenly disappear without operative interference.

He has recently been called three times to do colotomy for intestinal obstruction, but has each time succeeded in relieving the patients without it.

The question is, how did the wound in the ileum come there? It might he said that it was made when he put the enterotome on the epiron. This does not seem probable as he had taken the greatest precautions to prevent this very thing.

His explanation is that both openings were there at the first operation, but that only the fistula in the colon was discovered. The ileum being adherent to the colon, was drawn with it to the parietal incision and discharged itself upon the surface. Only the colon was, however, stitched to the wound. Either that was the way of it or it was made by the enterotome, for its existence for some time could not be doubted.

Dr. T. C. Smith asked Dr. T. from whence came the fæces which he says continued to well up even after he had seized the opening in the gut? Does this fact not confirm the idea that the break in the ileum was there at the first operation?

Dr. Thompson replied that he had been unable to tell whether he had the upper or lower opening of the colon in his hand, and that in all probability he had not absolutely excluded it, so as to prevent the escape of some fæcal matter.

He has been unable to find the report of a like case anywhere. The peculiarity of the case is that there were "two" fistulæ lying alongside of each other with the ileo cæcal valve between them, in the continuity of the gut.

Dr. A. F. A. King asked if what was taken at first for the colon might not have been distended ileum?

Dr. Thompson replied that he was certain that it was not.

Dr. S. C. Busey asked why, if the hole in the ileum was there at first, the contents had not continued discharging through it into the abdominal cavity?

Dr. Thompson replied that the ileum was adherent to the colon and was attached with it to the incision in the parietes, and that the fæces escaped the easiest way.

Dr. Busey said that this point was still not quite clear to him. Dr. Thompson says that the two openings were there from the first. Now, if the colon was stitched around the edges of the parietal wound, what prevented the fæces from discharging into the peritoneal cavity through the fistula in the ileum? So far as the peritoneal cavity was concerned it was shut off from the external air by the stitching of the colon to the knife wound, but he failed to see why fæces did not get into this cavity.

Dr. Thompson explained that the colon was not stitched to the abdominal incision all the way round, but only at the top and bottom, and that a drainage tube had been inserted to one side. There was, therefore, plenty of room at the side for the discharge of a fistula of the ileum.

If his theory, that the two adhered by the first inflammation, is correct, it is plain that a slough in the ileum would open into the colon, and that, having been stitched to the belly walls, the fæces from the ileum would discharge through it upon the surface.

ST. LOUIS MEDICAL SOCIETY.

Stated Meeting, March 19, 1887.

The President, S. Pollak, M.D., in the Chair.

Dr. F. S. Mooney exhibited

A STONE REMOVED FROM A FEMALE BLADDER.

It was a soft stone, weighing 405 grains. He removed it by cutting through the vagina into the bladder, and left the opening unclosed in order to get drainage. There was a great amount of cystitis which has been quite severe for four or five months. It was removed on Wednesday morning, when the patients temperature was 101° F., and since that time it has come down to a little above normal.

In reply to Dr. F. J. Lutz, why he did not stretch the sphincter, Dr. Mooney said he dilated the urethra sufficiently to introduce the finger into the bladder, and there was such a quantity of tough mucus there, and so much cystitis, that he thought it advisable to make a cut simply for drainage, if for nothing else. He believes it is a good plan to make an opening in case of cystitis, and without it it certainly would have been a good task to wash out all of this stone. He crushed it with a small uterine polypus forceps. It would not have been possible to remove the stone through the urethra without crushing it.

Dr. Lutz said it was surprising to what extent the female urethra can be dilated. It is a common thing to put the finger into the female bladder by simply introducing the dressing forceps and spreading the blades, and introducing the finger. He believes we should always avoid an incision in surgery if by any other procedure we can accomplish the object, and the stone, in his judgment, ought to be of exceedingly large size before the bladder is cut. There are other conditions engendered by the presence of the stone, or in some instance giving rise to the formation of calculus which might demand incision, such as cystitis, as in Dr. Mooney's case. Cutting the bladder gives a surface favorable for the absorption of noxious material, and thereby increasing the risks of the operation. Afterwards there is vesico-vaginal fistula to deal with.

Dr. L. K. Laidley said, that the question of the

mode of dealing with these cases was very correctly discussed by Dr. Emmet. He bases his reasoning for the use of the knife on the reports of Dr. Bozeman in his tables that in a large number of the cases which were dilated, dilatation destroyed the power of the neck of the bladder, and thereby inflicted injury on the patient. The number of cases that Dr. Bozeman reported convinces him that there is much less danger in cutting in than in dilating, and he thought Dr. Mooney was warranted in cutting in this case.

Dr. R. Funkhouser thought one point a very important one, which has only been casually mentioned—the cystitis. From his observation in connection with the treatment of cystitis in the male, and from the operation of button-holing the bladder, he would think the most proper operation in the present case would be cutting through into the bladder by the vagina. Dr. Mooney said that the patient suffered intensly from cystitis. There would be a greater surface for the absorption of morbid material if the attempt had been made to stretch the urethra instead of cutting. He finds that in dealing with the urethra, even for ordinary trouble, as in irritable urethra, there are not only one, but sometimes three or four fissures made by the dilatation.

Dr. Mooney said that this patient, before she was operated on, was taking 2½ grains of morphine daily to control the severe pains she had. Since the operation she has had one dose of morphine, of ¼ grain, and no more. The incision has not closed; it was only made three days ago. He does not think we necessarily have a vesico-vaginal fistula in these cases. Thomas and Emmet say it is very hard sometimes to keep the opening patent. He explained to the patient that she would probably have to have another operation performed.

Dr. H. C. Dalton gave the history of a case of

STRANGULATION OF THE BOWEL.

The case was brought to the City Hospital three days since with symptoms of acute intestinal obstruction. He was a delicate looking man, about 34 years of age. He stated that some ten years ago he had dysentery; also again about three years ago, shortly afterwards he had an attack very similar to the one for which he entered the hospital. Three days prior to admittance he was taken very suddenly ill with intense pain in left iliac region, which soon extended over the entire lower portion of the abdomen. It was intermittent in character. His bowels had not moved since the attack, nor had any flatus passed. He had vomited persistently, ejecta being stercoraceous. The least pressure over the abdomen gave intense pain. His condition bordered on collapse. I ordered morphia, stimulants, hot bottles, etc., and concluded to wait for some reaction before operation. The vomiting did not again occur, and reaction was established by the following morning. When Dr. Lutz saw him, his condition appeared so good that we thought it advisable to delay the operation. Dr. Lutz performed laparotomy at 4 P.M. The patient did not rally, and died two hours afterwards. Dr. Lutz will describe the operation.

Dr. Lutz said, the man's history was a peculiar one, he had twice before been supposed to have suffered from intussusception. As is usual, the attack came on suddenly. Meteorism was not extensive. The tenderness was limited to the region below a line drawn across the abdomen at the umbilicus. Diagnosis approximately made was strangulation by a band, based on the previous history of peritonitis. In opening the abdominal cavity and introducing his hand, the first thing he struck was a band firmly binding down the gut, beginning in front and passing over the bowel, downward toward the pelvis, where it is united with a number of adhesions which bound together several of the coils of the intestines. This adhesion, he thought, was the one which caused the strangulation, because it seemed that from that part upward the black strangulated portion began and extended six inches. The other portions of the bowel, which were matted together, were not in that apparently lifeless condition. The question came up, whether or not the bowel which appeared black and lifeless was possessed of sufficient vitality to warrant its retention in the abdomen. It was replaced without performing excision. We know that in many cases of strangulation the bowel is returned because the blood supply is extensive and the gut soon regains its vitality. In removing the band which held a portion of the intestine down, the peritoneum was removed from the portion of the gut over which it passed. This is an important question in excision of a portion of the stomach or intestine. Whether or not the vitality of the bowel suffers to any extent after removal of the peritoneum, he was not prepared to say, but he would judge from observation and reasoning that the limited portion removed from the bowel would not seriously interfere with the nutrition, and is not productive of a sufficient amount of peritonitis to jeopardize the result of the procedure. The fact that the bowel was made impervious by this band had demonstration by the escape of the intestinal contents after the removal of the compressing force. There is no question in his mind that the procedure was justifiable, nor was the diagnosis of intussusception warrantable from the symptoms.

Dr. I. N. Love thought the developments following the operation fully justified Dr. Lutz in performing it. The important lesion that we learn from this case is that we should direct our attention to the local condition.

GYNÆCOLOGICAL SOCIETY OF BOSTON.

Annual Meeting, January 13, 1887.

The President, H. O. Marcy, M.D., in the Chair.

H. J. Harriman, M.D., Secretary.

The following were elected

OFFICERS FOR THE ENSUING YEAR.

President, H. M. Field, M.D.
Vice-President, Horace C. White, M.D.
Secretary, H. J. Harriman, M.D.

Treasurer, W. Symington Brown, M.D.

Committee on Membership: Drs. A. L. Norris, C. W. Stevens, E. C. Keller.

Committee on Pathology: Drs. E. W. Cushing, A. P. Weeks and H. O. Marcy.

The President, Dr. H. O. Marcy, read his Annual Address, entitled "*Recent Advances in Abdominal Surgery.*"

Dr. E. W. Cushing reported a case of

MELANCHOLIA; MASTURBATION; CURED BY REMOVAL OF BOTH OVARIES,

and presented the ovaries. The history of the case was as follows: French Canadian, 33 years old. Since the age of 15 has suffered from dysmenorrhœa and intense pain in both ovaries; has been a confirmed masturbator. Had lately lost flesh rapidly, and had sunk into a state of profound melancholia on account of the belief that she had committed the unpardonable sin, and was eternally damned. Was unable to attend to any occupation, and begged that some operation might be performed in hope of relief. She was seen by Dr. H. I. Bowditch and Dr. H. O. Marcy, who advised removal of the ovaries. The ovaries were removed by Dr. Cushing in the presence of Drs. H. I. Bowditch, S. N. Nelson and Geo. W. Galvin. The Fallopian tubes were somewhat enlarged; ovaries slightly enlarged, and one contained a small cyst.

The question of how much effect the operation will have in these cases is important. Clitoridectomy is inefficient, but removal of the ovaries has in some cases been done with advantage. Dr. Cushing asked the sentiment of the Society in regard to the advisability of removing the ovaries in such a case. In reply to Dr. A. D. Norris, as to the condition of the clitoris, Dr. Cushing said that it was somewhat enlarged and congested, but not markedly changed. He had examined the patient but once, and then his manipulations induced a strong orgasm.

Dr. A. P. Clarke saw the patient prior to operation and found her in a deplorable condition.

At the meeting of the Society held on February 10, exactly four weeks after the operation by Dr. Cushing, the discussion of the case was resumed.

Dr. Cushing made a short supplementary report in regard to the case. The patient recovered from the operation without a bad symptom, and now complains only of some tenderness about the pelvis. Since the operation she has been entirely free from melancholia and sexual passion. She describes her improved mental condition by saying "a window has been opened in heaven." Some scoff at the idea that insanity can be favorably influenced, in any case, by removal of the ovaries, but the operation has been done repeatedly, and with a degree of success sufficient to prove that ovarian trouble can cause mental derangement. The operation is not a severe one, and is not as dangerous as a major amputation.

Dr. H. I. Bowditch, a guest of the Society, was asked to discuss this case. He said that he had come to the meeting for the sole purpose of saying something in regard to Dr. Cushing's case. Of all the triumphs of surgery none equal this operation. He had seen the patient prior to operation and found her a poor, miserable, wretched being, on the verge of suicide. Since the operation the change in her condition was marvelous. She is now clothed and in her right mind; her whole manner is changed and she is quiet and pleasant. There is still slight tenderness about the pelvis, but no sexual passion. He had been so much interested in the case that he had visited the patient twice since the operation. He believed that the risks of death should be run in order to gain such a wonderful improvement, and that a physician who would not do this operation or would not permit it to be done would be wanting in humanity. He said that there are many cases in our insane asylums, similar to the one described, which might be cured by removal of the ovaries. In reply to Dr. Cushing as to whether, in his opinion, there was any hope of curing such cases by moral means. Dr. Bowditch said that there was absolutely no hope from moral means. In reply to Dr. L. F. Warner, he asked if Dr. Bowditch would advise the corresponding operation for a similar condition in a man. He said that he had never seen a case in a man resembling the one described by Dr. Cushing, but that if he met such a one he would recommend the corresponding operation.

Dr. Warner referred to a case exhibited to the Society years ago by Dr. H. R. Stover, which resembled in many respects the one under consideration. In that case the clitoris and all the tissues down to the pubic bone were removed and recovery followed. He was opposed to all such operations, and believed that the favorable results reported came from the powerful moral influence of the operation.

Dr. E. C. Keller saw Dr. Cushing's patient, both before the operation and afterwards. She believed her infinitely better off since the removal of her ovaries. The woman is not now more mutilated than before. As to the charge that such an operation unsexes the patient, Dr. Keller did not regard that a misfortune in such a case. Marriage is not for such a person, and children springing from such parentage are not wanted.

Dr. R. J. P. Goodwin raised the question as to the legal responsibility of the physician who performed this operation upon a person who was not mentally capable of giving consent. Have we a right to operate in such cases?

Dr. E. W. Cushing said that the same rule would apply in these cases as to one in which a person was found unconscious with a limb crushed. The consent of relations and friends should be gained, and the operation performed.

Dr. W. Symington Brown said that in cases like that of Dr. Cushing many things should be considered. Is the operation likely to result in a cure? This question can be answered with a fair degree of accuracy by determining whether the ovaries are actually diseased. If one or both ovaries are diseased, remove them; otherwise let them alone. Americans are given to overdoing things, and are likely to err in the same direction in surgery; one successful case may inspire similar operations in cases not suitable for operation, and thus bring a justifiable oper-

ation into disrepute. If the patient is incapable of earning a living, and is a nuisance to herself and friends, the operation should be performed. If doubt exists as to the state of the ovaries, an excision should be made. He believed that if nymphomania was a disease of any one organ, it was a disease of the brain and not of the ovaries. On this theory any shock may cause an improvement, whether it is purely moral or the effect of a radical operation. A case was cited of delirium tremens, followed by insanity. When the recovery from insanity took place the appetite for strong drink had entirely disappeared.

[Reports from Dr. Cushing's patient as late as March 10 show that she is still entirely free from mental derangement and excessive sexual passion.]

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, March 3, 1887.

The President, Thomas M. Drysdale, M.D., in the Chair.

Dr. D. Longaker read a paper on the

TREATMENT OF LABOR IN CONTRACTED PELVES.

The most frequent forms of contracted pelves are the flattened and the generally contracted. In the former the conjugate diameters alone are shortened, and in the latter all are less than normal. This paper is limited to the consideration of those cases where the narrowing is moderate and not sufficient to render the birth of a living child impossible; this embraces flat pelves having a conjugate of three inches or a little less, and generally contracted pelves having a conjugate of at least three and one-third inches. Dr. Longaker here followed with a description of the peculiarities of the flat non-rachitic pelvis and the flat rachitic pelvis.

Reports of six cases were given. In the *first*, with a conjugate of three and one-half inches, craniotomy was performed in consequence of the large size of the head and an unchangeable bad presentation of the head, after attempts to deliver with the forceps had failed. The mother ultimately recovered. A careful study of the change from a vertex to a brow presentation is given, and the increased dangers in multiparæ follows, with a criticism on powerful traction efforts first with one pair of forceps and then another until three or four have been tried. *Case* 2 was delivered with forceps of a living child. *Case* 3 was also delivered with forceps of a living child. *Case* 4. Rachitic flat pelvis, conjugate of three inches, second pregnancy; delivered by means of Tarnier's traction forceps. Her first child had been born without assistance after sixty hours of labor. A large portion of the posterior cervix had sloughed away as the result of this prolonged labor. The head was transverse and semi flexed at the superior strait. He applied the forceps over the face and occiput and delivered a living child. The mother did well. *Case* 5 was a counterpart of the fourth. Tarnier's forceps were used and mother and child did well. With version in contracted pelves he has had no experience. Under favorable circumstances the operation can be done so easily that it may be regarded as without danger in itself. *Case* 6 was a breech presentation in a contracted pelvis, third pregnancy. The first child had been still-born, the second was delivered alive by means of the forceps. In this, the third labor, the extraction of the after-coming head was very difficult and the child was still. The day after delivery signs of internal hæmorrhage and peritonitis appeared, and the mother died twenty-four hours after delivery. Rupture of the uterus and vagina were found at the autopsy. Three other cases of uterine lacerations in breech presentation in contracted pelves were given, and after a study of the mechanism of this tendency to laceration he came to the conclusion that it will be best to restrict version to cases in which there are other reasons for it than the mere existence of flattening—some of these being the presence of the occiput on the smaller side of an unequally contracted pelvis, the saggital suture over the symphysis pubis, presentation of an ear and prolapse of the cord. He extols the axis-traction forceps in these cases, and exhibited an instrument of his own devising, which he had used in two cases. He has no hesitation in applying the forceps high up in the uterus when the head is arrested at the brim of the pelvis, and cites fifteen cases of such application in proof of his opinion. After some remarks on estimation of the conjugate diameter, he concludes with the following propositions:

In the flat pelvis and in the flat rachitic pelvis decided degrees of disproportion at the brim may be overcome by the natural efforts when the head presents.

In the forceps, and especially in the axis-traction forceps, we have the means of extending still further the possibilities of successful delivery when the head is arrested at the brim. The forceps, judiciously used, is a safe instrument for mother and child. The existence of contraction of the pelvis in itself is no reason for preferring version. In flat pelves with a conjugate diameter of not more than three and one-fourth inches and not less than two and three-fourths inches premature labor should be induced.

Dr. Hirst differs from Dr. Longaker on two points: the propriety of always applying the forceps in flat pelves before the head has become engaged instead of turning and delivering by the breech; and in the propriety of applying the forceps over face and occiput in transverse positions of vertex presentations, as in this latter operation the biparietal diameter must be increased.

Dr. H. A. Kelly agreed with Dr. Hirst. He considered the paper of Dr. Longaker a very timely one, which in all its leading features he must heartily endorse. It is certain that an intelligent use of the axis-traction principle is destined to revolutionize the treatment of labor in contracted pelves. In cases in which craniotomy has been the custom, axis-traction will save many lives. A few important rules should be borne in mind. First of all, Dr. Kelly

would differ from the speaker most decidedly in one practice, and lay down the rule that "axis traction" cannot be applied to the head above the brim. There is no axis above the brim, and any traction on the rod merely causes the head to rotate around its own axis, but can under no circumstances be efficient in inducing it to engage. Axis-traction applies to heads engaged in the pelvis. Again, the ordinary use of this principle should be to *assist the pains*. Further, it is important in using Tarnier's forceps of this model to constantly attend to keeping parallel the shanks of the prehensile blades and the proximal end of the traction rod.

If the handles of the forceps rise during a traction and it is felt by the examining finger that the head has not really advanced, then either the head has rotated in consequence of an excentric grip or the forceps has slipped; and here lies the great difficulty of the Tarnier instrument. The frequency of this accident, together with some other considerations regarding the mechanical construction of the instrument, have demonstrated to my mind the fact that it is only approximately axis traction. He showed a pair of forceps with which he delivered a dwarfed woman two weeks ago of a full-sized live female child through a three-inch conjugate. This pair of forceps was shown him first by Dr. Porak, of the Hôpital St. Louis, Paris; and he believes that by them he attains the most perfect axis-traction which has yet been devised. The principle is applied in a very simple manner to any long forceps. Each of the four blades of the spoons is perforated with a small oval tube as near the centre of the oval of the spoon as possible. Two long tapes are taken and one passed through the holes of one side, the four free ends are brought down under the forceps, and after their application hang out at the vulva. These ends are brought through a hole at the extremity of a traction rod, curved as ordinary traction rods, with the usual transverse handle at the outer extremity; this is then drawn up to the head and the ends of the tapes fastened on the rod at the apex of the angle where the vaginal turns down into the perineal curve. The advantages of this forceps are many: 1. The application is extremely simple. 2. It can be applied to any forceps. The Tarnier cannot be. as it is only suitable to narrow heeled instruments. 3. The child's head is grasped by the centre of its figure owing to the position of the attachment of the tapes. 4. This same factor renders unnecessary the screw which is so dangerous in Tarnier's forceps, as the traction does not tend to force the blades apart, but approximates them. 5. The perfectly movable connection between forceps and rod, *i. e.*, the tapes, allows the head to flex and follow the curve of the pelvic canal. He has used Tarnier rods and the Poullet forceps on the same patient several times, and his experience accords with that of Dr. Porak: where the Tarnier rods fail and the forceps slips, the Poullet forceps holds and works easily. An interesting incident of a short time since shows well the comparative value of axis-traction. He had described his Poullet forceps to a friend who has a large obstetric practice. He soon called him out with a note, "bring your French forceps." He found the head well engaged but wedged tight. The physician had made many well directed vigorous efforts with his own forceps and finally gave up in despair, producing no effect. Dr. Kelly applied the Poullet forceps, and with a moderate traction on the rod, the head moved gently and steadily until it came directly to the outlet without apparent effort. Mr. Gemrig, of Philadelphia, keeps the rods on hand; they are the only essential part of the instrument.

Dr. R. A. Cleeman said there was one feature of Tarnier's forceps which appeared to be barbarous and unscientific, and this feature was retained in the instrument shown; the device of the screw, which is intended, by clamping the blades against the child's head, to prevent the slipping of the instrument. Slipping should be prevented by the proper adjustment of the blades to the child's head and the moderate pressure induced through traction. To accomplish such adjustment in extreme cases a pelvic curve should be given to the shank of the instrument; such adjustment cannot with safety be replaced by the mechanical pressure induced by the screw. (*Amer. Jour. Obst.*, April, 1878, p. 341 et seq.)

Dr. Longaker had not had time to read Dr. Winter's article in the original (*Zeitschrift für Geb.*), but gained his information from an editorial in the *Medical News*, which stated that an expectant plan of treatment and forceps are advised for primiparous and early version for multiparous. He still thinks the occipito-frontal application of the blades does not appreciably increase the biparietal and bitemporal diameters of the fœtal head. It may increase the vertical diameters, as the cervico-bregmatic and sub-occipito-bregmatic. A simple experiment on the mannikin of Budin demonstrated the truth of this proposition. A full term fœtus, still-born, was placed in position at the brim, the sacrum being thrown forward so as to make the conjugate measure three inches. With the axis traction forceps the relative disproportion between the head and the pelvis, which was considerable, was easily overcome. With blades having a sufficiently marked cephalic curve the depression need be but slight. There seems to be some misconception as to what is meant by the head being at the brim of the pelvis. The head is at the brim until the greatest transverse diameter, the biparietal, has passed the plane of the superior strait. With a head entirely above the superior strait the use of any forceps would hardly be appropriate. If fixation of the head could not be secured, version would be the best measure. He did not see how traction exerted by means of tapes could be more efficient than with stiff rods. The fixation screw is a necessity, there being no free hand to make the necessary compression by the handles. Moreover, it is not objectionable. Continuous pressure is avoided by relaxing the pressure in the intervals. This was one of the chief objections urged by the late Albert H. Smith.

A little reflection and application of well recognized principles would dictate the proper method of applying traction. Simpler axis traction forceps have been devised by Breus and by Braun.

(*To be concluded.*)

FOREIGN CORRESPONDENCE

LETTER FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

Antiseptic Pulmonary Medication—Pathogenesis of Renal Congestion—Hypnotic Anæsthesia.

In a lecture on "Antiseptic Pulmonary Medication," recently delivered, Prof. Dujardin-Beaumetz says, that antiseptic pulmonary medication, such as it may be imagined in an ideal manner, constitutes the most important therapeutic measure for pulmonary affections. The air being the greatest factor of the contagiousness of diseases, if one could succeed in removing from it the infectious germs which it contains, one would have rendered the greatest service to medicine and to hygiene. Thanks to the interesting researches of M. Pasteur, and to the patient investigations of Dr. Miquel, we know the number of microbes contained in a limited volume of air, and we know that the greater part of these micro-organisms are aërobies, that is to say, they require oxygen to live and develop. Whilst on the summit of Mont Blanc, microbes are rarely found in the air, in cities, on the contrary, they abound, and their number varies according to the place. Thus, at the park of Montsouris (which is one of the most elevated positions in Paris, one finds only fifty-one microbes to each cubic metre, in the Rue de Rivoli, a street that runs along the buildings of the Louvre, the Palace, and the garden of the Tuilleries the number amounts to 680 for the same space, and they are found still more numerous in the confined air of the rooms of apartments and in the wards of hospitals. In a bed-room in the Rue Monge, in the neighborhood of the Jardin des Plantes, they attain the figure of 5,260, but in the wards of the hospitals they literally swarm, for in one ward alone in La Pitié Hospital 28,000 to the cubic metre were found.

Attempts have been made to prevent the penetration of microbes into the breathing passages, and several works have been published on the subject. It is true that by a happy arrangement, man breathes only accidentally by the mouth, and that air penetrates particularly by the nasal fossæ which, by their anfractuosities, pretty well represent the arrangement of the filtering balloons employed by Pasteur for purifying the air. But this filtration is evidently often incomplete, as it is by the pulmonary passages that contagious and infectious maladies are transmitted. Among the antiseptic gases, the author places at the head of the list sulphurous acid, basing his theory on the experiment that a dose of 20 grammes per cubic meter, sulphur destroys micro-organisms plunged in a liquid, and that a dose of 40 grammes destroys the same micro-organisms in a state of desiccation; but unfortunately this gas is not respirable.

The discovery of the microbe of Koch in 1882, to which must be joined the more recent one of the microbe of Friedländer in pneumonia, indicates the therapeutic measures that should be adopted for the future, which consist principally of two; the one by which we should endeavor to oppose by medicinal means the multiplication of bacilli, and the other by which we should endeavor to modify by hygienic means the culture soil of these same bacilli. Prof. Germain Sée, in his work on bacillary phthisis has, since the discovery of Koch, insisted on the direction which the therapeutics of tuberculosis should take, and the conditions which the anti-virulent agent which he calls "necrophytic" should fulfil, to attain the object proposed. To the first group of these agents belong principally medicinal inhalations, and medicines which are eliminated by the lungs. It was with this idea the elimination by the pulmonary surface, Dr. Bergeon has proposed rectal injections of sulphohydric and sulphurous acids, having carbonic acid for the vehicle. The medicinal inhalations consist of iodine, iodoform, eucalyptol, corrosive sublimate, carbolic acid, in a word the antiseptics the least irritating should be prescribed. Besides inhalations against phthisis, Listerian sprays have been employed in this affection. The lecturer considers the latter inferior to inhalations, as it was only exceptionally that the sprays penetrate into the interior of the lungs.

In a recent communication to the Medical Society of Hospitals on the mechanism of the pathogeny of renal congestion, Dr. Albert Robin reported two cases which led him to conclude that cold excites the reflex functions of the kidneys, which in consequence do not allow the waste tissues of the organisms to pass through. These latter, not being eliminated, intoxicate the patient at different degrees, according to the duration of the suppression of the functions of the kidneys. Dr. Pitres recently presented at the Anatomical and Physiological Society of Bordeaux a hysterical woman, easily hypnotized. She was habitually hemianæsthetic on the right side, the left side of the body having preserved its normal sensibility. The patient was affected on the left thigh with an abscess caused by a subcutaneous injection of morphia. The tumor was fluctuating, and the surrounding parts were considerably inflamed and very sensitive, so much so that it was impossible to touch the abscess without causing great pain, in consequence of which the patient refused to allow it to be opened. She was then put to sleep by the operator simply fixing his eyes upon her (hypnotic sleep), she was then desired by him to allow him to open the abscess without feeling any pain after being awakened, even if a bistoury should be plunged into the skin. The patient was then awakened from her hypnotic sleep, the abscess was incised, the skin having been cut through layer by layer. A claret wine glassful of a thick, creamy reddish colored pus escaped. The edges of the wound were strongly pressed to evacuate the pus. During the whole of the operation, the patient looking at the surgeon with a smile, never offered a single complaint. She then expressed her astonishment that after so much suffering the surgeon should have been able to open the abscess without causing her any pain.

DOMESTIC CORRESPONDENCE

VAGINAL TAMPONNEMENT—GALVANIC MEASURE.

Dear Sir:—I beg the privilege of your pages for the correction of some statements which have of late appeared in various numbers of THE JOURNAL, as they concern subjects in which I am especially interested, and which I believe to be of great practical importance.

First, as regards the vaginal tampon: In your issue of March 27, 1887, Dr. Etheridge, in an article entitled "Antiseptic Tamponnement of the Vagina in Pelvic Inflammation," page 344, conveys the idea that in my "Dry Treatment," *I use medicated cotton throughout for all conditions*, and very correctly says that he has found considerable satisfaction from the use of iodine, tannin, iodoform and other prepared cotton tampons in the treatment of pelvic inflammation. Thinking that he had followed out my plan he failed, as he naturally must do as he understood it, and he has now found the antiseptic wool to be the material for tamponnement in inflammatory conditions. He is perfectly correct, and as others may have misunderstood my suggestions as Dr. Etheridge has, and may for this reason condemn the "Dry Treatment," I will here reiterate what I have so often stated, what I constantly teach, and what is again emphasized in my paper on "The Details of the Dry Treatment" to appear in an early number of the *American Journal of Obstetrics*, viz: that *for all purposes of support, rest and compression an elastic material, non-compressible, non-absorbent, must be used for the tampon.* I use finely carded sheep's wool or jute, with long and fine fibre, advocating plain, ordinary cotton when these are not to be had, *never prepared cotton.* The *medicated cotton I employ merely as a covering*, more or less thick, according to the object in view.

It is natural that when support, rest, or, in inflammatory cases, compression of vessels is desired, the medicated and absorbed cotton tampon is useless, as it soon mats and is compressed into a firm doughy wad. In such cases I apply my remedy in the form of an outer covering layer of medicated cotton over the elastic jute or wool tampon, and medicated cotton alone; for the entire tampon I rarely use, only in cases where medication solely is desired, and neither support nor compression. The elastic wool or jute tampon coated with medicated cotton has a double advantage over the tampon solely of wool; it assists pressure by medication, and it brings a softer surface in contact with the vaginal tissues, in place of the wool, which, when used alone, I have seen to cause discharge by irritation of the parts by its fibre.

I will moreover add, as Dr. Etheridge lays stress on the new *antiseptic absorbent wool*, that for general use, for the elastic tampon basis I decidedly prefer the *plain* finely carded wool: the material I obtain is whiter, finer and of longer fibre, and more elastic than the prepared absorbent wool. It is elasticity that we want, and the quality is deteriorated by the process of preparation; the wool is rendered less effective for the very purpose by preparation. It is the oily, fatty matter which prevents absorption and keeps the fibre elastic, hence I prefer the natural wool, if of good quality, or the jute to all absorbent preparations. I render the tamponnement antiseptic by the powder with which I dust the tissues or which I inclose in the wool, jute or cotton, and as an antiseptic application to the tissues *I know of nothing better than pure bismuth* (subnitrate); this is a most agreeable, soothing application to the vaginal walls, a sedation, a most excellent absorbent, and the very best material to keep the tampon sweet, better than iodoform, and without odor of any kind. Tampons so prepared may remain in place two or three, even four days, without becoming in the least offensive. I trust that this explanation and my coming paper in the *American Journal of Obstetrics* will do away with any lingering belief that I have urged the medicated cotton for aught but medication, or for use as the tampon body.

Secondly, I wish to call attention to some erroneous statements in regard to electric dosage in THE JOURNAL of February 5 and February 12, 1887, which may mislead greatly and which reflect very unfavorably upon American electro-therapy if allowed to stand uncorrected.

In No. 6, February 5, 1887, page 167, Dr. Cutter says that Apostoli uses currents of 1.25 to 1.5 *ampère.*—Apostoli has never used and never claimed to have used currents of such intensity. I presume that Dr. Cutter intended to say that Apostoli had used *125 and 150 milliampères*, which is about *one-eighth and one-seventh of one ampère.* If Dr. Cutter's battery measured 27 to 30 ampères, this does not tell us the intensity of the current actually used upon the patient, as the resistance of tissue and electrodes is not given, and the battery-strength alone does not afford any clue as to the strength of current effectively engaged in action on the diseased part.

In No. 7, February 12, 1887, page 195, Dr. Martin tells us that he has used from 25 milliampères *to 10 ampères* through a fibroid tumor, *with one surface electrode*, and *without causing pain enough to require an anæsthetic.* Ten ampères, *10,000 milliampères* would search the body as would a stroke of lightning. This is impossible. I am glad to see that Dr. Martin is seeking to define and record his treatment more accurately, and that he is resorting to currents of higher intensity. It is a satisfaction to me to see that he has accepted my criticism of his paper which I made before the Section on Obstetrics and Diseases of Women, at the St. Louis meeting of the American Medical Association, in 1886. I then urged the importance of the galvanometer, and the necessity of exact measurement, strong currents and short sittings, if electricity were to be made serviceable in practice, recording successful cases with the use of high intensities, in three and four sittings.

Dr. Martin's later papers prove him a convert, but he is seriously at fault somewhere. No man ever has or ever will pass *ten ampères* (10,000 milliampères) through living tissue, as this would scorch the skin and destroy the activity of the nerve tissue.

The scientific world was astounded when Apostoli employed 100 milliampères, which he has increased to a possible 250 milliampères (I have even used 280 milliampères with one surface electrode), but this is a current of utmost intensity with surface electrodes. If we use both poles within the tissues of a part meagrely supplied with nerves, we may use higher intensities, but not with surface electrodes and without anæsthesia. The use of ten ampères with one surface electrode, and without giving excessive pain and burning the integument, is simply impossible, and I feel that the error must be corrected, in order that those desiring to follow may not be lead into mischief, and that foreign operators may not lose faith in American reports.

I have waited so long with this correction, as I had expected some explanation from Dr. Cutter or Dr. Martin in one of the following numbers; but as no statement has appeared, I beg you now to insert this. Very respectfully yours,

Geo. J. Engelmann, M.D.

3003 Locust St., St. Louis, Mo., March 31, 1887.

HAY ASTHMA IN A CHILD EIGHT YEARS OLD.

Dear Sir:—I wish to report the following case of "Hay Fever," because I have not seen any case reported in a subject so young.

Helen O., farmer's daughter, aged 8 years, has been troubled with hay asthma from the middle of June until September, every year since she was 3 years old. During the remainder of the year she is free. During the summer the symptoms are constantly present, worse at times, especially in going into a meadow or cornfield, and her nights are a torture because of her inability at this season to sleep, the dyspnœa being so great. The patient has two aunts in Vermont who suffer from the same malady, and only get relief by going every year to the White Mountains.

When she first presented herself to me, June 22, 1886, she had been suffering for about one week. Her breathing was truly asthmatic, face flushed, nasal passages were obstructed, eyes red and swollen, and suffused with tears. Her temperature was 100° F. An examination of the nasal passages revealed much tumefaction of the turbinated bodies. After the application of a solution of cocaine, it was seen that the lower turbinated bones on both sides stood away from the outer wall of the passage toward the septum, and on the right side the bone was in actual contact with the septum.

On July 1, with the nasal cutting forceps, I removed a portion of the right lower turbinated bone. This was followed by a vaseline spray, and at intervals of a few days by applications of glacial acetic acid in both nostrils. After the operation repair took place kindly, all symptoms of the disease disappeared promptly and have not yet returned.

Yours truly,

H. Moulton, M.D.

Stuart, Iowa, April 7, 1887.

BOOK REVIEWS.

Medical and Surgical Memoirs: Containing Investigations on the Geographical Distribution, Causes, Nature, Relations and Treatment of Various Diseases. 1855–1886. By Joseph Jones, M.D., Professor of Chemistry and Clinical Medicine, Medical Department of Tulane University of Louisiana; Visiting Physician of Charity Hospital; Honorary Fellow of the Medical Society of Virginia, etc., etc.

Volume II. Containing Researches on the Origin and Effects of Epidemic, Endemic, Infectious and Contagious Diseases; Investigations on the Nature, Causes, Relations and Treatment of Malarial (Paroxysmal) Fever, Intermittent, Remittent, Pernicious and Hæmorrhagic Malarial Fevers; Comparative Pathological Anatomy of Malarial, Typhoid and Yellow Fevers; Indigenous Remedies of the Southern States; Albinism in the Negro Race; Oriental Leprosy; Elephantiasis Græcorum, Elephant's Leg (Elephantiasis Arabum). New Orleans, La.: Joseph Jones, M.D., 156 Washington Avenue, cor. Camp Street, Fourth District. 1887.

Such is the title of a ponderous volume of more than 1,300 pages, copiously illustrated, and containing a large part of the results of a lifetime of untiring, methodical, yet varied and intelligent observation and research. The first volume of Dr. Jones's Medical and Surgical Memoirs was published in 1876, and was occupied largely with the results of his studies and observations concerning diseases of the nervous structures of the body, the various morbid conditions of the blood, pneumonia, etc. It embraced 820 closely printed pages, constituting a most valuable storehouse of facts hardly to be found elsewhere.

The second volume, just issued from the press, is printed on good paper, plain type, with many fairly well executed plates, and substantially bound. It is not a systematic treatise on practical medicine, or on any special department of medicine, but is rather an aggregation of the author's studies and observations concerning a large number of most important diseases, accompanied by the results of long continued original researches, not only at the bedside of the sick, but in the morgue and the chemical and microscopical laboratories, and is consequently a storehouse of etiological, histological and pathological facts of great value. Even a brief analysis of the contents of this extensive work would occupy more time and space than we can give, but the reader may form some idea of their nature and importance from the general heading of the several chapters as follows:

Chapter 1. Investigations on endemic, epidemic, infectious and contagious diseases, and on the nature, causes, relations and treatment of malarial paroxysmal fevers; mode of investigating the origin, nature and effects of malaria; classification of the various forms of malarial fevers. Occupying 59 pages. Chapter 2. Physical and chemical characters and changes of the blood in malarial fevers and other

diseases—210 pages. Chapter 3. Comparison of the changes of the blood in malarial fever and other diseases, pyrexial and phlegmasial; microscopical characters and changes of the blood in various diseases; micro-organisms in malarial fever and other diseases—221 pages. Chapter 4. Hæmorrhagic malarial fever; malignant forms of malarial paroxysmal fever; malarial hæmaturia—199 pages. Chapter 5. Circulation, respiration, temperature, state of the skin, tongue, and changes of the urine in intermittent, remittent and congestive fever. Principles of treatment based upon these observations—142 pages. Chapter 6. Pathological anatomy of malarial fever. Changes of the organs and tissues, and apparatus of the bodies of those who have died with the different types of malarial fever, intermittent, remittent and congestive. Comparison of these changes with the phenomena of malarial fever, and with similar changes in other diseases, and with the organs, tissues, and apparatus of men and animals in the normal condition—149 pages. Chapter 7. Treatment of malarial fever. Prevention of malarial fever. Indigenous remedies of the Southern States of the United States of America; which may be employed as substitutes for sulphate of quinia in the treatment of the various forms of malarial fever. Prevention of malarial fever by hygienic, dietetic and therapeutic measures. Principles of the treatment of the various forms and effects of malarial fever—152 pages. Chapter 8. Changes of color in the human race. Observations and researches on albinism in the negro race—28 pages. Chapter 9. General observations on leprosy in America. Chapter 10. Yaws, libbens, sivvens, pian, epian, frambœsia, syphilis Ethiopica. Chapters 11, 12. Leprosy, elephantiasis Græcorum. Notes on the history of leprosy in the Southern States. Chapter 13. Etiology: Causes and origin of leprosy (elephantiasis Græcorum) in North America, and more especially in the valley of the Mississippi River. Chapters 14, 15. Morbid anatomy of leprosy; bacillus lepræ. Chapters 16, 17. Treatment of Oriental leprosy; views of the older writers. Elephantiasis Arabum, elephant's leg, Barbadoes leg.

The volume is illustrated by 127 engravings, some of them colored. For more than thirty years the author has been actively engaged not only in the general field of practice, but also in the special departments of hospital, sanitary, and military work, and has at all times brought to his aid in the investigation of the causes, nature and results of disease a thorough knowledge of analytical chemistry and of microscopy. His original researches have not been undertaken for the purpose of rectifying or refuting the theories or discoveries of others, but rather for the simple purpose of gaining a more perfect knowledge of whatever came before him relating to etiology and morbid changes in the fluids and solids of the human body. Consequently, every page of the volume bears the individual impress of the author, and is, in the true sense of the word, an American work. Yet every chapter shows the author's familiarity with the entire literature of every subject of which he treats. To every intelligent American practitioner this volume would be of more value than ten times its cost, if for no other purpose than as a work of reference; for in it he can find something to throw light on almost every question he meets in relation to the etiology, pathology, therapeutics and prophylaxis of diseases. And we hope that the author, who is his own publisher, will receive an ample pecuniary reward for the sale of so valuable a work.

The Functions of the Brain. By David Ferrier, M.D., LL.D., F.R.S., F.R.C.S., Professor of Forensic Medicine, King's College, London, etc. Second edition, re-written and enlarged, with numerous illustrations. 8vo, pp. xx 498. New York: G. P. Putnam's Sons. 1886.

Our welcome of the masterly work of Professor Ferrier is none the less hearty if it has been delayed so long. It would only be expected that the second edition of the work, published ten years after the first, would be in many respects a very new and much changed work; and such is the case. It was looked upon, from the first, as a thoroughly original work, with nothing of the too frequent mechanical compilation about it. The great advances made in the last few years in the diagnosis of lesions of the brain, and in the surgery of the brain, make such a work interesting to both the physician and surgeon; doubly so too, because it is a subject the proper study and investigation of which present problems of the greatest intricacy and complexity.

The title of the work does not comprehend its entire scope. Including the medulla oblongata, the second and third chapters, containing 57 pages, are devoted to the spinal cord.

A general review of the book may be regarded as unnecessary. Dr. Ferrier is already almost as well known to Americans, and his work as much respected by them, as on the other side of the Atlantic; and we think it quite sufficient to notice the appearance of the second edition of this work.

Lehrbuch der Geburtshülfe für Aerzte und Studirende. Von Dr. Paul Zweifel, ordentlicher Professor und Director der geburtshülflich-gynäkologogischen Klinik in Erlangen. Mit 212 Holzschnitten und 3 Farbendrucktafeln.

Elements of Obstetrics for Physicians and Students. By Dr. Paul Zweifel, Professor and Director of the Obstetrical and Gynecological Clinic in Erlangen. With 212 wood-cuts and 3 colored plates. 8vo, pp. iv—792. Stuttgart: Ferdinand Enke. 1887. Chicago: Koelling, Klappenbach & Kenkel.

Those who do not believe in antiseptic, or aseptic, midwifery, would do well to read the first 18 pages of this thoroughly practical book, the product of a man of large experience, and written with all the impartiality of the scientific man. These pages are devoted to the subjects of puerperal fever, disinfection, and the mortality of child bed. He wastes no time in theoretical discussion; to him puerperal fever is not the result of occult atmospheric conditions; disinfection does not mean to him the killing or disguising of a smell; the prophylaxis of puerperal fever is not to

be settled by men who have half a dozen cases of midwifery during a year.

The discussion of the pathology of pregnancy, labor and child bed, occupy almost 300 pages, and is thorough. The remainder of the book is devoted to obstetric operations. The whole work is singularly free from the redundancy and unnecessary wandering off into minor details, the positive verbosity in fact, which is frequently characteristic of German writers, and unlike most foreign books it has a good index. One gets and retains the idea all through that the author wrote it because he had something to say, not because he simply wished to write something.

MISCELLANEOUS.

Illinois State Medical Society.—The thirty-seventh annual meeting of this Society will be held in the Methodist Church Block, corner of Clark and Washington streets, Chicago, commencing on Tuesday, May 17, at 10 o'clock A.M. All regular City, County and District Medical Societies in the State are entitled to *one* delegate for every *five* of their resident members.

The following standing and special committees are expected to report:

On Practice of Medicine—Daniel R. Brower, of Chicago, A. K. Vanhorn, of Jerseyville, and P. H. Oyler, of Mt. Pulaski.

On Surgery—D. A. K. Steele, of Chicago, C. Goodbrake, of Clinton, and B. F. Crummer, of Warren.

On Obstetrics—Ellen A. Ingersoll, of Canton, C. DuHadway, of Jerseyville, and W. H. Conibear, of Morton.

On Gynecology—Otho B. Will, of Peoria, J. M. Armstrong, of Evansville, and Catherine Miller, of Lincoln.

On Drugs and Medicines—J. G. Tapper, of Elgin, T. M. Cullimore, of Jacksonville, and Maria J. Mergler, of Chicago.

On Ophthalmology and Otology—S. J. Jones, of Chicago, A. E. Prince, of Jacksonville, and C. R. Parke, of Bloomington.

On Diseases of Children—Geo. W. Jones, of Danville.

On Physiology—A. Wetmore, of Waterloo.

On Dermatology—H. J. Reynolds, of Chicago.

On the Diseases of the Throat and Nose—E. Fletcher Ingals, of Chicago.

On Hydrophobia—Geo. N. Kreider, of Springfield, and others.

President—Elias Wenger, of Gilman.

Permanent Secretary—D. W. Graham, of Chicago.

Chairman of the Committee of Arrangements—Ephraim Ingals, of Chicago.

Bacteriological Laboratories in Siberia and Russia.—The Medical Society of Irkutsk, the capital of Eastern Siberia, will soon have a "bacteriological station" in the little city of 40,000 inhabitants. The Kharkov Medical Society has received from the Kürsk Government Assemply 1,500 roubles (about $750) to establish a bacteriological laboratory in Kharkov, and will receive 700 roubles yearly to support the laboratory.

Missouri State Medical Association.—We are informed by Thos. B. Jackson, M.D., Chairman of the Committee of Arrangements, that the next annual meeting of the Association will be held in Macon, Mo., May 10, 11 and 12. A full attendance is expected.

Health in Michigan.—For the month of March, 1887, compared with the preceding month the reports indicate that erysipelas, measles, tonsilitis, and consumption of lungs increased in prevalence. Compared with the preceding month the temperature in the month of March, 1887, was slightly higher, the absolute humidity and the day ozone were about the same, the relative humidity and night ozone were less. Compared with the average for March in the nine years, 1879–1887, measles and erysipelas were more prevalent, and remittent fever, intermittent fever, pneumonia, scarlet fever, influenza, bronchitis and diphtheria were less prevalent in March, 1887. For the month of March, 1887, compared with the average of corresponding months for the nine years 1879–1887, the temperature was lower, the absolute humidity and the ozone were about the same, the night ozone slightly less.

Including reports by regular observers and others diphtheria was reported present in Michigan in the month of March, 1887, at forty-six places, scarlet fever at fifty-two places, typhoid fever at thirteen places, and measles at thirty-five places. Reports from all sources show diphtheria reported at twelve places more, scarlet fever at ten places more, typhoid fever at three places less, and measles at eleven places more in the month of March, 1887, than in the preceding month.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 2, 1887, TO APRIL 8, 1887

Capt. John Van R. Hoff, Asst. Surgeon, ordered for duty at Ft. Reno, I. T. S. O. 43, Dept. Mo., April 4, 1887.

Capt. W. H. Corbusier, Asst. Surgeon, granted leave of absence for one month. S. O. 35, Dept. Ariz., March 29, 1887.

Capt. H. G. Burton, Asst. Surgeon, ordered to Plattsburg Bks., N. Y., for temporary duty. S. O. 78, A. G. O., April 5, 1887.

Capt. L. A. La Garde, Asst. Surgeon, ordered for duty at Ft. Assiniboine, M. T. S. O, 78, A. G. O., April 5, 1887.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE WEEK ENDED APRIL 9, 1887.

Bailhache, P. H., Surgeon, detailed as chairman Board of Examiners, to meet in Washington, April 25, 1887. April 4, 1887.

Purviance, George, Surgeon, detailed as member Board of Examiners, to meet in Washington, April 25, 1887. April 4, 1887.

Godfrey, John, Surgeon, detailed as recorder Board of Examiners, to meet in Washington, April 25, 1887. April 4, 1887.

Irwin, Fairfax, P. A. Surgeon, to proceed to Baltimore, Md., on special duty. April [illegible], 1887.

Pettus, W. J., Asst. Surgeon, to proceed to Norfolk, Va., for temporary duty. April 4, 1887.

ORIGINAL ARTICLES.

TREATMENT OF FIBROID TUMORS OF THE UTERUS BY ELECTROLYSIS, WITH A DESCRIPTION OF APOSTOLI'S METHOD.

Read before the Chicago Medical Society, Dec. 20, 1886.

BY FRANKLIN H. MARTIN, M.D.,

PROFESSOR OF GYNECOLOGY IN CHICAGO POLICLINIC; CLINICAL LECTURER ON GYNECOLOGY IN SOUTH SIDE DISPENSARY, CHICAGO; FELLOW OF CHICAGO GYNECOLOGICAL SOCIETY, ETC.

Unfortunately, the term "electrolysis," as applied to the treatment of disease, has been by many, for some unaccountable reason, greatly misunderstood. Because an electric battery is one of the requisites of treatment by electrolysis, the term has become synonymous with any form of electrical application, whether of the galvanic, faradic or static variety. This is a mistake. To successfully treat any particular diseased condition by electrolysis, certain scientific principles are involved, that are as necessary for us to understand as it is for an inventor to understand certain scientific principles before he can successfully construct an electric motor.

Electrolysis is simply an expression for an electrical phenomenon. It is necessary for us to have certain conditions present in order to obtain this phenomenon: 1. A continuous current of electricity; 2, an electrolyte; 3, means of conveying the current through the electrolyte. And unless we have present in every case upon which we operate these requisites, and bring them into such relationship that the electrical current conveyed through the electrolyte by means of suitable conductors will dissolve the molecules of the electrolyte into their constituent elements, we do not get electrolysis.

So far as the phenomenon electrolysis has been utilized in medicine, it has been for the purpose of removing abnormal tissue. In order to accomplish this, certain other requisites are necessary. 1, the tissue to be dissipated must be an electrolyte or contain electrolytes; 2, the tissue must be in a position where it may be electrolysized without endangering neighboring tissues; 3, its surroundings must be such as will favor the removal of the *ions* by absorption or otherwise, that have been freed by the electrolytic action; 4, some means of ascertaining the strength of the current must be at hand.

Before considering the above points more in detail, I wish to refer to two other phenomena of the constant galvanic current, which do not properly come under the head of electrolytic action, but which are utilized in the treatment of fibroid tumors. I refer, 1, to the cataphoric action of the current; 2, to the local effects of the two poles.

The subject of the treatment of fibroid tumors of the uterus by the continuous galvanic current, therefore, presents the following points for our consideration: 1. The tumor. 2. Means for generating a continuous current of electricity. 3. Means of measuring or gauging the current. 4. Electrolytic action of the current. 5. Cataphoric action or electrical osmosis. 6. Local effect of the poles. 7. The apparatus and general detail.

I. *Consideration of Tumors.*—I will not go into a long discussion of the history, causes and pathology of fibroid tumors of the uterus, because it does not particularly bear upon the subject of the evening. However, to facilitate a description of my method of treatment, I will make the old division according to location into, 1, submucous; 2, interstitial; 3, subperitoneal. The nomenclature of this division sufficiently explains itself. To still further expedite matters, allow me to divide these tumors according to their condition, into the hæmorrhagic and the non-hæmorrhagic. By hæmorrhagic we will include those tumors that produce from a simple excess of the menstrual flow to the most alarming continuous hæmorrhage. The non-hæmorrhagic will include all others.

II. *The Current.*—The current of electricity used in electrolytic therapeutics should be one of moderate quantity compared to the intensity. It should be very uniform and without interruption. The direction of the current should always be known. Any means of generating electricity that will be practicable, and at the same time answer the above requirements, will be suitable for our purpose. I have found nothing better than some form of the chemical battery. In the beginning of my work with electrolysis I used some form of the ordinary zinc and carbon battery with a solution of dilute sulphuric acid and bichromate of potash. For purposes of epilation, strictures of the urethra and uterine canal, and other of the smaller operations, this battery answers the purpose admirably, where it is properly cared for. For accomplishing more decided work, however, this variety of battery becomes impracticable, because of the labor required to keep it in proper order. The results of my experiments have led me to adopt for office purposes the ordinary crowfoot gravity cell. This cell is furnished to me by the

McIntosh Galvano-Faradic Co., of this city. These cells are coupled in tandem, and connected with a selective switch board arranged in such a manner that any number of cells from any part of the battery can be brought into the circuit. A large number of these cells can be placed in a closet or other convenient place and attached to the switch-board by means of a cable of wire. The storage battery can be utilized for this purpose, but is as yet impracticable for long and constant work. The dynamo has been suggested, and will without doubt, with time and improved motors, take the place of all other forms of generating electricity for office use, both for cautery and, with proper resistance coils, for electrolytic work.

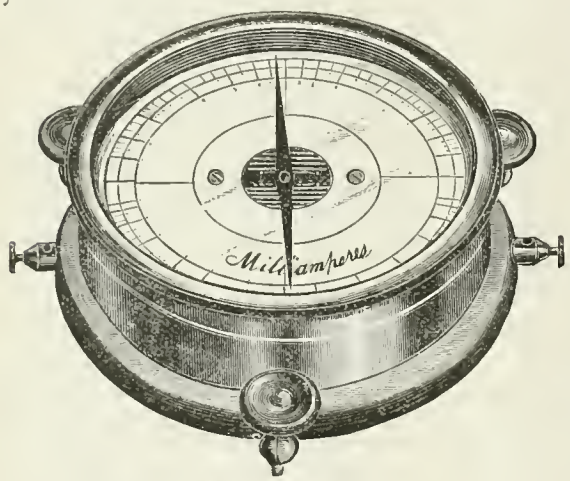

Fig. I.—McIntosh's Milliampère Metre.

III. *Measurement of Current.*—With the advance in electrical therapeutics we have found it necessary to adopt some means of measuring approximately the strength of current employed. Especially is this desirable when the enormous strength of current is used that is necessary in the treatment I am describing. It is unwise to employ a current of more than 25-milliampère strength through the vital tissues of the body, without being in a position to watch every variation of intensity, and this can only be determined with accuracy by the employment of a galvanometer (Fig. 1). I take pleasure in being able to exhibit a galvanometer to the Society this evening that answers all requirements for therapeutic purposes. This instrument was constructed, after a large amount of work and experimentation, by Dr. McIntosh, of the McIntosh Galvano Faradic Co., of this city. It has been graduated in the presence of an absolute galvanometer, and each instrument that is constructed is graduated by actual comparison in the same way, which is a point that is absolutely necessary if accuracy of measurement is to be obtained. Many of the galvanometers that have been thrown upon the market of late, for medical purposes, have been little better than worthless. This instrument is graduated for milliampères, and will measure accurately a current from 1 to 1,000-milliampère strength.

The maximum current that can be safely passed through the body, consistent with our present experience and knowledge, is about 1,000 milliampères. To get this power I use a battery composed of 115 gravity cells.[1]

IV. *Electrolysis*, the principal action that we seek in causing the absorption of fibroid tumors or any other pathological growth, is not a new phenomenon in electro-chemistry. This action has been utilized in the commercial world for a number of years, and its value is constantly increasing. The same principle that is used in electro-plating can be made valuable in medicine, in relaxing the loosely combined elements of a fibroid tumor and causing their deposit where they will be carried from the system.

A strong current of electricity is passed through a growth of this character, and in its substance it finds many electrolytes which are dissolved into their constituent elements. These elements, according to their electrical tendencies, travel toward the negative or the positive pole of the battery, and may be disposed of in the following four ways: 1. "Many of them immediately make similar or dissimilar combinations with neighboring elements of opposite electrical tendencies, making thereby new compounds which act as foreign particles; as foreign bodies they are promptly removed by the nearest absorbents. 2. Other elements, as they become free from their original molecules, make combinations with elements which are already leaving the tissues through one of the innumerable minute vascular canals. 3. Many, in the form of gas, pour into the atmosphere beneath and surrounding the electrodes. 4. Others attack the electrodes and are disposed of in the form of deposit on their surfaces."

The cataphoric action of the galvanic current should also be recognized as playing its part in the promotion of absorption. It is by this property that fluids are determined in mass from the positive to the negative pole. This action, in producing an unnatural turgescence of fluid at the negative pole, favors its osmosis into the surrounding absorbents, and thereby accomplishes its removal.

The local effect of the current at the two poles of the battery is very different with a high tension current. The effect of the positive pole is termed by Dr. Apostoli the galvano caustique effect of the positive pole. This is an action of a great deal of importance, and from which a great advance is contributed in the treatment of hæmorrhagic fibroid tumors of the uterus. The phenomenon is obtained only by the employment of a very strong current, from 50 to 1,000-milliampère strength, and concentration of this current at the point of contact of the positive pole of the battery to the tissues. This electrode must be of small size, and of some unattackable metal. The effect obtained upon vascular tissues or mucous membrane by thus concentrating the current is to produce an eschar. This eschar, however, if the current has been proper, will be found to be simply a coagulation and a hardening of the mucous membrane and the tissues beneath it for some little distance. This process of contraction and coagulation modifies the calibre of the vessels of the circulation so that hæm-

[1] Since writing the above I have been able to use still higher currents in special cases.

orrhages are less liable to occur at the point of application; at the same time it does not destroy the circulation sufficiently to produce strangulation and death of the part. There is nothing that will so effectually stop all forms of excessive hæmorrhages or leucorrhœa, without producing a troublesome slough, and a subsequent contraction, as this particular application of electricity when made to the mucous membrane of the uterus.

The local effect of the negative pole is the opposite of that of the positive when the current is strong and concentrated. The action of this pole is one of liquefaction instead of hardening and coagulation. Its eschar resembles much that of a caustic alkali.

V. *The Electrodes* used in the treatment of fibroid tumors by Dr. Apostoli's method are few in number. Two electrodes are always necessary at every operation. One of these is applied externally on the surface of the body, the other in some form internally. Where powerful currents are employed, such as I have described, the first object is to devise means of conducting them through the parts desired, without producing harm to innocent tissues, or pain to the patient. One pole, the internal, is usually the active one. This is either a sound that fits accurately the uterine canal, or a pointed electrode which enters a presenting portion of the tumor. This is constructed of unattackable metal, platinum when in form of sound, platinum and iridium when in form of needle.

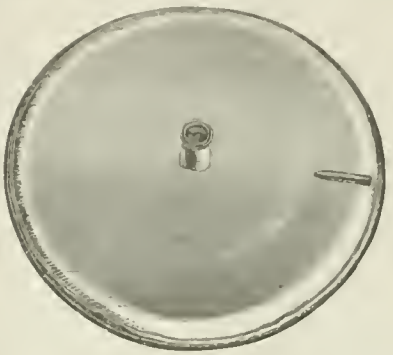

Fig. III.—Martin's Abdominal Electrode.

soft metal, of appropriate dimensions, has loosely stretched over its concavity an animal membrane which is fastened to its circumference securely enough to render it water-tight. Between the concavity of the disk and the membrane is left a space one and one-half inches in thickness, which is filled with a warm saturated solution of chloride of sodium. The electrode is filled through a stopper on the surface of the metal. The connections are also made from this surface.

This electrode, when filled, is applied to the surface of the body so that its membrane surface is in contact with the skin. It adapts itself accurately to all irregularities, covers a large surface, and causes a

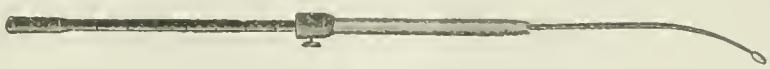

Fig. II.—Martin's Inter-uterine Electrode.

Some means of insulating the vaginal portion of the electrode must be devised. (Fig. 2.) Needles used in electrolysis should be insulated up to within one inch of the point in order to protect external tissues. After the proper internal electrode has been selected and placed in position, and before the current is turned on, the circuit of the battery must be closed by applying some form of convenient electrode externally that will give the minimum resistance without excessive pain. This has been one of the most difficult things to accomplish in the use of strong currents. This external electrode should be placed upon the abdomen in as close proximity to the internal one as possible. It should have a large surface in order to diffuse the current. All parts of the surface should conduct equally, and fit accurately into all irregularities of the surface.

Dr. Apostoli at last hit upon the following plan, which he has found to answer the purpose perfectly: A mass of potter's clay is made about into the consistency of soft dough by moistening with water, and is then spread upon the abdomen of the patient in a mass an inch or more in thickness. This is connected with the battery by placing upon its free surface a plate of soft metal with appropriate connections. This apparatus, while it answers the purpose, is a very inelegant form of electrode. In this direction I am able to offer a very decided innovation. Dr. McIntosh has succeeded in constructing for me this electrode (Fig. 3). A concave disk of

diffusion of the current so perfectly, and makes connections so complete, that I have been able repeatedly to use a current of 75 to 1,000 milliampères without producing the slightest blistering of the integument and without producing even a disagreeable sensation.

VI. *Details of Application.*—There are three distinct operations that are called for in the rational treatment of fibroid tumors of the uterus by electrolysis. They vary both according to symptoms and conditions. The first that I will consider is for the relief of excessive hæmorrhage. I consider this of first importance because it is one of the most distressing symptoms we meet with in dealing with these difficulties, and a symptom which often baffles every other resource.

I will not go into a description of the different conditions that *may* be present in hæmorrhagic fibroids, but will confine myself to the few conditions that must be present to allow of benefit from this treatment. We have excessive hæmorrhage which may be continuous or periodic. The hæmorrhage is from the cavity of the uterus. The uterine canal must be accessible to a flexible probe. There must be no acute metritis, peri- or parametritis present. With these requisites, positive and negative, we may proceed to operate. An assistant, if the patient is reasonably strong, is not necessary. The application is preferably given in the office.

The patient's clothing is loosened, and she is in-

structed to assume the dorsal position upon an operating chair or table. A speculum is introduced or not according to convenience of operator, and the direction, size and depth of the uterine canal is ascertained by means of a soft metal probe. A uterine sound electrode composed of pure platinum, corresponding as nearly as possible with the size of the uterine canal, is selected, and made to conform to the general direction of the canal as indicated by the probe. This electrode is then introduced to the bottom of the uterus, and the insulating shield is pushed up until it touches the cervix and covers perfectly the intra-vaginal portion of the metal. When the electrode has been satisfactorily applied and connected with the positive pole of the battery, Martin's large abdominal electrode, properly prepared and attached to the negative pole of the battery, is applied to the lower portion of the patient's abdomen in such a manner as to bring its whole surface in contact with the skin.

After the electrodes have been securely placed and the connections are found to be perfect, the operator should commence turning on the current. This should be done very gradually at first in order that the patient may experience no shock. If the patient complains of a dull pain internally while the current is being increased, the operator should stop for a few seconds, and he will often find that the pain will cease, after which the current can again be increased to the desired strength without excessive pain. At the first not more than a 50-milliampère current should be used. If the patient bear this well, it should be increased at each succeeding operation until a strength of from 100 to 500 milliampères is obtained. The first operation should last about five minutes, and if well borne the succeeding ones can safely be lengthened to ten or twelve minutes. In finishing the operation the current should be decreased in strength a cell at a time very slowly, until it is entirely excluded. After the operation the patients should remain quiet for half an hour, when they can return to their homes, with instructions to keep very quiet for at least twenty-four hours.

This operation has two effects. It checks hæmorrhages, and reduces the size of the tumor. The local coagulating effect of the platinum electrode upon the inner surface of the uterine canal checks the hæmorrhage, and the electrolytic effect of the powerful current through the tumor favors its absorption. A number of repetitions of the operation are necessary to control severe hæmorrhages. It is impossible, at one sitting, for the internal electrode to come in contact with all the surface of the canal, no matter how much pains may be taken to make an accurate adjustment. Nothing but repeated operations can accomplish this. Unless the current is too strong there will be but very little subsequent sloughing at the place of contact of the positive pole. If troublesome sloughing *should* occur after an application, a somewhat weaker current should be used afterwards. It must be remembered that coagulation, and not cauterization of the tissues, is the point sought.

The second operation to which I will call your attention is for the reduction of tumors that have grown in such a manner that they have distended or occluded the uterine canal so that it will not admit a sound electrode, and thereby renders intra-uterine *treatment proper* impossible. In these cases an *artificial* canal should be established in the obstructing portion of the tumor by means of negative-galvano-puncture entering the tumor from the cervical canal. For this operation the patient is also placed in the dorsal position. The position of the cervix is ascertained, and by aid of a proper speculum a sharpened probe of platinum and iridium is thrust a safe distance into the centre of the presenting fibroid. The vaginal portion of the electrode is properly insulated as in the other operation, and is then connected with the *negative* pole of the battery. The abdominal electrode is attached to the positive pole and applied as for the previous operation, and with proper precautions the current is gradually turned on until the desired strength is obtained, this being as high as 150 milliampères, often without pain or harm to the patient. Contrary to ordinary expectations, the *pain* produced by this operation is not sufficiently severe to require an anæsthetic, and with the exception of the first séance, when the new canal is established, the succeeding treatment is no more disagreeable than the ordinary use of the internal electrode in the uterine canal. Before any internal needle or puncture operation a vaginal injection of 1 to 5000 bichloride of mercury should be given, and repeated each day as long as the treatment is continued. An interval of about five days should elapse between the first and second applications, and the duration of the séance should be from five to ten minutes.

The first effect derived from the employment of this method is the establishment of a new channel to take the place of the distorted and obstructed uterine canal and by which subsequently the tumor will be treated. The second effect is the direct electrolytic action of the current upon the growth. The channel left after the withdrawal of the probe is somewhat larger in diameter than the electrode itself, and will remain for a number of days penetrable to the probe. There is but slight suppuration from its surface, but should there be any considerable hæmorrhage from the artificial canal, one application of the electrode with the current reversed making the positive pole the internal will give relief. One imperative point in these operations is the proper selection of poles to be employed. The immediate effect of the negative pole is to liquefy the tissues with which it comes in contact like a caustic alkali, and it should be selected for the establishment of a canal, while the effect of the positive pole is to coagulate and harden tissues coming in contact with it, like a caustic acid, and it should always be employed to check hæmorrhage either from the artificial canal or the natural uterine canal itself. Therefore for the rapid reduction of the tumor the negative pole is decidedly preferable, and should always be applied unless the presence of hæmorrhage demands the use of the positive.

The third and last operation to which I will call your attention is the extra-uterine galvano-puncture, or the needle operation proper. Tumors that call for this form of treatment are those that are not

amenable to the other two forms already considered.

This variety, usually of the sub-peritoneal type, often pedunculated, can be reached either by puncture through the vaginal wall, using great care not to injure the bladder or other important organs, or where this is not feasible by puncturing through the abdominal wall. Everything else being equal, the needle should be introduced into the tumor through the vagina, because if it is at all possible, the tumor lies in contact with the vagina; consequently the tissues that it is necessary for the needle to traverse are unimportant, while the abdominal wall with its fat, muscle, and peritoneal layers is too formidable to penetrate even with a needle unless actuated by absolute necessity. If the puncture is to be made through the vagina, a thorough vaginal injection of the bichloride solution should be employed, and for this operation, unless the patient has more than ordinary fortitude, an anæsthetic should be administered. For this purpose I employ, as preferable, the mixture of equal parts of alcohol, ether and chloroform, on account of its prompt action and transient effects.

After it has been definitely determined that this operation is the only alternative the patient is placed in the dorsal position, and all instruments being in readiness, the anæsthetic is pushed promptly to a surgical degree and then entirely withdrawn. A suitable speculum is introduced and a needle with proper curve, and insulated with hard rubber to within one inch of the point is thrust through the vaginal walls into the tumor. The position of the bladder should have been ascertained by means of a probe or catheter, before commencing work. When the needle has been satisfactorily adjusted the speculum is carefully withdrawn and the needle connected with the negative pole of the battery. The same external electrode, should be adjusted with the same care, and in the same manner as in the other operations described and connected with the positive pole. The current is now gradually turned on until a strength as indicated by the galvanometer is reached of 500 to 1,000 milliampères. In the meantime the patient is allowed to come out from the influence of the anæsthetic, which usually occurs without any struggling; a peculiarity of the anæsthesia by the A. C. E. mixture which makes it very desirable for this work.

This operation should last for about eight minutes the first time, and subsequently, if it is deemed desirable, a longer time can be given. When the operation is terminated, and the current has been gradually withdrawn, the needle will be found loosened and its removal is accomplished with ease and very little pain.

The abdominal operation is performed where the tumor is of the large sub-peritoneal variety, that cannot be safely attacked from the uterus or vagina, and where the tumor rises above the cavity of the pelvis, and is in contact with the abdominal wall. Here, after necessary antiseptic precautions have been carried out, the needle is thrust through the abdominal wall into the substance of the tumor at its most prominent part, and is then connected with the negative pole of the battery. The other electrode, the same variety as described in the other operations, should be placed upon the abdomen in close proximity to the needle. The current should be 300 to 1,000 milliampères strength, and the duration of the operation ten minutes.

Herein I have endeavored to give you an idea of the present status of the treatment of fibroid tumors of the uterus by means of the strong current of electricity. The use of the strong current was adopted by Dr. Apostoli, of Paris, he being the first to devise electrodes and rational means by which it could be made tolerant. To the extent of discussing the strong current and utilizing the coagulating effect of the positive pole for the checking of uterine hæmorrhages, I have described Dr. Apostoli's methods. Otherwise I have not confined myself to any one system, but have endeavored to give the best means, according to my knowledge and judgment, that have been developed, up to the present time, for the relief of this distressing malady. The scope of the subject is too broad to admit its being satisfactorily dealt with in one short paper, and, I therefore beg to submit, at the risk of wearying your patience, the following conclusions, which may cover a few points of importance that time would not allow me to discuss in the body of the paper.

CONCLUSION.

1. A means of generating a continuous current of electricity which can be increased per 10 to 1,000 milliampères in strength, is necessary in order to obtain all the benefits of this treatment.

2. Hæmorrhages from hæmorrhagic fibroid tumors can be cured by the local coagulating effect of the positive pole applied inter-uterine.

3. The inter-uterine electrode, when positive, should be of unattackable metal, conforming as nearly as possible to the size and shape of the uterine canal and having the vaginal portion insulated.

4. When the cervical canal cannot be entered a negative galvano-puncture should be made into the presenting part of the obstructing mass of the tumor and an artificial canal, which is to take the place of impenetrable uterine canal, in all subsequent treatments be formed.

5. The intra-uterine electrode should in all cases be negative, unless there is hæmorrhage or excessive leucorrhœa, when the positive pole is always required. The same patient may, however, present successive symptoms demanding the use of each pole.

6. The strength of the current should be the strongest possible consistent with the desired therapeutic effect and the endurance of the patient.

7. Cases of intolerance of high doses arrange themselves under the three following heads: 1. Hysteria. 2. Enteritis. 3. Acute nephritis, peri- or parametritis; the most tolerant being the deep uterine and profusely hæmorrhagic.

8. The duration of the operation should be from eight to ten minutes, according to the toleration of the patent.

9. The number of operations is necessarily dependant upon and influenced by the result to be accomplished. A severe hæmorrhage can be checked in from four to five séance, while a general reduction of

the tumor necessitates many operations, varied, of course, according to size and location. In many cases simply a restoration to health and a relief from the prominent and annoying symptoms must be accepted as a substitute for an actual cure.

10. The time of commencing the treatment matters but little, if the tumor is not rapidly growing, and no excessive hæmorrhage is present. The operation should be inter-menstrual, if possible, but if hæmorrhage is continuous operate during the flow. The séances should occur two or three times a week if compatible with the endurance of the patient, and should be as regular as possible.

11. Extra-uterine puncture should be regarded only as a last resort, but every means of reaching the tumor through the uterus being impracticable, seek, if possible to make the operation extra-peritoneal, should this in turn prove equally unadvisable, use as a final alternative the abdominal puncture.

12. Strictest cleanliness and thorough antiseptic precautions are absolutely demanded in operations connected with this treatment.

163 State Street, Chicago, February, 1887.

VAGINAL PRESSURE IN THE TREATMENT OF CHRONIC PELVIC DISEASE.

Abstract of a paper read before the Chicago Gynæcological Society, February 18, 1887.

BY A. REEVES JACKSON, M.D.,
OF CHICAGO.

The brief paper which I have to present this evening, was suggested by some remarks, with which the society was favored at its last meeting by Dr. Etheridge, entitled a "Preliminary Note on Antiseptic Tamponnement of the Vagina in the Treatment of Pelvic Inflammation." It would have afforded me pleasure to endorse the treatment which was advocated at that time, had an opportunity been given for so doing, for I have had occasion to make frequent use of it, and to learn its advantages, during the past eight or nine years.

My attention was first called to this subject by reading a paper which was published by Dr. V. H. Taliaferro, of Atlanta, Ga., in 1878, on "The Application of Pressure in Diseases of the Uterus," in which the writer presented many facts and arguments to prove the great therapeutic efficacy of the principle of pressure as applied to the treatment of diseases of the uterus and other pelvic organs, which are characterized by habitual passive congestion and its results, namely, uterine displacements, enlargement, relaxation, cervical erosions, menstrual disorders, etc. The method consisted in firmly packing the vagina with sheep's wool made antiseptic with carbolic acid, with the aid of a Sims' speculum, the patient being in the knee-chest posture. At first Dr. Taliaferro used cotton pledgets, saturated with glycerine, but observing that the cotton packed quite hard, he very soon substituted wool because of its resiliency, a quality with which it was found to retain under pressure and moisture.

[In illustration of the results of this method of treatment, Dr. Jackson detailed a number of instructive cases in which it had been used by him. In one of these, the patient was suffering from supra vaginal elongation of the uterine cervix, complicated with complete cystocele and vaginal eversion, the involuted parts protruding from the vulva and forming a tumor of considerable size. The uterine canal measured six inches. The parts were restored and the vagina packed with cotton, a process which was repeated every two or three days for a fortnight, at the end of which time the depth of the uterus was reduced to three inches. Other symptoms were correspondingly improved. The patient, who had been only able to drag herself along with pain and difficulty, could, after the first packing, move with rapidity and comfort. She was subsequently cured by a plastic operation on the vagina. A number of other cases, some of them furnishing results almost equally striking, were detailed by the writer.]

Dr. Taliaferro strongly emphasized the importance of applying the tampon with the patient in the Sims' position, in order that the vaginal canal should be distended and elongated to its utmost capacity. He further advised that the first few pieces composing the tampon should be of cotton, for the reason that a greater amount of glycerine may be incorporated with that substance than with wool. It was claimed that the therapeutic effects of this treatment are as follows:

1. It diminishes blood supply and nutrition.
2. It promotes absorption.
3. It removes hyperplastic tissue by retrograde metamorphosis.
4. It diminishes nervous action.
5. It rectifies malpositions.

I was much impressed by the stated results of the treatment, and determined to give it a trial. It seemed to promise a valuable substitute in some of the objectionable and uncertain methods of local treatment then and now in vogue, such as cauterization, local blood letting, tents, intra-uterine medication, iodine painting, hot douches, etc. Since then I have used it in many cases of chronic pelvic disease, and am able to corroborate the favorable statements that have been made concerning its efficacy.

Dr. P. F. Mundè, who gives an abstract of Dr. Taliaferro's paper in his "Minor Surgical Gynæcology," edition of 1885, says: "Of the value of this steady and elastic pressure and support in reducing the size of an engorged hyperplastic or (better still) subinvoluted uterus, and restoring the normal circulation to the œdematous and congested pelvic cellular tissue, I have no doubt whatever; neither of the potent alterative effect of this pressure on old peritonitic or cellulitic exudations and adhesions."

I had not applied this dressing many times before I observed occasionally on removing the tampon, that on various parts of the vaginal wall, and also around the os uteri, erosions appeared sometimes bleeding slightly on exposure. I attributed this to the fact that the packing had either been too firmly or unequally placed. In cases of moderate laceration of the cervix uteri, this accident is especially likely to occur if the packing is so applied about the vag-

inal portion in such a manner as to widely open the os uteri. Hence, in all such cases I endeavor to at first push the uterus upward with a single pledget, and then to pack the entire vaginal fornix about it so as to press the cervical labia together as much as possible.

When any part of the mucous membrane appears soft and succulent, I have found advantage in combining with the glycerine a solution of tannin or alum. The contact of glycerine is not equally well-borne by all vaginas, and in a few cases I have not been able to persist in its use on account of the irritation it caused. In these cases I find an excellent substitute in vaseline, which, although it does not produce the peculiar serous drain which comes with the use of glycerine, is unirritating, and makes possible the employment of the pressure, which is the more important element in the treatment.

When I first began to use this pressure treatment I chose carded wool, in accordance with the suggestion of Dr. Taliaferro. But it was difficult to obtain a well prepared article, and next to impossible to incorporate any considerable quantity of glycerine with it. I was obliged to use cotton for the upper part of the vagina. I next tried successively oakum and jute. These substances were elastic—especially the former—and also antiseptic; the former containing tar, and the latter carbolic acid. However, since sheep's wool has been so prepared as to be free from fatty matter, and is comparatively absorbent of water and glycerine, it more completely and perfectly meets the indications than any of the other substances I have named.

As regards the form of the tampon, I have used it both in single and multiple pieces, and unhesitatingly give preference to the latter in many cases. It is very important that the vagina be packed in such a way as to insure an equable pressure against every part. This cannot be so certainly done with a tampon made from a single piece, or a few large ones as with a number of smaller sizes. When moistened the pieces should not exceed a walnut in size. Time may be saved, however, and the object accomplished, by using a single piece of wool for the lower half of the vagina.

Commonly, the only medication I have used with the tampon besides the glycerine or vaseline, has been the occasional addition of tannin or alum. But when, for any reason, I have wished to have the dressing remain longer than two days, I have, after saturating the separate pledgets, rolled them in boracic acid so as to take up two or three drams of the latter.

The cases in which I have found this method of treatment especially beneficial are those which are characterized by soft engorgement—such as the earliest stages of subinvolution, with or without cervical laceration. In these cases I have seen more marked change effected in two weeks than is commonly seen in two months—or more than is seen at all sometimes—under the use of hot water douches, however perfectly and assiduously the latter may be used.

Permit a slight digression. Without wishing to disparage in the least the use of hot water irrigations, in the treatment of chronic pelvic inflammations, I desire to say that for some years I have held the opinion that their efficacy great as it is, has been overrated. Indeed, they have been so eulogized that perhaps we have expected more from them than was reasonable. One serious drawback to their usefulness arises from the fact, that the sittings cannot be continued usually for a sufficiently long time. If it were practicable to keep a stream of hot water playing against an inflamed or engorged tissue for thirty hours rather than thirty minutes, we should doubtless obtain more prompt and more permanent results. But as the hot water douche is usually employed, it effects in constricting the over full vessels are of short duration. I have seen a turgid, purplish cervix subjected to a hot stream for forty minutes; at the end of the time it was pale and shrunken; at the end of another hour, the patient continuing meanwhile on her back, I have found the same cervix as turgid and as purple as before.

Now, just on this account, a manifest and very great advantage may be urged in favor of a means of treatment which, equally with the hot water douche, has power to unload the vessels of their stagnant contents, and which may be continued day after day and week after week, without remission and without reaction. Such a means is, I believe, to be found in this persistent pelvic pressure and tissue drainage.

Were it needful I could cite many cases illustrative of the beneficial effects of this treatment, but will content myself with but two.

Case 1.—A married woman, 34 years of age, had two children at term, and subsequently a miscarriage at the fifth month. After this latter event menstruation became more profuse and the periods were protracted. At the end of two years her general health was greatly impaired and she was markedly anemic. Ordinary remedies were used without success. At my suggestion, her physician curetted the interior of the uterus, and then swabbed the cavity with Churchill's solution of iodine. Febrile symptoms followed, and lasted a week. Temporarily there was improvement as regarded the hæmorrhage; but in three months she was worse than before, and rarely free from a bloody discharge. It was then determined that I should repeat the curretting. Remembering the inflammatory sequel to the previous operation, I was moved to pack the vagina a few times as a preparatory measure. She was flowing when the first packing was placed. When the latter was removed at the end of forty eight hours, the only appearance of blood was a slight staining of that portion of the tampon which had been pressed against the os uteri. Another tampon, larger than the first, was placed, carrying the uterus as high as possible in the pelvis. On its removal two days later no blood at all was perceptible. This treatment was continued three weeks, combined with suitable medicinal and hygienic means, with the result of permanently stopping the hæmorrhage, and the ultimate restoration of the patient's health.

Dr. Mundé, in speaking of this means of treat-

ment in connection with another class of cases, uses these words: "When the retro-displaced fundus uteri is adherent, these daily emollient and hydrogogue tampons may in time, by their combined pressure and alterative action, bring about the absorption, or at least stretching, of the adhesion, and permit a replacement of the organ." I submit a case in point.

Case 2.—Mrs J., aged 24 years; had several induced abortions; no child at term. Had been treated for displacement by pessary, with apparent benefit. Afer a time the symptoms returned, and the physician introduced a larger instrument. It caused pain at once, and in a few hours there was a chill and then rise of temperature. I saw the patient next day and advised the removal of the instrument, which was taken away. It was a very large one. A sharp attack of inflammation ran its course in ten days. No abscess formed. A few weeks later I found the uterus retroverted and the fundus immovably fixed by adhesions in its mal position. At the request of the attending physician I then took charge of the patient. The treatment consisted wholly in the use of tampons of cotton with glycerine and boracic acid. The pledgets were small at first, and were placed in the posterior vaginal fornix, pressed into position with as much force as the patient could readily bear. The pledgets were increased in size and others were placed in front of the cervix. The vagina was packed below more and more fully and firmly each time with wool, until the canal was distended to its utmost capacity. At first the dressing was renewed daily, then every two days. At the end of two months the uterus was thoroughly replaceable, all tenderness had disappeared, and no evidence remained of the former presence of adhesions.

A CASE OF INNOMINATE ANEURISM TREATED BY SIMULTANEOUS DISTAL LIGATION OF THE RIGHT CAROTID AND SUBCLAVIAN ARTERIES. RECOVERY.

Read before the College of Physicians, of Philadelphia.

BY H. R. WHARTON, M.D.,

ASSISTANT SURGEON, HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA

The following case was operated upon by Professor John Ashhurst, Jr.:

Andrew C., aged 42 years, who was born in Scotland and served for a time in the British army, and whose present occupation is that of a gardener, presented himself at Professor Pepper's clinic at the University Hospital with the following history: Eighteen months before his admission to the hospital he began to experience pain running from the throat to the right shoulder and arm, and this continued to be noticed at intervals until six months ago, when he began to be troubled with shortness of breath and complained of a paroxysmal cough and difficulty in swallowing; at this time he noticed a swelling above and a little to the right of the sternum.

From this time he suffered much from the symptoms above described, and had also great difficulty in sleeping in the recumbent position and spent a large portion of his nights in the sitting posture. The patient had never had syphilis, and the only thing to which he could attribute his present condition was a severe fall upon the right shoulder which had occurred two years previously.

The result of the examination by Prof. Pepper was as follows: The patient presented a swelling above the sternum extending from the middle line two inches to the right along the line of the clavicle. Inspection showed decided pulsation in the swelling and palpation revealed its expansile character. Auscultation detected no bruit or thrill in the tumor, but the heart sounds were heard over the area of swelling with great clearness; no murmur was detected over the right carotid or subclavian arteries; examination of the heart showed that its sounds were clear. There was noticed great venous suffusion of the face with distension of the venous trunks when the patient leaned forward. The left pupil was large, the right of moderate size; the right pupil promptly responded to light, the left one acted sluggishly. The radial and other accessible arteries were soft to the feel, so that there was no evidence of widespread arterial disease. A sphygmographic tracing taken by Dr. Westcott, showing the differences in the radial pulses, is subjoined. As the result of his examination, Prof. Pepper was of the opinion that the patient was suffering from an aneurism of the innominate artery.

The case was referred to Prof. Ashhurst and was admitted to the surgical ward. Prof. Ashhurst, after a careful examination of the patient, concurred as to the diagnosis of innominate aneurism and decided that the treatment by simultaneous distal ligature of the right common carotid and right subclavian arteries was that which offered the most hope of a cure of the aneurism or at least of benefiting the patient's condition.

On November 13, one week after his admission to the hospital, the patient was etherized and Prof. Ashhurst cut down upon and ligated the right common carotid artery just above the omohyoid muscle with a catgut ligature; the right subclavian artery was next exposed and ligated in its third part just outside the anterior scalene muscle with a ligature of the same material. The wounds were closed with silver sutures, drainage tubes being introduced, and were dressed with oiled lint, the whole right arm being wrapped in cotton.

No immediate effect was noticed in the aneurism from the application of the ligature, nor were there any cerebral symptoms. The patient did well after the operation, and on the succeeding day the temperature and color of the right arm were good. The wounds did well and in the course of a few days it was noticed that the tumor at the root of the neck had become smaller and firmer and that its pulsations had diminished in force; the dyspnœa and dysphagia had also diminished very markedly, and the patient was able to sleep comfortably in the recumbent posture. Up to the time of his discharge from the hospital repeated examinations failed to discover any pulsation in the radial artery. After this time the patient's improvement was continuous and he

was discharged from the hospital on January 13, just two months after the operation, at which time he was examined by Prof. Osler, who made the following report:

Inspection shows no pulsation visible; right sterno-clavicular articulation prominent. Palpation reveals systolic shock at right sterno-clavicular articulation and upon firm pressure a feeble pulsation can be felt; this is also noticeable when the finger is placed in the sternal notch. Percussion gives a clear sound beneath the first bone of the sternum until you approach close to the clavicle. There is a small area of dulness beneath area of prominence. Examination of the heart shows the apex beat visible just below the nipple; feeble cardiac pulsation felt on deep pressure. No increase of heart dulness; heart sounds clear at apex; at second right interspace, first sound feeble, second sound loud and ringing. Accentuated sound over first bone of sternum. Over the swelling at the right clavicular articulation, first sound is dull, free from murmur, and the second sound is loud. The accentuation of the second sound is heard as far as the middle of the right clavicle; most careful examination fails to discover any indication of murmur.

The treatment of innominate aneurism by the consecutive or simultaneous application of distal ligature to the right common carotid and subclavian arteries has been employed in a sufficient number of cases, and the results following the operation have been of such a nature that it is now established as a well-recognized surgical procedure in the treatment of this affection.

The *rationale* of the treatment of innominate aneurism by the distal ligation of the right common carotid and subclavian arteries are as follows: By the occlusion of the right common carotid and subclavian arteries, if both be tied simultaneously, the amount of blood passing through the aneurismal sac is diminished about two-thirds, and there is a proportionate slowing of the circulation of the blood through the sac; the circulation continuing through the aneurism is, probably, about one third of the usual amount, representing the blood sent to the large branches given off from the first part of the subclavian. By means of this diminished and retarded circulation we have, in favorable cases, consolidation, to a greater or less extent, of the aneurism, either from the formation of a laminated clot on the inner wall of the sac, or from the extension backward of a thrombus which starts at the site of the distal ligatures upon the carotid or subclavian arteries.

If the ligatures be applied consecutively to the carotid or subclavian arteries, the circulation of the blood current through the aneurismal sac is diminished to a less degree upon the application of the first ligature. In cases which terminate favorably after this operation the aneurismal tumor diminishes in size and becomes firmer, the pulsation becomes less distinct, and the pain and pressure symptoms, if they had previously existed, disappear; that pulsation at the site of the aneurism is seldom entirely wanting is accounted for by the fact that a certain amount of blood still finds its way through the sac to supply the vessels given off from the first part of the subclavian.

The question as to whether it is better to practise simultaneous or consecutive ligation of the carotid and subclavian arteries in this form of aneurism, is one upon which the highest surgical authorities hold some diversity of opinion. Mr. Barwell, whose successful cases and writings upon this subject have given a great impetus to the treatment of innominate aneurism by distal ligature, is of the opinion that the most rational form of treatment consists in the application of simultaneous distal ligatures to the carotid and subclavian arteries in properly selected cases. He opposes the application of consecutive ligatures unless in exceptional cases; and in this opinion he is sustained by Mr. Erichsen, on the ground that by tying one vessel only, time is allowed for the gradual dilatation of the collateral vessels given off from the first part of the subclavian artery, thus rendering the application of the second ligature less effective in diminishing the amount of blood passing through the aneurismal sac. He concludes that the result of tying the right carotid artery alone for innominate aneurism is not satisfactory, as this vessel has been ligated for innominate or aorto-innominate aneurism thirty times, with twenty deaths; and in case of aortic or aorto-innominate disease it has been tied seven times, and in only one instance has it proved beneficial; he concludes, therefore, that in low innominate aneurism, which almost always involves, to a certain extent, the aorta, it is safer to tie simultaneously the carotid and subclavian arteries than to tie the carotid alone.

Mr. Holmes, upon the other hand, looks with more favor upon the consecutive application of the ligatures; he considers the carotid ligature most important, and recommends its application first, and reserves the ligation of the subclavian for a subsequent period. He is in favor of ligating first the vessel in the direction in which the aneurism exhibits the greatest tendency to spread. He also believes that the distal ligature is efficacious in the treatment of innominate aneurism which is of the mixed variety, which is associated with marked aortic disease; in this opinion controverting the previous teaching that innominate aneurisms associated with aortic disease are unfavorable cases for distal ligation. In this latter opinion he is supported by the favorable results following the ligation of the left carotid artery for aortic aneurism, as suggested by Mr. Cockle.

So far as I am able to ascertain, consecutive double distal ligation of the right carotid and subclavian arteries has been practised for innominate aneurism (as diagnosed) in eight cases, with three recoveries and five deaths, although there was temporary relief in one of the fatal cases.

I have been able to find the records of thirty-two cases of simultaneous double distal ligation of the right carotid and subclavian arteries for innominate aneurism (as diagnosed), in which the operation was followed by recovery in twelve cases, death in sixteen cases, and by temporary improvement in four cases. It will be seen that the results of both methods of treatment as regards the number of recoveries are nearly equal, but it must be remembered that the number of cases in which consecutive liga

tion was resorted to is very small in comparison with that in which simultaneous ligation was employed. I think, therefore, that at the present time the weight of surgical opinion is in favor of the views of Mr. Barwell that, in innominate aneurism, the simultaneous double distal ligation of the right carotid and subclavian arteries is both a more efficient and safer procedure than the consecutive ligation of these vessels.

MOUTH BREATHING AND ITS TREATMENT.

BY N. R. GORDON, M.D.,
OF SPRINGFIELD, ILLS.

The evil results of mouth breathing, are due to the inspiration of atmosphere at a low temperature, the presence of dust and foreign matter in the air, the desiccating effect on the mucous membrane over which the air passes, and the disuse of the nasal passages for the normal function of respiration.

The pathological results are; chronic inflammation of the pharynx, larynx, and bronchi, and the adjacent tissues, accompanied with cough, hoarseness, loss of resonance of voice, impairment of sense of smell, and hearing. The pernicious effect of oral respiration is not impressed upon the minds of medical men, nor is it scarcely recognized as being an evil practice by the public. The practice is a very common one, especially during the winter season; there are a great many habitual mouth breathers.

A condition which gives rise to partial or complete nasal stenosis, is adequate cause for mouth breathing. Chronic hypertrophic catarrh is the most frequent cause of partial stenosis; the frequent congestion of the cavernous tissue from repeated colds, causes hypertrophy of the turbinate bodies, which partly close the nasal lumen, requiring the subject to resort to oral respiration; the necessity for mouth breathing is in proportion to the nasal stenosis; the transition from nose breathing to mouth breathing is gradual, and the parts by degrees become accustomed to the transfer of function. Many persons have a partial obstruction of the nasal passages; they breathe with comparative ease while in a state of repose, but upon taking exercise, such as walking, they resort to mouth breathing to supplement the deficiency in the nose; others resort to it only during sleep; many contract mouth breathing from a careless habit, or possibly from a succession of colds in which the subject is forced to breathe through the mouth; in such cases the obstruction in the nose is the result of thickened mucosa.

A deflection of the septum to one side or the other, will produce a partial obstruction of the nares; the septum may be contorted like the letter S, giving a stenotic effect in each nostril; often coupled with deflection there is hypertrophy of the opposite tissues, making the stenosis complete. Any of the tumors that occur in the nasal cavity, such as the gelatinous, or mucous polypi, malignant growths, the adenoid growths of the post nasal passage, or exostosis of vomer may produce partial or complete stenosis of the nares; foreign bodies, such as seeds, buttons, stones, may lodge in the meati, and occlude the passage; paralysis of the dilator alae nasi prevent free nasal respirations; enlarged tonsils, tumors of the palate or uvula may interfere with nose breathing. Adhesions of the soft palate to the posterior wall of pharynx, and bands uniting the two lateral walls of the nostrils, the result of cicatricial contraction from strumous or syphilitic ulceration, will prevent nasal breathing.

The function of the nose is of a three-fold character: 1. Respiration. 2. Special sense of smell. 3. Vocal resonance. The temperature of the air, in its passage through the nose, is increased, and foreign substances, such as dust, is lodged on the irregular mucus surface of the nasal passages. If the inspired air is dry, it also gathers moisture. The terminal filament of the olfactory nerve are very properly distributed to the superior portion of the nasal passages, where it readily comes in contact with the odor-bearing atmosphere. In order that the vocal resonance should be perfect, the nasal and post-nasal passages should be free and open; any increase in tissue or obstruction in these passages impair the resonance of the voice.

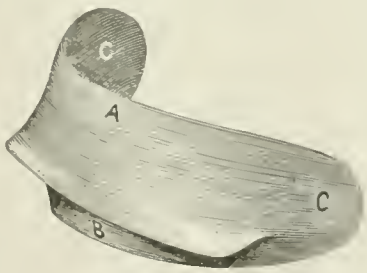
In oral respiration the air enters the larynx at a temperature somewhat lower than is given it by a passage through the nasal chambers; this cold air excites inflammatory action, producing soreness, cough, hoarseness and other symptoms of pharyngeal, laryngeal, and bronchial irritation. The dust and foreign matter floating in the air finds but little to impede its progress until coming in contact with the vocal bands, and the adjacent sensitive tissues, thus adding another factor, in the production of inflammation. Owing to the dryness of the atmosphere in our dwellings, the mucus membrane of the mouth and throat, in its efforts to furnish the required additional moisture, becomes very dry and parched. Infiltration with thickening of the mucus, submucus, and glandular tissue, of the entire nasal and post-nasal passages occur, as the result of deprivation of the normal stimulus, afforded by respiration; such thickening interferes with the resonance of the voice, hearing, and sense of smell. The results arising from the loss of nasal breathing, are as important as the direct evils from mouth breathing.

Treatment.—The method of treatment adapted for the cure of mouth breathing will depend upon the cause. If the obstruction is due to deflection of septum, I have found the rotating burr and dental engine, the most practical and satisfactory method of relieving the difficulty. Exostosis can be removed in the same way. Abnormal growths of whatsoever character, must be removed by such means as seem best adapted to the various conditions existing in each particular case. The adhesions of the soft palate with the posterior wall of pharynx, should be dealt with in the most approved method for relieving such conditions; adhesions of the nasal walls should be severed, and pledgets of cotton kept in situ until the part heal. If the nasal stenosis is due to indurated hypertrophy of the turbinate processes, these will require removal by the galvanic cautery or Jarvis' wire snare.

So far as the successful treatment of the habit of mouth breathing is concerned, I am unable to find anything in the literature upon the subject, better than the use of bandages, or similar appliances, around the head for holding the mouth closed, which are unsatisfactory and produce great discomfort to the patient. The frequency of mouth breathing and the evil consequences, are sufficient to enlist our attention in the prevention and cure of this practice. As we have said, the greater number of cases of mouth breathing are due to nasal catarrh; a succession of colds have produced a soft and œdematous condition of the nasal mucosa, and mouth breathing ensues as a necessity; upon recovery or partial subsidence of the cold, the subject continues to breathe through the mouth, and the conditions which characterize chronic hypertrophic catarrh are developed.

In all such cases, and indeed, in all others where the obstruction is not indurated, fixed, or complete, and in cases after an operation for the relief of stenosis, where it is desirable for the patient to overcome the habit of mouth breathing while asleep, I have found an instrument, the device of Mr. William Fisher, of this place, to be admirably adapted for their relief. It is made of celluloid, simple in construction, and fits nicely between the teeth and lips without the aid of bandages or other appliances, and is worn during sleep without any apparent discomfort. I wish to call especial attention to the value of this instrument in the treatment of mouth breathing, due to the above causes; it is also a useful adjunct in the treatment of nasal disease where mouth breathing is present. It acts by actual prevention of oral breathing, and the normal stimulus of respiration restores the intra-nasal tissues to a healthy condition. It also overcomes the habit of snoring, which is due to ora-nasal respiration.

The accompanying cut gives a very good idea of the instrument.



THE RESTORATIVE TREATMENT OF SLEEPLESSNESS FROM BRAIN EXHAUSTION.

BY BOARDMAN REED, M.D.,

OF ATLANTIC CITY, N. J.,

FORMERLY PHYSICIAN TO THE MERCER MEMORIAL HOUSE FOR INVALID WOMEN

One of the lessons strongly impressed upon me by my experience in practice is that insomnia when due (as is most frequently the case) to brain exhaustion, is best cured by tonic or restorative treatment, rather than by narcotics. It has been a source of gratification, therefore, to see the same lesson strongly inculcated by Dr. W. G. Eggleston in THE JOURNAL for February 19. I desire to confirm emphatically all that he said in his paper.

It has been alleged by somebody that man is the only animal that can be taught to sleep on an empty stomach. But when suffering from brain-fag this teaching may fail even in man. Unquestionably a lunch at bedtime is wholesome and conducive to sleep, especially in brain workers who sup early and retire late. But the lunch should be simple. Indigestible food taken at bedtime may easily disturb the sleep.

The cold plunge or sponge-bath is another excellent hypnotic and a rational one, since it at the same time diverts blood from the brain to the capillaries of the surface and invigorates the nervous system.

At this health resort, where many of the broken down people of the United States sooner or later come as to a sort of Mecca for the afflicted. I see large numbers of persons whose chief complaint is that they cannot sleep. Most of them have taken bromides persistently and often without advantage except at first. When such patients come with definite instructions from their physicians to persevere with a course of some bromide mixture, I have always encouraged them to give the remedy a thorough trial, but when the cause of the insomnia has been, as it is nine cases out of ten, some form of cerebrasthenia, the result has generally been disappointing, even in this air which is exceptionally bracing and predisposes most persons to sleep.

The cases of nervous break-down which are serious enough to have caused a compulsory vacation from business and a sojourn here at the seashore, frequently require medical treatment to reëstablish the habit of sleeping, and thus enable the exhausted nerve centres to be rested and reinvigorated; and no sedative or narcotic drug yet tried by me, whether opium, chloral, the bromides, hyoscyamous, hyoscine or paraldehyde has proved satisfactory in such cases. The tonic effect of the sea air with good food, moderate exercise and cheerful company often prove sufficient. When it does not, a light lunch at bedtime with occasionally a few teaspoonsful of whisky in milk added and the sponging of the body with sea-water followed by a thorough rubbing with a Turkish towel are highly useful measures. But sometimes these all fail, and when they do, my experience teaches that to begin administering any narcotic medicine is usually a mistake. My most frequent recourse now is to give some one of the nutrient nerve tonics, such as the compound syrup or glycerite of the hypophosphites—a teaspoonful two or three times a day—or in some cases the compound syrup of the phosphates, commonly known, in Philadelphia at least, as Parish's Chemical Food. When the patient has a weak heart and insomnia results from a passive congestion of the brain, a condition frequently met with among neurasthenics, a little digitalis may work wonders and may usually be advantageously combined with very small doses of strychnia and quinine as well as with moderate doses of iron when this is otherwise indicated.

Of course it goes without saying that bad sleepers should have their stomachs and liver put in as good order as possible, and when kidney or other organic diseases has a causative influence it demands the chief attention.

There will remain, then, a certain proportion of cases in which drug treatment of all kinds has been tried and failed, and continues to fail even when tried again under the better conditions existing with rest and good hygiene in this invigorating seaside climate. When such patients fail to sleep and are driven almost insane for want of sleep, it is impossible to deny them a trial with narcotics. Yet I have seen an overtaxed journalist take astonishing doses of morphia besides really dangerous amounts of chloral and hydro-bromate of hyoscine without getting more than an hour or two of sleep and then sleep soundly after one or two treatments by the continued galvanic current from eight to fifteen cells passed directly through the brain. This was an exceptional case, but it is a constant experience with me to see electricity in some of its forms prove of the utmost value in cases of insomnia as well as in all the other forms or manifestations of nervous exhaustion. Massage is another promising auxiliary.

If these few hastily recorded results of a considerable experience with insomnia serve to help physicians who are not satisfied with the effects of the so called hypnotic drugs, my object will have been achieved. Nerve tonics are often the best hypnotics. At my last visit, this evening, a puerperal woman who had been sleeping badly, said to me, "You put some quieting medicine in that last mixture." It was simply compound syrup of the phosphates.

Atlantic City, N. J., March 1, 1887.

MEDICAL PROGRESS.

The Toxicity of the Cholera Bacilli and the Treatment of Cholera.—Much in the course of cholera, especially in foudryante cases, points to the toxic action of the bacilli. The poison may be derived from the vegetative activity of the comma bacilli, may be a ptomaine that has been formed in the intestinal canal, or it may be secreted by the bacilli, or the bacilli in themselves may be poisonous, those that have perished in the intestinal canal being digested and acting in the manner of poisonous mushrooms. To determine upon what this toxic action depended Cantani, of Naples, by boiling sterilized a three-days pure culture of comma bacilli and injected it into the peritoneum and the subcutaneous tissue of dogs. The animals sickened with symptoms of cholera and recovered in twenty-four hours. Control injections of sterilized meat-broth gave negative results. The older the culture the less poisonous was its action. Cultures of living bacilli gave negative or almost negative results. Living cultures in *simple* meat-broth were almost without effect, while living cultures in *peptonized* broth gave rise to violent symptoms of cholera intoxication. Cantani thinks he can explain the latter observation by the luxuriant growth and the early death of the bacilli in peptonized broth, while in simple broth their growth is slow and their vitality is retained a much longer time. Cantani draws these conclusions from his experiments: 1. There is a cholera poison which is dependent on the comma bacilli. 2. The cholera poison is independent of the living bacilli found in the intestinal canal. 3. The dead bacilli yield more poison to the fluids in which they have lived than do the living bacilli. Cantani is of the opinion that the comma bacilli are in themselves poisonous, like the poisonous mushrooms. There are two indications for the treatment of cholera: to limit the multiplication of the bacilli in the intestinal canal, and to hasten the excretion of the poison from the blood. The fact that tanners escape cholera, directed Cantani's attention to tannic acid. He had constructed many years ago an enteroclysma, consisting of an irrigator holding 3 or more litres, hung up 2, 3 or 4 metres above the bed of the patient and terminating in an intestinal tube. With this apparatus he can overcome the ileo-cœcal valve in the majority of cases, and, as he has demonstrated by many experiments, also the pylorus, for infusion of senna, etc., injected by the apparatus, is vomited after fifteen to thirty minutes. In cholera he injects, by means of the irrigator, 3, 5 or 10 grams of tannic acid in 1½ to 2 litres of sterilized water of a temperature of 38, 39, or even 40° C., with 30 to 50 grams of gum arabic and 10 to 30 drops of laudanum. Prof. Maragliano, of Genoa, has employed with great success as much as 20 grams of tannic acid. The results were astonishing. After every enteroclysis the discharge ceased for six, eight or twelve hours. The sooner the treatment was begun the better results were obtained. After the cholera diarrhœa had lasted a number of days the symptoms of cholera intoxication could no longer be forestalled, though even then they were much milder. And in the premonitory diarrhœa, he had obtained the impression that the disease had frequently been aborted.

A few moments after the enteroclysis the patient goes to stool and voids one-third to one-half of the injected fluid. The injection should be made shortly after a passage, so that it may be retained as long as possible in the small intestine. Usually no more than two to six injections are required a day. Cantani states that during the Naples epidemic he was sanitary inspector to the orphan asylum for children whose parents had died with cholera. During the first weeks as many as six cholera cases developed a day which had to be taken to the cholera hospital. He then began to inject the hot tannic solution as soon as diarrhœa began to appear, and from this time, of several hundreds of orphans admitted to the institution, he had seventy-six cases of mild and thirty-two cases of severe diarrhœa (fifteen with vomiting) which, from the genius epidemicus, must be ascribed to cholera infection, and in none of them did the specific symptoms of cholera declare themselves. This method has gained great popularity among the profession and the people of Italy. Tannic acid in 1 per cent. solution of 37° C. destroys the bacilli, and in ½ per cent. solution prevents their further development. The stimulating and the vivi-

fying effects of the hot injections are of great importance in this treatment.

No method of treatment fulfils better the second indication, to hasten the excretion of the cholera poison from the system, than does hypodermoclysis of hot saline solution. Cantani employs in the algid stage ½ to 1 litre of sterilized water at a temperature of 38 to 39° C., in which 4 per cent. of sodium chloride and 3 per cent. of sodium carbonate have been dissolved. Of 187 most desperate cases, that had been given up, he was able to save 60 per cent., while the mortality for this class of cases, according to Griesinger, is 80 per cent.; a reduction of the death-rate one-half. Hypodermoclysis is borne well. Even in the cases that finally succumb to cholera typhoid the temporary good results are astonishing. The injections are best used in the sides of the abdomen below the costal arches, where the skin can be most easily pricked open and the solution is rapidly absorbed.

In conclusion, Cantani recommends the tannic enteroclysis as a prophylactic during the prevalence of cholera epidemics. The chief of the cholera hospital in Buda-Pest has adopted Cantani's method, and from it alone has obtained positive results in the treatment of cholera.—*St. Petersb. Med. Wochenschr.*, No. 52, 1886.

Terpine in the Treatment of Neuralgia.—Dr. Ducroux, in a paper recently read before the Société Médico-pratique, described some cases showing the good effects of terpine in neuralgia. The first was that of a woman, aged 47. Two years before, she had been attacked with neuralgia, consequent on occupying a damp house. Sulphate of quinine, and afterwards aconitine, gave temporary relief. On February 15, 1886, she was suffering from constant neuralgia on the right side of the lower jaw, in the right cheek and temple. There was also pain in the supra-orbital notch, the mental foramen, and in the occiput. The patient complained of a constant feeling of heaviness in the head, and of cold in right side of head. Terpine (.60 centigramme) was given in three pills between meals, during three days. On February 19, considerable relief was obtained. The pains and the feeling of cold had disappeared, and also the heaviness of head, which had persisted for two years. The pains having returned in a few days, terpine was again administered in the same manner on February 25. The pains ceased, then recommenced, but in a milder form, and without any heaviness of the head. Terpine was again given on March 8. Neuralgia having again come on, doses of .80 centigramme were administered in four pills, beginning on March 16, and being continued for three days. During the month of April, these doses were repeated at intervals. At the end of that month, the back of the head was still sensitive, but all other pains had ceased. At the beginning of May and June, terpine was again administered, the pains having reappeared. On June 15, the patient was able to go out without extra covering on the head. Dr. Ducroux is of opinion that the patient may be again obliged to have recourse to terpine, as the neuralgia shows a tendency to recur, though in a milder form. The therapeutic effect of the terpine seems to cease after a few days. In cases of obstinate neuralgia, it might be advisable to give it for three days every week. The second case was that of a married woman, aged 35. At the age of 22 she had intermittent fever. From the age of 13 or 14, she had suffered from headache from time to time, and when she was 22 she had intermittent fever. Menstruation had ceased for six years. A week ago she was attacked with pain in the right side of the head differing from her habitual headache. This pain, which gradually increased, extended in front, around the ear, and over the temple and cheek, and behind, over the mastoid region. There was also pain in the external auditory meatus. The pains were accompanied by a humming in the ears. Terpine (.60 centigramme) was given in three pills, to be taken between meals. On April 29, the pains had disappeared, but the humming in the ears continued; .50 centigramme of sulphate of quinine was administered during three days. This had no effect. A few days before May 17, the humming in the ears diminished, and took a different form. The sound in the ears was no longer that of humming but of running water. The patient could neither hear herself nor others speak. Terpine was again administered in the same way. The sounds in the ears diminished and completely disappeared two or three days after the last dose. Dr. Ducroux believes that the disappearance of the pains was due to the use of terpine, and that it had some effect upon the sounds in the ears. The third case was that of a man aged 23. Fifteen years before he had suffered from bronchitis, with hæmoptysis. In May, 1885, he was attacked with severe pain over the right eye, in the supra-orbital notch, and about the occiput. A blister was applied to the temple, and dressed with 1 centigramme of morphine; terpine (.60 centigramme) was given in the way already described. The first morphine dressing did not relieve the pain, but the second, applied the following evening, was more effectual. The patient had then taken three terpine pills. As the improvement continued, only eight pills were administered in the three days following the second day. The neuralgia was completely cured. Dr. Ducroux attributes this result to terpine, as the morphine application produced no effect.—*British Medical Journal*, Jan. 8, 1887.

Schede's Method of Dressing Wounds.—Professor Mikulicz communicates to the *Przeglad Lekarski* an account of fifty cases of surgical operations which were treated by the method recommended by Dr. Schede at the last Surgical Congress in Berlin—viz., to allow blood to fill the wound, and to lie between the lips after they are brought together, any deficiency in the quantity of blood being remedied by the use of the knife, the idea being that the blood either actually becomes organized or serves as a protection for the granulations as they are formed. The wound is covered with protective, to prevent evaporation. Professor Mikulicz's observations included six resections of joints, four amputa-

tions, six dissections, two ligatures of arteries, seven extirpations of large tumors, etc. In thirty-six of the fifty cases union took place without suppuration, in four there was extensive formation of pus, in five superficial suppuration starting from the points of suture, and in the remaining cases pus had existed previously to the operation, and the disinfection at the time not having been complete, it continued subsequently. The general condition of the patients was highly satisfactory, even in those cases where suppuration occurred, the temperature in no case rising much beyond normal. The dressings were not removed or changed for at least a fortnight, sometimes not for a month. This appears to be of great advantage in the case of bone and joint operations, where complete immobility of the parts is a desideratum. Other specified advantages attributed to this plan are that wounds attended with a loss of substance rapidly fill up, and the cicatrices that form are peculiarly soft and smooth. Professor Mikulicz does not find, as Schede did, that the existence of silver sutures in osseous lesions has any unfavorable influence on the cicatrization of the wound. He remarks that it is important not to bind the external dressings too tightly to the wound.—*Lancet*, March 19, 1887.

"Dead Space" in Certain Chemical Reactions.—The most important discovery now spoken of in Berlin medical society is that of Prof. Liebreich, who only a year ago presented us with the new basis for ointments. His latest discovery is more in the sphere of pure chemistry, but it is also interesting to physicians. Professor Leibreich observed that when reaction takes place only some time after mixing certain liquids together, it does not occur throughout the whole liquid; in some parts a space is left, in which no reaction is seen, and this he calls the "dead space." He has observed the same in several reactions—for instance, on mingling sulphuric acid, iodic acid, and starch together, or hydrate of chloral with carbonate of sodium, or chloride of gold, sodium lye and sugar, and in many other cases. The so-called "dead space" is not always the same, but varies according to the kind of vessels into which the liquids are poured. If, for instance, narrow tubes are used, the "dead space" is very small, while in capillary tubes no reaction whatever takes place. If the liquids are poured into closed vessels with rigid sides, the "dead space" cannot be seen, but if the closed vessels are of membranous structure, it may be observed. Thus, for instance, in a prepared rabbit's bladder the "dead space" is at the top and bottom, whilst the reaction takes place in the middle in the shape of the yolk of an egg. If a piece of gut is taken and divided by means of little rings into a number of small compartments, and if one of the above-mentioned liquids is poured into it, in each of the compartments the reaction is seen taking place in the middle, while at the top and bottom there is a "dead space." As the "dead space" depends upon the size of the vessel, it may be inferred that for every chemical mixture yielding a reaction, proportions can be imagined in which reaction ceases. The laws of reaction, therefore, are dependent on the space in which the effect takes place, and hence, these observations have an important bearing on the organism. In testing the effect of certain medicinal agents, not only must their chemical constitution be taken into account, but the laws governing their reaction in large and small spaces respectively.—*British Medical Journal*, January 8, 1887.

Adonis Vernalis in Heart Disease.—Dr. J. G. Herrmann, of St. Louis, writes that he has recently had considerable experience with the use of adonis vernalis in cardiac affections. He believes that his experience, which has extended over ten months, warrants his statement that, while free from the evil effects of digitalis, infusions of adonis vernalis are quite as efficacious as that drug. He prescribes it in the form of an infusion, of the strength of three drachms of the herb to six ounces; of this he gives a tablespoonful every two hours. He refers to several cases in which this drug proved successful even after digitalis had failed. One was a case in which the feet were highly œdematous, and there was general anasarca from heart lesion. In two weeks of treatment with the infusion of adonis vernalis every two hours, in tablespoonful doses, almost perfect relief was secured. So also he states that he has caused great relief to a case of ascites, produced through heart disease. He noticed that it increased the fulness of the pulse and strengthened the cardiac pulsation. In asthma also he has combined it with quebracho with very satisfactory results.

The following are some of the prescriptions which he has employed:

℞ Fl. ext. adonis vernalis.
Sig.—From 2 to 6 drops, as necessary.

℞ Fl. ext. adon. vernal. ..... ℥ ss
Syr. menth. pip. ..... ℥ vi
Combined as desired sometimes with brom. sodium and tr. opii camph.
Sig.—℥i to ℥i every two hours daily.

In asthma:

℞ Fl. ext. adonis vernalis. ..... ℥ss
Fl. ext. quebracho ..... ℥ii
Tr. opii camph. ..... ℥ii
Syr. menth. pip. ..... ℥vi ℳ
Sig.—℥i every two hours.

—*Therapeutic Gazette*, March 15, 1884.

The Aniline Treatment of Phthisis.—Dr. Kremianski's idea of curing tuberculosis by converting the blood into a dilute solution of aniline has been tried by Dr. Nesteroff on a patient who was about to be sent to the south, with the result that he became rapidly worse and died in a fortnight. The Moscow Medical Society, before whom the matter was brought were nearly unanimous in the opinion that the aniline treatment would be not merely useless, but positively dangerous.—*Lancet*, April 2, 1887.

"Black Drop" and Carbolic Acid in Painful Emesis.—Pecholier uses liquified carbolic acid ℥ij, acetum opii ℥vj, gtt. 4 in sweetened water t. i. d. five or ten minutes before meals.—*Therap. Monatshefte*, March, 1887.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS.

SATURDAY, APRIL 23, 1887.

A NEW PATHOLOGY OF PREGNANCY.

In the March and April numbers of the *American Journal of Obstetrics*, may be found a most interesting article by DR. A. F. A. KING, of Washington, entitled "A New Explanation of the Renal Troubles, Eclampsia, and other Pathological Phenomena of Pregnancy and Labor." The purpose of the paper is to present a new explanation (as the author thinks) of the etiological relation between pregnancy and the nephritic derangements that so often attend it; though the paper does not deal with renal difficulties alone, but other correlative pathological states also.

Passing over the preliminary discussion, though it is interesting, we come to the following brief statement of the theory: Disturbances in the renal circulation and renal functions are produced chiefly by pressure of the gravid uterus upon the abdominal aorta or its branches, or upon the vena cava or its branches, or upon both or all of these, *in consequence of the child and womb not maintaining during pregnancy their normal lateral obliquity above the pelvic brim.* This, says Dr. King, is the pith of the whole matter. Before going further, however, it is necessary to define what is meant by the *normal attitude of the child in utero during pregnancy, before labor begins*, and the *normal position of the gravid uterus*. In regard to the first, it must be understood that it does not refer to the attitude or presentation of the child during labor, but during pregnancy before labor begins. He defines this attitude as follows: The normal "presentation" and "position" of the fœtus *in utero* during pregnancy, before labor begins, is the dorso-anterior position of an oblique presentation (commonly known as a transverse presentation). A head presentation (presentation of the head towards the centre of the canal of the pelvis and os uteri, with the long axis of the child parallel with the axis of the plane of the pelvic brim) is therefore abnormal.

The normal position of the gravid uterus is thus defined: The normal position of the gravid uterus, *in abdomine*, during the later months of pregnancy, before labor begins, is the lateral oblique position corresponding, more or less, with the oblique position of the child; the fundus uteri, maintaining the pelvic extremity of the fœtus, being usually directed towards the right side (exceptionally to the left) of the lumbar vertebræ. This definition of course, applies to the position of the uterus as shown by abdominal palpation, the apparent position being partly due to the shape of the uterus as it conforms to the shape of its contents; vaginal examination will show that the os and cervix have little or no deviation from the median line, while the fundus is towards one side of the woman's spine.

Having stated that the renal troubles, etc., are produced in consequence of the child and womb not retaining (or maintaining) their normal lateral obliquity *above the pelvic brim*, Dr. King now draws a contrast between the abdominal and pelvic cavities. The womb and child having risen, after the fifth month, from the pelvic to the abdominal cavity, "in the latter they should remain until the advent of labor. The pelvic canal, in so far as it is concerned with reproduction after this period of gestation, is simply, or chiefly, the channel of exit, and no part of the child should again enter here until it is ready to go out and be born." It should remain entirely within the abdominal cavity until the time of labor. This leads to a remark that may astonish many obstetricians, but which, though lacking in direct proof, is certainly in accord with reason: normal reproduction is the same in primiparæ as in multiparæ. That is to say, under *normal* conditions, there is no reason why in multiparæ the head of the child should rest during pregnancy upon one of the iliac fossæ, and in primiparæ should descend into the pelvic cavity three months before full term; if such be the case, why do obstetricians teach that descent into the pelvic cavity is (*not* the first, but) the second stage in the mechanism of labor? Can it be, asks Dr. King, that this second step in the mechanism of labor *normally* occurs in primiparæ three months before it is time for labor to begin? He therefore believes that the oblique presentation, with the lower end of the fœtus resting upon an iliac fossa, is normal for primiparæ as well as multiparæ.

If what Dr. King calls the "normal obliquity" of the womb and child be maintained during pregnancy, there will be no injurious compression on any blood-vessels, with the usual dorso-anterior position of the child. The long axis of the child, when thus obliquely placed, explains Dr. King, will occupy a *trebly* complex diagonal position: oblique to the horizon, the breech being higher than the head; oblique laterally, the breech to the right, the head to the left; and oblique antero-posteriorly, the head more in front, the breech more behind. With this position there is space posteriorly for the projecting lumbar vertebræ and the large vessels placed upon them. So also, the lower part of the gravid uterus, containing the fœtal head, resting upon the psoas and iliacus muscles in the iliac fossa, will, on account of the downward and forward inclination of this base, tend to glide forwards, away from the left side of the spine, away from the large vessels. In this position there is most economy of space. But with the womb and fœtus in a vertical position, that is, with their long axis in line with the axis of the plane of the pelvic brim, there is no economy of space; they are crowded by their abdominal surroundings, the crowding being towards the lumbar vertebræ and the large blood-vessels.

We now come to the question, will pressure of the gravid womb upon the aorta, vena cava, and their branches produce renal trouble? and we may answer this affirmatively without discussion. To this we may add the effect of compression of the ureters upon the kidney, for admitting either one by no means excludes the other; in fact, it is more than likely that a body compressing one will compress the other at the same time. Now, when the head presents during pregnancy at the brim, and descends into it three months before full term, all neighboring canals, whether arteries, veins, ureters, or lymphatics, may receive disastrous pressure and interference with the transit of their contents. Aortic and vena-caval compression during pregnancy and labor are easily diagnosticated. As a point of exclusive diagnosis of the former Dr. King gives feeling the pulsation of the femoral arteries below Poupart's ligament. In twenty-one pregnant women examined in this way the femoral pulses could be easily felt, and appeared to possess their normal tension, but in none of these women was there any abnormal tension of the radial pulse, nor any albuminuria or other indication of renal derangement.

Having proceeded thus far, Dr. King hopes to show that eclampsia during pregnancy and labor, the several kinds of cases and their alleged preceding pathological states, may be traced back to malposition of the child-presentation of one end of the fœtal ovoid instead of an oblique presentation. As to the cases with albuminuria, nephritis and uræmia, we know that renal trouble is the prime cause; but as regards the cases explicable upon the "uterine irritation" theory of Tyler Smith, we must account for this abnormal irritation of the uterine nerves. It certainly is not physiological; "and with our hitherto prevalent notions of what constitutes normal pregnancy, the occurrence of eclampsia from uterine irritation before labor begins is the more difficult. When, however, we have decided that conditions hitherto called normal are really abnormal, the matter becomes more easy. I therefore beg to maintain that premature obliteration of the cervix uteri, premature distension of the cervical canal and lower uterine segment, with thinning of its muscular wall, and tearing of its decidua; and the premature descent of the lower end of the fœtal ovoid below the pelvic brim;" all due to a want of the lateral obliquity of the fœtus during pregnancy, "are amply sufficient to account for the uterine irritation. Whether the convulsions be due to uræmic intoxication, to uterine irritation, to cerebral hyperæmia, or to reflex local irritation in other viscera, or to several of these coincidently, they may all be accounted for by pressure of the gravid womb and child, when the normal obliquity of the latter is wanting."

The causes of the disturbance of the normal lateral obliquity of the womb and child, and of their premature descent below the pelvic brim, especially in primiparæ, are, according to Dr. King, dress, corsets, coitus, and certain abnormal postures. It would certainly add materially to our knowledge of the influence of these factors could a study of pregnancy be made among those nations whose only clothing is the atmosphere.

We now come to a question which must be more correctly answered in the future than is now possible: Do convulsions, nephritis, etc., occur in cases of "transverse" presentation during labor, and in most of which cases the child was, it may be presumed, oblique and wholly above the pelvic brim during pregnancy? In discussing the "obstetric treatment" of eclampsia authors refer almost exclusively to head presentations. In regard to "obstetric indications" in transverse presentations they are silent; and we may conclude, though not with certainty, that such cases are rarely or never met with. It is interesting to note that Schauta has found that in 315 cases of eclampsia (in 134,345 deliveries in the Vienna Hospital from 1834 to June, 1880,) the head presented

304 times, face, 4; breech, 5; foot, 1; and transverse 1. In 306 of these cases 253 were primiparæ. From an analysis of Rambotham's 59 cases of eclampsia, it is fair to assume that there was not one of transverse presentation. Of the 14 cases in 7,404 deliveries in Guy's Hospital Lying-in Charity, there were 13 head presentations, no transverse. In short, in a total of 300,018 labor cases collected by Dr. King, with 212 cases of eclampsia, there is only *one* distinctly isolated coincident occurrence of eclampsia and transverse presentation during labor; and in regard to this case there is no concise account.

As Dr. King very fairly adduces arguments against his theory, and discusses them impartially, yet without at all disproving it, we may now rest the case with the reader, but with the regret that we cannot go more fully into the subject. The theory, or explanation, is reasonable, and the paper is one of rare interest.

LOUISIANA STATE MEDICAL SOCIETY.

The ninth annual meeting of this Society was held in Alexandria, La., April 11, 12, 13, 1887. Some valuable papers and reports were presented, and several topics of special interest to the profession of that State were discussed. The following officers were elected for the ensuing year: President, Dr. Joseph Jones, New Orleans, La.; Vice-Presidents, Drs. F. H. Parham, of New Orleans, H. D. Bruns, of New Orleans, Thomas Hebert, of New Iberia, F. M. Thornhill, of Arcadia, I. J. Newton, of Bastrop, and T. T. Tarleton, of St. Landry; Secretary, Dr. P. B. McCutcheon, of New Orleans. The next annual meeting is to be held at Monroe, La., on the third Wednesday in April, 1888.

Tennessee State Medical Society.—At the annual meeting of this Society, held in Nashville, April 12 and 13, 1887, the following officers were elected for the ensuing year: President, Dr. P. D. Sim, of Chattanooga; first Vice-President, Dr. Happel, of Trenton; second Vice-President, Dr. R. Douglas, of Nashville; third Vice-President, Dr. J. M. Masters, of Knoxville; Secretary, Dr. Ambrose Morrison, and Treasurer, R. Cheatham.

The Society contributed $250 for the Treasury of the International Medical Congress to be held in Washington, D. C. Its next annual meeting, in 1888, will be held at Knoxville.

Addresses in the General Sessions of the International Medical Congress.—Many of the medical journals in this and other countries have announced the fact that Professor F. Semmola, of Naples, Italy, is to give a general address on "Bacteriology and its Clinical Therapeutics," to the Congress in general session; and we will add that general addresses are also promised by Dr. Neudorfer, of Vienna, Austria, "On the Military Medicine of the Present and of the Near Future;" Dr. Esmarch, of Kiel, Germany, "On Bloodless Operations in Surgery;" Dr. Lutaud, of Paris, France, "On the Influence of the Discoveries of American Surgeons on the Development of Gynecology in Europe," and Dr. Austin Flint, of New York, N. Y., on "Fever, Its Cause, Mechanism and Rational Treatment"—all topics of interest to the whole profession.

James Stewart Jewell, M.D., died at his residence in this city on the morning of April 18, 1887, aged 49 years and 7 months, after many months of progressive exhaustion. For mental activity, persevering industry, extent and accuracy of knowledge of the specialty to which he was devoted, and in purity of Christian character, Dr. Jewell will be remembered and honored by all who knew him. A more extended sketch of his life and labors will be given next week in the proper department of The Journal.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, March 21, 1887.

The President, Edmund J. Doering, M.D., in the Chair.

Dr. James I. Tucker reported a case of

HERPES OMO-BRACHIALIS.

This class of skin diseases belongs to the neurological group. J. P., aged 36, had for many years been an invalid. In his youth he had been sexually intemperate and had used liquor to excess. He was of a family every member of which had been afflicted with some form of nervous disorder. When he came under the author's care five years ago he was emaciated, anæmic and suffering from profuse diarrhœa. He had pursued the vocation of proof reader until six months previous, when he broke down. His habits were and had been for some time past good in every respect. His principal trouble was a cough of deep, sepulchral sound, which gave him no rest night or day. No mucous or other foreign matter was expectorated. On the 3rd of December there was a neuralgic pain in the right shoulder; on the next day an eruption appeared there attended with an almost insufferable sense of heat.

The vascular eruption was fully developed by the 9th and occupied the shoulder and outward aspect of the arm, following the branch of the brachial plexus and terminating in an immense boil on the ball of the thumb. These vesicles passed through the various stages of vascular irritation, inflammation and resolution, and had entirely disappeared by December 15th. And more remarkable still the chronic cough disappeared altogether. To relieve the pain and burning sensation I used hot fomentations and oleate of cocaine and ointment of glycerine. It was of no use to employ opiates, for although the patient was nervous and sleepless, morphia had no effect upon him. He took 240 grains of chloral hydrate of his own accord at a single dose without any other effect than to make him slightly delirious. The question arises what may have been the relation between the cough and the eruption and why did the cough cease on the disappearance of the eruption?

DR. JOSEPH ZEISLER, in opening the discussion, thought cases of herpes zoster were comparatively rare here; in the last two years he had met with only one, affecting the fourth and fifth intercostal spaces of the right side. Although physiological and anatomical examinations have not yet proven the existence of true trophic fibres in the nerves, there can be no doubt that zoster must be considered as a trophoneurotic disease. The case was especially interesting from the possibility of syphilis being the cause of the disorder, and from the large area involved.

DR. TUCKER said that one point in reference to zoster, especially zoster frontalis, is that chronic bronchitis is sure to follow it, and life generaly terminates in that way.

DR. CHARLES WARRINGTON EARLE asked if the author had not found that these cases almost always require the same tonic treatment that neuralgias do, viz., the exhibition of quinine and iron, and a good, generous diet, before a cure can be effected.

DR. TUCKER replied that all the patients he had seen suffering from the disease have been depleted, and certainly the remedies just mentioned would be needed.

DR. E. L. HOLMES reported a case of

CHANCRE OF THE EYELID.

Cases of chancre of the lids are of interest not so much on account of their rareness as of the difficulty in establishing a certain and early diagnosis, and the fact that suspicion even may not be awakened till quite late in the development. It is many years, probably twenty, since I have seen a case of primary specific sore on the genital organs. If I remember correctly what I formerly observed and what I learned from competent authorities, it is undoubtedly true that even an ulcer on the genital organs cannot always be easily diagnosticated. The swelling of the preauricular glands is quite often the result of simple abscess of the lids, especially if it is situated near the external angle. When, however, a circumscribed disease of the lids is accompanied by multiple preauricular and submaxillary glandular enlargement, suspicion becomes almost certainty. This has been the fact in four of the five cases which I have seen. In one case there was not sufficient swelling of the glands to attract either my attention or that of the patient.

Some months ago I mentioned in this Society the case of a laborer in a rolling mill who received a severe burn on the side of the body from a "flash" and on the left upper lid from a drop of the molten slag. This small round burn became infected from some source unknown to the patient, and after some time presented the appearance of a true chancre with glandular swellings and characteristic eruptions. No evidence of a lesion could be found on the genital organs. Every symptom disappeared under energetic mercurial treatment.

Very recently Mr. P. M., 45 years of age, married, also a workman in a rolling mill received a "flash," a portion of which struck the left upper lid and inflicted quite a severe burn of the integument. The conjunctiva was also slightly burned. At the end of a week the patient came to me with the lids much swollen, red and tender, with a hard, dry, thin and red incrustation as one sees on a superficial abrasion of the skin. The patient stated that he had rubbed the lids several times during the week with the back of his hand, which was more or less covered with grime and sand. He did this to relieve the irritation of the eye. There was nothing in the appearance of the lids or of the eye to excite my suspicion of any complication. For ten days I treated the eye with mild lotions and ointments without the slightest benefit. On the appearance of preauricular and submaxillary swelling I referred the patient to Dr. Hyde. I suspected the true nature of the case, although there was still no trace of ulceration on the lid. Prof. Hyde could simply suspect, but preferred to delay definite opinion for a few days. In a week or more the characteristic eruption appeared with increased severity of the local symptoms. Large doses of blue mass and iodide of potassium relieved all the symptoms, local as well as general. The eye assumed its normal appearance in about three weeks.

DR. F. C. HOTZ said that as the author wished the discussion to be conducted on the line of experience of general practitioners, not specialists, he hardly felt that he was the right person to open it. As the author states, these primary syphilitic ulcerations, chancres of the eyelids, are of very rare occurrence, and in a long experience of private and hospital practice in this country and Europe he could remember but one case coming under his observation of a primary syphilitic sore, and it was located on the conjunctival surface of the upper lid, a most curious place for the infection. A patient came to him about two years ago with the lid tender and very much swollen, and on turning it he saw a large ulcer with all the typical appearance of chancre of the prepuce. There was no doubt of its syphilitic character, but it puzzled him as to how the infection could have taken place there. On questioning the patient he learned that four or five weeks previously he got a little cinder or something in his eye and his room mate turned the upper lid, saw the foreign substance and removed it with his tongue. Further questioning brought out the fact that this man was syphilitic.

Dr. Joseph Zeisler mentioned the possibility of contamination by kissing and by instruments. The most peculiar cases of chancre in regard to the locality, had been related by Deloir in his "Decours sur la Syphilis," some of which could only be explained by certain French habits.

Dr. William T. Belfield said, in reference to one point raised by Dr. Holmes, viz., infection without ulceration, he thought it was a well known fact that it has frequently occurred. There is nothing about syphilitic infection that implies ulceration. The morbid material is introduced into the skin and occasions a certain amount of inflammation at the point of infection. Whether that results in ulceration depends upon the nutrition the parts receive, if they are well nourished there need be no ulcer, but as a rule some of the cells that are formed die and ulceration is the result. Occasionally the inflammation is so slight that neither ulceration nor even induration is produced locally; since syphilis is undeniably inoculated—in exceptional cases—without the production of any features of the hard chancre. Nor is the syphilitic the only virus whose local effects are thus variable; thus, the virus of charbon, or "wool sorters' disease" while usually producing a malignant pustule at the point of inoculation, may be communicated without any local ulceration, indeed by simple inhalation.

Dr. D. A. K. Steele read a paper entitled

INTUSSUSCEPTION IN INFANTS.

Intussusception or invagination of the upper into the lower part of the intestine, embraces three layers of the bowel which include all the coats of the intestines. The diagnosis of intussusception in an infant is usually an easy matter; a baby previously in good health, is taken with sudden violent vomiting, with loud cries and evidence of abdominal pain and uneasiness occurring at frequent irregular intervals accompanied with severe straining and the passage at first of fecal matter, then a mucous tinged with blood, and later of blood alone in considerable quantities. Thirst, anxious expression and collapse are marked symptoms. A distinct sausage shaped tumor can frequently be felt at the seat of the obstruction in the abdomen.

Treatment may be divided into medicinal, mechanical and operative. The medicinal plan is palliative but rarely curative.

The author described the details of the mechanical plan of treatment as follows: Having clearly established a diagnosis of intussusception and previously given an opiate to quiet all peristalsis. I anæsthetize the child with chloroform and then carry a rectal tube or large catheter about six inches within the anus. Attached to this tube I have a flexible rubber tube two or three feet long attached to a small glass funnel. Into this funnel I pour alternately solutions of soda bi carbonate and tartaric acid, thus generating carbonic acid gas and rapidly and safely inflating the large intestine. Three drachms of each will generate enough gas to completely distend the colon of a child. If this pressure is not sufficient to relieve the obstructions, I attach an ordinary double bulb syringe and inflate with air about as much a I think the bowl will stand, while the abdomen is being carefully manipulated by an assistant. I patiently, persistently and repeatedly employ these measures coupled with massage, abdominal taxis, inversion of child, etc., from twenty-four to forty-eight hours, when, if there is no relief, I advise laparotomy. In case the obstruction is at the ileo cæcal valve and is irreducible and an artificial anus cannot be readily formed, an ileo-colotomy or implantation of the divided ileum above the obstruction into a slit-like orifice in the colon below the obstruction would be justifiable procedure. Senn's recent experiments on animals prove that it can be done with success. Several cases were reported which had been successfully treated by the mechanical method.

Dr. C. W. Earle, in opening the discussion, said that Dr. Steele had presented the symptoms of this terrible difficulty so fully that there is little more to be said. He was glad that the author dwelt upon the symptom of constriction of part of the bowel, which is probably one of the chief causes for this accident. He must take issue with him in regard to the ease with which he diagnosticates some of these cases. Dr. Steele's experience has been very different from his own when he is able to say that the diagnosis of intussusception in a child is made out without much difficulty. In a number of cases he has seen there has been an absence of all the symptoms which the author has narrated. He remembered a case which occurred several years ago in an outside village, in which he made the post-mortem examination and found a very distinct intussusception. In that case we could get none of the symptoms Dr. Steele has spoken of; there was no tenesmus, no bloody discharge, no protrusion of the invaginated portion of the intestine, no sausage-shaped tumor of the abdomen, and yet the child had intussusception, probably from eating a large amount of cherries as a number of cherry pits were found in the bowel at the autopsy.

As a medical man it might be expected that he would oppose a surgical procedure, but the medical treatment of this difficulty is so absolutely hopeless that it seems to him if laparotomy offers anything at all we should be ready to accept any procedure the surgeons have to offer. However, the results of Dr. Steele's process of treatment by inversion and shaking and filling the bowel are really better than those of surgeons up to this time. It is a well known fact that laparotomy for the relief of intussusception is followed by greater mortality than laparotomy for any other cause. But if the diagnosis is well made out, and particularly if the pulse is rapid and the child shows profound symptoms which point unmistakably to this difficulty, it seems to me we are hardly justified in waiting three days; he thought at the end of twenty-four hours we should cease to try the ordinary methods and proceed to do the operation.

Dr. F. E. Waxham said he agreed with Dr. Earle in regard to the difficulty of making the diagnosis in cases of intussusception, especially in infants. In many cases he thought the diagnosis very difficult indeed, and sometimes a certain and absolute diag-

nosis is almost impossible. This is true for the reason that all the symptoms that have been enumerated as characteristic of the disease are not present in every case; the tumor is as frequently absent as present, if a small amount of intestine is involved in the intussusception it is impossible to detect it. Again, the bloody discharges are frequently absent, and the protrusion of the intestine from the anus which is given as a prominent symptom, is often absent. Indeed, in many cases the incessant vomiting, obstinate constipation and the tenesmus are the only symptoms. He would refer to the differential diagnosis of intussusception: fecal impaction occasionally presents symptoms analagous to intussusception. Impaction is rare in infancy, but is more frequently observed in the adult and in the older children. It may give rise to a tumor, vomiting, tenesmus, tympanites and even protrusion of the intestine from the anus. These symptoms closely resemble those of intussusception, but in impaction the vomiting is not usually as obstinate and large, copious enemas will cause the disappearance of the impaction. Again, in impaction we do not get the rapid and great prostration that is observed in intussusception. Cholera infantum may be mistaken for intussusception, for we have the same rapid and great prostration and collapse, we have the incessant vomiting, but in cholera infantum we have the large, copious watery passages instead of the obstinate constipation followed by the bloody discharges. Dysentery presents symptoms closely resembling intussusception in many cases; we have vomiting tensmus, frequent straining, bloody passages and not unfrequently protrusion of the intestine from the anus, but in dysentery the vomiting is not so obstinate nor the prostration so great. Typhlitis may present symptoms very closely resembling intussusception, as the result of inflammation at the ileo cæcal valve we will have vomiting, intestinal pain, tympanitas, obstinate constipation which it is impossible oftentimes to overcome. The diagnosis in these cases is very difficult, and I know of one case of typhlitis where several surgeons thought seriously of operating for a suspected intussusception.

But in typhlitis the tumor, which results from inflammation and infiltration is in the right side, while in intussusception the tumor when observed is in the left iliac region or in the transverse colon, for although the intussusception takes place at the ileo-cæcal valve if the tumor is large enough to be observed the smaller intestine rolls in the larger until the tumor appears in the left side instead of the right. In typhlitis we have a history of acute inflammation, not so in case of intussusception. Peritonitis will also frequently give rise to symptoms resembling those of intussusception; we have frequent vomiting, obstinate constipation, abdominal pain and tympanites. He remembered a case that was treated for several days for intussusception, and not until the administration of morphia and lime water was the vomiting overcome and a correct diagnosis made. The vomiting could not have been relieved by medication in a case of intussusception. In peritonitis we usually have the gradual onset of the disease, more sudden in case of intussusception. In peritonitis we have the symptoms of acute inflammation existing for several days before we get symptoms of obstruction. In intussusception the symptoms of obstruction and shock appear early. In peritonitis, although the constipation is often obstinate, yet the vomiting is not as frequent and uncontrollable as in intussusception, nor do we have the rapid prostration in the former disease that is so characteristic of the latter. There are other forms of obstruction, such as the twisting of the intestine upon itself, pressure upon the intestine by a band of lymph, or strangulation of the intestine in a congenital opening in the diaphragm, any of which will give rise to symptoms exactly corresponding to intussusception.

In regard to the treatment, little remains to be said. Not infrequently when an intussusception is suspected, the cases are treated with physic, castor oil, croton oil, or quicksilver, in order to prove the diagnosis. This treatment should be mentioned only to be condemned. No remedies should be given that will increase the peristaltic contraction, but opiates given to prevent it. Quicksilver may be used with benefit in those cases where the invagination is low down in the bowel, or where the intussusception is of such extent that it reaches into the lower bowel, or perhaps near the anus. In such cases the child should be inverted and the quicksilver used per rectum, and the pressure and weight of the quicksilver will assist greatly in the restoration of the invaginated mass. He fully agreed in the recommendation of laparotomy in cases where mechanical measures fail. When we have faithfully but unsuccessfully tried medicinal and mechanical measures, he thought we should resort to laparotomy, providing a positive diagnosis can be made, and we should not delay too long, for the longer the operation is delayed the less the chances are of recovery.

Dr. A. E. Hoadley wished to make one suggestion as to the surgical treatment of these cases. The author, on going into the surgical treatment thoroughly, had left the idea, he thought, that about all that can be done for cases of acute invagination of the intestine is to unfold the invaginated intestine, and if this cannot be done, it must be excised and an artificial anus made. Of course he does not advise the resection of the invagination, but advises an artificial anus as a temporary means. Now where this invagination is acute it obstructs the lumen of the intestine, and all the urgent symptoms are consequent on the obstruction of the bowels, not that the tissues are liable to ulceration or sloughing provided that the tension above the invagination is promply relieved. If the tension above the stricture is relieved the tissues at the stricture can take care of themselves, the strangulation will be immediately relieved in a measure, so that the circulation can be carried on at the seat of invagination. Relief of tension controls peristalsis and no further invagination will take place, congestion will be relieved and the tissues saved. There has been an operation suggested for that purpose which is applicable in all cases where to unfold the invagination is more dangerous than to leave it alone or excise and establish

an artificial anus. The operation is to bring that portion of bowel above the invagination to that immediately below and there make an opening in each, stitch the openings together, and thus form an outlet for the distended intestine above. In case the invaginated portion loses its vitality there is no objection to its sloughing, as the slough can readily pass down, as the gut is not closed above. In his own practice he had seen two cases of recovery from intussusception, in which there was no doubt about the diagnosis; in one case a sausage-shaped tumor could be felt across the median line, with all the acute symptoms except, perhaps, the bloody discharges. The invaginations in these cases were of the colon, and not ileo-cæcal, and the lumen of the gut was not completely closed. There was no particular distension, but there was a large and painful tumor, with tenesmus and diarrhœa. In one case, in which the diagnosis was confirmed by several physicians, the tumor remained for more than a year, and at any time, if pressure was made over it, there would be tenesmus of the bowel, yet the child, who is now 8 years old, has fully recovered. He has a patient now under treatment in whom two and a half months ago there was probably intussusception of the colon. A painful tumor presented on the left side which could be plainly felt from day to day, associated with all the irritable symptoms of the bowels, but the invagination did not occlude the lumen of the bowel, therefore the most distressing symptoms were absent. This tumor has gradually grown smaller, less tender, less painful, and the child is now about free from the irritation caused by that invagination.

Dr. J. Frank asked if, when the invagination is situated above the ileo cæcal valve, water injected would pass the valve itself? He hardly thought the small amounts the author speaks of having injected would have reduced the invagination. He was not opposed to giving cathartics in cases where they might do good, and thought sometimes they do not do as much harm as an operation. The intestines are held up by mesenteries, and if the principal part of the intestine cannot invaginate itself where it is held fast it cannot come down. A cathartic which produces a peristalsis is always towards the rectum, and if the part is held up by the mesentery, the peristaltic motion will not bring it down any further, and yet will relieve the intussusception. He thought many cases are cured by cathartics. He had a case some time ago where the child was pulseless and cold, the eyes turned on the sockets, there was tenesmus and vomiting. After trying nearly everything an enormous dose of calomel was given, and as soon as there was a movement of the bowels the child was all right.

Dr. J. E. Colburn said that some years ago he had an interesting case; in the early morning he was called to see a child whom he found breathing with great difficulty and presenting many symptoms of acute bronchitis. He listened carefully and thought he located the region of the disturbance. Leaving some remedies he went away, promising to call late in the afternoon. During his absence the family became alarmed at a change of symptoms and called in another physician, who assured them that he was mistaken; that the child had acute gastritis. When he went back in the evening the child was purging and passing blood. He made an examination and found a tumor corresponding to the tumor described to-night. He gave a grave prognosis, left directions for the use of some remedies, and promised to see the child in the morning if it was still alive. The next morning when he called the mother told him the child was better, and showed him a chicken's foot and leg that it had swallowed.

Dr. Earle asked Dr. Steele to give the statistics in regard to the use of chloroform and ether with children.

Dr. Steele, in closing the discussion, said, in regard to Dr. Earle's query as to the ease of making the diagnosis: I would say that the diagnosis is not always an easy matter, and I do not wish to convey that impression. In the first case I reported the diagnosis was easy, because the case presented the symptoms laid down in the books as nearly as could be: there was vomiting, tenesmus, bloody stools, absolute constipation and a lozenge shaped tumor—but that is the only case of the four reported in which we had all the symptoms; in two there were no tumors at all, in one the tumor was indistinct and irregular in outline. There was no pain in that case. In none of the cases was the diagnosis verified by a post-mortem. There is an element of doubt as regards the diagnosis, but it had been formed in each case after careful examination by competent physicians, and was considered fairly certain. In regard to the relative safety of ether and chloroform in children, I cannot give the statistics, but the administration of chloroform to children is a very safe procedure as compared with its administration to adults. In regard to the differential diagnosis, Dr. Waxham presented all the points very fully. In a paper of this character I did not wish to go into that subject. In regard to the operation of cutting the bowel above and below the point of obstruction, that I alluded to as an operation having been done experimentally on animals with success by Dr. Senn, of Milwaukee. So far as I know there are no statistics showing that it has been done on man. The case of obstruction occurring in a child, with painful tumor, spoken of by Dr. Hoadley, was a case of chronic obstruction in which the lumen was not perfectly occluded, and those cases are not dangerous. So long as the lumen is not absolutely interfered with the processes of nutrition go on. Cases of chronic obstruction were not considered in the paper; I spoke only of acute obstruction due to intussusception. Water passes the ileo-cæcal valve by dilatation from over-distension. I have seen the experiment tried on animals; by opening the abdomen and forcibly injecting water the colon would become distended to its utmost capacity, and by-and-by the tissues would begin to yield, the valve would become incompetent and the water would pass. The quantity of water used for injections was smaller than if the obstruction had been higher up. The case of acute obstruction mentioned by Dr. Frank, that was relieved by a large dose of calomel, was probably acute enteritis, such a case as would have been relieved by bleeding,

many years ago. When we are called to these cases of acute intestinal obstruction where there is a doubt as to its cause, we should take into consideration all the factors: the age of the child, the sex, the suddenness of the onset, the presence of a majority of symptoms that are said to be present in intussusception, and then make a thorough, complete and systematic palpation of the abdomen, aided, if necessary, by the distension of the colon with carbonic acid gas. By the alternate injection of an acid and alkaline solution into the rectum you can distend the colon so that it can be mapped out perfectly, and you can distermine the location of the obstruction.

Dr. Elbert Wing exhibited some pathological specimens, and said: These specimens were obtained at the County Hospital to-day, and I bring them to you to-night because specimens are more interesting when they are fresh. The case came to the dead-house without any history except that the man was known to have some trouble with his heart. The internes were careless and no careful record was kept. The man was about 60 years old and very fat. There was no fluid in the abdominal cavity. The pericardium contained perhaps 30 cu. cm. of clear serous fluid, and the heart was considerably larger than the man's fist, with one or two of the so-called "milk spots" on the surface. The right auricle was distended with dark, partly clotted blood, the right ventricle contained a very small quantity of fluid blood and a small clot; the left auricle and ventricle were empty. Upon section the heart showed no lesion of the valves; there was slight atheroma at the base of the aorta. The endocardium showed the streaks and bands of grayish discoloration which are taken as evidence of chronic endocarditis; there was also, over the surface of the endocardium, the mottled appearance of myocarditis with fatty degeneration. The left pleural cavity was empty and without adhesions. The surface of the lung presented a few spots of emphysema, and upon section the bronchial tubes were found extremely congested and lined with a thick coat of mucus throughout the bronchial tree. On the right side there was an adhesion along the median line, and on breaking this found 3700 cu. cm. of a clear serous fluid, slightly reddish, containing no shreds and no plaques of fibrin. The entire costal pleura of this side was much thickened, of a slightly velvety appearance and bright red color, easily separated from the underlying tissue and easily torn in manipulation. The deposit of fibrin could be removed only by considerable force, and the pleural surface then showed manifold small red dots, resembling the mouths of severed capillaries. Completely covering the surface of the right lung there was a film of lymph which varied in thickness from that of a heavy sheet of blotting paper to 1 or 2 millimetres. Over the lower lobe this had taken on organization and contained bands of connective tissue. Throughout the extent of the visceral layer of the pleura it could be removed, leaving the surface smooth and glistening. The lung on the cut surfaces is of a steel gray mottled with spots of pigment discoloration. It is completely devoid of air, and a piece cut out from it and thrown into the water sinks. Upon the superior border of the spleen there is a small plaque in which the connective tissue of the capsule is largely increased. The cut surface of the organ presents a mahogany color and as a whole is quite firm, verifying the diagnosis of what we would expect to find in such cases, chronic passive hyperæmia of the spleen causing an increase of the connective tissue. The kidneys were hardly enlarged at all, the capsule was not thickened and was easily removed. Upon section the cut surfaces of each of the organs was a very dark red color, the vessels all full of dark-colored blood, and the organs slightly firmer than normal. The left lobe of the liver presented a peculiar appearance. It looks and feels a little granular, and that seems to be due to a wrinkling of the capsule. There was a similar appearance along the anterior border, and near the line of the suspensory ligament. This large spot was triangular upon the surface, say 5 cm. along each side, and extended into the organ in a pyramidal shape, the apex being near the hylus of the organ. The line of demarcation between this wrinkled and the unchanged surface of the organ is sharply defined. On section these portions of the organ present the characteristic appearance of advanced simple atrophy, a dark brown slate-color, the lobule distinct but very much diminished in size. That portion of the organ not described is in the condition known as "nutmeg liver." The omentum is in a condition rarely seen. It is $25 \times 12 \times 1.5$ cm., somewhat lobulated, and along the anterior surface there are broad radiating bands of fibrous tissue. The organ as a whole is very firm and solid, and on section little lobules of fatty tissue can be isolated. The condition is that of marked hypertrophy of the fatty tissue of the organ, together with a great increase of the connective tissue, the latter due to chronic passive hyperæmia, the former part of the general marked increase of adipose tissue throughout the body. There was also considerable œdema of the right leg, but no thrombosis in the iliac vein. Examination of the veins outside of the abdominal cavities not permitted. With the conditions described as a basis, the diagnosis is: chronic endo-myocarditis with fatty degeneration; chronic pleuritis (costal) with effusion, atalectasis from compression, right side; chronic passive hyperæmia of spleen, kidneys and liver, with added circumscribed simple atrophy of the latter; hypertrophy and chronic passive hyperæmia of the omentum; chronic venous thrombosis with œdema of the right leg.

(*To be concluded.*)

CHICAGO GYNÆCOLOGICAL SOCIETY.

Stated Meeting, Friday, February 18, 1887.

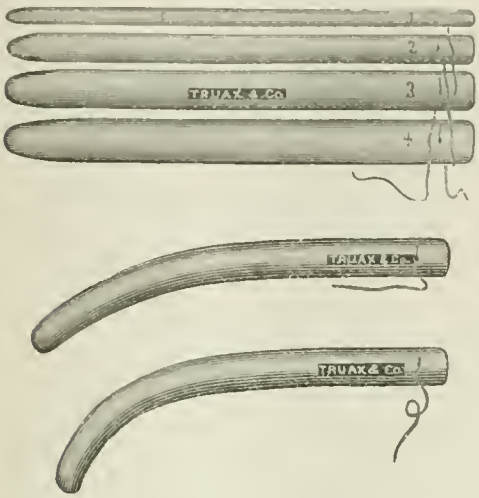
Philip Adolphus, M.D., in the Chair.

Dr. Henry T. Byford made the following remarks on

THE SLIPPERY ELM TENT.

For quite a number of years, I have been using slippery elm tents in the treatment of uterine disease.

Within the last few weeks, I have received from Messrs. Charles Truax and Co., of this city, some improved tents made out of the compressed bark. By compression, its dilating power is increased so as to render it useful as a substitute for tupelo, sea-tangle and compressed sponge in many cases.



The characteristic of slippery elm bark is that upon being moistened a slippery substance exudes, which acts both as a lubricant to the tent, and as a protection to the mucous membrane against that injury or abrasion which sometimes follows the use of dilators of this class. Another advantage is the rapidity of its action. The tents expand sufficiently within an hour or two for the introduction of a larger size, or two or three of the same size. This may be repeated until the desired dilatation is obtained, and since the expanded tents are both soft and slimy, with a minimum amount of injury to the parts.

A small elm tent may be introduced at the office and left for twelve or twenty-four hours and thus serve, providing it be used once or twice a week, as a mild substitute for the intra-uterine stem in cases of sterility. The patient can go home and keep quiet until she removes it by the attached string, upon the advent of severe pain, or at the end of the twenty-four hours. A glycerine tampon placed under the cervix is necessary in such cases to retain it in place.

These tents are also available as applicators, for the exuding lime carries the drug out from them instead of into them, gradually dilutes it, and thus limits its action.

As dilators and applicators in vaginitis, vaginismus, urethritis, urethral stricture, etc., they are also useful, and may be ordered of any size, shape or curve desirable.

They should be kept in a tightly covered box or bottle, as they become brittle and lose their rapid expansive power when they get too dry. It would be a good thing to dip them in gelatine or cocoa butter when they are to be preserved for a long time.

Dr. A. Reeves Jackson: I have used slippery elm tents a great many years, and I have no doubt that the form in which they are now presented by Dr. Byford will render them more suitable for dilating purposes than heretofore. In this form, however, I have made use of them recently, and have been disappointed as regards their dilating power. Slippery elm forms a slimy mass at the expense of its substance, and while this mucilaginous mass and the mucous discharge which appears with it causes the tent to seem large, the latter does not exert much dilating power, and I was surprised to find that after moistening one of these compressed tents for several hours in water, it was very little larger than before. I have had a great deal of satisfaction in using flat pieces whittled out of the slippery elm bark, in the following manner: I use a small sponge tent, and in order to get the expansive power of that material surround it with a cordon of these slips, so as to protect the mucous membrane from injury. I think that in the combination of sponge tent and slippery elm we have the best means for tent dilatation. In this way we get the dilating power of the sponge with the protective effect of the slippery elm.

In cases which stenosis seem to be the cause of sterility, I use non-expansive stem pessaries. My experience in the use of the intra-uterine stem has been very large, and I find, in order to effect any change of structure, that it is usually necessary to carry out the treatment for many months. I have never succeeded in changing materially and permanently the direction of the cervical canal in less than six or eight weeks, and sometimes over a year has been required. The stem may remain undisturbed for many months. This makes a great difference to the patient, who otherwise is obliged to have the instrument changed frequently. I use chiefly a very flexible soft rubber stem, which may be introduced and worn for months without irritation. It may be of different degrees of flexibility, a very small one at first and of very slight straightening power, and by and by another, larger and stiffer, and so on until at the end of some weeks or months the desired change is produced. I think the use of a substance that is not absorbent and does not dilate superior in these cases.

Dr. H. T. Byford: I have had many cases of sterility of several years' standing, dating from marriage, cured by three or four or more small tents used once or twice a week. Their power is milder than that of compressed sponge, and less radical than that of the intra-uterine pessary. These negative qualities are the accompaniments of nearly all safe remedies. If Dr. Jackson had watched the compressed elm tent, which seemed to expand so little in several hours, he would have found that it expanded two or three times its own diameter in less than two hours, and then became smaller again by having its softer portion dissolved out. In the uterus its substance is not washed away as rapidly as in a basin.

Dr. W. W. Jaggard exhibited a

PLACENTA WITH MARGINAL INSERTION OF AN ABSOLUTELY SHORT UMBILICAL CORD, MEASURING NINE INCHES IN LENGTH.

The specimen, placed at his disposal by Dr.

Charles Caldwell, was of interest in connection with Dr. John Bartlett's paper, read at the January meeting. The absolute shortness of the cord in Dr. Caldwell's case did not constitute a mechanical hindrance to the progress of labor, although there was some slight difficulty in ligaturing the organ, after birth of the child, on account of the proximity of the navel of the child to the vulvar orifice of the mother.

Dr. Jaggard also made some remarks on

THE ANTISEPTIC OBSTETRICAL PADS OF DR. H. J. GARRIGUES AND DR. WM. L. RICHARDSON.

Dr. H. J. Garrigues describes the application of the pad in the following words: The well closed vulva is covered with a pad of absorbent cotton, wrung out in the solution (1,2000). Outside of that comes a piece of oiled silk or preferably thick guttapercha tissue dipped in the solution. To keep this antiseptic part of the dressing in place I use a large pad of dry absorbent cotton, and a rectangular piece of canton flannel or square piece of unbleached muslin, half a yard in both directions, and folded diagonally like a cravat. Dr. Wm. L. Richardson substitutes absorbent scrap or waste done up in cheese cloth for the absorbent cotton. Of course, Dr. Richardson does not insist upon the pad as essential. There is nothing peculiar about the pad except that it seems to me to be a very convenient and safe form of dressing to use. The main thing is the use of antiseptics all through the delivery, and the pad is all that is needed for the convalescence.

The important services, rendered to the profession and community, in the prophylaxis of child-bed fever, by Garrigues and Richardson, demand recognition. In the New York Maternity Hospital the mortality from sepsis—Oct. 1, 1882, Oct. 1, 1883, 429 patients—was 6.06 per centum. Garrigues has reduced this mortality to—Oct 1, 1885, Oct. 1, 1886, 463 patients—21 per centum.

In the Boston Lying-In Hospital, the mortality from sepsis, Jan. 1, 1882, Dec. 31, 1882, 288 patients—was 5.55 per centum. Richardson has reduced this mortality to—Jan. 1886, 373 cases—.0 per centum.

The American woman insists upon wearing some kind of a napkin to absorb the lochia. If she wear one at all, it must be antiseptic.

(To be continued.)

DOMESTIC CORRESPONDENCE

GALVANIC MEASUREMENT.

Dear Sir:—The enterprising spirit of Dr. Engelmann, as exhibited in his letter to The Journal of April 16, in which he criticises me for statements in reply to Dr. Cutter's letter in The Journal of February 5, is really very refreshing.

First, he says: "In No. 7, February 12, 1887, p. 195, Dr. Martin tells us that he has used from 25 milliampères to 10 ampères through a fibroid tumor, with one surface electrode and without causing pain enough to require an anæsthetic. Ten ampères . . . would scorch the body as would a stroke of lightning. This is impossible." Dr. Engelmann continues on this line: "No man ever has or ever will pass 10 ampères through living tissue, as this would scorch the skin and destroy the activity of the nerve tissue." I would like to inquire as to the kind of scientific man who dares to make such unqualified statements in regard to the past, and assert such absolute prophesies of limitations in regard to the future of a subject which all unbiased minds admit is but in its infancy! It is with reluctance that I must remind him that for once he occupies the position which the scientific world did when it "was astonished when Apostoli employed 100 milliampères, which he has increased to a possible 250 with one surface electrode." Here, in Chicago, by means of our improved abdominal electrode of very large surface, the principles of which I described in a paper to the Chicago Medical Society December 20, 1886, an abstract of which appeared in The Journal of January 15, 1887, and the full text of which appears in this week's number of The Journal, I have frequently used a current of 500 to 1,000 milliampères without an anæsthetic, without severe pain, and with the same surface electrode double, I have used on one tumor, with very great depth of uterus, a current of 10 ampères; and this, too, without an anæsthetic, without "giving excessive pain;" without "burning the integument;" without scorching the skin and without "destroying the activity of the nerve tissue."

Secondly—Dr. Engelmann says: "I am glad to see that Dr. Martin is seeking to define and record his treatment more accurately." I am surely very much gratified to have the fact duly recorded that he notes signs of improvement in my later writings, be they ever so slight; because to admit no progress would be to infer retrogression. At the same time, I am willing to have my first paper on electrolysis thoroughly examined, by an impartial critic, for any loose or inaccurate statements.

Thirdly—Dr. Engelmann further modestly remarks: "It is a satisfaction to me to see that he (Dr. Martin) has accepted my criticism of his paper which I made before the Section of Obstetrics and Diseases of Women at the St. Louis meeting of the American Medical Association in 1886." "I then urged," he continues, "the importance of the galvanometer and the necessity of exact measurements, strong currents, and short sittings." If Dr. Engelmann remembers—and if he does not a perusal of my paper referred to may serve to freshen his memory—he will find that the above advice was entirely superfluous so far as it was applicable to me, with the exception of his reference to stronger intensity. In regard to this latter point I will confess, in order not to seem under too great obligations to Dr. Engelmann, that I had heard of Apostoli, and had investigated pretty thoroughly his method and recognized its advantages, long before I ever had the honor of hearing Dr. Engelmann's views.

Finally, I will state, in order to more definitely define my present position, that I am obtaining very gratifying results in the treatment of fibroid tumors

by a modification of Dr. Apostoli's method. By the employment of improved surface electrodes by which the current is widely diffused, by which the complete adaptability of the surface of the electrode to the surface of the body is accomplished, by which the minimum resistance is obtained consistent with minimum pain, I have been able, as stated above, to use a current of much higher intensity than Dr. Apostoli, or even Dr. Engelmann. The current that I ordinarily employ now varies, according to indications in different subjects, from 100 to 1,000 milliampères, and this without ever arousing one alarming symptom. Respectfully yours,

FRANKLIN H. MARTIN, M.D.

163 State St., Chicago, April 8, 1887.

NECROLOGY.

DANIEL DRAKE CARTER.

DANIEL DRAKE CARTER, M.D., of Versailles, Woodford Co., Kentucky, was born in that place, October 12, 1837, died of congestion of the lungs at the residence of his mother, in Versailles, December 12, 1886. He was the son of Dr. Joseph Coleman Carter, who was born in Charlottesville, Va., December 23, 1808. A kinsman on his mother's side of Dr. Daniel Drake with whom he studied medicine. He took his medical degree at Jefferson Medical College, Philadelphia, Pa., 1831. Died January 26, 1876.

His grandparents on his father's side were Goodloe and Mary (Crenshaw) Carter. He was therefore descended from the eminent Robert Carter, of "Carter's Hall," Virginia. The mother of the subject of this notice, still living at the age of 77, is the youngest daughter of George Carlyle and the granddaughter of Robert Carlyle, who came to Virginia from Scotland, in 1730. George Carlyle removed from Virginia to what is now known as Woodford Co., Kentucky, in 1784, and in 1790 married Margaret Crockett, daughter of Alexander Crockett. George Carlyle died in 1827, aged 73 years. This branch of the Carlyle family is somewhat noted for longevity, as five sisters and one brother of Dr. Carter's mother lived to celebrate their golden wedding. Dr. Daniel Drake Carter, the subject of this note, was of delicate constitution from infancy. In consequence of this his education was mainly conducted by his father, or at home schools, the village academy and by private tutors. With a view to strengthening his constitution his father had him spend as much time as possible in the summer seasons on his farm, near Versailles, and endeavored to have him become interested in agricultural pursuits. Knowing the severe labor and exposure attending the practice of medicine in that section, he did not wish his son to enter the medical profession. Dr. Joseph C. Carter was a scholarly man, who enjoyed and deserved a large practice, and had his residence been in a populous city, his proficiency in chemistry and the natural sciences would have of themselves won him a place among the leading teachers and scientists of his day. While attending a large country practice he therefore made his desultory studies and observations in geology and botany a sort of recreation. His love of study and high appreciation of scientific education made him the more solicitous to secure a good education for his son. This was not a difficult task, for from his early youth he took to books and rapidly acquired knowledge. But notwithstanding the father desired him to select some profession or pursuit other than that of medicine, his son adopted physic after mature deliberation, preferring it to any other calling.

Before Dr. Carter began the regular study of medicine his father made a most advantageous business arrangement for him with a firm of bankers at Davenport, Iowa, where he spent one year. Drake, as he was familiarly known, then made known to his father that he earnestly desired to study medicine and pursue the practice notwithstanding all the exposure and exactions attending a physician's life. Returning home, he at once entered upon its systematic study with his father. In 1859, he entered the Long Island College Hospital, New York, for the spring or reading term. He also returned the following year. His tickets to the course in practical chemistry bearing date March 29, 1860, and for 1861, now lie before me. The second was, however, abruptly terminated by the medical students of the South withdrawing from the College and returning to their homes, owing to the political excitement and the beligerent attitude assumed by the Southern and Northern States toward each other. Dr. Carter at once returned to Kentucky, and matriculated in the University of Louisville where he attended lectures the remainder of the season, and was examined and received his diploma at the commencement in January, 1862.

He wrote his thesis on "The Blood, its Source and its Function." Dr. Carter warmly espoused the cause of the South, and without going to his home accepted the position of surgeon in the 5th Kentucky Cavalry under Col. Howard Smith, in the command of Gen. Buford. He also served as brigade surgeon on the staff of Gen. John H. Morgan, and was captured at Buffington's Island in the Ohio river, in July, 1863, as was most of that command. After having been paroled he went to the City of New York, where he resumed his medical studies with his warm personal friends Drs. James R. Wood and Lewis A. Sayre. He spent the winter in the hospitals and at the Clinics of Profs. Wood, Sayre, Flint and of other leading teachers in that city. In the spring of 1864 he grew impatient and could no longer remain idle while his friends in the South were putting forth all their energies to repel coercion and maintain their sovereignty. Not being able to pass through the army lines to the South, he went to Halifax and from thence sailed in a blockade runner for Wilmington, N. C., hoping to get into the Southern Confederacy and render such services as he could to aid the cause. The vessel, however, was captured just as she was entering port. He was one of three on board who would not swear that they were

British subjects, and was consequently sent as a prisoner to Fort Lafayette, New York, and afterwards transferred to Fort Warren, Boston harbor, where he was kept as a prisoner of war until May, 1865.

Dr. Carter, on regaining his liberty, returned home and immediately entered upon the practice of his profession in conjunction with his father. The young doctor was well prepared by extensive reading, careful college and hospital training, to discharge the responsible duties of a physician. He was most enthusiastically devoted both to the study and the practice of medicine. His efficiency and zeal soon won for him an extensive and lucrative business. He was a man of high culture, gentle in disposition, courteous and dignified in his intercourse with patients and his medical brethren; fond of music and the fine arts and of cultured society. He was strictly temperate, never using tobacco or intoxicating liquors. And what is rather uncommon with physicians a good business man, collecting his earnings and invested his means with rare judgment. He was a consistent member of the Presbyterian Church from his youth. His parents and grandparents on both sides belonged to the same religious denomination.

Although Dr. Carter was of slight frame, he possessed much mental activity and great physical endurance. The amount of labor he was capable of performing was a surprise to all his friends. He possessed special aptitude for surgery, having a comprehensive and an accurate knowledge of anatomy and physiology, and the dexterity, courage and fortitude so essential to make the successful operator. He performed with success some capital and hazardous operations in the circuit of his practice, rarely undertaken except by specialists in well organized hospitals. His neighboring physicians, too, had a high regard for his judgment in difficult cases, and frequently called him in consultations. His great forte was at the bedside, where his real genius showed itself in diagnosis and in the suggestions of new methods and in giving encouragement and comfort to the despondent patient. For a busy rural practitioner he made an unusual number of post-mortem examinations, and was, to the close of his busy life, a student and a careful observer, and would undergo any amount of labor to verify or disprove the diagnosis of an obscure case. The writer of this sketch was for a time, in 1875, somewhat out of health, and having accepted an invitation to rest a couple of weeks at one of Kentucky's most hospitable of homes, on the splendid estate of "Spring Hill," near Versailles, where he became well acquainted with the subject of this sketch. Here he met daily and often during the day, Dr. Carter, then in excellent health, and in the enjoyment of a full practice. The high opinion then formed of Dr. Carter as a skillful physician and affable gentleman, the universal esteem in which it is evident his memory is held by the profession in Kentucky, has been fully justified. We visited the celebrated stock farm of Mr. Alexander, known as Woodburn, and together attended the burial of the great race horse "Lexington," whose skeleton was obtained from the owner on my application and Dr. Carter's intercession, and is now handsomely mounted and forms a part of the great collection of comparative anatomy in the Smithsonian Institute, in Washington, D. C.

In 1875, Dr. Carter met with an accident while performing a surgical operation by wounding the index finger of the left hand, and from which he suffered blood poisoning. This accident and its results for a time alarmed his friends and did seriously impair his health, and it is probable that he never entirely recovered his full degree of vigor afterwards. In the fall of the same year he suffered an attack of bilious fever, which ran a more than ordinarily protracted course, from which he, however, slowly recovered.

In 1876, he had an attack of pneumonia which still farther debilitated him. His practice was at that period large, and being ambitious, he overworked and entirely neglected himself. Although he continued to labor efficiently for years, he nevertheless labored at a disadvantage from a naturally delicate constitution which was farther impaired by disease.

Dr. Carter was twice married. His first wife was Miss Louisiana Hart Gibson, a most lovely and accomplished lady, the sister of Senator Randall L. Gibson, of Louisiana, to whom he was united February 15, 1876. She survived her marriage by but one year, dying February 14, 1877, leaving a daughter, who followed its mother to the spirit land April 12, 1880. His second marriage was on the 31st of October, 1882, to Miss Sallie, daughter of Humphrey and Elizabeth (Scott) Fullerton, of Chillicothe, Ohio. From this union one child, a son, Joseph C. Carter, was born July 28, 1884, who, with his mother, survives. Dr. Carter's mother and three sisters survive him. During the later years of the doctor's life, he attempted to lessen his professional labors and retired to his farm, "Rock Castle," but his patrons followed him there and he was obliged to seek rest at a distance. He made three pilgrimages to Florida for his health. In April, 1886, he had an acute attack of double pneumonia, which seriously impaired his health and alarmed his friends, and after spending some time on his farm was advised to go to Asheville. N. C. This change brought no relief, but added to his suffering and discomfort, and he returned home, where he received every attention from medical friends and from a devoted wife, his mother and sisters, until his soul returned peacefully to the Giver of life.

Dr. Carter was a member of the Kentucky State Medical Society and was sent by it as a delegate to the American Medical Association in 1872; he also attended the meetings in 1873, 1874, and 1875. He was a member of the Masonic order and a Knight Templar of the Commandery of Versailles. This Commandery held a special meeting and passed a series of appropriate resolutions of respect for his worth, and of sympathy for his bereaved family, which were published in the Versailles paper.

His funeral took place from his late residence and that of his mother, in Versailles, on Wednesday the 15th of December, 1886. The services were solemn and impressive, and were largely attended by the community which sincerely mourned the loss of a good citizen and a beloved physician. J. M. T.

INTERNATIONAL CONGRESS.

OFFICERS OF SECTION V.--GYNECOLOGY.

PRESIDENT.

Henry O. Marcy, M.D., 116 Boylston Street, Boston:

SECRETARIES.

Ernest W. Cushing, M.D., 168 Newbury Street, Boston.

Horatio R. Bigelow, M.D., American Exchange, Berlin, Germany.

Dr. Carl Pawlik, Vienna, Austria.

Dr. George Apostoli, Paris, France.

VICE-PRESIDENTS.

Prof. Robert Barnes, London.
Prof. A. Breisky, Vienna.
Prof. Fr. Schauta, Innsbruck.
Dr. Robert Bantoch, London.
Dr. Ludwig Bandl, Prague.
Dr..N. Bozeman, New York.
Dr. A. Cordes, Geneva.
Prof. Matthews Duncan, London.
Dr. A. Hegar, Freiburg.
Prof. Graily Hewitt, London.
Dr. Thomas Keith, Edinburgh.
Prof. Gilman Kimball, Lowell, Mass.
Dr. A. Landau, Berlin.
Prof. Leopold, Dresden.
Dr. A. Martin, Berlin.
Prof. P. Müller, Bern.
Prof. C. Rokitansky, Vienna.
Dr. Sänger, Leipsic.
Prof. H. R. Storer, Newport, R. I.
Mr. Lawson Tait, Birmingham.
Prof. T. G. Thomas, New York.
Dr. Knowlsly Thornton, London.
Prof. F. Winckel, Munich.
Dr. J. Veit, Berlin.

The following gentlemen will also furnish papers:

Dr. W. Alexander, Liverpool, Eng.
Dr. J. M. Burton, Liverpool.
Dr. A. P. Carpenter, Cleveland, Ohio.
Dr. A. P. Clark, Cambridge, Mass.
Dr. E. Cutter, New York.
Dr. Duncan Godson, London.
Dr. F. A. Garcell, London.
Dr. Addinell Hewson, Philadelphia.
Dr. C. H. Hughes, St. Louis, Mo.
Dr. Francis Imlach, Liverpool, Eng.
Dr. F. H. Martin, Chicago.
Prof. Menière, Paris.
Dr. Leopold Meyer, Copenhagen.
Dr. Michel Middleton, Charleston, S. C.
Dr. Samuel N. Nelson, Boston, Mass.
Dr. J. W. Nowlin, Nashville, Tenn.
Dr. Wm. L. Reid, Glasgow.
Dr. F. Semeleder, Mexico.
Dr. J. H. Scarff, Baltimore.
Dr. Shauta, Innsbruck, Austria.
Dr. Valliet, Geneva, Switzerland.
Dr. Wm. H. Wathen, Louisville, Ky.
Dr. Wyder, Berlin.

COMMITTEE OF ARRANGEMENTS.

The following memorandum is published by order of the local Committee of Arrangements for the information of persons desiring to attend the Ninth Meeting of the International Medical Congress, in Washington, D. C., in 1887:

RATES OF TRANSPORTATION.

Red Star Line, $100; Antwerp to New York and return.

Inman Line, $100; Liverpool to New York and return.

Hamburg Line, $90; Hamburg to New York and return.

Royal Netherlands, $80; Amsterdam to New York and return.

North German Lloyd Line, $187.50; Bremen to New York and return.

Same rates are allowed for the families of members.

Cunard Line, 10 per cent. reduction for members of the Congress only.

HOTEL RATES IN WASHINGTON.

Arlington Hotel, from $3.00 to $3.50 per day.
Riggs House, from $3.00 to $3.50 per day.
Willard's Hotel, from $3.00 to $3.50 per day.
Metropolitan Hotel, $3.00 per day.
National Hotel, $3.00 per day.

Other hotels conducted on European style will furnish rooms at $1.00 to $2.00 a day. Good lodging-houses will also furnish rooms from $1.00 to $1.50 a day.

Proper accommodations have been secured for the meeting places of the Congress and its Sections.

Transportation within the limits of the United States has not yet been determined upon, but will soon be made public. Particulars of the plan of entertainments will be published in the official programme, and all notices will be published in THE JOURNAL in due time.

Official: A. Y. P. GARNETT, *Chairman.*
C. H. A. KLEINSCHMIDT, *Secretary.*

BOOK REVIEWS.

A TEXT BOOK OF MEDICINE for Students and Practitioners. By DR. ADOLPH STRÜMPELL, formerly Professor and Director of the Medical Policlinic at the University of Leipsic. Translated from the second and third editions by HERMAN F. VICKERY, A.B., M.D., and PHILIP COOMBS KNAPP, A.M., M.D., with editorial notes by FREDERICK C. SHATTUCK, A.M., M.D., Instructor in the Theory and Practice of Medicine in Harvard Medical School. With 111 Illustrations. 8vo., pp. 981. New York: D. Appleton & Co. 1887. Chicago, A. C. McClurg & Co.

This is one of the most compact and yet full treatises

that has appeared on this subject during the last four years. The work has been very popular in Germany, having rapidly gone through three editions there. The characteristics of the work are conciseness and completeness, coupled with a presentation of the most recent and best views concerning etiology and pathology. The clinical history of diseases is clearly and well described. In many ways the treatment advocated differs from that followed in this country.

The topics taken up are described in the following order: Acute General Infectious Diseases; Diseases of the Respiratory Organs; Diseases of the Circulatory Organs; Diseases of the Digestive Organs; Diseases of the Nervous System; Diseases of the Kidneys, the Pelvis of the Kidney and the Bladder; Diseases of the Organs of Locomotion; Diseases Affecting the Blood and Tissue Metamorphosis.

The section devoted to nervous diseases is very complete and presents in a collected form the latest information pertaining to the subject.

In reading the volume through many thoughts are noticed that have not yet found their way into the American text-books generally. The author adopts freely the most advanced views of the bacteriologists, accepting as facts what in this country are regarded as still under judgment. To illustrate, the following is the first sentence under the head of etiology of acute articular rheumatism: "Acute articular rheumatism is an infectious disease. This is shown by all clinical and anatomical peculiarities of the disease; and although the specific organic pathogenic poison cannot yet be demonstrated, still this view of the disease, which was first brought forward by Hüter is the only one which enables us properly to understand its symptoms and course."

The book is a valuble addition to medical literature, as it gives us in a compact and yet comprehensive manner the best and most recent views of the most famous German physicians.

MISCELLANEOUS.

The Murphy Tenement Bill.—The New York Legislature has passed what is known as Murphy's Tenement bill. It provides for the detail of fifteen policemen to enforce the sanitary code of New York city, so far as it relates to tenement and lodging houses. The Board of Health is to make a report annually upon its work. The Mayor, one Commissioner of Health, the Commissioner of Public Works, one delegate from the Bureau of Inspection of Buildings, and the Street Cleaning Commissioner shall meet annually between Nov. 15 and Dec. 30 to consider the subject of tenement and lodging houses in New York and make such recommendations for the change of the laws as will best protect the interests of the people, which are to be made to the Governor and Legislature before Jan. 15. The bill provides that certain conditions must be observed by owners of tenements. Some of these are that where more than one family reside on a floor the halls must open directly to the outside air with sufficient windows and without obstruction to ventilation. Each tenement-house shall be provided with such privy sinks as the Board of Health may require, one for every fifteen occupants in lodging-houses, and one for every two families in dwelling-houses, which shall be plumbed properly and be adequately ventilated; all such receptacles shall be connected with the sewer by air-tight pipes as directed by the Board of Health. The law also contains a provision that every owner of a tenement or lodging-house must file with the Health Department his name and address; a description of the property by street numbers, the number of apartments, the rooms in each apartment, the number of families occupying each apartment, and the trades or occupations carried on in them. In case notices are served for the abatement of nuisances, they shall be posted five days in the house and mailed to the owner also. The law requires a semi-annual inspection by the Board of Health of all tenements and lodging-houses, and in case the owner fails to comply with the rules of the Board of Health, any court of record is authorized to issue injunctions restraining the owner. Water is to be plentifully supplied on each floor, and cellars shall be concreted and made water-tight. The bill is a long one and embodies the experience of New York sanitarians with this vexed question.—*Sanitary News*, April 2, 1887.

Medical Association of the District of Columbia.—At the regular meeting of this Association held April 5, 1887, the following officers were elected for the ensuing year: President, Dr. J. W. Buckley; Vice-Presidents, Drs. J. W. Bayne and W. O. Baldwin; Secretary, Dr. Lachlan Tyler; and Treasurer, Dr. S. S. Adams.

Chicago Medical Society.—At the annual meeting of this Society, held at the Grand Pacific Hotel, April 4, 1887, the following officers were elected for the year: President, Dr. Wm. T. Belfield; Vice-Presidents, Dr. J. H. Etheridge and Dr. A. E. Hoadley; Secretary, Dr. Frank Billings; and Treasurer, Dr. H. N. Moyer.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 9, 1887, TO APRIL 15, 1887.

Capt. Jno. J. Kane, Asst. Surgeon, resigned April 13, 1887. S. O. 85, A. G. O., April 13, 1887.

Capt. Chas. Richard, Asst. Surgeon, granted two months' leave of absence, on surgeon's certificate of disability. S. O. 82, A. G. O., April 9, 1887.

First Lieut. Freeman V. Walker, Asst. Surgeon, ordered from Ft. McIntosh, Texas, to Post of San Antonio, Texas. S. O. 45, Dept. Texas, April 11, 1887.

The Army Medical Board, New York City, N. Y., is dissolved. S. O. 82, A. G. O., April 9, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING APRIL 16, 1887.

Griffiths, S. H. P. A. Surgeon, detached from the U. S. S. "Lancaster," and waiting orders.

Hibbett, C. T., P. A. Surgeon, detached from duty on iron-clads, City Point, Va., and waiting orders.

Marsteller, E. H., P. A. Surgeon, ordered to duty on iron-clads at City Point, Va., the 20th inst.

THE

Journal of the American Medical Association.

EDITED FOR THE ASSOCIATION BY N. S. DAVIS.

PUBLISHED WEEKLY.

Vol. VIII. CHICAGO, APRIL 30, 1887. No. 18.

ADDRESS

ON

SOME NEW ASPECTS OF THE CHOLERA QUESTION SINCE THE DISCOVERY BY KOCH OF THE COMMA BACILLUS.

Delivered before the Medical Society of the District of Columbia, March 16, 1887.

BY E. O. SHAKESPEARE, M.D.,

OF PHILADELPHIA.

LATELY U. S. CHOLERA COMMISSIONER.

I appreciate the honor of an opportunity of coming before your learned body this evening to say something, although in a desultory manner, about some of the new aspects of the cholera question since the discovery of the comma bacillus of Koch, particularly those aspects which have more forcibly struck me in the study which I have had the opportunity to make of this question during my wanderings in Europe and India, under the direction of the President of the United States, for the purpose of investigating the cholera subject, with a view of making a report to the President concerning my labors. The subject is so vast that, of course, it would be utterly impossible to speak to any extent of all the features of cholera. In fact, I can only very briefly advert to some of the points which I think worthy of bringing to your attention to-night. It is unnecessary before this Society to go much into the history of the investigations of Koch and his associates of the German Commission, or into the investigations of other Commissions which have followed him in various fields concerning this matter. At the commencement of the invasion of Egypt, in 1883 by Asiatic cholera, it has been pretty well agreed, as you know, by most of the medical world, including the gentlemen, who, under the direction of the Marine Hospital branch of this Government, made an investigation and a most valuable report of the last cholera epidemic in this country—that of 1873—that the disease was in all probability due to a specific action of a specific virus, which in all probability was of material form, which had a natural habitat in some part of India, and was exotic in the rest of the world. They regarded cholera as a contagious or an infectious disease; that is transmittible from man to man and, therefore, transportable from place to place in various ways. So that, when Koch undertook to discover this specific germ he did nothing more than endeavor to bring before the eyes an object which already was believed to have an existence.

And, notwithstanding the fact that various microorganisms in past years had been found associated with cholera, because of the fact that Koch was the recognized leading bacteriologist of the world—with the exception perhaps of Pasteur—and because of the fact that in all of his announcements to the medical world of his previous discoveries he had universally, as I understood without exception, received a wide confirmation of the announcements which he had made. Therefore more than a usual degree of expectancy was created by the mission of Koch to Egypt and India, with a view of undertaking an investigation of the etiology of cholera. When his announcements were made, in various bulletins to his Government, of the discovery of a peculiar organism in the dejecta of cholera patients, with characters enabling one to distinguish it readily from all other micro-organisms; and when he announced at the same time that this micro organism was not to be found in any other disease, and therefore constituted a reliable diagnostic sign indicative of Asiatic cholera, many medical men throughout the world were already predisposed to accept these announcements as at least worthy of serious investigation. The result of his discoveries confirmed the conviction of those who believed in the existence of a living contagium as the cause of cholera, regarded cholera as a contagious or communicable and a transportable disease, and also thought that in order to prevent visitations of the rest of the world by cholera, some quarantine measures and other means of prevention, as absolutely necessary to be enforced.

The English Government was being most interested in the question of quarantine, and held—especially their representatives in India—that there is nothing contagious about the disease, that it is no more transmittible from place to place than malaria, and that measures of quarantine, and other restrictions are not only useless, but unjustifiably harmful to the conduct of trade between the East and the West. That Government was, therefore, naturally the first to send out another Commission to the scene of Koch's labors, for the purpose of reëxamining his investigations. As you know, that Commission returned to London in due time, and published a report in which not only the conclusions of the German Commission were contested, but almost every detail of the report of that Commission was flatly contradicted; at the same time the report of the British contained indirect statements—I should rather say contained statements which indirectly supported the

assumption very widely entertained by high officers of the British Government, and particularly those in India, of the non-infectiousness of cholera dejecta. Following this contradiction many others occurred in due course, but is not necessary for me here, nor have I the time to relate them.

The United States Government, being as much interested in the question of the etiology and the prevention of cholera as any other by reason at least of its sixty millions of inhabitants (a number almost twice as great as the inhabitants of any European country outside of Russia), concluded that it would be advisable to have the grounds of these differences of opinion investigated by one of their own representatives.

I went to Europe in the fall of 1885, when cholera was almost ended there. It was, however, still existing in the City of Palermo, and in some parts of Spain. I went to Palermo because that was the largest field of investigation at the time, and I remained there until the epidemic ceased. From there I went to Spain by way of the Italian and French Riviera, stopping at different places which had been visited by cholera in 1884 and 1885, for the purpose of examining into their hygienic condition, and of learning something of the history of the epidemic in them. I reached Spain when cholera was no longer existing in that country—that is, acknowledged officially as existing—except in the south, along the Straits of Gibraltar. I had ample opportunity to make bacteriological investigations concerning the relation of the comma bacillus of Koch to Asiatic cholera, as well as the relation of other germs to that same disease, as also opportunities to inform myself concerning the grounds of difference between Koch and his opponents as regards matters of fact. These opportunities also were somewhat extended by my visit to India. I had no difficulty whatever in confirming the statements of Koch with regard to the constant existence of the comma bacillus, in certain stages of Asiatic cholera in the dejecta of patients suffering from that disease; and in confirming also his statements as to the distinctive characteristics of the bacilli distinctions, which enable one to separate them readily from all other micro-organisms known up to the present time.

As you know, the comma bacillus of Koch is a curved organism, and you know also that other curved bacilli have been found in various localities and in various diseases. The statements of Dr. Lewis, of England, were among the first announced against even the assumption of Koch for the diagnostic value of his comma bacillus. He found a curved bacillus very much resembling, under the microscope, the comma bacillus of Koch in the normal secretions of the human mouth. Curved bacilli were also found in the intestinal contents of diarrhœa and dysentery patients, in leucorrhœal discharges, in ordinary river water, in well water, in sewage water, and what not. I myself, before I had paid much attention to the bacteriological study of the question of cholera, had met with them in the exudation of the lungs of pneumonia patients, had seen them in diarrhœa, in leucorrhœal discharges, and also in river water. I found even a curved bacillus once in some broken-down beef broth which had been exposed to the air of my laboratory.

The peculiar characteristics of the gelatine tube and plate cultures of the comma bacillus and of some of the other curved bacilli, such as the Finkler and Prior bacilli, which were found by these authors in the dejecta of cholera nostras, and the curved bacillus found by Deneke in decomposed cheese are fairly shown both in the photography and the camera-leucida drawings. These appearances in the plate and tube cultures, as you see, enable one to easily distinguish between the various growths.

I can only say that I agree entirely with Koch as to the diagnostic value of the comma bacillus, and therefore disagree with the conclusions published in the first report of the English Commission, with Dr. E. Klein at its head. I would say at this point that I regard this as the most important point of Koch's investigations. In the discovery of a reliable and an easily applicable distinctive means of diagnosis of Asiatic cholera at the very first moment of invasion of a locality or a country, I consider that Koch has conferred upon the human race an inestimable benefit for, with the proper application of this means of diagnosis, health authorities and Governments will now more than ever before have it in their power to prevent an invasion of cholera, and cut short the spread of an epidemic. The value of this discovery, as I have said before, I consider incalculable.

But, as to the other part of the claim of Koch—for his claim is two-fold—in the first place the discovery of a reliable diagnostic sign, in the second place, the discovery of the active agent or cause of Asiatic cholera—I think there is still reasonable ground for doubt. The fact that, so far as we know at present, there are none of the domestic animals which are naturally susceptible to this disease makes it difficult to settle the question as to the pathogenic power of the comma bacillus by means of experimentation upon animals. It is true, that a *quasi* cholera has been and can be readily produced in Guinea-pigs, and according to some also in dogs and rats, by the inoculation of these animals with pure cultures of the comma bacillus of Koch; but there is lacking the complete chain of symptoms with which we are familiar in genuine Asiatic cholera in man. The vomiting is usually absent, and also the diarrhœa; nevertheless, a cyanosis, or algidity, and sometimes the cramps, and the death of the animal with the well known characteristic intestinal contents are met with after the inoculations. I myself have performed numbers of these inoculations and satisfied myself as to that point. But still there is a question—at least in the minds of a great many—as to whether the symptoms following inoculations of these germs are really those of Asiatic cholera or not, and on that account it seems to me that the question of pathogenesis of cholera must for a time remain open. In the course of my remarks I shall have occasion to say something about the results of the human inoculations which were extensively performed in Spain, with cultures of the comma bacillus.

I will remark here, that I found in my visit to India, a very good explanation of some of the differences between the English and the German Commissions as to the diagnostic value of the comma bacillus. Koch distinctly states in all of his communications (and every one who has had any experience in the investigation of this matter knows it to be true) that by means of morphology alone it is absolutely impossible to distinguish between the comma bacillus and various other curved organisms. As you will see by some of those photographs and drawings which have been handed round, there is no great difference as to shape and the size between the comma bacillus of Koch and the bacillus of cholera nostras, or that of Finkler and Prior, and the cheese bacillus discovered by Deneke; and I may say the same of the new curved bacillus of which I spoke, or of those found in the normal mouth, in river water and elsewhere. No man more positively states this than Koch himself, even in his very first communications about the matter. He most distinctly stated that it is absolutely necessary for the recognition of the comma bacillus, and the separation of it from other micro-organisms, that plate cultures and tube cultures in flesh-peptone-gelatine be resorted to. Without this means it is utterly impossible for anyone, even Koch himself, to distinguish between these various curved bacilli. The great fault, as we consider it, in the investigations of the English Commission in India, as refers to this matter, is that they did not seem to have fully appreciated the necessity of resorting to gelatine cultures for the purpose of distinguishing the micro-organisms which they were examining; in fact, in Calcutta where most of their observations were made, as far as I know they did not resort to any sort of culture of these micro-organisms, but relied entirely upon the microscopic examination of simple cover-glass preparations. After leaving Calcutta, and on their way homeward stopping at Bombay, it appears that they did resort to some cultures in Agar-Agar. But Koch had already explained, and every one who has since that time practically worked in the matter, knows that there is no characteristic of the colonies of the comma bacillus in Agar-Agar plate cultures which enables them to be safely distinguished from the other curved bacilli. So that the method of examination of these micro-organisms followed by the English Commission was virtually inadequate to distinguish between them and the others. They erred, to my mind, in assuming that every curved bacillus which they found in the intestines of cholera patients or in other diseases, or in tank water and other places, were to be regarded as really the comma bacilli of Koch. On their return to England, these faults were pointed out by one of the most distinguished bacteriologists of that country, Mr. Watson-Cheyne.

The head of the English Commission has recently published a communication, although not of the same official character as his official report to the British Government.

While Dr. Klein still adheres to his denial that the comma bacillus has any causal relation to Asiatic cholera, he admits now, as I understand, the mistake which he had previously made in stating that in gelatine plate and tube cultures the comma bacillus had no characteristic which would enable it to be distinguished from ordinary germs of decomposition. That statement he has withdrawn; and he has practically admitted the diagnostic value of the comma bacillus of Koch for the purpose of recognizing Asiatic cholera and distinguishing it from cholera nostras, malignant malaria, and other diseases.

I now drop the subject of bacteriology and come to another point which had been more or less overlooked in an extraordinary way up to the time of the present epidemic, although scattered observations appear here and there in the history of the subject—observations, I may say, however, made by the most distinguished writers on the subject. I refer to certain peculiarities which have been noticed in the course of cholera in individuals, in villages and in countries. James L. Bryden was the first to point out the periodicity of epidemics of cholera in India, but did not undertake to explain it except by the influence of the monsoon. Subsequent investigators of cholera in India have also noted this periodicity. The periods of recurrence of cholera epidemics in different parts of India range from three to four years as a rule, whilst the periods of recurrence of small-pox vary from five to six years. For the provinces outside of the endemic area, there is a very marked periodicity and a very considerable similarity between the rise and fall of cholera and of small-pox. Charts showing the annual mortality from cholera in the other provinces strikingly indicate the periodical character of epidemics of cholera in various sections of India.

This periodicity has attracted the attention of many investigators, although the fact seems to have passed by without any general notice, and yet it seems to be closely connected with the explanation of some of the important peculiarities of cholera in India as well as elsewhere. It has been noted in India, for instance, that instead of cholera advancing down the course of the rivers it invariably travels up them in certain countries. In the Eastern part of India in the epidemic years cholera travels up the Ganges toward the northwest, instead of moving down stream. The movement of an epidemic down the Ganges to Bengal is unknown in the history of cholera in India; the only part of Hindostan where it often goes down with the current is in western and southern India.

Another remarkable and hitherto unexplained fact is that cholera dies out in the localities visited without having smitten the whole population; and the further fact that where large percentages of the inhabitants of a place invaded by cholera flee to a distance and subsequently return to their homes before the epidemic has entirely ceased, the ravages of the epidemic continue mainly among the returned refugees; in other words, among the people who have not become subjected and habituated to the cholera influences which are still prevalent in the town to which they return is still more inexplicable. Then again there is the strange fact that a recurrent

attack of cholera is an extremely rare thing. It is indeed so rare that very few people whom I met with in the countries where they severely suffered from cholera, had ever seen a recurrent attack of it in the same epidemic. Recurrent attacks in a second epidemic are not extremely infrequent, but it appears to be quite as rare to observe a recurrent attack of cholera during the same epidemic in a person who has recovered complete health after his first attack, as to see such a thing in scarlet fever or measles, or I might say also, in small-pox.

In speaking of these questions I might refer to the researches of my friend, Dr. John L. Keating, of Philadelphia, who is greatly interested in the diseases of childhood, and who, at my request, kindly looked up some records regarding early recurrences of scarlet fever and other infectious diseases for use in my official report. I regret that time does not permit me to lay before you the valuable table which he has furnished, but I will read you a portion of his letter accompanying it, as follows: "I may say that as a rule all the zymotic diseases protect from recurrent attacks, or at least have a tendency to lessen the severity of these recurrences, the exceptions which prove the rule occurring very frequently in each disease." "In my table I have not included the relapses which are most frequent in typhoid fever, but I have only mentioned those attacks that have been followed by restoration to health, and in which after a shorter or longer period of time there has been a recurrence of the disease; measles present these peculiarities oftener than any of the others, but it is by no means uncommon in variola, scarlet fever and whooping cough." In his table, in the main relating to well authenticated early recurrence of scarlatina, many instances of recurrence in two or three weeks of attacks of scarlet fever and measles are recorded.

When in Spain I addressed a series of twenty-four questions bearing upon the cholera in that country to the physicians of every village in that country which had suffered from cholera in 1885. Among those twenty-four questions was one which requested the physician to inform me whether he had any personal knowledge of a recurrent attack during the same epidemic; if so, to give me the details. Among the large number of replies to the 2,500 letters which I thus addressed, I received only eight which related to recurrent attacks. Six of those eight recorded, according to the details given in the letter, appear to have been *relapses* before the establishment of perfect health, after imprudences in diet, and imprudences of other kinds, rather than recurrent attacks of cholera, and the number was thus reduced to two, which may have been genuine recurrences or have been attacks of cholera morbus (or nostras).

The French Academy likewise addressed a series of questions to the villages in France which had suffered from cholera in 1884, and one of the questions in their circular letter bore upon the same point. In the replies received an account of ten recurrences (or relapses) the distinction between relapse and recurrence was not made in their replies.

These are matters which have attracted the attention of some of the most distinguished observers, and caused them to admit an immunity following an attack of cholera, as you will notice when I cite some of the history of the opinions of authorities upon this point. Among the early writers is Moreau de Jonnes (1832) who said that: "If a few rare or doubtful cases are excepted, it (cholera) does not attack the same individual twice, although he finds himself under the same condition as when he contracted the disease." Dr. Sámano, of Spain, in 1858, declared that "genuine cases of relapses are few, and recurrences are still more rare," and Lebert, one of the most distinguished investigators of his time, firmly believed in the immunity which an attack of cholera confers.

Many of the International Health Congresses discussed this matter, particularly that of Constantinople in 1866. They distinctly admitted in their conclusions, adopted by a unanimous vote, that there is a certain amount of immunity which is produced in a town by a visitation of cholera. Speaking of the pernicious effects of crowding together of people, they pointed out as an amelioration that an habituation to the choleraic influence and the experiencing of choleraic attacks counterbalance these bad effects; and they said the same of crowds upon ships. The next in order of time (1868) is Griesinger, who distinctly stated that next to good hygiene and pure water, an attack of cholera is the greatest protection against the invasion. Colvin, (in 1879) although he distinctly expressed as his conviction that there is no such thing as immunity against an attack of cholera, in the course of his book refers to facts which most positively support the assumption of an immunity, particularly in the history he gives of cholera in the Crimea during the war, and in the accounts of some military epidemics.

In later times, 1883, Dr. Proust, the distinguished hygienist of the University of Paris, as also Fauvel, another distinguished hygienist of France, after a thorough discussion of the facts of the subject, most positively declare that there is an immunity following an attack of cholera, more or less lasting, as there is with the other infectious contagious diseases, and they class cholera in the latter category. Dr. Proust ends his remarks on that subject thus:

"Indeed the facts newly acquired by science relate to questions of immunity and illuminate them from a side heretofore unknown.

"The etiology and prophylaxsis of cholera in particular may deduce from it (immunity) new indications.

"These facts moreover, appear to be the expression of a law which embraces the whole of another special category of pestilential diseases due to a contagium and leaving after them an immunity more or less lasting."

Griesinger, Wunderlich and Pettenkofer, in their "Cholera Regulation," most unequivocally affirmed the existence of an immunity of considerable duration and force. And lastly, we come to Koch, who in the discussions of the cholera question before the recent Berlin Cholera Conference, after relating the facts upon which his conclusions were based, most positively expressed his acceptance of an immunity, more

or less lasting, from an attack of cholera, and classified that disease among other zymotic diseases which are followed by immunity. He affirmed that unless the immunity theory be accepted, there is no possible way of explaining why it is that epidemics cease in a town without attacking the whole of the people who are living together under miserable conditions, and why it is that recurrences are so extremely rare, and there is no other way of explaining satisfactorily the peculiarities of the course of cholera in India, viz., the periodicity of the disease there, and the fact that it travels up rivers in the East instead of going down them. But I cannot occupy your time further in the citation of distinguished investigators who up to the present time have regarded cholera as among those diseases which confer a more or less lasting immunity after an attack, and I shall be obliged to leave unsaid much of that which I intended to speak.

I have spoken of the immunity which follows an attack of cholera. I believe immunity to be as certain a sequel of cholera as it is of most of the other zymotic diseases. Otherwise it is impossible to explain why it is that a person in the early part of a long epidemic suffers the disease and recovers, with his digestive apparatus in a miserable condition, perhaps with chronic dyspepsia and chronic diarrhœa for weeks and even months, and yet that person, living under the same conditions under which he took the disease, passes through the epidemic free of a second attack, especially so in view of the fact, as is well known, that in a person who is not already protected by a previous attack, digestive disturbances are very sure to dangerously increase the predisposition to an attack of cholera. And yet, as I have pointed out, it is the rarest thing to meet with a second attack of cholera in the same person in the same epidemic.

This brings me to the question of the Ferran anticholeraic inoculations. The German Commission stopped with the announcement of their belief in the immunity which follows cholera, not dreaming of making any practical applications, notwithstanding their reference to the practical use of this immunity which the Indian Government makes in their directions for the government of the troops during epidemics of cholera. I allude to the standing orders to select the nurses from the native population, and especially from that which has recently experienced an epidemic of the disease. Ferran, as you know, became notorious throughout the world from his announcement of a preventive inoculation against cholera. Previous to this announcement, I may say, that Dr. Ferran was regarded in Spain as one of the leading, if not the most prominent bacteriologist in the country, he having been awarded a year or two before a gold medal by one of the medical institutions in Madrid, for researches relating to bacteriology. His reputation as a bacteriologist and as an earnest, reliable investigator was such, that when the cholera broke out at Toulon, he was selected by the Government of Barcelona as the head of an official Commission to go to Toulon for the purpose of investigating the cholera, and reporting officially. His first communication on the subject of inoculation was addressed to the municipality of Barcelona, and some time after his return from Marseilles and was referred to the Royal Academy of Medicine, of Barcelona, which is regarded in Spain as perhaps the most distinguished medical body in that Kingdom, for their judgment of the report. That medical body appointed a Commission to investigate the grounds of Ferran's claim. The investigation ran through two or three months, comprising experiments by Ferran performed before them upon Guinea pigs, the making of cultures, and the performance also of human inoculations, to a certain extent, among the members of that Academy mainly. The report of that Academy was confirmatory in most respects of the announcement of Ferran, and it was this report upon the Ferran question which first reached and excited the interest of the rest of the world.

The French Government, among the first, as also the Belgian, sent a Commission to Spain to investigate the grounds of Ferran's claim. Upon their arrival in Spain they laid down a programme for Dr. Ferran, but he refused to follow it, suggesting, on the other hand, one of his own for them to follow. The result, as you know, was that the official investigation of the Commissioners ended before it began, and the Commissioners went back to their respective countries, much chagrined, and reported unfavorably Ferran. Still, the medical profession and the public of France were not quite satisfied with this report, and another Commission was sent, with Dr. Brouardel at its head associated with two other physicians, one of them a recently graduated medical student, who was selected mainly on account of his knowledge of the Spanish language. (Neither Dr. Brouardel nor the other Commissioners were able to speak Spanish, and none of them, by the way, were bacteriologists, however distinguished they are in other respects.)

The second Commission met with pretty much the same reception as had the first, and undertook to enforce the same sort of programme which the first had attempted to lay down for Ferran, and with no better results. After breaking off negotiations with Ferran, the second French Commission undertook to collect the statistics then existing (they were in Valencia in the summer) of the results of the human inoculations which were being so extensively practised by Dr. Ferran. In the meantime, however, the Spanish Government itself had appointed three Commissioners to investigate the Ferran question, and those Commissioners had reported that the inoculations were harmless, and that they were made with pure cultures of the comma bacillus of Koch, thus exploding many widely published statements to the contrary, and recommended that they be continued. The statistics collected for and presented to the Minister of Commerce of France by the second French Commission, and the criticisms which have been made concerning them, are practically the only quasi-reliable data which the rest of the world had of the results of the inoculations in Spain. The objections raised against the statistics obtained by Dr. Brouardel (such as they were, strongly in favor of the claims of Fer-

ran), were that they were not detailed enough; that they did not have any real official character, and that they were collected by the partisans of Ferran. The judgment of the world (myself among the number) of course naturally was most uncomplimentary to Dr. Ferran and to his anti-choleraic inoculations. When I reached Spain, however, I found that by that time the official statistics had been collected, and that they had been collected not by the partisans of Ferran, but by the representatives of the Spanish Government, who from the known history of the Ferran question in Spain, at least, cannot be accused of being friends of Ferran.

The Provincial Governments are somewhat peculiar in Spain in that these Governments change with the changes of the Cabinet at Madrid; so that the Provincial Governors always reflect the sentiments of their respective ministers at Madrid. It is no secret in Spain, but very well-known that the Ferran inoculations received no favor, and in fact, active hostility from the Minister of the Interior at Madrid, and the same sentiments towards Ferran personally, and towards his work, were reflected among the political officials throughout the various provinces in Spain, wherein the inoculations were practised. The same also may be said with regard to the Governments of the municipalities; they were also subject to the political influences of the Provincial Governments, and therefore also to those of the Government at Madrid. The Spanish Government ordered at the time of the appointment of the second Commission, that official and careful statistics should be collected concerning the Ferran inoculations, by the usual or by special officers for that purpose. In this manner provision was made for the collection of official statistics, which, by the way, had been collected and published some weeks and months after the publication of the unofficial statistics obtained by the Brouardel Commission. The official statistics are signed and attested in the first place by the physicians of the villages where the inoculations occurred; in the second place, by the municipal judge; in the third place, often also by the president judge of the judicial district in which the village is located; in the fourth place, they are attested by the Curé of the parish; in the fifth place, by the secretary of the municipality, and by the mayor; and lastly, they are attested by the notary public of the district. So that, of official formality, there seems to be no lack.

These official statistics, whatever value they may otherwise have, cannot now be subjected to the same charge which Brouardel made, very justly, against those which he obtained. They still lack detail in many respects, usually failing to indicate the social position and the hygienic surroundings of the persons attacked or inoculated. Such as they are, however, they seem very strongly to support the claim of Ferran that there is an immunity against cholera, produced by the inoculations of the comma bacillus of Koch. The nature of these statistics is such, and their results so striking, notwithstanding their great faults, that it now seems to me imperative that Governments of Europe and of this country, and serious scientists throughout the world should re examine this whole matter for the purpose of getting at the real truth of the question as to whether there is or is not an immunity produced by the inoculations of cultures of the comma bacillus of Koch.

I referred a few moments ago to these inoculations, being the only ones which were made with the comma bacillus to any extent in the human subject. Ferran himself, and one or two other investigators, as a basis for attempts at inoculation in man, claim to have produced immunity in the inoculated guinea-pig. I may say just at this point, that I was very much surprised in India in an interview with D. D. Cunningham, the celebrated cholera authority there (known throughout the world for his investigations), who told me most positively that he had produced such a condition in guinea-pigs which he had inoculated hypodermatically with cultures of the comma bacillus of a certain amount, that it was impossible to kill the same pigs with subsequent inoculations which in fresh guinea-pigs would prove certainly fatal. This is, perhaps, the most important confirmation which the statement of Ferran concerning an immunity produced in animals by means of inoculations by the comma bacillus of Koch, has yet received. I mention this point for what value it may have. I refer to it also as an interesting matter, because it shows that Dr. Cunningham who, after the departure of Koch from India, set himself to work seriously to investigate the relations of the comma bacillus to cholera has radically changed his views concerning Koch's discovery since prosecuting those investigations. From an opponent he has come to be a strenuous advocate of the first part of the claim of the German Commission; that is, that with the comma bacillus we have found a reliable means of diagnosis of Asiatic cholera.

Now I will say, after this short digression, a few words about the result of the anti-choleraic inoculations in Spain, and then will close, feeling that I have already held your time too long.

The published official statistics comprise reports from twenty-two villages in Spain where the inoculations were performed, having among their inhabitants 30,491 inoculated, leaving 104,561 not inoculated. Among the inoculated there were 387 attacks, or 12.69 per thousand, and 104 deaths, or 3.41 per thousand, giving a mortality of the attacked of 26.87 per cent.; whilst among the non-inoculated there were 8,406, or 80.28 per thousand, and 3,512 deaths, or 33.50 per thousand, giving a mortality of the attacked of 41.80 per cent. Now these figures are striking, as you see. I have drawn a diagram which represents, according to the analysis of these statistics, the relative protection of the people against attacks and death by cholera insured by ordinary hygienic measures, sanitary cordons, disinfection, and other measures in vogue at the time, as compared with that of the inoculations. A short line drawn on the diagram being the unit of protection of the inhabitants in the inoculated villages against attack by cholera produced by the hygienic and other measures, this long line represents the degree of protection which has followed

inoculation: that is, a degree of protection 6.06 times greater than the degree of protection from attacks afforded by hygienic and other measures. This short line again being the unit which represents the protection from death by cholera of the general inhabitants afforded by hygienic and other measures. a longer line represents the amount of protection which, according to the statistics, seems to be afforded the inhabitants from death by cholera by the inoculations: in this case it is 9 84 times greater than the protection afforded by the usual measures of hygiene, disinfection, etc. This chart is based, I should state, solely upon the statistics furnished by one inoculation. Ferran himself claims (although the statistics are not full with regard to this point) that the height of the protection comes after a reinoculation; that one inoculation only partially protects, while a second inoculation completes whatever degree of protection there may be from the inoculation. For instance, it is a rare thing to find a death recorded among those reinoculated. Furthermore, I have not attempted to estimate the deaths among the inoculated who might have had the germs of cholera acting within them at the time of the inoculation.

I have diagrams representing the course of cholera in two villages where the inoculations were performed. In the village of Livia, where of a population of 9,460 there were 1,419 inoculated, leaving non-inoculated 8,041, among the inoculated there were 40 attacks and 7 deaths; among the non inoculated there were 561 attacks, and 354 deaths. In the village of Benifayó there is a population of 3,615, and among that number there were 2,723 inoculated, leaving 160 dead and 732 not inoculated; there were also 2,000 reinoculated. A great number of inoculations (2,315) were performed at this point in the course of the epidemic, a day or two before this sudden fall in the epidemic which you notice, and you will see that its course is suddenly brought to a termination.

Now I have made an analysis of the official Government statistics lately published by the Spanish Government of 361 villages in the province of Valencia, and in a few other provinces that were invaded by cholera, with a view of getting at the average course of the epidemic of 1885 in Spain. There were 361 villages, with a population of 996,546 inhabitants, the attacks by cholera being 88 per thousand of the inhabitants. The average duration of the epidemic in these 361 villages was forty-four days; this period was divided into a rise of fourteen days, a stationary period of eleven days, and a decline of nineteen days, the decline being longer than the rise. The epidemic in Spain in this respect coincided with the course of epidemics the world over.

I will end this Ferran matter by saying that, while I do not regard these official statistics of the results of inoculation as by any means conclusive, yet I consider them sufficient not only to warrant, but to imperatively demand that this question shall be thoroughly and scientifically investigated, a thing which has not yet been done, notwithstanding the visit to Valencia of numerous Commissions which have gone there for the purpose of investigating the matter.

When in Spain I investigated 361 villages where there has been an attack of cholera, and the following are some of the points which were brought out by that investigation: In the 361 villages cholera was introduced 211 times by persons already affected or bearing the germs of the disease within them; eighteen times by clothing; fourteen times by sick persons and soiled clothing. It was stated only once that merchandise was the means of the introduction of the epidemic, and only fifteen times did they attribute the introduction of cholera to drinking-water.

I am sorry that I have not time to speak of the hygienic condition of the people of Spain, and point out the fact that it is almost impossible for people living in the irrigated districts of Spain—which are, by the way, the portions which have always most severely suffered from cholera epidemics—to have water which is not contaminated either by their own sewage or by the sewage of villages immediately above them in the course of the irrigation canals; for these canals are used frequently not only as public sewers, when they pass through the town, but they are used also as public lavatories, and as a supply of water for drinking and other domestic purposes. And yet, in Spain and in Italy also, in studying the course of cholera, this matter is usually overlooked. In only fifteen villages did I find any reference to the possibility of introducing cholera by means of the irrigation canals in the replies sent to my inquiries.

One of the statements made by the foreign official Commissions that went to Spain reflected very severely upon the knowledge of Dr. Ferran of the rudimentary principles of histology, bacteriology and microscopy. I can only say that my personal experience in Dr. Ferran's laboratory was entirely different from that. I have photographs of some of his preparations, and I venture to say that no handsomer photographs have been made with a microscope anywhere in the world, and no more handsomely stained preparations of the comma bacillus, and no more pure specimens of the comma bacillus in gelatine have I seen in the laboratories of Berlin or of Paris than I saw in Dr. Ferran's laboratory, modest though it was, in the city of Tortosa, where he lives. I may say that, although Dr. Ferran may be mistaken, and probably is, in some of his claims, especially with regard to the morphology of the comma bacillus, and he may also be mistaken in his views about inoculation, my own personal experience with him, and what I could learn from disinterested sources in Spain from all sides, leads me to believe that instead of being the charlatan he has been represented, he is a gentleman, in the first place, and in the second place a well informed physician, an investigator, and a microscopist of no mean skill; and that whatever he may have stated about this matter of anti choleraic inoculation, it is his honest belief.

I must apologize to you, Mr. President, and to your Society, for having so outrageously taxed your patience, and also for the disconnected manner in which I have had to bring some of these important points to your notice; but it has been impossible for me to do otherwise, inasmuch as during my stay for the last three or four weeks in Washington I have been constantly engaged in the completion of my official re-

port, which I hope to be able to place in the hands of his Excellency the President soon, and I have really not had the opportunity even to properly arrange in my mind what I should endeavor to say upon this subject.

ORIGINAL ARTICLES.

PERSISTENT VOMITING DURING LABOR RELIEVED BY ANÆSTHESIA.

Read before the Medical Society of the District of Columbia, March 21, 1887.

BY SAMUEL C. BUSEY, M.D.,

OF WASHINGTON, D. C.

Nausea and vomiting at the beginning or during the progress of labor is not uncommon. When occurring during the early period it usually ceases with the evacuation of the stomach, or only recurs occasionally. In some cases the patient will vomit at long intervals until the delivery is accomplished. Such vomiting is usually regarded by the laity as beneficial, the popular belief being that "sick labors are easy labors." Obstetricians do not seem to have attached any special significance to the occurrence of such gastric disturbances during the first stage of labor; but when persistent during the second stage, producing exhaustion and lessening the activity of uterine contractions, the safety of the patient may demand immediate delivery.

The complication of labor with persistent vomiting must be very rare, as I have not found a single case reported in detail, after an extensive examination of obstetric literature. Only a few authors casually refer to the subject. The following case, though probably not a unique observation, may prove instructive, in so far as it may attract attention to the subject, and, possibly, suggest a method of treatment not previously employed.

Previous History.—The previous history of this patient is instructive and important, not only because it may offer an explanation of the persistent vomiting, but because it will introduce the details of another rare complication which fortunately did not present the obstacle to delivery anticipated. The mother of the patient was the third child of an "old Englishman and a young Irishwoman," and was the only one of a large family of children afflicted with exostoses, which were mostly located on the long bones in proximity to the joints. The patient is one of eight children of this mother, all of whom inherited this peculiarity of the osseous system. In most of these children the exostoses are located in the neighborhood of the ankle and wrist joints. They have not been observed previous to the seventh or eighth year of age, and have been believed to have followed injury to the bone or joint involved.

The patient had a miscarriage at three and a half months, November 21, 1885, while residing in one of the Territories. Her statement is that she suffered during the continuance of this pregnancy, almost constantly, from nausea and vomiting; that the pains during the miscarriage were very severe, and that the placenta was not delivered until the fourth day. For several weeks following she was confined to her bed with fever, and for three months afterwards she "had hæmorrhages from the womb," so that she was greatly emaciated and reduced in health and strength. During her illness the nurse discovered an exostosis arising from the right ramus of the pubis, midway between the symphysis and inferior spinous process of the right ilium, nearly globular in form and measuring one and a half inches vertically. The patient had been aware of the presence of this tumor from early childhood, but as it had not perceptibly increased in size, nor occasioned any discomfort, had supposed it was normal until informed by the nurse to the contrary. The nurse had also volunteered the information that, in consequence of its position, she could not give birth to a living child at term.

In April, 1886, she consulted me, at my office, with special reference to this statement of the nurse, at the same time expressing a great desire to have a child, and a willingness to incur any reasonable risk. I was quite willing to assure her that the exostosis, located as before described, would not obstruct delivery at term, but declined to express the opinion that she could give birth to a living child, at term, *per vias naturales*, unless I could have the opportunity of a careful examination of the pelvic cavity. To this both the wife and husband finally consented and, by appointment, this exploration was made two days afterwards, at their residence in this city. This examination disclosed the existence of a sharply pointed exostosis jutting obliquely upwards from the inner surface of the ramus of the pubis immediately below the external and larger tumor, measuring (approximately) three-fourths of an inch in length. The upper border of its base seemed to be on the *linea ilio pectinea*; otherwise the pelvis seemed to be normal.

When informed of the existence of this exostosis the emphatic and definite statement was made, in the presence of her husband, that she was unwilling to continue, as she had done since her miscarriage, to deny to her husband the privileges and pleasures of conjugal rights, and that her desire to have a living child was so great that she was willing to incur any danger, short of certain death. These declarations were followed by the inquiry if the bony tumors could be removed, and if such an operation would be more or less dangerous to her than the birth of a living child? To this I replied that such an operation might be performed, but that I thought the chances of survival would be less than from some one of several obstetric procedures which might be expedient in the event that she should again become pregnant.

Then followed the graver question: Could she be delivered of a living child at full term? My reply was as follows: Premature delivery at the seventh, eighth, or eighth and a half month might, under certain circumstances to be ascertained during the progress of pregnancy, be considered the wisest procedure. If permitted to go to full term Cæsarean section or one of its modifications, or gastro-elytrotomy, might be considered the proper methods.

Either of these operations might secure the birth of a living child, but would be attended with considerable danger to her. That craniotomy might be less hazardous to her than either of the other surgical procedures referred to, but the child would necessarily be destroyed. She promptly and positively rejected craniotomy, and expressed a decided preference for one of the surgical methods because they seemed to her to offer better chances for a living child. I then added that I believed, under certain favorable circumstances, she might give birth to a living child at full term *per vias naturales*. These were: a female child, a small and flexible head, a vertex presentation either in L. O. A. or R. O. P. position, or, if the presentation and position were recognized in time, the change of either the R. O. A. or L. O. P. to one or the other of those positions of the vertex, so that the head would descend with the side and not the face or occiput towards the exostosis. If the presentation should be breech the chances would be less, but not necessarily fatal to the child.

She accepted these possibilities with the greatest pleasure, and with exultation expressed her determination to take the chances with the risks. We parted with the agreement that if she should become pregnant I would receive notice as soon as she was entirely satisfied of the fact. To this I reluctantly consented, for I would have preferred to have terminated my services with the expression of my opinion and been superseded by some colleague more anxious than I to witness the possibilities of the future.

Her womanly courage proved equal to her heroic enthusiasm. Late in July I received a note from her communicating the information that she was pregnant and requesting me to call. She dated her pregnancy from the 7th of May. I found her in perfect and robust health, full of enthusiasm, and equally determined as when we parted in April. The whole subject was again calmly and deliberately discussed. I left her with the injunction to give me immediate notice of any symptom of ill-health, and especially of the first movements of the fœtus. On September 8 I was informed that the first sensation of motion of the fœtus had been felt the day before. My examination of the pelvis verified the condition ascertained in April. I could not discover any other obstacle to labor than the exostosis before described. The date of confinement was then fixed for February 7, 1887. I left her with the statement that I would not, if then, interfere in any manner before the completion of the seventh month, unless something unexpected should occur. At this visit, as at every visit made by appointment during her pregnancy, she had a severe rigor with marked trembling. Similar attacks were not infrequent, and were attributed by the patient to "nervousness." They were always relieved by a potation of whiskey without any subsequent ill effects. These tremblings, usually lasting a half-hour, were so general and tumultuous that an examination could not be conducted until they had subsided.

After a careful examination in December, during the early days of the eighth month, I concluded to defer the induction of premature labor, because I was convinced the fœtus was small, probably a female with a small head. Her health had continued, without interruption, good. She thought she never had enjoyed such health as since her pregnancy began.

January 2, 1887, Dr. J. Taber Johnson made a careful examination. We concurred in the decision that she should be permitted to go to term. This decision was accepted with marked pleasure.

Labor began at 5 P.M. on February 8, and terminated successfully at 3:30 A.M., February 9. I arrived at 10 P.M., five hours after the hour named when labor commenced. The os was dilated sufficiently to admit two fingers, and dilatable. The bag of waters was forming but not protruding. The head presented in L. O. A. position. The sutures were easily distinguished. The head was small and flexible. The pains were frequent and sharp, but ineffective. Just at the moment of greatest intensity of every pain violent retching and vomiting would set in, which ceased with shivering. The pains seemed to cease spontaneously with the onset of these complications. The patient and nurse agreed in the statement that the gastric disturbances had continued from the beginning of the pains as I had witnessed them. Her pulse and general condition were good, except that during these attacks her pulse would rise rapidly, sometimes to 120, and then subside during the interval to 80 or 90. There was also a frequently recurring, irresistible desire to pass water. Her courage was unabated, and her cheerfulness and enthusiasm were unimpaired. The bowels and bladder had been freely evacuated before my arrival. The shiverings were arrested by the usual potation of whiskey, which the nurse had refused to allow without my consent. The vomiting not only continued, but manifestly increased in duration and violence, notwithstanding my efforts to arrest it with pellets of ice, alkalies, and hot water. The matter vomited was fluid, very slightly streaked with mucus. The intervals of relief grew shorter and the pains more acutely teasing and worrying. The signs of exhaustion were shown in the more continuous frequency and feebleness of the pulse, varying from 110 to 124, increasing restlessness and anxiety, with a facial expression of suffering and tire, and constant appeals for assistance. From the time of my arrival until midnight there was no appreciable progress in the labor. The relations of the head and condition of the cervix remained unchanged.

With the end of my index finger against the most dependent portion of the bag of waters during a pain, I frequently recognized the simultaneousness of the beginning of the vomiting and subsidence of the uterine contractions, and their correspondence with the moment when the pain or contraction had reached its maximum intensity. If this observation were correct, and the method adopted correctly measured the duration and degree of the uterine contractions, no progress in the labor could be expected during the continuance of the conditions which produced the inertia. Three methods of relief were considered: rupture of the amniotic sac, a rectal injection of chloral hydrate, and anæsthesia. I determined to try the last first and, in the event of failure, each of the others in retrograde succession. At 11:50 P.M. I began the administration of the A. C. E. mixture.

The vomiting ceased; the pulse improved in force and volume, and slowed, and the pains became more direct and distinctly intermitting. After continuing the anæsthesia for three-quarters of an hour it was suspended. The vomiting recurred. The anæsthetic was resumed and not again withdrawn until the head had escaped. The vomiting did not return.

At 1:30 A.M. I ruptured the amniotic sac, and delivery was completed at 3:30 A.M., February 9. The sac was ruptured because its persistence retarded the labor. After the cessation of the stomachal complication nothing worthy of special notice occurred. During the progress of the descent of the head I examined the relation of the head to the exostosis several times. It did not present any obstacle to delivery. There was not upon any part of the child any mark of its impingement. The child, a female, weighed 7½ pounds. Her convalescence was satisfactory, except unusual thirst and hunger during the first day, and delay of milk until the sixth.

The patient was a healthy, robust young woman, bright, intelligent and cheerful, and possessing more than ordinary will-power, self-control and courage. Nevertheless, as admitted since her confinement, she was, from the beginning to the termination of pregnancy, under continuous and very severe mental strain. At times, when disturbed by some perturbating circumstance, such as a visit by appointment from me, the dominating influence of her will would lose its controlling power, hence the rigors and shiverings. These, as well as the persistent vomiting, must be regarded as nervous, perhaps hysterical phenomena. The condition of her health during the period of pregnancy excluded uræmia and every disorder of the chylo-poietic viscera which could have borne any etiological relation to the hyper-emesis. Mental strain with loss of will-power culminated with the onset of labor. The knowledge of the fact that with the beginning of the pains the travail had commenced, to which for nine consecutive months her highest and noblest aspirations, as well as the gravest forebodings, had pointed as the most momentous act in her life, was quite sufficient, even in one so courageous and self-poised, to produce some serious neurotic complication.

The causal relation of the mental condition to the persistent vomiting is affirmed by the fact that obliteration of consciousness, pain and cerebration by narcosis, arrested the stomachal disorder, which recurred upon the restoration of these faculties, but again ceased, not to return during anæsthesia, notwithstanding the contractions of the womb continuously increased in intensity and duration during the same time. The coincidence between the uterine contractions and the vomitings does, however, seem to establish the relation of cause and effect. Sick labors are usually associated with rapid dilatation of the cervix. In this case the os had dilated to two fingers' width (about the size of a silver half dollar) at the expiration of the seventh hour of continuous labor, and dilated much more rapidly after the arrest of the vomiting.

Vesical tenesmus is constantly found in connection with a rigid os, but in this case it was persistent with a dilatable os, and ceased with the vomiting during narcosis. The slowed dilatation was undoubtedly due to the arrest of uterine contraction by the simultaneous attacks of nausea and vomiting. With a dilatable os there was no protrusion of the amniotic sac, and the amount of liquor amnii was small, so that intra uterine pressure could not be considered a factor unless, perhaps, the small quantity of amniotic fluid permitted closer contact of the uterus with the irregularities of the fœtal ovoid. During the first pregnancy the patient had suffered continuously from nausea and vomiting, but during the second she had been entirely free from any digestive disorder. Thus, while I would not deny the reflex relation between the contractions of the uterus and the stomachal complication, the history of the case, and rather singular array of phenomena occurring during labor, together with the relief obtained by semi narcosis, compel me to reject it as the sole or chief element of causation of the persistent vomiting.

This case is another striking illustration of the value of anæsthesia in labor. The contractions of the uterus were concentrated and increased in power. Usually I do not commence the administration of the anæsthetic before the beginning of the second stage, but I have quite frequently witnessed a similar result when, in consequence of some perturbation, the uterine contractions seem to be ill defined, diffused, and as it were wasted. In very many cases anæsthesia expedites labor, in a few it retards it, and in very rare instances it is not well borne, and has to be withdrawn. During the past two years I have most frequently employed the A. C. E. mixture with satisfactory results. It seems to be equally effective in lessening suffering, with less narcosis.

AN UNUSUAL CASE OF LACHRYMAL STRICTURE.

BY H. D. THOMASON, M.D.,
OF ALBION, MICH.

S. C., male, aged 15 years, presented himself at my office two months ago, suffering from, and presenting all the characteristic symptoms of, stricture of the lachrymal duct. There was also a fistulous opening situated below the junction of the canal and duct, making an ugly sore, and discharging tears and pus. This stricture was of several years' standing, and had been annoying, but the fistula was recent, and it was for this that his parents brought him for treatment.

His history was not encouraging—there were strong reasons to suspect hereditary specific taint. He presented an anæmic appearance, had been afflicted with partial hemiplegia since babyhood, and for years had been the victim of severe chronic pharyngeal and nasal inflammation, accompanied with ulceration of the turbinated bones.

I placed him on anti-specific and tonic treatment, and by means of douches and sprays, nasal, post-nasal and pharyngeal, endeavored to modify the difficulty. By means of Ancl's syringe efforts were made to pass a stream through the fistulous opening and the lower punctum into and through the duct, but

unsuccessfully. The fistula, however, healed, but an absolute stricture remained. With a set of Bowman's probes, I decided to dilate the stricture. The patient was of such a nervous temperament that nothing could be accomplished unless under an anæsthetic, which was always employed when the probes were used. The lachrymal canal was thoroughly laid open to its junction with the duct, and a No. 1 probe inserted. This was arrested at a point a little below the junction, but by gentle perseverance this point of resistance was passed. Other slight obstructions were overcome, until, when estimated to be within one-twelfth of an inch of the final termination, an obstinate obstruction was encountered, which conveyed the impression it was an obstruction of bone, and which successfully resisted the further passage of the instrument. A No. 2 probe was easily passed to this point and then arrested. A few days later, again placing the patient under an anæsthetic, beginning with a No. 2 probe, Nos. 3 and 4 were successively passed to and arrested at this same point.

Then, after passing all the set of probes, including No. 8, and being unable to get beyond this obstruction, an instrument was ordered and made by Chas. Truax & Co., of Chicago, of the form and diameter of a No. 8 Bowman probe, but armed with a steel drill at the distal extremity. A regular No. 8 probe was passed to the obstruction and withdrawn, in order to open as well as could be the tract, and the armed probe entered. There was a little difficulty experienced in passing it, owing to the disposition of the sharpened edges of the drill to catch in the membrane, but patience and perseverance overcame this, and the obstruction reached, several rotary motions of the drill were made, and there was no difficulty in detecting when the bone was perforated. The drill was withdrawn, a No. 8 probe passed the entire length without difficulty. The patient experiences great relief, and is in a large measure free from the troublesome symptoms attending a lachrymal stricture.

Albion, Mich., April 16, 1887.

A NOTE ON TANNIC ACID AS A SURGICAL DRESSING.

BY T. J. HUTTON, M.D.,

OF FERGUS FALLS, MINNESOTA.

Tannic acid forms an excellent dressing in three classes of wounds, viz.:

1. Incised wounds—applied after the sutures are inserted, or adhesive plaster is on—if the wound does not require stitching.

2. Small wounds of irregular form and recent occurrence.

3. Wounds of moderate size in compound factures. Wherever applicable it excels all other dressings in the following respects:

1. Convenience.
2. Cheapness.
3. Cleanliness.
4. Efficiency.

It is always ready. It costs but a trifle. It requires no greasy mixing, measuring or muddling and has neither smut nor smell. While of its efficiency I can only say after sixteen years use that I am satisfied: I ask nothing better. I first called attention to this neat, choice dressing in an article entitled "Fifty Fractures in Mining Surgery," which appeared in the *Medical and Surgical Reporter* for September, 1878.

The method of application is simply to keep the wound covered with the powder. Wounds thus treated heal on the average in about one-third of the time required for similar ones treated by liquid, oily or salve dressings. In converting compound fractures into simple fractures by this method, the flesh wound is often healed in one-twelfth of the time required to heal it by wet dressings or salves that are frequently removed and re-applied. Illustrations are unnecessary if I have clearly defined the classes of wounds in which this dressing is applicable. Although hundreds of cases thus treated could be adduced that would prove interesting reading, I will describe the last case only in which this dressing was employed:

F. J., aged 16, German, on January 26, 1887, was struck by a falling tree. Next day he was brought to my office. There was a semi-circular scalp wound six inches in length over left parietal bone, and a fragment of this bone almost the size of a silver quarter dollar, stuck up trap-door fashion. The flaps had shrunk wide apart and were swollen and angry, as the injury had occurred twenty hours previously. The whole wound looked bad, being full of hair, dirt, serous effusion, chips, leaves and brush-wood. The patient was very feeble, but conscious. A dose of whisky and hot water was administered and the wound douched for one hour with warm carbolized water. When the bony fragment had been gently depressed almost to normal position, (I could not succeed in reducing it to the normal level) the scalp-wound was sutured with horse hair. Tannic acid was then applied, and directions given that it be dusted on freely every few hours, more especially if moisture should appear over any part of the wound. A laxative was administered, also small doses of aconite and bromide of potassium.

The flesh wound healed by first intention. No fever ensued; the pulse never exceeded 92. The patient went home on the 31st—the fourth day of treatment, and two weeks later his father reported that he was "all right."

April 9, 1887.

MEDICAL PROGRESS.

INFLUENCE OF ALTITUDE ON PHTHISIS.—SURGEON MAJOR NATHANIEL ALCOCK says: The explanations hitherto offered of the action of altitude upon phthisis amount to three: greater expansion of the chest from aerial rarefaction; absence of bacterial organisms from the air and general tonic effect.[1] Were the first of these effective, some improvement would be expected to follow the use of gymnastics at lower levels; of the second it may be said that every consumptive carries his own microbes with

[1] The Lancet, Jan. 8, 1887.

him; and the third is too vague to need discussion. It may therefore be assumed that no satisfactory explanation has as yet been suggested. The specific organism of tubercle has an established identity; consequently the disease must be ranked among the special infections and its aggravation or arrest must depend upon the fertility or sterility of the microbe to which it is due.

Pasteur, in his splendid researches on the poison of splenic fever, has shown that "splenic fever can never be taken by fowls; in vain are they inoculated with a considerable quantity of splenic blood." "Now, the temperature of birds being between 106° and 108°, may it not be," said Pasteur, "that the fowls are protected from the disease because their blood is too warm? A hen was taken, and, after inoculating it with splenic fever blood, it was cooled down to 100°. At the end of twenty-four hours the hen was dead. Again, a hen was inoculated, subjected like the first to cooling, and when the fever was at its height it was wrapped in cotton-wool and placed in an oven at 95°. In a few hours it was fully restored to health. Hens killed after having been thus saved no longer showed the slightest trace of splenic organisms." Thus it is proved that the microbe of one of the most virulent diseases reaches its condition of highest life and greatest reproduction in blood at a temperature of about 100°, but that in the same blood at 107° it ceases to exist. Presumably, then, if the subjects of some forms of bacterial infection could survive a proportionate elevation of temperature, they too would overcome the poison.

The question here arises, Are there any conditions in which the blood of a living man can be made to assume the molecular action equivalent to a temperature of 105° while the animal heat remains at 98°? Clearly such is quite possible by diminishing atmospheric pressure while the temperature remains fixed. We know that it would be quite impossible to boil water at the sea level with 199° of heat, but if the water be removed to St. Gothard, 6808 ft. high, boiling will at once take place. Professor Thomson, in his opening address at the British Association, said: "It is scarcely possible to help anticipating in idea the arrival at a complete theory of matter, in which all its properties will be seen to be merely attributes of motion." It is already accepted that the only difference between the liquid and gaseous states is that of a molecular motion. Consequently, if 199° of heat can make water boil at St. Gothard, it is apparent that this temperature can there produce an amount of molecular motion which not less than 212° could excite at the sea level. Further, as 199° is to 212° so is 98.4 to 104.8°; therefore the rate of molecular motion to which a temperature of 98.4° would give rise at St. Gothard could only be attained at the sea level as the result of a temperature of 104.8°.

Professor Clifford has shown that "the energy of the single particles is always proportional to the temperature of the gas," provided the pressure remains unaltered. Consequently, since the condition of every organism is but the aggregate of its ultimate atoms, if a man whose temperature at the sea level is 98.4° be removed to St. Gothard, it is evident that both the gaseous and liquid molecules in his blood must attain a rate of motion corresponding to what would have been produced at sea level by a temperature of 104.8°. But the experiment of Pasteur has demonstrated that the optimum temperature of certain infecting organisms is about 100°, and that when the vibration-rates equivalent to 106° or 107° are communicated to their constituent molecules, disorganization follows. Hence, it is intelligible that, if a consumptive patient whose temperature at sea level is 98.4° be raised to an elevation of 6000 ft., such alteration of molecular motion will take place in the blood as to be incompatible with the healthy existence and effective reproduction of the tubercular microbe; in fact, the patient will be placed in the position of the bird to the splenic fever poison. If this reasoning be sound, wide is the vista with regard to the epidemic levels of yellow fever, malaria, cholera, etc., which it must open up, and strange the possibilities which might result from the artificial production of the required conditions.—*Lancet*, March 19, 1887.

Treatment of Boils by Injections of Carbolic Acid.—Dr. Bidder, of Paris, has described a method of treating furuncles by parenchymatous injections af carbolic acid. If the boil is a small one, he gives one injection of a few drops of a solution of carbolic acid (2 per cent.); if it is of median size, two injections are given, the half or the whole of a Pravaz-syringeful of the solution being used on each occasion. In the case of large furuncles, for example, half the size of a man's hand, Dr. Bidder injects at four different spots the contents of four Pravaz syringes half or wholly filled with a solution of 2 per cent. of carbolic acid. These injections are given only once. This treatment is strikingly successful. There is some smarting at the seat of injection at first, but the pain soon disappears, and the next day there is a marked improvement in the patient's condition. The inflammatory swelling subsides very quickly, and in eight or ten days even the largest furuncle is dispersed. By this plan no unsightly scars are left, a circumstance, which in many cases is of considerable importance. The success of the treatment is probably to be accounted for by the fact that either the microbes which cause the disease are killed, or the medium in which they flourish is destroyed—*British Medical Journal*. [This treatment has been in use in America for almost ten years.]

Hypnone.—Von Schüder writes of fourteen patients treated by hypnone, in whom favorable results followed. A dose of from 2 to 4 drops was sufficient to produce sleep of several hours' duration; the effect was especially happy among the phthisical. No ill effects were observed. In one case only, after 6 drops had been given, the patient awoke from a long sleep with headache and slight vomiting. The effect dependent upon the dose and individual peculiarities was manifested after from one-half to one and one-half hours.—*Der Pharmacent*, Feb. 1, 1887.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

The Editor of this Journal would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SATURDAY, APRIL 30, 1887.

THE IRRADIATION OF MOTOR IMPULSES.

If a man perform work with the muscles of, for example, his right hand exclusively, and to the point of fatigue, can he thereafter perform as much work of the same nature, with the left hand as he could if the right hand had not been previously exercised? Such is the question discussed by Dr. N. A. Randolph before the College of Physicians of Philadelphia on March 2. The question does not relate to a comparison of the work of the two hands, but to an examination of the work which may be done by one hand as conditioned by the previous exercise or non-exercise of its fellow; and it is clear that the answer to question depends solely on intracranial processes, and that the answer would throw light on the functional independence or interdependence of the two halves of the brain. And to answer the question two conditions are prerequisite: the subject of experiment must be ignorant of the object of the investigation, as otherwise he will be unconsciously a partisan of one hand, and there must also be a strong inducement for him to exercise his volition to the utmost.

Suitable subjects were found in the persons of some of the more vigorous and intelligent convicts in the Eastern Penitentiary, the stimulus being a money prize to the one who performed the most work in a given time. In the first series of experiments rubber-bulb syringes, identical in all their measurements, were used, the work performed being estimated by the amount of water which the men could transfer from one vessel to another in a given time. The uniform result of some forty observations was that either hand could do more work when its exercise preceded than when it followed the similar exercise of its fellow. "It was found, however, that the muscular effort could not be entirely restricted to one side of the body in this method, as great fatigue was always accompanied by a grimacing and writhing which implicated the muscles of both sides of the face and trunk." In the next experiments a Morse telegraph instrument was used, the muscular movements being restricted to an up-and-down motion of one finger of each hand, the number of such movements in a given time being recorded on the telegraph slip as dots or dashes, in accordance with the rapidity of contraction and relaxation of the flexors of the fingers. The results of these experiments were uniformly confirmatory of those in the first experiment; but the method caused such eye-strain in counting that it was abandoned. A clock-work instrument was then made, so that the records could be made on a dial and easily noted. Six subjects were used, and to each was given fifteen minutes in which to make his record with, for example the right fore-finger, after which the left fore-finger was similarly exercised. The same process was repeated on the following day, but beginning with the finger of the hand used second on the previous day.

These results were also practically uniform. "The man who for fifteen minutes flexed and relaxed his right forefinger with the greatest speed possible to him would, on the following day, accomplish on an average, nearly 10 per cent. less work with that finger when its exercise was consecutive to a similar exercise of the forefinger of the opposite side, than when its work was initial." As a rule, more work was accomplished by the simultaneous exercise of the two forefingers than by their successive exercise. In such simultaneous exercise of both hands, apparently from some unconscious effort at rhythm, it was seen that the movements of the left forefinger were generally more active and rapid than when used alone. This is in accordance with experience of many pianists. It will be seen that these facts are closely related to the observations of Weir Mitchell and Morris Lewis in regard to the knee-jerk. It will be remembered that they have shown that the knee-jerk is reinforced by any voluntary movement in any part of the body, and that this reinforcement is apparently due to such an irradiation of motor impulses from the active centres to other similar centres, as placed them and their related muscles in a condition of heightened responsiveness to external stimuli. Dr. Randolph's experiments seem to confirm this, and show that fatigue of one centre may induce a sympathetic fatigue in other centres. These

observations further suggest that the centres for volition, attention and coördination are not, as regards their functional activity, bilaterally symmetrical and independent; that is to say, "these functions have not attained complete differentiation into right and left will, attention, or coördination; that, probably, the first effect of the voluntary activity of a portion of one cortical motor area is a stimulation of the corresponding portion of the other hemisphere—a stimulation that may result in its slightly premature fatigue; that apparently more work can be effected through the voluntary simultaneous exercise of two such portions of the motor apparatus than by their independent exercise one after the other."

Can we explain Dr. Randolph's facts by saying that the overflow of energy on to symmetrically related centres, or on to others, is competent to weaken them without being strong enough to cause motion? Dr. Weir Mitchell inclines toward the use of the overflow theory to explain the lowered capacity for work by one hand after exhaustion of the other. It will explain why in consentaneous use of two symmetrical parts more work is done than when they follow one the other. The overflow would be in this case valuable, and not damaging or wasteful. He referred to the fact, which he and Dr. Lewis have established, that "When we use the maximum power of one hand on a dynamometer, the coinstantaneous use of the other hand adds nothing to the result; and this form of experiment has been commonly used as a test of the reinforcing capacity of the opposite member. If, however, using two fingers, or the grip of the thigh adductors, on the bulb of a mercural dynamometer until great exhaustion occurs, and we then make a new effort at the moment of violent use of another member, the mercury leaps quite to the level attained during the first effort by unfatigued muscles. It does not seem easy to explain this fact, except by assuming that the overflow of energy usually wasted is in this case made efficient."

This experiment brings up the question of muscular and ganglionic tone. When we strike the patellar tendon, a sudden, distant, voluntary act adds reinforcement. What happens to the muscle or ganglion so influenced? Is it made more sensitive to impressions, or is there with this a slight flow upon it of motor energy? And if so, can we measure the effect, and thus influence what we conceive of as muscular tone? Dr. Mitchell has been engaged in discovering if these reinforcements do cause motion —*i. e.*, a slight preparatory muscular contraction making the subsequent volition, or other excitatory activity, more potent in its results. He has been able, so far, to prove that in some spastic cases distant muscular effort, such as a grimace, really causes distinct and measurable movement in the extensors of the thigh and presumably elsewhere. But it is not yet clear whether in *normal* man remote motion is thus capable of causing slight shortening of all other muscles. We often speak, says Dr. Mitchell, of nerve power as if there were a common stock from which are drawn the supplies needed by every active organ, and reason that it is unwise to try to carry on at once two functions which exact large expenditures—as digestion and intense thought, or digestion and exercise. Practically the difficulty may be one chiefly of blood supply. This is illustrated in the not rare fact that some feeble people cannot digest except when at rest. These facts suggest the idea that perhaps Dr. Randolph's cases would lose 10 per cent. of mechanical capacity after a period of exhausting mental labor or during digestion.

In regard to the old theory for explaining the principle of counter-irritation, that there is a certain amount of nerve force in the system, and that when by means of counter-irritation the nerve force is drawn to a distant point, it is removed from the inflamed part, we may agree with Dr. H. C. Wood that, while modern science does not recognize the truth of this theory, it looks as though there is a certain amount of truth in it. "Every one who has worked in a gymnasium will recall the fact that he cannot use the two hands simultaneously with the same force as he can when the two hands are used separately. This shows some relation between the nerve centres which we have not as yet got at." It would seem that when we use our muscles vigorously, two kinds of fatigue are produced; a local fatigue and a general fatigue. If a man uses the right arm vigorously, he not only fatigues the right arm, but also the whole body. Dr. Wood believes that if these investigations are continued, it will be found that after prolonged use of the leg, there will be loss of power in the arm, perhaps as great as after previous use of the other arm. As suggested by Dr. Mitchell, "the relation between muscular exertion and mental exercise should be studied. Each one knows by personal experience that when mentally fatigued he is incapable of performing the usual amount of physical labor. This is probably independent of any question of overflow, and goes back to the higher cerebral centres and their relation." As suggested by Dr. Mills, it is a well-known clinical fact that an old hemiplegic, if examined carefully, will be found to have not only the decided loss of power and

accompanying conditions resulting from the lesion on the opposite side of the brain, but also a certain diminution of strength in the limbs of the other side; a condition which is not entirely due to the general loss of physical power present. The phenomena exhibited in certain cases of unilateral spasm seem also to be related to this subject.

Experiments such as those of Dr. Randolph are not only of great interest in connection with pure physiology, but also in connection with psycho-physiology, or physiological psychology, which is now receiving more and more attention, and on which Prof. Ladd, of Yale, has recently written a most valuable book.

ANNUAL REPORTS OF PUBLIC HOSPITALS.

The twenty-sixth annual report of the Cincinnati Hospital, which has just been laid on our table, reminds us of the many and great advantages that would result, if all public hospitals for the sick and injured were required to make full annual reports, for which the one before us would afford an excellent pattern. It is a neatly printed pamphlet of only 78 pages, yet contains a concise description of the hospital buildings; full list of the officers, medical staff, resident physicians and nurses; complete financial statement of all receipts and expenditures, including every item of quantity and cost; the number of admissions and discharges, medical, surgical, obstetrical and gynæcological, with the particular disease or accident affecting each patient, and the results of the treatment; and also the total number treated during the year, the average time in the hospital, the total cost and the average cost per day per patient. If every public hospital containing fifty or more beds would publish annually a complete official report on the model given us in the twenty-sixth annual report of the Cincinnati Hospital, we would soon have the materials and data for solving many important problems, both economical and medical much more satisfactorily than at present. Enough can be gleaned from the few, and often important, reports of hospitals now furnished to the public, to show great differences in the expenses per patient in different hospitals, even when located in the same city, and apparently receiving the same class of patients; and almost as much disparity in the results of treatment, both in the general aggregate and in relation to particular diseases. Thus in one hospital the total cost per day for each patient is given at about $1.20 and in another at only 0.67\frac{7}{10}$. In the report of the Cincinnati Hospital the net cost per patient per day is given for each year from 1868 to 1886 inclusive, and varies from 47.7 cents to 72.6 cent. The percentage of deaths to the whole number of patients was 6½, that of typhoid fever alone nearly 17, and that of pneumonia 45 per cent.; while in another hospital the ratio of deaths from typhoid fever is only 5 per cent. and from pneumonia less than 15. A series of official reports from the public hospitals of different cities would enable us to explain these important differences, and deduce practical lessons of much value.

AMERICAN PUBLIC HEALTH ASSOCIATION.

The preliminary circular announces that the next annual meeting of this important organization will be held in Memphis, Tenn., November 8, 9, 10, 11, 1887. The Executive Committee have selected the following topics for special consideration at the meeting: *a.* The Pollution of Water-Supplies; *b.* The disposal of Refuse Matter of Cities; *c.* The disposal of Refuse Matter of Villages, Summer Resorts and Isolated Tenements; *d.* Animal Diseases Dangerous to Man. No more interesting or important topics could be selected for the thorough study of the Sanitarians of this country at the present time. All papers intended for this meeting should be plainly written or printed, and be in the hands of the Secretary at least twenty days before the date of the annual meeting. Notwithstanding the enumeration of the topics mentioned, it is understood that papers of merit on other subjects will not be excluded. George M. Sternberg, U. S. A., Baltimore, is President, and Irving A. Watson, Concord, N. H., Secretary.

American Surgical Association. — The next annual meeting of this organization is to be held in Washington, D. C., commencing May 11, 1887, and is expected to continue three days. The preliminary programme contains a list of many papers, furnishing interesting topics for discussion. Hunter McGuire, M.D., Richmond, Va., is President, and J. R. Weist, M.D., Richmond, Ind., Secretary.

State Medical Society of Wisconsin.—The next annual meeting of this Society is to be held at Oshkosh, commencing on Tuesday, May 3, at 8 o'clock P. M. Reports of such a number of Standing and Special Committees are expected as to make a full amount of interesting and profitable work for the meeting.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, March 2, 1887.

The President, Jos. Taber Johnson, M.D., in the Chair.

Dr. S. C. Busey read a paper entitled

PERSISTENT VOMITING DURING LABOR RELIEVED BY ANÆSTHESIA.

(See page 484.)

The President stated that he had seen the cases reported by Dr. Busey and would confirm his statements. He suggested that in addition to the subject for discussion mentioned in the paper, the subjects—"Exostosis as a Complication of Labor," and "Anæsthesia in Labor" be discussed.

Dr. L. Mackall said that he had recently attended a case of labor in which the use of anæsthetics had not only proved efficacious in relieving very distressing nausea and vomiting but also promoted a speedy delivery. He was called in January last to see Mrs. C—in her second confinement. Arriving between 10 and 11 o'clock P. M., he found the os dilated to the extent of a silver dollar, and dilatable; the bag of waters protruding; the vagina relaxed and the pains recurring at short intervals but not expulsive. Up to this time nausea and vomiting were not present, and from the favorable state of the patient he anticipated a speedy delivery. She soon began to complain of sick stomach, which became distressing, with frequent retchings and diminished frequency of pains.

He found upon examination about an hour after his arrival that labor had not only not advanced but that the soft and dilatable os had become rigid and unyielding. During the next two hours there was much sick stomach and frequent emesis of mucus and water. The pains were diminishing in strength, were not all expulsive. Between 2 and 3 o'clock A. M. he made another examination and found that there had been no advance in labor and that the os was quite as rigid as before.

He felt convinced that the irritable stomach and the tardy labor were due to a too great determination of nerve force to the solar plexus, thereby depriving the hypogastric plexus of the requisite amount of force necessary for the accomplishment of labor, and that in order to overcome this abnormal state he had either to administer by the stomach some agent capable of relieving the overcharged nerve center, or would have to resort to an anæsthetic, which by its action on the cerebro spinal system, would probably withdraw nerve force from the solar plexus to the cord and that then a due determination to the hypogastric plexus would take place. He resolved, in order to accomplish the desired end, to try first a cupful of crushed ice given as rapidly as could be swallowed, as he had previously learned that ice so administered not only allayed gastric irritability, but quickly promoted efficient uterine contractions and prompt delivery. In this connection, he felt it incumbent upon him, to again make special reference to the good effect of ice when properly administered in labor attended with inertia, and he was satisfied, that many cases occurred where, if it had been administered, the use of forceps might have been dispensed with. He could recall a case where uterine contractions had ceased almost entirely, although large and repeated doses of ergot had been given, and the application of the forceps seemed inevitable, but before using them, he gave a large teacupful of ice as rapidly as could be swallowed, with the result of restoring efficient pains and a rapid delivery.

In the case under consideration, however, the crushed ice failed to accomplish a good result, so he determined to put the patient under the effects of the "A. C. E." mixture. Six or eight inhalations, during pains, reduced her to partial unconsciousness.

After the first inhalation there was no recurrence of the nausea or vomiting, and the character of the pains quickly changed, becoming strong and expulsive. The os was found to have lost its rigidity and to be rapidly dilating, and in a half hour the child was born. Contraction of the uterus promptly followed with expulsion of the placenta without hæmorrhage.

In referring to a statement made in Dr. Busey's paper, that nausea and vomiting were regarded by many as favorable to the progress of labor, Dr. M. stated that this might be true if the vomiting resulted from reflex action due to a rapid dilatation of the os, but that in those cases this condition should be regarded as the effect not the cause. In other cases where the nausea, vomiting, pyrosis, etc., resulted from great irritability of the stomach, caused probably by a sudden determination of nerve force to the solar plexus, he had found that no favorable or decided progress was made until these symptoms were relieved by appropriate treatment. Indeed he rather dreaded such cases, for he then anticipated that probably many hours must elapse before the patient and doctor would be relieved.

Dr. L. Eliot related a case also attended by vomiting. When called he found the os dilated and every evidence that the labor was progressing. After trying various remedies without effect, tincture of iodine finally controlled the vomiting, but the pains ceased. He had her sit up in bed for awhile and in two or three hours she was delivered.

Dr. J. F. Hartigan has used anæthesia in cases of tedious labor with satisfaction. We should be cautious in its use and the selection of the anæsthetic. For instance, the primary effect of chloroform was upon the heart, while ether is known to have produced hæmorrhage from the air passages and lungs. The "A. C. E." mixture, he thought, was the safest and most popular.

Dr. L. Mackall referred to the recently published article of Dr. Fordyce Barker upon the subject, in which he claims that chloroform is perfectly safe.

The President remarked that he preferred chloroform in labor, and that he used it in perhaps seven-tenths of his cases. He only used it, however, ex-

cept in operative procedures, when the patient asked for it, and he began giving it in the latter part of the second stage. He puts twenty to thirty drops on a handkerchief and allows the woman to inhale it herself just as a pain is coming on. In this way she gets enough to dull her sensibility to pain, but not enough to keep her unconscious between whiles. In a large number of cases there may be a few instances in which anæsthesia has retarded labor enough to make the forceps necessary, but he does not think that it will produce post-partum hæmorrhage. On the contrary, the restlessness and exhaustion produced by a long labor without relief is much more likely to cause hæmorrhage than the chloroform. He prefers chloroform to ether in heart or kidney disease.

Dr. T. C. Smith thought that anæsthesia did sometimes help post partum hæmorrhage.

Dr. Busey has seen hæmorrhage follow anæsthesia, but he did not attribute hæmorrhage to it, but rather to protracted and exhausting labor. Chloroform was safer than ether, but the "A. C. E." mixture was superior to any. Narcosis was not so profound as by the former while it is just as effective in relieving pain. Although anæsthesia is a great boon in midwifery, it may sometimes prolong labor instead of expediting it.

Stated Meeting, March 16, 1887.

The President in the Chair.

Dr. D. S. Lamb presented the specimen and read the history of

A CASE OF OSTEOMALACIA.

Dr. Mary Parsons reports the following history: Charlotte J., white, single, Virginian, seamstress. In November, 1865 (she was then 47 years old), while walking home one day, she was suddenly seized with severe pain in dorsum of left foot; this was found to be swollen and reddened. The pain continued through the night. The late Dr. W. B. Magruder was called in the morning. After careful examination he failed to find the cause of the trouble. The pain, redness and swelling recurred at intervals for two years, sometimes preventing sleep and finally interrupting her work. In the autumn of 1867, after an unusually severe paroxysm, lasting several weeks, she fell and sprained her left ankle, for which she was treated by the late Dr. S. B. Blanchard. She kept her bed several months and never resumed her regular occupation, but did some sewing at her house. She was able to get about the house with comparative ease and sometimes walked short distances. About a year later she had a second fall and another severe sprain of the same ankle, after which she walked with much difficulty and had constant pain. In 1872, unable to earn her living, she was admitted to the Home of the Women's Christian Association. She then walked with a cane, waited on herself and took care of her room. November 15 she was sent to Columbia Hospital. She had then constant pain in her left leg and ankle, pain along course of post-tibial nerve, and some œdema about the ankle. Treatment seemed of no benefit. Dr. J. Harry Thompson removed a portion of the nerve at the seat of the severest pain. Wound healed by first intention, but no relief followed. She returned to the Women's Home. She now went on crutches and with great difficulty; pain more severe. Six weeks afterwards she had an unusually severe paroxysm of pain in the foot, which was reddened and swollen; she was put to bed and never left it again in fourteen years. During this time she had constant and severe pain, sometimes excruciating; she became emaciated and anæmic; the toes of the left foot became flexed, finally causing ulceration of the under side of the foot; foot œdematous, œdema extending to knee. Diet generous, her fancies gratified, but she never improved in her general condition. She often had "drawing" pain in the foot, and just before a storm extending to the thigh; and spasm of the leg which gradually diminished as the disease progressed. For several years she did fine needlework and depended on conversation for pastime, being unable to read. About 1881, she had irido-choroiditis of left eye, which recurred sometimes in one eye, sometimes in the other, and at times in both. In December, 1885, an ulcer appeared on the right cornea, and perforated; eye removed by Dr. S. M. Burnett. During these years the pain steadily increased, the foot rotated outwards, and in 1885–6 the leg rotated outwards at the knee. The œdema increased and the limb became a shapeless mass. For the last six months of life she could not lie down because of the "drawing" pain. Her pains increased much in stormy weather, and this led many physicians to diagnosticate rheumatic arthritis. Her appetite became capricious, constipation obstinate, urine scanty and loaded with urates. Through her later years she was a marvel of patient endurance. Died June 15, 1886.

Necropsy by Dr. D. S. Lamb: Body much emaciated; bedsores on buttocks; right eye had been removed. Right lower limb œdematous; left, flabby; linear white scar on inner side of left ankle; eczematous scabs above ankle; muscles of limb showed fatty atrophy; bones of thigh, leg and foot atrophied, the atrophy increasing from above downwards. The compact substance was thin, porous and very friable; in some places so soft as to be cut with a knife without turning its edge; the cancellous substance appeared as plates and fibres loosely held in a mass of white granular matter, largely composed of fat, in some places of a gelatinous appearance, filling all the medullary canals and spaces. Brain showed increase of subarachnoidal fluid; cysts of choroid plexus. Old pleuritic adhesions both sides, especially at apices, under which was fibroid induration; both lungs showed red and gray hepatization in lower lobes. Heart normal: aorta and pulmonary artery congested on pericardial surface; aorta showed fatty degeneration. Liver somewhat atrophied; gall bladder full. Spleen somewhat atrophied. Pancreas normal. Stomach normal. Small intestine full of flatus. Large intestine contained much soft fæces which excessively distended the rectum. Right kidney cirrhotic; surface showed many minute aqueous cysts and about

a dozen prominent yellowish masses, size of pinheads and larger, which on section turned out granular matter; at lower end of kidney was a sarcoma, size of small walnut, encapsulated, and slightly encroaching on kidney tissue; mulberry calculus, weighing 10 grains, found in pelvis. Left kidney cirrhotic; small superficial aqueous cysts. Right suprarenal capsule of usual size; left not noticed. Bladder normal. Uterus and appendages atrophied. Lower aorta and common iliac arteries showed chalky plates. Left external iliac artery normal; no obstruction. Lumbar glands normal.

The history and necroscopy of this case correspond so closely to those of mollities ossium or osteomalacia that I am inclined to that diagnosis.

The disease is very rare. Dr. Fagge, in his "Principles of Medicine," 1886, states that he had seen but one case, and that in the care of his uncle, Mr. Hilton, at Guy's Hospital, in 1864. Ten out of every eleven cases occur in the female sex, and two out of every three in women, either during pregnancy, shortly after parturition, or about the time of the climacteric. The age is usually between 25 and 35, rarely under 20 or over 50. The cause is speculative, although many cases seem to have a dependence upon dampness. The earliest symptom is pain, varying in seat and character, sometimes "wandering," and then leading the physician to the diagnosis of "rheumatism." Lassitude, irregular appetite and constipation are usual symptoms. Gradually locomotion becomes difficult and the patient is very liable to fall. In consequence of falls, and, indeed, sometimes even on slight motion, fractures occur, with little or no tendency to heal, and accompanied, therefore, by deformity. Eventually the patient is confined altogether to bed, becomes emaciated, exhausted, and dies. The duration of the disease is usually four to six years, but cases are recorded of its terminating in death in three months, and again lasting for eight, ten, or even fifteen years; in the case now reported, nearly twenty-one years. I see no reason why it may not endure for any period within the ordinary limit of life.

Why the bones should be thus decalcified and softened, so that they can be readily cut with a knife, is not yet clear. Lactic and carbonic acids both have been assigned as the causative factors. No excess of phosphates or carbonates of lime is found in the urine except incidentally; although, as in this case, calculi are found in the kidney and bladder in many cases. The inorganic portion of the bone may be reduced to 30 per cent., the diminution in lime being much more relatively to that of its combining acid. The compact tissue may become a mere shell; the cancellous tissue sometimes seems like medulla, of a deep red color with ecchymoses; sometimes yellow, soft and fatty; sometimes mucous and translucent. This softening may cause deformity of the female pelvis and thereby difficult parturition; and the softening of the ribs may be so extreme as to stop respiration. The disease differs from rickets in this: rickets is due to a failure to deposit the calcareous salts; osteomalacia to the removal of the salts after deposition.

DR. E. O. SHAKSPEARE, of Philadelphia, then addressed the Society upon

SOME NEW ASPECTS OF THE CHOLERA QUESTION SINCE THE DISCOVERY BY KOCH OF THE COMMA BACILLUS.

CHICAGO GYNÆCOLOGICAL SOCIETY.

Stated Meeting, Friday, February 18, 1887.

PHILIP ADOLPUS, M.D., IN THE CHAIR.

(*Concluded from page 472.*)

DR. A. REEVES JACKSON exhibited

TWO DERMOID CYSTS OF THE OVARY.

Case 1.—First seen by me May 27, 1884. Julia C., aged 40 years, was married at twenty, had one child two years later, and no other pregnancy. Commenced menstruating at 17, and was regular after the first year. Always had good health. Five month ago, weighed 176 pounds. Three and a half months ago she took a long walk in the evening, while menstruating. After her return she had a slight chill, and severe pelvic pain, the latter chiefly referable to the bladder, micturition frequent and painful. She seemed never to recover her health; vesical symptoms continued, appetite and nutrition failed; she became rapidly emaciated; a swelling appeared in the lower abdomen; menstruation appeared regularly and without pain. She could not walk, but rode out in a carriage. A few days before I saw her she rode out, with enjoyment, but returned fatigued and soon began to vomit. Her upper extremities moved involuntarily, and there was a complete loss of power in the lower ones. A "metaphysician" was called to see her and gave the assurance that there was no bodily ailment—the mind only was at fault. The assurance was repeated twice a day by the Christian scientist, who on these occasions sat out of sight of the patient, the headboard of the bedstead separating them. However, the patient and her friends thought she was getting rapidly worse, and I was asked to see her. At the time of my visit she was lying in bed on her back. Her hands and arms were in constant motion; she seemed powerless to keep them still a moment; she could make no co-ordinate movements, indeed had no control whatever over either the upper or lower extremities; the latter were, however, motionless. The functions of the bladder and bowels were voluntary; the tongue dry and covered with a brownish coating; there was great thirst; pulse 110, small and almost imperceptible at the wrist. The temperature was not observed. She was very restless, and had not slept more than ten minutes at one time during the past three days. At short intervals she vomited a greenish, frothish, tenacious fluid. On examination I found the abdominal walls soft and free from tenderness on pressure. There was a feeling of doubtful fluctuation with dulness at the sides, also in the right iliac region. The higher parts of the ab-

domen, as the patient lay on the back, were resonant. She died the following day, and in the evening an autopsy was made with the assistance of Drs. Brower, Danforth and E. Ingals.

On opening the abdomen we found besides other evidences of acute inflammation the exudation of perhaps a quart of pus. As this was being removed it was discovered that its source was a partially collapsed cyst, which still held about one pint of pus, and from the opening through which the pus came there protruded a few hairs. This fact settled the diagnosis. The woman had died of a ruptured dermoid cyst. The kidneys showed evidence of chronic disease. The cyst with the ovaries and Fallopian tubes, was removed. Here I show you the opening, which was somewhat enlarged after the autopsy for the purpose of freeing the inner portion of the cyst. In addition to the hair there were also some rudimentary teeth and some plates of bones which I sent to a pathologist for examination, and received from him a photograph showing the bony constituents of the cyst. Apparently all of the dermoid tissue was centered in this space. The amount of hair was large, as you see. This was matted together in the usual manner, and has been freed from the sebaceous matter which accompanied it by shaking it in ether. This is a miniature switch made by an artist in such matters from a portion of the hair. These dermoid cysts, of which I have now seen three, possess great interest to me, pathologically. I confess to not understanding them, so I asked Professor Fenger to be here to night, and he promised to bring some additional specimens and to talk about them.

Case 2. Dora B., 35 years old, wife of a physician residing at Normal Park. Saw patient on February 10, 1886. Married fourteen years; two children, age respectively 11 and 7 years; also two abortions, one three years and the other two months since. Nine months ago, while lying on her back, patient noticed a swelling the size of an orange in the right iliac region. It was soft, smooth, movable and insensitive; has slowly encroached on the opposite side; five days ago, after sneezing, experienced a sharp attack of pain in pelvis which lasted twenty-four hours, keeping her in bed. I found on examination an abdominal tumor occupying the hypogastric and right iliac region, extending upward as high as the umbilicus, and into the left iliac fossa. On February 23, she entered my Infirmary, and the tumor was extirpated on the 25th. It weighed about eight pounds. There was a main cyst, containing a limpid serum, and inside of this a smaller cyst about the size of a mandarin orange, containing bone and hair. This tumor possesses an interesting feature that I have never observed before in either of the cases I have seen. It is this, there are two distinct kinds of hair, one of an auburn color, very curly, portions of which are still attached to the part, and two tufts springing from other portions of the rough, orange-rind like skin, which are long and straight, quite free from curl, and of an entirely different color. The kinds of hair that I have seen from other specimens, while they have usually differed in color from the patient's hair, have always been uniform throughout. In the first case I saw, several years ago, the hair was thirty-six inches long. In that case, the part from which the bony substance and hair sprang were in one part of the tumor, occupying a small space. The patient had carried this for many years without symptoms. Finally, it commenced to grow and formed a tumor sufficiently large to attract her attention. There were two cysts. The first one was a very large one, containing a semi colloid matter very much resembling soft soap, and in great abundance. Separate and distinct from this there was a cyst not larger than a goose's egg, soft, and which could be indented readily, and when it was opened there came out a mass of hair together with other dermoid characteristics. So it seemed that the cyst which contained the fluid and made the growth perceptible was secondary, and this fact would account for the clinical fact of these patients carrying a tumor for many years without any impairment of health, until an additional cyst is formed, that may present any of the characteristics of an ordinary ovarian cyst.

Dr. Christian Fenger made some remarks on

DERMOID CYSTS OF THE OVARY,

with illustrations from specimens:

In entering upon the question of the dermoid cysts of the ovary, I wish to call attention to the two theories of their origin. According to Heschl, dermoid cysts in general owe their origin to isolated islands of the epiblast, displaced during embryonal development and located somewhere in the territory of the mesoblast. This theory of fœtal inclusion did not explain the origin of the dermoid cysts in the testicle and ovaries. It was not until his had shown that the internal genital organs are developed from a part of the embryo, the so-called "axenstrang," in which all the germinal layers are included, that we were able to understand the presence of dermoid cysts in those genitary glands.

The second theory of the origin of dermoid cysts in the ovary is the view of the older authors, recently adopted by Waldeyer. Epithelial cells of the ovary, capable of transformation into the ovum with all its formative possibilities, may enter into an irregular formative activity and produce a dermoid cyst—a process almost analogous to a partheno-genetic development, as Ohlshausen states it. This second theory would only explain the origin of dermoid cysts in the ovary, and would not enable us to understand their presence in all other parts of the body. Consequently, it seems more natural to accept the Heschl-His theory, as this gives a satisfactory explanation of the origin of dermoid cysts in general, and is in conformity with Cohnheim's theory of the origin of all other new formations, from an isolated group of embryonal cells, dormant until the unknown cause of the new formation calls them into formative activity.

A dermoid cyst is always a monocyst, and if, as is seldom the case, we find more than one in the same ovary (Ohlshausen in one case found three), we may expect to have had more than one embryonal matrix,

from each of which a cyst has developed, the one independent of the other. It often appears as if a dermoid cyst of the ovary were a multiple one, but closer examination will prove that we have before us a combination of a dermoid cyst and a proliferating cystoma, or more rarely a dermoid cyst with multiple local colloid degeneration of the stroma of the wall. Cystic transformation of the sweat glands —extensive cysts to the size of a fist—was seen in one case by Friedländer.

I shall not go any further into the subject of the dermoid cysts here, but only present to the Society three specimens removed by laparotomy within the past year, and will call attention to the points of interest illustrated by each one in particular.

Case 1.—This specimen, at the time of the operation the size of a fist, now much smaller from shrinking in the alcohol, was removed from a girl of 20. There was no difficulty about the removal, but I am sorry to say the patient died from acute sepsis thirty-six hours after the operation. Besides the sebaceous matter and the hairs, which you have already seen in Dr. Jackson's specimens, we find in dermoid cysts very commonly—in from 20 to 50 per cent. of the cases—teeth inserted in the soft dermoid wall or in pieces of bone contained in the latter, or finally, free in the contents of the sac. As a rule, there are only a few teeth in a cyst; but Schnabel has seen, in a case of a girl of 13, over 100, and Autenrieth describes a case in a 22-year-old woman, in which 300 teeth were removed and as many more left in the cyst. As Ohlshausen states, it is impossible to understand the presence of such numbers of teeth without the explanation that, the same as in children, multiplication of the enamel germ takes place, and a set of milk teeth are followed by a set of permanent ones. That this is more than a mere theory is proved by a specimen in Rokitansky's collection in Vienna, in which there is seen a milk tooth with the root absorbed down to the crown by atrophy from pressure of the overlying permanent tooth. Spencer Wells, in his "Ovarian Tumors," states that he has seen one similar instance. In the specimen before us this fact is illustrated to perfection. From the soft parts on the surface of this little piece of bone, in the wall of the cyst, you see attached a tooth corresponding in shape and size exactly to a temporary incisor of the upper jaw. I have made an incision through the gum, if we may use that expression, and, as you see, the root is absorbed almost down to the crown. When we turn this milk tooth to the side, we see the crown of the overlying tooth. This is larger, and has the exact shape of the corresponding permanent incisor.

Case 2.—The next specimen is a very large dermoid cyst, from the left ovary of a woman at 50. It filled the whole abdominal cavity up into the cardia and gave the exact symptoms of a proliferating cystoma or multiple cyst, as there were felt, besides the main cavity, harder, lobulated portions, which I supposed to be smaller and more tense cysts. As she gave the history of a cyst which ruptured when she was 14 years old, causing months of suffering from peritoneal symptoms and then disappeared, not to return until after the age of 45, I thought that a dermoid cyst was out of the question. At the operation, which was difficult on account of many adhesions and the nature of the contents of the cyst, I found this very large dermoid cyst, containing—(a) Three or four gallons of a brownish fluid, in which floated hundreds of thousands of round, yellowish-white, small bodies, the size of a hemp seed up to a pea. I pass round a sample of them in these two glasses. These bodies are soft, have the consistency of butter and are found under the microscope to consist of irregular masses of amorphous fat, with pavement epithelial cells interspersed here and there, single or in groups; (b) A yellowish-white, butter-like mass the same as the small bodies if matted together, filling up entirely some of the chambers of the cyst, with no fluid mixed with it. This peculiar arrangement of the fat is rare. Rokitansky saw in a cyst seventy bodies the size of a hazlenut, and very many the size of a pea swimming in a brownish fluid. Routh, according to Spencer Wells, saw a similar case, the balls showing under the microscope concentric layers of amorphous fat around a nucleus of cholesterine crystals. Franekel, cited by Ohlshausen, found the whole contents of a dermoid cyst to be numerous hard, mostly round or irregular balls, consisting of amorphous fat, fatty degenerated epithelial cells and hairs. The shape of the cyst is peculiar, inasmuch as it gives the appearance of a conglomeration of cysts, But close inspection shows that all of these communicate with each other so as to form one large, though very irregular cavity. Thus, in reality, we have before us a monocyst, characteristic of the dermoids, as I mentioned before. In the wall, however, we find a number of smaller cysts the size of a pea to a hazlenut—these do not contain the same fatty material as the main cyst, but a colloid mass, and are due to secondary colloid degeneration in the wall of the latter. The inner surface of the large dermoid cyst shows in some places irregular masses of bone imbedded in the wall, and further, as in Dr. Jackson's cases, the following condition: We do not find typical skin with hairs, sebaceous glands, epidermis, and so on everywhere on the inside. This is found on only part of it, forming one or several irregular islands. The remainder of the cyst wall is smooth, has the characteristics of an ordinary cystoma, with a single layer of epithelial, cuboid, or cylindrical cells. It may be that the dermoid portion of the wall secretes the fat and the cystoid portion mainly a serous or albuminous fluid. Movements of a cyst containing at the same time a thin serous fluid and sebaceous matter might (Rokitansky) shape this suspended fat into the small round masses just the same as butter when in the process of churning. However, if this was the right explanation, it appears, that this peculiar formation is seen only in very exceptional cases. The right ovary was transformed into a dermoid cyst the size of an orange. Notwithstanding the dermoid cysts on both sides, the woman had a number of children, the youngest 16 years old at the time of the operation. The patient never rallied from the shock of the operation, and died twelve hours afterward.

Case 3.—The third specimen is a dermoid cyst taken from a girl of 23. It was noticed for about one year and a half before the operation, at which time it was one and a half times as large as a child's head. There was no particular difficulty about getting it out. When I opened the abdomen and came on the cyst it was transparent, so that I did not think it was a dermoid cyst, and I inserted a Köberles trocar, which, of course, we should never do in dermoid cysts if we can help it. Immediately the trocar was stopped up by what I found later was a mass of hairs and sebaceous matter, so that I had some difficulty in keeping the abdominal cavity clean. However, she recovered without any greater trouble than a little abscess in the abdominal wall from one of the sutures.

Before demonstrating the specimen I wish to make a few remarks in regard to malignancy of dermoid cysts. As a rule, we regard a dermoid cyst as a benignant new formation, and a malignant character is here a rather rare exception. We make a distinction between malignancy of a dermoid cyst, *per se*, and malignancy from a combination of dermoid cysts with carcinoma or sarcoma. The malignancy of a dermoid cyst as such is very rarely seen. Kolaczek relates a case, operated upon by Martini, in which, besides a common dermoid cyst with a perfectly smooth surface, there was found in the walls of the peritoneal cavity small nodules in great number, the size of a millet seed and of a yellowish color. Many of these little tumors had a light-colored hair sticking out from their centres into the peritoneal cavity. Similar were seen in a case operated upon by Billroth, reported by Fraenkel.

Malignancy of a dermoid cyst from combination with carcinoma, sarcoma and myoma. These tumors originating in the tissues of the cyst are not so very seldom met with, and have been observed more commonly of late years, because a more minute microscopical examination is made now than in former years. Ohlshausen mentions as bearing upon this subject, a statement of Doran, that he had seen in several instances malignant tumors of the abdominal cavity follow extirpation of dermoid cysts. On examining the main wall of the specimen before us, we find on the dermoid island with its hairs and a plate of bone in the wall, the following unusual formations:

(a) A large black mole. It is of irregular lobulated shape, two by three inches in diameter, slightly elevated over the surrounding skin, and has a velvetty uneven surface without hairs. Microscopic examination shows the common structure of pigmented moles, which, as you will remember, has a great similarity to that of a sarcoma.

(b) A papilloma the size of a pea. You will see it outside of the mole on the skin over the bony mass. It is surrounded by a thick wrinkled skin beset with hairs. On transverse section it shows a solid centre covered with the pointed excrescences, resembling exactly a large wart with long papillæ, as we sometimes find them on the skin of the hand. A detailed microscopic examination and description of all the specimens is not as yet finished, but I intend to give it in a future discussion. It is sufficient, however, here to call attention to the important bearing, the two benignant new formations found in this cyst have upon the malignancy just spoken of. It is well-known that moles often furnish the soil for sarcomas, and that warts or papillomas for years benignant, sometimes all of a sudden commence to grow, because they are transformed into a carcinoma or sarcoma. The rapidity with which a dermoid cyst sometimes will grow involves a great nutritive hyperactivity. I can understand that this, in its turbulent way of forming tissues without an etiological object, could cause the physiological resistance to disappear, and thus open up the gates for malignant tumors.

Dr. A. Reeves Jackson read the following paper, entitled:

VAGINAL PRESSURE IN THE TREATMENT OF CHRONIC PELVIC DISEASE.

(See page 454).

Dr. Philip Adolphus: In the treatment of chronic pelvic disease by vaginal pressure, we may avail ourselves of the two methods of massage and columning the vagina. The latter has a much wider range in the treatment of pelvic disease than massage.

These methods have been hitherto applied to the removal of congestions, exudates, and recent slight adhesons of the serous tissues in the pelvis, which were in reach of vaginal pressure.

We often thought we had succeeded in removing by them old adhesions and bands, when merely recent effusions surrounding old deposits had become absorbed, just as nature will, without our aid, absorb a large pelvic effusion in a recent pelvic inflammation.

Neither method, however, can cause the removal of old cicatricial bands, firm adhesions and imbedded organs; and both are contra indicated when inflammation of the serous tissues exist.

But where dilatation and congestion are present, and comparatively recent adventitious and hyperplastic tissues are to be removed, the stimulant and alterative influence of pressure on the pelvic vessels induces absorption by either of these methods.

The treatment by massage will not, in future, be resorted to as often as formerly; for it is inefficient in its methods, dangerous in its tendency, as well as troublesome and indelicate to the physician and patient.

The sole object of massage is to induce sufficient irritation in order to effect absorption. But the tamponnement of the vagina does much more than massage.

It supports and relaxes tense ligaments; elevates the movable or adherent vagina, bladder, uterus and ovaries, provided they are not adherent to the pelvic walls; depletes congested, inflamed and subinvoluted organs; overcomes spasm and irritation, and induces physiological rest in the parts.

Tamponnement per vaginam is therefore indicated in all cases where pelvic tenderness is present which is not due to an acute attack, or where absorption is needed; it is efficient in cases of mal-position and

prolapse of the uterus, ovaries, ligaments and vagina, where elevation of the organs and mechanical support are required, preparatory to the use of pessaries, or where these cannot be borne.

Columning the vagina is effected in the knee-elbow position by means of Sim's or Simon's speculum. A large pinch of iodoform, boric acid or salicylic acid is first applied to the cervix, a few tampons saturated with glycerine are laid in the vault of the vagina, and then ordinary cotton wool, absorbent wool or iodoform gauze is systematically packed into the vagina, to remain there for three or four days. This packing is to be renewed until the effects are produced which the practitioner desires. The patient is not obliged to remain in bed, and the pelvic, sacral and hypogastric pains, together with urethral irritability, are frequently relieved in a short time by this method, which is altogether a more successful, cleanly and decent mode of procedure than that of massage.

Dr. James H. Etheridge: I have nothing additional to say except that the continued use of this method in many selected cases has produced most desirable results. But I would protest most emphatically against being understood as recommending it for every trouble of a pelvic nature. For the class of cases Dr. Jackson has enumerated I think it a vastly superior treatment. I was much impressed with the article of Dr. Taliaferro. He tampons the uterus cavity, with the patient in the genu-pectoral position, using a speculum of his own device, which is flanged at the lower end so as to separate the posterior portion of the vaginal orifice, the cervix being held steadily down by the vulsellum, and with a long-toothed forceps he pushes the cotton into the uterine cavity. The true explanation of the benefit which comes from this treatment is, that by elevating the uterus the pressure from its great weight is relieved. There is a mechanical obstruction to the return of blood from the uterus, and what is done by the tampon is to push up the uterus and permit its decongestion, and along with that comes the improved nutrition of the organ, and the reflex symptoms in the way of pain, menstrual disturbances and the like readily disappear. I cannot tell exactly how I was put upon this method of treatment; I don't claim that it is anything new. Several years ago Dr. Bozemann, of New York, tamponned the vagina, calling it "columning the vagina. He spoke of several cases of positive elongation of the posterior wall of the vagina with this continual pressure. His paper was published in full in the transactions of the American Gynæcological Society.

Dr. H. T. Byford: I agree with Dr. Etheridge, that any pressure that can be made by the vaginal pack could not cause the relief. The benefit of pressure upon enlarged veins in any part of the body, as in the leg or testicle, is only temporary unless some other curative influence be added. Nor do I think that a low position of the uterus causes the venous stasis, for this is not found in all cases, and often is found when the uterus is held high up by contracted and indurated sacro uterine ligaments. The veins are large, long and tortuous, and are made to admit of considerable change in position of the uterus in almost any direction. The rapid improvement comes from the support to the uterus, and sometimes also to the ovaries, taking away the traction upon inflamed and indurated ligaments, and thus promoting the absorption of exudations that either diminish the caliber of the veins or prevent them from accommodating themselves to the position of the uterus and its adnexa. This relief of strain and promotion of absorption in the pelvic tissues is the great remedy for subinvolution in the subacute stage, the same as rest in bed is the remedy in its acute stage, viz., soon after labor. It is in the subacute stage of pelvic disease that the vaginal pack finds its great sphere of usefulness. Dr. Jackson's second case serves as a good illustration. When the inflammation and induration are in the sacro uterine ligaments, two or three soft glycerine tampons, made of the best ordinary cotton batting (not the absorbent), placed under and in front of the cervix every second day at the office, and left till the next night, will often relieve the traction and bring about rapid improvement. When it becomes necessary to apply the complete pack, we will get the best effects by so placing the cotton and cotton wool as to relieve the traction upon tender parts, which should be found beforehand by a careful diagnosis.

Dr. Jackson: I think the subject has been very thoroughly discussed and the principal of the treatment clearly illustrated. The important fact is, that it is not a difficult method of treatment; that it is efficacious there can be no doubt; the clinical facts justify this assertion. The method pursued by Dr. Bozemann seems to me to be peculiarly objectionable. Strapping a woman on to a machine for the purpose of packing the vagina, seems both irksome and unnecessary. I am very glad there is such unanimity of opinion in regard to the clinical efficacy of this method of treatment.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, March 3, 1887.

The President, Thomas M. Drysdale, M.D., in the Chair.

(*Concluded from page 445.*)

Dr. Howard A. Pardee read a paper entitled

PERINEORRHAPHY AS PERFORMED BY DR. W. GILL WYLIE.

(See page 432, Journal of April 16.)

Dr. Parish had for years performed a similar operation, but carried his denudation farther up the vagina, and thus avoided the formation of a pocket-like place in which discharges accumulate. He has found it in some cases a cure for constipation.

Dr. Baldy did not think Dr. Pardee understood Emmet's operation.

Dr. Price prefers Emmet's operation.

Dr. H. A. Kelly thought this an unsatisfactory modification.

Dr. Pardee was well acquainted with Emmet's

operation as performed two and a half years ago. The obliteration of the rectocele in that operation was by drawing down a stretched wall, leaving it thin over the rectocele. In his experience opium had not been needed after the operation to control pain. The external stitches are needed to secure a neat external healing.

Dr. Joseph Price exhibited a specimen of

DOUBLE PYOSALPINX, WITH COEXISTING OVARIAN CYSTOMA ON BOTH SIDES.

Mrs. H., æt. 30 years, two children, labors normal, complains of irregular and profuse bleeding; constant pelvic pain, greatest on left side. General health poor. Examination revealed a small fibroid on posterior wall of the uterus; a cyst on the right side extending high up, inflammatory masses laterally. *Operation*, section. The appendages on both sides were distended by pus and generally adherent, left ovary cystic and suppurating, and matted to the pavilion of tube and the sigmoid flexure. The right ovary was cystic and adherent to the vermiform appendix. The pelvis was filled with an irregular conglomeration of cysts and pus-tubes, intimately adherent to pelvic organs, and overlying all this were the bladder and omentum, also firmly adherent. The omentum was perforated at two points, and the mass was removed by careful dissection. A glass drainage-tube was used. Recovery was rapid and perfect; no opium, no catheter, tube out on fourth day, stitches out on seventh day.

Dr. W. H. Parish reported a

PORRO-MÜLLER OPERATION,

performed by Drs. O. H. Allis and W. H. Parish because of an impacted shoulder presentation. Mary Leparo, æt. 26 years, of small stature but good general health. When about six months pregnant she had been hooked by a cow and narrowly escaped a miscarriage. She reached full term and had been in labor seven days when Dr. Allis was telegraphed for by Dr. Groom, of Bristol, Pa., in whose care the patient had been. The membranes ruptured four hours after the pains began. On the sixth day the pains became more severe and the cord prolapsed. About the same time a hand protruded from the vagina. The child died about this time. Version had been tried by Dr. Groom and others, without and with anæsthesia, but could not be effected. The child was evidently of large size; the patient was restless, exhausted, and with a pulse of 120 per minute. The pains were constant and the uterus was firmly contracted above the child. The patient's surroundings were unfavorable, the ignorance and poverty of the family rendered proper nursing impracticable. An offensive fluid was escaping from the uterus; the cervix was rigid and but slightly dilated. It seemed impossible to deliver the patient by either cephalic or podalic version, and the conclusion was made that evisceration was not advisable, because there was every reason to believe that the uterus had done itself irreparable harm by reason of its prolonged retraction against the eminences of the child. The contusion incident to the retraction and the admission of atmospheric air over a period of seven days, with the character of the discharge, rendered it certain that gangrenous changes had been going on in the endometrium and placenta, and that septic inflammatory action of the uterine lymphatics had already begun. The patient was in a condition of exhaustion. Evisceration alone would not have sufficed to secure delivery; it would have been necessary to have bisected the child in the lumbar region and to have removed separately the lower and upper sections. The condition of the uterus and the small size of the pelvis would have rendered this procedure a lengthy and an exceedingly difficult one, and would have added additional serious injury to the uterine tissues. The removal of the child would have left a putrefying endometrium and septic lymphatics. I felt certain the patient would die if thus delivered. All present thought Cæsarean section indicated. The operation was performed by Dr. Allis. The uterus was elevated from the abdomen and a rubber tubing was placed about the cervix, securely controlling the hæmorrhage. Escape of fluids from the uterus was guarded against by means of warm antiseptic pads adjusted about and over the abdominal incision. A vertical incision was now made, and the child extracted without difficulty. The placenta was not in the line of incision and there was no hæmorrhage. Two transverse pins were carried through the cervix, and a constricting wire was substituted for the rubber tubing about the junction of the cervix with the body of the uterus. With the uterine body were removed also both broad ligaments and their contents. The uterine stump was secured externally by means of the transfixion pins, and wounds closed by carbolized silk sutures. Antiseptic measures were taken throughout the operation, but the spray was not used. Immediately after the operation the pulse was 130 per minute. The patient died in forty-eight hours, apparently from heart failure. A full account of this case will be found in the *American Journal of Obstetrics*.

Dr. R. P. Harris remarked that the Cæsarean operation has been performed in the United States in cases of impaction of the fœtus in a transverse position twelve times. In eleven cases the fœtus was dead. In the twelfth it was saved, but the operation was believed to have been uncalled for by a physician who performed laparotomy with success after the woman had ruptured her uterus, in her next labor. The pelvis had been computed to have a conjugate and a transverse diameter of three inches. In one other of the twelve cases the pelvis was deformed, and the woman saved. The arm was protruding in seven cases, five of which recovered. In two the shoulder presented; one saved; and in three the presenting part is not named. Of the twelve cases nine, or 75 per cent., recovered. Of the three cases lost one was ninety-six hours in labor, three days in charge of a midwife. Another wes twenty-six hours under a midwife who had given ergot and ruptured the membranes; and the third had been long in labor, but time not stated. Her death was caused by fright and exhaustion; she rose from her bed to defend her mother against her husband, who had come home drunk on the third day. He knew

of but one case of impaction in Europe in which the Porro operation was performed, but in this the pelvis was deformed. The operation was by Fehling, of Stuttgart, and the woman was saved. Putridity of the fœtus may require the removal of the uterus in a case of impaction. One woman was saved, without its removal, in the United States after seven, and another after ten days of labor, by uterine suturing to prevent escape of fluid; but it is safer to remove the organ where there is danger of poisoning, and particularly where the patient appears to be already threatened with it. In the Porro case of Candido Ramello, of Turin, the woman had been six days in labor, the fœtus was putrid, and the mother in great danger of septicæmia. The removal of her uterus with its contents was followed by an improvement of her symptoms, and she recovered.

FOREIGN CORRESPONDENCE

SURGERY IN LIVERPOOL AND MANCHESTER.[1]

I spent two days in Liverpool, and became personally acquainted with Rushton Parker, Reginald Harrison and Mitchell Banks. Parker lectured on "Sarcoma" to a class of fourteen students. Looking at his class-list I noticed twenty-seven names. The lecture was delivered in a colloquial style and gave evidence of a good clinical acquaintance with his subject, but no deep points in histology or pathology were elaborated. I visited with him the Royal Infirmary and the various departments of the University, which is located in close proximity to the hospital. The chemical branch of this institution was erected and endowed by some of the rich manufacturers of the city, and is a model of usefulness and perfection.

Harrison is a man of middle age and is an enthusiast in his specialty. He showed me several cases of rupture of the urethra followed by extravasation where he had made external urethrotomy and incisions through the infiltrated tissues. He places great stress upon the necessity of removing the extravasation by firm compression, relieving the tissues at once of the fluid in the same manner as squeezing a sponge. The result of this procedure is to prevent sloughing and hastening the suppurative process. He drains the bladder only for a few days with his drain. He is a firm advocate of boutonnière for diagnostic and therapeutic purposes. He looks upon this operation as a trivial procedure almost devoid of danger. He introduces the drain along the groove of a Wheelhouse's gorget. He also demonstrated upon several cases the advantages of his "whip bougie." This instrument is about twenty inches in length, and if previously warmed is so flexible that it doubles upon itself, when fully introduced, without doing damage to the walls of the bladder. As the instrument is conical in shape, one introduction is followed by the same degree of dilatation as the introduction of a number of the ordinary filiform bougies. He favors treatment of strictures of urethra by gradual dilatation, and reserves the cutting operation for exceptional cases.

He is not favorably inclined to the crushing operation for stone in the bladder, and showed a case of lateral operation done a few days before where the wound had almost completely healed.

In plastic operations upon the urethra he performs the buttonhole operation, and drains the bladder as a preliminary measure. You can readily conceive the advantages accruing from this precaution, as it secures to the wound the two essential conditions for rapid healing: rest and the possibility of an aseptic healing. In draining the bladder he stitches the margins of the wound closely around the tube so as to prevent leakage between the drain and the soft parts.

In hypospadias and epispadias he makes the new urethra by tunneling the tissues from the apex of the glans penis to the abnormal opening, and secures patency for the new channel by introducing a drainage-tube until the healing process is completed. As a last step the abnormal opening is accurately closed over a catheter and the urethral continuity is restored. To guard against subsequent constriction of the new canal the patient is instructed to introduce a good-sized bougie at least once a week.

Mr. Banks operated upon a case of carcinoma of the breast, and although the axillary glands did not appear to be involved, a clean dissection of the axilla was made to the axillary vessels. Wherever a vessel was recognized it was ligated at two points and divided between the ligatures, consequently very little blood was lost during the operation. A spectator was readily convinced that the operator had been for years a teacher of anatomy. Spray was used, as I was told, more for the purpose of irrigating the wound than for its supposed effect in sterilizing the atmosphere. The wound was completely closed with silver sutures and drainage established in the lower posterior recesses of the wound. As an antiseptic dressing sublimated wood wool cushions are are used. I received the impression that dressings are too frequently changed in this hospital, thus depriving the wounds of that perfect rest required in a typical wound-healing and exposing the patients to the risks of subsequent infection during the frequent dressings.

Mr. Banks also operated upon a lad who had received a scalp wound nearly three months ago. No brain symptoms were present after the injury or for some time subsequently. During the last few weeks rise in temperature, slight suppuration of wound. For the last few days greater rise in temperature, vomiting and sopor; both pupils contracted. At site of injury over the left frontal region the wound presented a granulating appearance and a probe could be passed through a small aperture into the skull. Probable diagnosis, suppurative pachymeningitis. The field of operation was carefully disinfected, and while patient was under the influence of chloroform the opening in the bone was enlarged with bone forceps. The dura bulged into the wound and did not

[1] This letter from Dr. N. Senn is published by the kind permission of Dr. Christian Fenger and Dr. Senn. Others will appear.

pulsate. The meninges were incised with a sharp bistoury without having made an exploratory puncture, but no pus or any other fluid remained, and after some superficial probing the wound was dressed without making any further attempt to search for a deep-seated abscess.

Mr. Thos. Jones, of Manchester, one of the surgeons of the Royal Infirmary, is lecturer on Clinical Surgery in Owen's College, and a surgeon who is esteemed not only in his own city but throughout the United Kingdom. The Infirmary contains about 300 beds, and, although an old building, is well ventilated and well furnished. Typical resections of the hip and knee are in favor, and many cases were shown in which this operation had been performed. Antiseptic wound treatment is followed, but many of the more minute details are not carried out. Sublimated wood wool dressings are used almost exclusively. Many of the operation wounds showed evidences of imperfect wound treatment. For immobilization of the lower extremity Thomas's splint is used in preference to any other. Fractures are treated with removable splints until swelling has subsided before the plaster-of-Paris splint is applied.

Mr. Hardy was met in the operating-room, where he was putting on the finishing touches in a rhinoplastic operation made by transplanting distal phalanx of left index finger for a bony support and a covering of a flap taken from the anterior surface of the left arm. Interval between the several steps of the operation of about three or four weeks. Present cosmetic results quite satisfactory. He has done this operation three times, and always with a satisfactory result.

I was shown a case of myxœdema in a girl 21 years of age. Mr. Jones also called my attention to a case of metastatic carcinoma following scirrhus of the breast, of more than twenty years' standing, which had resulted in a pathological fracture of the left femur and right humerus. The interesting feature in this case consisted of rapid swelling at the point of fracture with subsequent subsidence of swelling, but no union between the disunited bones.

A case of multiple fibromata of a congenital origin also attracted my attention. The patient was a male about 50 years of age, thousands of tumors covering the entire surface of the body from the scalp to the plantar surfaces of the feet.

In the afternoon I visited Owen's College in company with Dr. Sinclair, who introduced me to the eminent physiologist, Dr. Stirling, the translator and annotator of Landois' "Physiology."

A visit to a private hospital for women and children with Dr. Sinclair, the attending gynecologist, proved interesting and profitable. I was shown three cases in which abdominal section had been done for different indications; in all of them the dressing was removed and the glass drains emptied by suction with a syringe mounted with a rubber tube. In all of them a small quantity of a reddish serum was removed and the drains washed out with ¾ per cent. solution of chloride of sodium. The temperature was normal, or nearly so, in all of them. The operations are all done under the strictest antiseptic precautions. Dr. Sinclair is a gynecologist who has the interests of his profession at heart, and who has a promising future before him.

I visited Dr. Ross at his home with Dr. Robertson. He lives in a comfortable, almost luxurious mansion in one of the most beautiful suburbs of the city. With a capacious park surrounding his house, completely isolating him from the turmoils of a great city, we can readily conceive how a man of his intelligence and indomitable energy should accomplish so much. I met him on the following day in his wards at the Infirmary, and was pleased to follow him in his elaborate description of three cases of peripheral neuritis then under his care. The diagnostic tests were applied in presence of the class and could not fail to bring conviction to all of those who were fortunate enough to be within his hearing.

I also went to Oldham, the home and field of labor of Dr. Robertson, who showed me his cases at the Infirmary, a neat hospital containing 90 beds. Everything in the wards showed perfect discipline and the most careful management. Dr. Robertson is a young physician who furnishes a good illustration of what can be accomplished by modern aggressive surgery. Three simple cases of abdominal section had recently been done and had proved fatal within twenty-four hours from acute septic peritonitis. A search for the cause showed that defective drainage had occurred by the leakage of sewer pipes in the basement. The last case was operated upon in a cottage near the hospital, and was progressing favorably. At this place I had an opportunity of examining a patient with a fusiform aneurism, where the pulsations were distinct, but no bruit could be heard on auscultation. The patient contracted syphilis many years ago, and this disease was undoubtedly the result of mes-arteritis.

In the Manchester Royal Infirmary I saw Mr. Whitehead make a cholecystotomy. The patient was a male, about 50 years of age, who for four months had suffered from periodical pain in the region of the gall-bladder, followed by progressive jaundice. On palpation it was thought that the margins of the distended viscus could be felt. Under spray an incision was made parallel to and about a finger's breadth below the costal arch on the right side, sufficiently long for the operator to introduce two fingers for making the necessary exploration. As this opening appeared to be inadequate, another incision was made, at a right angle with the first, in a downward direction, when the gall-bladder, distended to the size of a small pear, was readily brought into the wound for inspection and palpation. A superficial examination showed that it contained no stones, but as its contents could not be emptied by compression, and palpation of the bile ducts did not satisfy the operator as to the presence or precise location of a probable stone in the ducts, the organ was stitched into the wound in the usual manner, to be opened and explored after adhesions had been secured.

I visited the Pendlebury Hospital for Sick Children, about four miles from the centre of the city, with Mr. Wright, one of the attending surgeons. This institution has a capacity of 300 beds, is con-

structed upon the pavilion plan and located in one of the most salubrious suburbs of the city. It is a model of architectural perfection. Mr. Wright is a most careful and prudent surgeon, and has done most excellent work. . He operates early in cases of hip joint disease, but has abandoned typical resections of knee joint disease in favor of arthrectomy and atypical resections whenever such a course appears practical. He showed six cases of resection of the hip joint done recently, and most of them were without temperature. Fixation of limb is secured by means of Thomas' splint. The spray is used during the operation, and sublimated wool dressings are in general use. For fixation of dressing the elastic webbing bandage is frequently used. Tubercular glands are removed early, and the results of this method of operation have been satisfactory.

Mr. Wright strongly advocates radical operation for hernia in children, and in his hands the operation has been followed by only one death out of a great number subjected to this treatment. He does not remove the sac, but secures perfect coaptation by making with a needle, armed with a catgut ligature, numerous points of transfixion, and tying the ligature.

The nurses are well trained and render intelligent assistance at operations, as was demonstrated by a number of operations made during my presence. In my next letter I will report upon the result of my observations in Glasgow, Aberdeen and Edinburgh.

N. SENN.

NECROLOGY.

DR. JAMES STEWART JEWELL.

By the death of Dr. Jewell the American medical profession has lost a member of whom it has had reason to be proud in all respects. A self-made man in every sense of the word, who had obtained his thorough education solely through his own unaided efforts, he had risen to a position of great eminence as authority in the line of nervous and mental diseases, and as a recognized leader in medical thought. With his extensive general and medical knowledge he combined a rare good judgment and tact, as well as a dignified and kind manner which made him the ideal representative of the medical profession in the eyes of the public. His thorough culture, coupled with modest though firm self reliance, could not fail to impress his patients, as well as the public in general. with the belief that his opinion on any medical subject reflected, indeed, the best and most recent views that medical science of the day could suggest.

Dr. Jewell was born in 1838, on a farm near Galena, Ill., where he remained until his 14th year. During this time his school life did not comprise over one year, and whatever knowledge he did acquire was picked up during times which others would have considered but proper rest from labor, unusually severe for one of his age. Subsequently his family removed to Marion, Ill. There he continued his farm work, by which he contributed largely to the support of his family. His thirst for education, aided by an unswerving persistence of purpose urged him to procure books whenever possible, often traveling long distances on foot to obtain the loan of some coveted volume. Over these treasures he would pore—even all night—and yet not allow them to interfere with the necessary daily routine of farm labor. His taste for science, and especially medicine was encouraged by Dr. S. W. Mitchell, of Corinth, whose library in later years afforded him the means of improving his education. It was to him as well that he owed his final preparation for college life. He entered Rush Medical College in Chicago in 1859, and finished in the following year in the first class of the newly founded Chicago Medical College. After passing a term as Interne in Mercy Hospital he returned to a country practice in Williamson County, but finally entered the army and served as surgeon in an Illinois regiment during the last year and a half of the war. In 1864 he returned to Chicago to fill the position of assistant to the chair of anatomy in the Chicago Medical College, but by reason of the resignation of the previous incumbent he was at once promoted to the full professorship. Having married he now devoted himself to general practice in this city until 1868, when he left for an extended tour through Europe and the Orient. Upon his return in 1870, the Chicago Medical College created especially for him the chair of nervous and mental diseases, to which specialty he then devoted himself exclusively. Without publishing much he became so favorably known in the profession through his teaching and personal intercourse that when he began his *Journal of Nervous and Mental Disease* in 1874, it was at once a complete success. This magazine was the first organ devoted to that specialty in the English language. Any one who has followed the American periodical literature since that time, can but admit that Dr. Jewell's journal has exerted a stimulating influence on the growth of that specialty in this country, as well as on the general diffusion of a knowledge of scientific medicine. In 1875, Dr. Jewell contributed largely to the foundation of the American Neurological Society, of which he subsequently became president. As the natural result of his well directed efforts he acquired a very large consultation practice in his specialty. In the field he had chosen he encountered naturally a great many sufferers from chronic diseases of unusual obscurity, and in this very line of practice his remarkable thoroughness and penetrating judgment enabled him to achieve practical triumphs which will keep his memory alive for years to come throughout the entire northwest.

Some six years ago his health began to fail. With many regrets he deemed it best to relieve himself of the severe tax which the management of his journal put on his time. In spite of continued suffering and distress he continued his arduous practice and managed for a time to struggle vigorously against his physical misfortune, increased by the blow which he received on the death of his wife. Repeatedly he broke down, however, and was forced to pass part of his winters in the south. About one year ago he began the *Neurological Review*, but his health did not

permit him to continue its publication for more than a few numbers. Although sinking steadily during the present winter, he did not abandon his practice until within a few days of his death on the 18th of April. He leaves behind a family of four, two sons and two daughters.

While Dr. Jewell's name was not coupled with any important discoveries in medicine, his teaching, both by word in the college and by means of his many valuable contributions to periodical literature, has been of unmistakable benefit to the profession. He was always an enthusiast in the application of all scientific data for scientific purposes. Thoroughly acquainted with everything that was being done in the scientific world, his steady aim was to investigate disease in the light of the most recent physiological developments. For many years he has been busy on a work on the pathology of the nervous system, on the basis of many hundreds of clinical records of unusual thoroughness, but whether enough of the manuscript has been completed to publish the book, is as yet uncertain. He had formed plans and collected material besides for several monographs, but it is unfortunately not yet positive whether his literary legacy is realizable.

Personally Dr. Jewell possessed a rare amiability and kind disposition not likely to be forgotten by his many friends. No man could have achieved his position under such difficulties, and surmounted such obstacles as he did during youth without possessing an undaunted energy and indomitable persistence of purpose. His undisguised contempt for all actions of a small calibre could not but arouse the opposition of some few envious of his success; but withal he had no open enemies. May the memory of a truly grand life serve as a model for others.

H. G.

INTERNATIONAL CONGRESS.

Section in Psychological Medicine and Nervous Diseases.

President, JUDSON B. ANDREWS, M.D., Buffalo, N. Y.

The following titles of papers have been presented for this Section: "The True Nature and Definition of Insanity;" "Lunacy in Scotland;" "Nervous Degeneration and Syphilis" (selected as a subject for Discussion); "Locomotor Ataxia and Syphilis;" "Original Investigations in Cerebral Syphilis, with Microscopic Preparations, etc.;" "Relation of Syphilis to General Paralysis;" "State Policy in Relation to the Construction of Buildings for the Insane;" "Hospital Arrangements and Classification as relates to the care and comfort of Patients;" "Modern Hospital and Asylum Structures for the Insane;" "The Borderland and Early Symptoms of Insanity;" "The Religious Delusions of the Insane;" "Mental Manifestations of Insanity caused by Sunstroke;" "The Remissions, Intermissions, and Manifestations of Insanity in an Individual;" "General Paresis; Its Varieties and Differential Diagnosis;" "Legal Relations of Epilepsy;" "Obscure Forms of Epilepsy;" "Sleep;" "Miliary Aneurismal Disease of the Spinal Cord and Brain Axis;" "Deformity of the Brain in its Relation to Congenital and Inherited Mental Disease;" "Cases Illustrating the Prow shaped Cranium with Neurotic Disease;" "Remarks on the Etiology and Pathology of Thomsen's Disease; "Tendon Reflex in Hemiplegia;" "Hyperæsthesia;" "Castration as a Remedy in Nervous Affections;" "Occupation in the Treatment of Insanity;" "The Treatment of Neuralgia from the point of View of the General Practitioner;" "The Disease of Inebriety and its Treatment;" "The Physiological and Therapeutical Effects of Currents of High Tension (Franklinization);" "The Private Treatment of the Insane, as Single Patients in England;" "Mental Diseases Produced by Changes in the Vessels at the Base of the Brain;" "An International Classification of Insanity;" "Monomania;" "Cocaine Inebriety;" "General Paralysis in Dogs." Several titles are yet to be received.

Among the foreign physicians who contribute to the foregoing list of titles of papers to be read, or who intend to be present and participate in the scientific work of the Section, are Sir James Creighton Brown, Drs. Rudolf Arndt, Buiswanger, Geo. Fielding Blandford, Bouchereau, Francis Pritchard Davis, Maurey Deas, J. Langdon Down, Edward East, A. Eulenberg, E. T. Girtstrom, V. Hinze, Megalhães Lemos, H. Rooke Ley, E. Mendel, Wm. Julius Mickle, Arthur Mitchell, O. Muller, M. Rosenthal, George H. Savage, Seymour J. Sharkey, J. Beverly Spence, Valdemar Sternberg, D. Hack Tuke, John Batty Tuke.

Communications relating to papers, discussions, etc., should be addressed to the Secretary of the Section, Dr. E. D. Ferguson, Troy, N. Y.

Section of Laryngology.

McNeil Whistler, London, England; Dr. Edward Woakes, London, England; Dr. Zeim, Danzig, Germany.

ASSOCIATION ITEMS.

OPHTHALMOLOGICAL SECTION.

The Thirty-eighth Annual Session will be held in Chicago, Ill., on Tuesday, Wednesday, Thursday and Friday, June 7, 8, 9 and 10, commencing on Tuesday, at 11 A. M.

"Sympathetic Ophthalmia." Dr. C. M. Hobby, Iowa City, Iowa.

"Some Observations on Displacement of the Crystaline Lens, from Congenital and other Causes." Dr. J. L. Thompson, Indianapolis, Ind.

"Hydrobromate of Hyoscine as a Mydriatic." J. M. Ray, M.D., Louisville, Ky.

"Treatment of Hypopyon Keratitis with frequent irrigations of Sublimate." Dr. F. C. Hotz, Chicago, Ill.

"Some of the Ophthalmological Clinics of Europe." J. W. Heustis, M.D., Pittsburg, Pa.

HOTEL RATES.

The following hotels in Chicago have thus far commuted their rates to delegates and members and their families who will attend the annual meeting in June —all promising first-class accommodations:

Grand Pacific Hotel.—A discount of 50 cents to each person per day in all rooms, except those at $3.00 per day, on which there will be no discount. By this arrangement a $3.50 room with bath may be had for $3 00, a $4.00 room for $3.50 for each person, and so on. A club room will also be placed *free* at the disposal of the Association for headquarters, if desired.

The Sherman House will give 50 cents *per capita* off regular rates, which are $3.50 to $5.00 *per diem*, as well 50 cents *per capita* off $3.00 per day rooms where more than one person occupy a room. Such committee rooms, etc., as may be required will be placed at the disposal of the Association free of cost. No cots are ever used at this hotel, and every one will be given a good bed.

The Tremont House offers 50 cents discount from regular rates, which are from $3.00 to $4.50 *per diem*. This rate applies to each person or delegate, both included.

The Palmer House gives a rebate of 50 cents *per capita* on the American plan, when two occupy a room. On $1.00 rooms, (European plan) a rebate of 25 cents *per capita* where two occupy a room. On rooms for which the rate is $1.50 and upwards, a rebate (on the European plan) of 50 cents *per capita* is offered.

The Briggs House.—The rates will be $2.00 to $2.50 per day for their *best* rooms, meals included, a reduction of 50 cents per day on transient rates.

The above hotels are located within a few blocks of Central Music Hall, the place where the general (forenoon) sessions will be held. Additional information as to hotel rates will be published in subsequent issues of THE JOURNAL.

RAILROAD RATES for delegates will be published in full next week. They will be one and one-third ($1\frac{1}{3}$) fare for the round trip issued on the certificate plan, as follows:

Tickets for return journey will be furnished those having paid full fare to place of meeting who procure tickets not more than three days before the Association assembles, if presented within three days after the date of adjournment. Some forty different railroads of the country having already agreed to accept return tickets issued under this plan. The names of these railroads will also be published in next weeks' issue of THE JOURNAL.

CHARLES GILMAN SMITH, M.D.,
Chairman Local Committee of Arrangements.
LISTON H. MONTGOMERY, M.D.,
Chairman Committee on Transportation.

MISCELLANEOUS.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 16, 1887, TO APRIL 22, 1887

Capt. Edward B. Moseley, Asst. Surgeon, ordered for duty at Whipple Bks., Ariz.. S. O. 89, A. G. O., April 18, 1887.

APPOINTMENTS.

Charles E. Woodruff, Julian, M. Cabell, to be Asst. Surgeons with the rank of First Lieut., to date from April 14, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING APRIL 23, 1887.

Russell, A. C. H., P. A. Surgeon, U. S. N. ordered to duty at Naval Laboratory, New York. May 2, 1887.

Heffenger, A. C., P. A. Surgeon, U. S. N., ordered to Widow's Island, Me., to superintend building a naval hospital, wharf and other improvements, under instructions of the Surgeon-General of the Navy.

Woodruff, Chas. E, Asst. Surgeon, U. S. N., resignation accepted, to take effect April 8, 1887.

CLINICAL LECTURE
ON
THE GENERAL PRINCIPLES INVOLVED IN AMPUTATION,
With a Consideration of Some Points in the Technique.

BY FREDERIC S. DENNIS, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK CITY.

[REPORTED BY SEYMOUR H. HOUGHTON, M.D., HOUSE SURGEON, BELLEVUE HOSPITAL.]

Gentlemen:—The late Sir Wm. Fergusson used to speak of amputation as "one of the meanest, and yet one of the greatest operations in surgery; mean when resorted to if better may be done—great as the only step to give comfort and prolong life." In studying the conditions under which amputations have been resorted to during the past half century, it is astonishing to see how limited in number those conditions are at the present day. Szymanowski once said that "we must reach such a state of perfection in amputation as to consider every amputation a plastic operation;" and with a view to the accomplishment of such an object I desire to direct attention to this subject in the lecture to-day.

There are four periods at which an amputation can be performed: *1. Immediate*—before reaction from shock; *2. Primary*—after reaction but before inflammation; *3. Intermediate*—after inflammation but before suppuration; *4. Secondary*—after suppuration is established. For all practical purposes these four periods can be reduced to the primary and secondary. As a rule, to which there is scarcely an exception, the immediate amputation should not be performed, as the patient is likely to die from shock during the operation. The double shock of the operation and of the injury is apt to kill the patient; and the shock of the injury of the limb may be complicated with shock from injury of some important internal organ from which the patient could never rally, and hence the impropriety of the amputation, and the needless addition of suffering to the patient on account of the operation.

It is sometimes necessary to amputate as soon as consistent with safety. Now, what is to guide the surgeon in his decision of so important a question? In cases of compound comminuted fracture, with injury to the main artery of the limb and with great loss and destruction of tissue in the soft parts, the hæmorrhage is often alarming, and amputation is called for imperatively as the only salvation for the patient. What is the earliest moment a surgeon should operate? Never during profound shock; and the rule which must govern a surgeon is, to employ all known means to control hæmorrhage and to bring about reaction from shock, and wait. If the patient has pallor and coldness of skin, weak and feeble pulse, sighing respiration, non-reacting pupils, traumatic delirium—internal injuries, no amputation is indicated. The earliest possible time an amputation can be performed, under great necessity from hæmorrhage, is when reaction is beginning; but unless the patient is likely to become exsanguined by delay the beginning of reaction is an unfavorable period for operation, and it is wise to defer it until reaction is fully established. Amputation should not be performed with a sub-normal temperature, a cold skin, a feeble rapid pulse, or during traumatic delirium—especially in children. The condition, then, of the temperature, the skin, the character of the pulse and the mental state, are all important factors in the solution of this problem. Delay in performing an amputation was formerly fraught with very great danger from septic infection; but with the modern methods of preventing sepsis in a recent wound, this obstacle is removed; and with antiseptic compresses applied tightly over the bleeding wound, and not above the wound upon sound tissue, hæmorrhage can be controlled and the wound kept from rapid sepsis a sufficient time to give the patient opportunity to react. I have seen an Esmarch elastic bandage applied above a lacerated wound, over sound tissue, and when the flaps were made a certain amount of sloughing followed from the compression. The wound itself is the proper place to apply firm compression, never above the seat of the wound. This point is one of practical importance, because the elastic bandage as a means of controlling hæmorrhage has been misused; instead of applying the compression over the bleeding part, it has been carried above the bleeding part and over sound tissue. As a result of this, gangrene in the flaps may occur, with its accompanying septicæmia.

The mortality of amputations depends upon a variety of conditions; even the state of the weather has been shown to have a causative effect on the death rate. Hewson has shown that with a rising barometer the average duration of life in the fatal cases was only 7 days, while with a falling barometer the average duration was 13 days; and that 75 per

cent. of the fatal cases died when the barometer was rising. The conclusion is that, while the state of the weather may or may not turn the tide for or against any given patient after amputation, barometric changes materially influence the condition of patients suffering from the effects of severe surgical operations, and have a slight influence upon the death-rate.

Age is also a factor in estimating the mortality after amputations. Holmes has proved "that the risk of amputations is constantly rising throughout life, and that at any given period after 30 years of age the risk is more than twice as great as it was at the same period after birth." Thus if, for example, it may be stated that 5 per cent. is the mortality after amputation in a child at 10 years of age, the mortality at 40 years would be 10 per cent.

The *seat* of the amputation is also an important factor. Amputations of the lower are more fatal than those of the upper extremities. In any given limb the death-rate increases in reference to the proximity of the amputation to the trunk. Thus if, for example, amputation of the thigh be represented by 50 per cent., the leg would be 40 per cent., the arm 25 per cent., the forearm 13 per cent. These figures are far too high since the introduction of antisepsis, but are quoted to show the relative figures in the different amputations.

The *part of the bone* sawn through affects the mortality. The mortality is greater where the shaft is divided so as to expose the medullary canal than where the cancellated tissue of the bone is sawn through; for in the former case, the risks of pyæmia and osteo myelitis are greater than in the latter case.

The primary amputation is much more fatal than the secondary. Sir James Paget states that the mortality is 12 times greater in the former case. This rate is perhaps too high; but the fact that the primary amputation is attended with a greater death-rate is due to the severe character of the injury. It has been stated that the amputation of expediency, performed for the relief of deformity, is attended with a greater mortality than either primary or secondary amputations.

The *general health* of the patient importantly influences the success of an amputation. The condition of the kidneys, lungs, heart, and vascular system, liver, brain, and other important organs, materially affects the results after amputations.

The *previous habits* of the patient is another important factor. A man of dissipated habits has his chances of recovery lessened by his profligate life, while the temperate man has his chances of recovery greatly increased. Pneumonia often causes death after amputations in those cases where the patients have been hard drinkers for many years.

The *hygienic conditions* are most important in affecting the mortality. Patients in the country do better than those in the city, and the latter do better in private practice than in hospitals. Always secure for a patient abundance of fresh air and plenty of sunlight. Too much stress cannot be placed upon his hygienic surroundings. While the weather, age of patient, seat of amputation, the part of the bone sawn through, whether for injury or disease or deformity—above all and beyond all the hygienic conditions stand out foremost; and if we exclude serious organic disease, nothing is so important as the sanitary arrangements. Sir James Y. Simpson showed that five times as many deaths occurred after amputations in large city hospitals as in private and country practice. To-day the mortality in amputations is very much less than in his day, and a large majority of the causes of death following amputations may be said to have been forever eliminated by the application of the principles of science to surgery. We will now discuss the indications for an amputation:

Aneurism.
Malignant disease.
Perforating ulcer of foot.
Uncontrollable hæmorrhage (primary or secondary).
The operation of expediency in deformity, in tumors and tetanus.
A disease of the joint.
The moist variety of gangrene.
In certain compound fractures and dislocations.
Old sloughing and varicose ulcers.
Necrosis of bone.

These ten indications for amputations have thus been arranged in an acrostic, which will always enable the student or surgeon to have at his command the information.

REQUISITES OF A GOOD STUMP.

1. The bone must be amply covered.
2. The flaps must not be adherent to the bone nor exert pressure on traction upon the cicatrix.
3. The nerves must not be adherent to bone or cicatrix.
4. The nerves must be cut high enough so as not to be affected by pressure or by atmospheric changes.
5. The bone must be smooth and capable of bearing firm pressure upon it.

CHARACTERISTICS OF A BAD STUMP.

1. Necrosis at end of bone.	Sequestrum from injury to bone in sawing, by rough use of saw, by suppuration in bone by injury to periosteum, by sawing without irrigation to prevent the saw from acting as an actual cautery.
2. Conical-shaped stump.	Insufficient covering, spasmodic retraction of muscles, growth of bone.
3. Neuralgia of stump.	External pressure, local and constitutional causes, bulbous enlargement, adhesion to cicatrix.

We may now direct attention to a careful study of the technique of the operation in its present perfected state. For the purposes of description of an amputation in general the following points are to be considered in an amputation of the leg:

First—Preparation of patient.

Second—Provision against hæmorrhage before operation.

Third—Formation of a suitable flap.

Fourth—Section of the bone.

Fifth—Provision against hæmorrhage during operation.

Sixth—Treatment of wound.

The preparation of the patient consists in a careful study of the patient's history, and also the special preparation of the member to be removed. Before the operation the heart and lungs should be examined, the urine analyzed, the general habits of the

patient inquired into with reference to intemperance, and opium habit, or previous disease, and other points of interest which influence the treatment after operation, as well as the mortality. In other words, the surgeon should study thoroughly the individual upon whom he is to operate, and make himself complete master of the situation. The local attention to the part consists in thorough ablution, shaving, and free irrigation with carbolic acid or bichloride of mercury solution.

Provision against hæmorrhage before the operation.—The limb should be elevated and held for a few minutes, and at the same time rubbed towards the trunk. The tourniquet should be now placed over the femoral just beneath Poupart's ligament, so as to press against the bone. It should be screwed down quickly upon a bandage placed under the bone and over the artery; if it is slowly turned a large amount of blood will pass into the limb, and the compression is soon sufficient to keep the venous return in the limb, but not enough to prevent arterial blood from entering the limb. Esmarch's bandage is often used instead of Petit's tourniquet, but the amount of oozing following its use is so great that I prefer digital pressure on the tourniquet, when properly applied. If the Esmarch bandage is used and the main vessels are ligated, the irrigation by hot water, as suggested by I. Varick, of Jersey City, will control the oozing better than any other means. If the hot water is employed for this purpose I should recommend that a weak solution of carbolic acid be prepared in anticipation, or else a mild solution of corrosive sublimate (say 1–4000). These solutions have the additional advantage of making doubly sure the aseptic condition of the flaps.

Third stage, formation of suitable flaps.—Circumstances often influence the surgeon as to the kind and shape of flaps in any given case, but if he can operate at a point of election instead of a point of necessity, either the circular skin flap, modified, if necessary, by two lateral sections, which converts the amputation into one of an antero-posterior skin-flap of equal length, or Teale's long anterior and short posterior flap, or the bilateral flaps, will be found best in all amputations. Whatever shape may be decided upon, all flaps should consist of skin and connective tissue only, and not muscle. At all points of the body where pressure is made against bone, skin alone covers the part; the os calcis and the olecranon, the tuberosities of the ischium, are good examples of this. If muscle be included in the flap on the supposition that it will form a soft cushion over the divided end of the bone, the fact that the muscle soon completely atrophies takes away the supposed advantage. If the muscle is included there is considerable bleeding from the cut surfaces and there is a much larger wound for healing.

The surgeon having decided on the kind of flap desired, everything is now ready to begin. One assistant gives ether, another hands the instruments, a third holds the limb to be removed, a fourth is responsible for the application of the tourniquet or the elastic bandage, and a fifth sponges and helps tie the vessels. Each assistant must understand his respective duties and he must not interfere with the duties of the others; thus the operation from beginning to end will be executed in perfect order, and with the least possible delay or suffering. The nurse should wash and wring out the sponges used during the operation; and what has been said of antiseptic preparation of the assistants must include the nurse.

The surgeon stands upon the right side of the limb to be removed, so that he can hold back the flaps with the scalpel, and in doing so he must remember to cut with his scalpel directed at right angles to the long axis of the limb, and the cutting edge slightly turned towards the part of the limb to be removed, and never towards the flap. In this way he cannot button-hole the flap, and the edge of the flap being cut at right angles to the long axis of the limb, will not slough, as it will do if the edge is cut obliquely. The flap should consist of skin and connective tissue and deep fascia down to the muscle; but it is not to include the muscle. The blood-vessels nourishing the flap run between the skin and the deep fascia, and if the edges of the flap be cut at right angles and not obliquely, the extreme edge of the flap is bountifully supplied with vessels. In dissecting up the flaps they should be held by the surgeon's fingers, and never by forceps, which contuse the flaps. The surgeon having dissected up the flaps to a convenient distance and holding the flaps back with his left hand, he is now prepared to make a circular section of the muscles down to the bones.

Before cutting the muscles an interosseous flap can be cut, as suggested by Linhart, of Würtzburg. The object of the interosseous membrane flap is to prevent the retraction of the tissues which carry the vessels up out of reach. A small catlin is thrust in close to the tibia and then carried down for about two inches parallel with the bone. The catlin should now cut across until it comes in contact with the edge of the fibula, and then upwards along the edge of the fibula to a point opposite to where the first incision was made. This will cut out a tongue-shaped piece of tissue composed of the interosseous membrane upon which and attached to which the anterior tibial artery is found. This interosseous flap retracts more readily than muscles, and consequently, being cut two inches longer than the muscles, the flap with the artery will be found directly upon the face of the stump.

With a large amputating knife the muscles should be severed at a point just below the point where the base of the flap is attached. It is best to allow for a certain amount of contraction of the muscle after it is cut, and if the circular division is made as described, the cut surface of the muscle extends down so as to be upon a plane corresponding with the bone or bones. A double-tail retractor, or a triple-tail retractor if two bones exist in the extremity, is placed in front of the face of the stump between the bones so as to keep the muscle from being injured during the sawing of the bones.

Fourth stage, section of the bone.—The leg must be firmly held during the sawing, and the assistant supporting the part to be removed must avoid any pressure downwards, this movement being likely to

cause fracture of the bone, or any movement upwards, which is likely to bind the saw and prevent its free movement. When the femur is to be sawn the saw should go through the linea aspera before completely severing the bone, and this will avoid splintering the edge of the linea aspera. When two bones are involved, as the tibia and fibula, they should be sawn upon the same level, remembering to saw through the smaller of the two bones first, so as not to disarticulate the fibula at its upper end. Volkmann has found that rapid sawing causes so much friction that great heat is generated, which produces circular necrosis at the end of the bone. The saw should be used gently and drawn lightly from heel to toe, and the sawing should be performed under continuous irrigation, so as to prevent the development of too much heat from friction. The surgeon should now pass his finger over the surfaces which have been sawn, and remove by Liston's bone-forceps any slight projection or splinter, and then bevel the edge of the tibia so that its sharp crest will not perforate the skin when the flap is drawn down over the face of the stump. If desirable, a small piece of periosteum can be pushed up from the bone before the saw is applied, and then the periosteal flap can be stitched over the front of the bone by a catgut suture. This procedure was formerly in vogue to prevent osteo myelitis, as the periosteal flap united by primary union, so that no suppurative discharge could be absorbed by the medulla.

Fifth stage, provision against hæmorrhage during the operation.—The surgeon should secure and tie the main artery first; then the other arteries in turn according to their sizes. Do not tie veins unless it is necessary. The artery forceps should embrace only the divided end and open mouth of the artery, and the ligature should involve the vessel only, none of the surrounding tissues. Catgut is preferable for ligatures, as it possesses the especial advantage of allowing the stump to be closed. If torsion is employed, the advantages are still greater; but this method is only safe in the hands of surgeons who understand its use thoroughly and are skilled in its practice. After all the vessels are tied or twisted some oozing may occur. This is controlled by hot irrigation, or by packing into the stump a number of antiseptic sponges wrung out in hot bichloride of mercury.

After hæmorrhage is completely arrested and the wound-surface perfectly dry, the last and sixth stage is entered upon, and this leads us to a discussion of a most important subject, viz.: *the treatment of the wound.* The different methods which have been devised are numerous, and many of them complicated. I pass by the Guérin pneumatic occlusion method and the Maisonneuve pneumatic aspiration method as too difficult and complicated for the use of the general practitioner. The cold water dressings as suggested by Liston, and the continuous bath recommended by Langenbeck, are methods to be employed in exceptional cases. Dressings of stumps, for practical purposes, may be reduced to one of two methods: either the closed or the open method. The great majority of cases should be dressed by closing the wound. In treating an amputation wound by the first method, it is assumed that all the details of antiseptic surgery have been carefully carried out; otherwise failure to obtain primary union is certain.[1]

In dressing a stump with a view to obtaining primary union, it is often advantageous to defer permanently closing the stump for several hours. This is especially indicated where there is much oozing from the surface of the wound. By deferring the final dressing for a few hours the wound is not closed until it is perfectly dry, and until a delicate film of coagulated blood glazes the surfaces.[2] Whenever the final dressing has been deferred I have irrigated the wound thoroughly with a hot solution of bichloride of mercury, and then packed with a large number of small sponges which have been taken immediately out of a glass vessel containing a solution of hot bichloride of mercury. The sponges should be wrung out as dry as possible and introduced into the wound, and the flaps brought over the sponges, and then a heavy bandage of antiseptic gauze placed over the stump with but moderate compression. In five or six hours, the patient in the meantime having reacted from the shock, is now perfectly conscious, and will permit, without suffering any pain, the completion of the dressing.

The bandage should be carefully removed from the stump and one by one the sponges removed from the wound; and all oozing having ceased, a thin film of iodoform can be dusted or sprinkled over the flaps and upon the face of the stump. A drainage tube of *red* rubber—because it contains no sulphur—should be placed in contact with the face of the stump, brought out at each angle of the wound, and cut off flush with the surface of the skin. The flaps should now be approximated and the sutures tied. Catgut should be employed; but three or four silver sutures should also be used, because the catgut often absorbed too quickly and the flaps are not held firmly. The silver relaxation sutures can be removed as soon as they show evidence of the slightest irritation. A button or silk suture or horse-hair can be used instead of the silver wire if the surgeon prefers. If the edges have been accurately approximated a thin film of iodoform can be sprinkled over the line of incision, and then the protector and then the hospital gauze lightly placed over the stump. The gauze next to the wound should be wet, having previously stood in a hot solution of bichloride of mercury or carbolic acid. The gauze should be wet, because dry carbolic gauze is not antiseptic unless it is warm. The absorbent cotton can be now placed over the entire stump and held in place by an antiseptic bandage. Over this dressing layers of antiseptic gauze can be placed with the Mackintosh; the latter can be dispensed with as a rule. The superficial dressing of hospital gauze should be dry and quite firmly

[1] These details of wound treatment have already been discussed in a previous lecture, a report of which may be found in THE JOURNAL of August 21, 1886, and it is unnecessary to repeat what has been said in regard to the technique of an aseptic surgical operation.

[2] Some surgeons have objected to deferring the permanent dressing several hours because the patient has come out of the influence of the anæsthetic, and the final dressing must be done while the patient is conscious. The objection is overruled if the sutures are introduced through the flaps but left hanging loosely. There is no pain in the mere approximation of the flaps.

bandaged to the stump, which should be placed upon a splint and bandaged to it.

In three days, if everything has gone on well, the dressing should be changed under irrigation so as to remove the drainage tubes, and a new dressing applied in the manner already described. This second dressing can remain unchanged for a week, and then a new and final dressing can be applied. It is thus evident that by this method all the great principles of wound treatment have been observed.

In exceptional cases, however, it is not best to close the wound because primary intention can not be obtained on account of the peculiar conditions of the wound. In cases of compound fracture, attended with great crushing of bone and soft parts, there is occasionally some contusion over a small area of the wound, which might prevent primary union, but is not sufficient to prevent a satisfactory healing by secondary intention, and thus securing a longer stump. Another circumstance where closing the wound is not best, is in an amputation of emergency, at a place where antiseptic dressings can not be secured immediately. I believe that under such circumstances no attempt should be made to secure primary union, because all the essential conditions are absent, and a failure under these circumstances would expose the patient to serious risks from septic infection. Half-way antiseptic surgery is more dangerous than full exposure of the wound to the air. I believe that leaving the wound fully exposed to the air is not only safe, but is in reality the best method where all the conditions of rigid asepsis cannot be controlled. During the past session I have treated two stumps by the open method, and both of them did just as well as regards constitutional disturbance as the others. The open method has one disadvantage; the wound does not heal so quickly; but it heals satisfactorily in the end. In the open method the highest type of antiseptic surgery is found. The frequent use of carbolic acid renders the soil unsuitable for the growth of germs, the causes of putrefaction. The unobstructed flow of the discharge prevents the secretion becoming putrid. The exposure of the wound permits evaporation, which renders the discharge too highly concentrated for the favorable growth of these germs; and, finally, as Pasteur has shown, this same free exposure, by the supply of oxygen to the microörganisms, prevents their disorganizing and breaking up the albuminous compounds in their struggle for one of the essentials of their being. The preservation of the albuminous compounds diminishes, and even prevents, the processes of putrefaction. The exposure of the wound lessens the chances of decomposition by causing it to become dry.

There is no real inconsistency between antiseptic surgery, as now understood, and treating a wound openly. A careful study of the principles of antiseptic surgery shows that both methods are in accord with its precepts, only that in the open method the wound heals by secondary union, and still the wound is aseptic In the open method the stump is irrigated every few hours with carbolic acid solution. Balsam of Peru is used to stimulate the granulations, and in ten days the granulating surfaces upon the flaps are approximated, and healing takes place between these two granulating, instead of between two fresh, surfaces. In epidemics of diphtheria I have found the open method preferable, because a healthy granulation surface is a barrier to the entrance of septic poison.

In conclusion, gentlemen, endeavor to obtain primary union in all amputations by using every detail requisite to success. When the conditions are unfavorable, aim at secondary union by the open method; but remember that even if the open method is best suited to certain cases, it is still antiseptic surgery in its highest and broadest sense, and that good judgment and a due regard for the best interests of the patient has persuaded you to adopt the method which is less brilliant in its technique, but more brilliant under such circumstances in its ultimate results.

PNEUMATIC DIFFERENTIATION AND THE PNEUMATIC DIFFERENTIAL PROCESS. ITS DEFINITION AND GENERAL SUGGESTIONS FOR ITS APPLICATION.

BY HERBERT F. WILLIAMS, M.D.,
OF BROOKLYN, N. Y.

The term "pneumatic differentiation" was first used by the author, in an article which appeared in the *New York Medical Record*, January 17, 1885. In this article, or in a subsequent one[1], certain improvements were spoken of which promised to enlarge the scope of the process there described. This paper is written for the purpose of giving a fuller description of what has now come to be known as the "Pneumatic Differential Process."

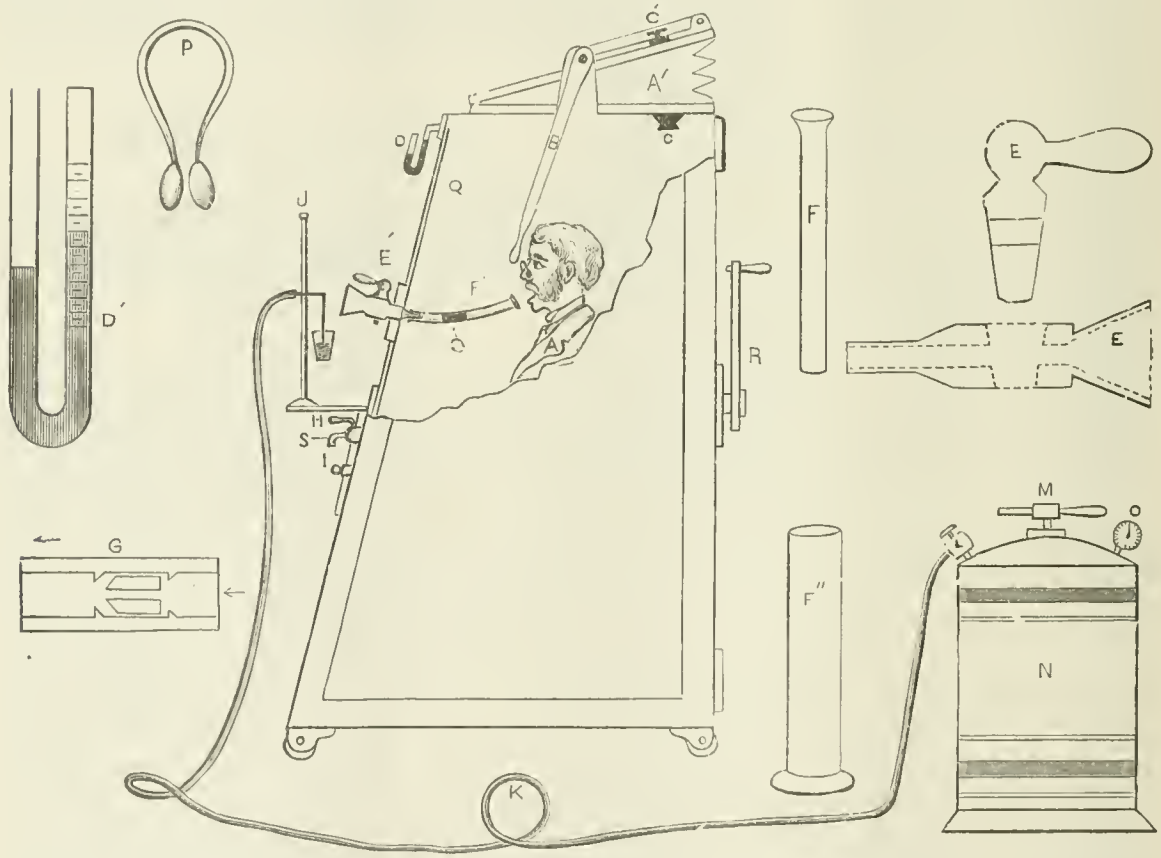
Pneumatic differentiation is the mechanical expression of the thoughts and ideas of two men, a physicist and a physician. However parallel their work may have been to earlier investigators, the labor has been entirely independent, and perhaps for this reason there comes a point of divergence which carries their investigations considerably beyond the labors of Hawk, Lange, Junod and Waldenberg. The cabinet in the hands of lung specialists is capable of nice and skillful adjustment to the various anomalies and contortions that are found where diseased action has not been impeded, and under the control of such in hospitals, sanitaria, or at the residences of patients, a certain range of cases will yield to treatment that might fail of permanent benefit in office practice. But the cabinet and its operation are equally well designed for the larger field of the general practitioner, who from the nature of his work, sees the earliest manifestations of pulmonary disease, and can easily arrange with, perhaps, a younger brother practitioner to secure to his patients the benefit that such a radical treatment will confer at the inception of diseased action.

[1] Which appeared in the New York Medical Journal, Oct. 3, 1885.

Description of Terms.—The pneumatic differential process can be said to comprise six principal acts, which may be enumerated as follows: *First*, residual air expansion; *Second*, forced inspiration; *Third*, inspiratory differentiation; *Fourth*, respiratory differentiation; *Fifth*, expiratory differentiation; *Sixth*, forced expiration.

These acts can be produced upon a patient when he is inclosed in a cabinet of suitable construction. The following diagrams may assist in the description of the several acts:

The valves c and c′ are so constructed that they can be arranged to produce either rarefaction, compression, or alternate rarefaction and compression of the air in the cabinet. The bellows a, is of about



A, patient. A¹, bellows. B, lever to operate bellows. C, cabinet valve. C¹, bellows valve. D, manometer gauge. D¹, same half size, showing 4-10 in mercury. E¹, breathing faucet in place. E, same detached, showing construction. F, breathing tube. F¹, same in position. F¹¹, bath jar for holding same in aseptic fluid. G, artificial glottis. G¹, same in position. H, adjustable stand for holding vaporizer. I, set-screw for holding same in position. J, vaporizer. K, rubber tube leading to condenser. L, regulator, to control flow of air at any given pressure. M, pressure pump. N, condenser. O, gauge for compressed air condenser. P, nose clip, to compel oral respiration. Q, glass front to cabinet. R, lever for opening same. S, accessory—stop-cock.

$\frac{1}{30}$ the cubic capacity of the cabinet, and of a calculated tensile strength somewhat less than the breaking strain of the cabinet. The artificial reversible glottis G, is so constructed that it can be placed in the breathing tube either at the oral end where it can serve as a mouth piece, or it may be placed farther down if preferred. It is provided with a perforated valve, the circumference of which has been ground to its opposed bearings. Its backward play being checked by two shoulders in the tube. An air current flowing in the direction indicated by the arrows would force the valve into its ground socket, and the circulation of air would continue through the central perforation. The air current being reversed would drive the valve against the shoulders, and the circulation of the air would become free around the valve. Hence, the valve can be used to produce free inspiratory and restricted expiratory aperture, or the reverse. The breathing faucet e and e′ may serve to produce either free or restricted inspiration or expiration, by fully or partially opening the stop-cock, but the action is not automatic, and hence, it can only be utilized when we wish to modify an individual inspiratory or expiratory act.

The breathing tube, F and F, is designedly of simple construction, which allows easy and complete cleansing. The oral end is expanded and comfortably fits the mouth, being placed between the teeth and lips. The patient while breathing taking care to open the jaws, but keeping the lips firmly around the flange.

1. To produce *Residual air expansion* valves c and c′ are set for rarefaction. The patient is told to make a full inspiration from the air in the cabinet,

and while he is maintaining himself in this act with his mouth and glottis open, rarefaction can be produced to the extent of from 1–2 inches. This will expand such air as may be occluded behind bronchial plugs. If we wish to expand residual intervascular air, the glottis should be gently closed after full inspiration. The patient can indicate by a prearranged movement of the hand, when he is prepared for the removal of the air about him, which, on account of the relative size of the bellows to the cabinet, can be effected in two or three strokes of the lever.

II. *Forced Inspiration.*—The valves c and c′ to remain as before. The rarefaction may be from $\frac{2}{10}$ to 2 inches. The patient now takes the tube in his mouth, and if the higher rarefaction is used the breathing faucet is partially opened and the weight of the normal air seeking to establish an equilibrium with the expanded rarefied inter-pulmonary air, will produce an easy and effectual expansion of the lungs. The expiratory act may be made into the cabinet. This will decrease the rarefaction in the cabinet, and as each respiration proceeds, the breathing aperture in the faucet may be opened wider, or the rarefaction may be kept high by an occasional stroke of the bellows. At a pressure of from $\frac{2}{10}$ to $\frac{6}{10}$ the patient may proceed to the third act.

III. *Inspiratory Differentiation,* which is effected by maintaining continued respiration through the breathing tube during the contrasted air pressures.

This converts the normal active inspiratory act into a passive movement, while the ordinary passive expiration becomes active to a degree dependent upon the extent of differential pressure. The nose-clamp should be used in this act if the posterior pharynx cannot be controlled, to prevent the escape of air, which will not only lower the rarefaction, but more seriously interfere with the full intent of the act, which compels the respiration of an elastic column of air, which after two or three inspirations secures a constant and even expansion from buccal cavity to the remotest alveolus. Radiation of body heat or any slight escape of air into the cabinet will after a few moments reduce the rarefaction, but this can be kept up without disturbing the treatment by the withdrawal of the air syncronously with the inspiratory act. If air is withdrawn from the cabinet when the patient is making an expiratory effort, the amount of energy which he unconsciously exerts to expel the lower differential pressure will be inadequate to overcome the increase. It is not necessary, however, to remove such a large quantity of air at once, for, by the gentle and occasional operation of the bellows, the rarefaction can be maintained, constantly at one point.

IV. *Respiratory Differentiation.*—This has become the principal act of the entire process[2], and its scope will not be reached until we are provided with special apparatus for the operation of its full principle in producing artificial respiration in all forms of suspended animation.

For the treatment of pulmonary disease an excursion of one inch Hg. is sufficient. The valves c and c′ are arranged to produce alternate rarefaction and pressure. The patient now takes the same position as for inspiratory differentiation, having been previously instructed to conduct his respirations syncronously with the movement of the lever, or inspiring in response to the word "in" and expiring at the word "out" as enunciated by the operator. The bellows are closely shut, air inside and outside the cabinet is at equilibrium. The patient takes the breathing tube in his mouth at the word "in," he makes an inspiration. The operator at the same instant depresses the lever and opens the bellows wide, thereby withdrawing about $\frac{1}{30}$ of the atmosphere less the cubic displacement of the patient, and producing a corresponding depression in the mercury. The accessory stop-cock is now opened to allow air to rapidly flow into the cabinet, when equilibrium is again established, which will take place in a few seconds, the accessory stop-cock is closed. The word "out" is called, and the patient makes an expiration. The operator recovers the lever and compresses the air in the cabinet to the limit of the contents of the bellows, which drives the mercury up the left arm of the manometer. These movements can be repeated from five to fifteen times per minute. The inflow or outflow of the respiring air can be retarded by the use of the artificial reversible glottis as already described. Further reference to this will be made in treating of its application to diseases. Should the entire contents of the bellows produce too great a force, the patient may commence respiration with the bellows half open, when its operation, as before, will give a reduced variation each way.

V. *Expiratory Differentiation.*—The valves c and c′ are arranged to produce pressure inside the cabinet, with $\frac{2}{10}$ to $\frac{4}{10}$ the patient will find his inspiration difficult and his expiration easy, just to the extent of the reverse of the inspiratory differential act.

VI. *Forced Expiration.*—Valves c and c′ same as in last act, high pressure from 1 to 2 inches is produced in the cabinet. The patient takes his inspiration from the cabinet air, but makes his expiration through the breathing tube, which the operator must close while the patient is inspiring. The bellows must be operated to keep up the pressure in the cabinet, for the patient is now reducing the pressure by the emptying of his lungs ten to twenty times per minute.

To these six acts another might be added, viz: *Residual Air Compression.* It differs from the last act in that the patient makes a full inspiration at equilibrium then closes glottis, when the operator rapidly produces pressure from 1 to 2 inches. This is exactly the reverse of Residual Air Expansion.

General suggestions for the application of these several acts.—Each patient is to be furnished with a separate breathing tube and jar, labelled for identification, which is to be filled with an aseptic solution in which the breathing tube is to be immersed when not in use. The breathing faucet should be cleansed and disinfected after each treatment; the cabinet should be kept cleansed and frequently disinfected.

[2]Dr. William B. Wood, N. Y. Medical Journal, March 5, 1887.

This can be easily accomplished by allowing the spray or vapor to flow into the cabinet with the door closed. The air should at least be fanned out after each treatment. Cuspadores should be cleansed and disinfected after each treatment—or separate ones supplied each patient. The patient should be so placed in position that a good free movement of the thorax and abdomen can be made.. The height of the chair and the distance from the breathing tube should prevent the possibility of the patient acquiring the habit of leaning forward while taking treatment. In warm weather or in heated rooms the cabinet doors should be opened occasionally during the sitting, and the patient gently fanned. A towel should be pinned about the neck of the patient, this should be of sufficient length and breadth to cover the lap, abundance of these should be provided and a fresh one supplied for each treatment. Every detail of refinement not only catches the attention of the patient, but gains his full confidence, and guards him against contamination, contagion and infection.

Patients applying for treatment should be classified if possible, into the following divisions: 1. Developmental, a, connection of faulty respiration, b, calisthenics; 2. Acute non-infectious; 3. Chronic non-infectious; 4. Acute infectious; 5. Chronic infections.

Where it is possible to pre arrange sittings, patients suffering from acute affections should follow each other, and precede the chronic cases, and es pecially the chronic infectious cases. Scrupulous attention should be given to the cleansing and disinfection of the cabinet, and such accessories as has been in use in such cases. Germicidal sprays and vapors should never be omitted in the treatment of infectious (tubercular) cases, even by those who do not sympathize in the belief of the assertion of their germicidal power.

SUGGESTIONS FOR TREATMENT.

First, as a means of Calisthenics.—Respiratory differentiation should be used at first. This may be conducted with the breathing faucet entirely open, but as the patient's respiratory power increases, it may be but partially open, the alternation of pressures can be made greater, and both respiratory and expiratory acts can be maintained until the pressures are equalized. Should there be a tendency to prolonged expiration, a portion of the sitting should be conducted by forced inspiration with high vacuum and a contracted inspiratory aperture.

The inspiratory muscles may be strengthened by maintaining respiration by expiratory differentiation, with a pressure of $\frac{2}{10}$ to $\frac{4}{10}$, expiratory strength may be acquired by the maintenance of the full inspiratory differentiation. This act should only be used when hæmorrhage has occurred or is anticipated, and in pulmonary congestion. In uncomplicated emphysema gentle respiratory differentiation; expiratory differentiation and forced expiration should be used. When there is complicating bronchial catarrh, the treatment may be interspersed by inspiratory differentiation, or forced inspiration with low vacuum $\frac{2}{10}$ to $\frac{4}{10}$, for the purpose of applying appropriate remedial agents. In bronchiectasis expiratory differention and forced expiration, with high pressure, should be the principal treatment. In simple laryngitis, trachetis, and bronchitis, inspiratory differentiation, forced inspiration, with low vacuum $\frac{2}{10}$ to $\frac{4}{10}$, where spray is projected by means of forced inspiration, calculation must be made upon its deep penetration, and sedative, lubricating and emollient agents alone should be used. Hot spray is more grateful to some conditions than the cold blast.

Acute inflammations of the respiratory tract occurring in persons of full respiratory power, do not well tolerate irritating sprays or vapors, and high pressures are unnecessary. Patients whose laryngeal, tracheal and bronchial mucous surfaces have become inured to the frequent passage of catarrhal inflammatory, and degenerative products are more tolerant to the stronger disinfectants, and where œdematous conditions of the bronchial mucous membrane can be inferred. Lugol's solution, 30–50 per cent may be occasionally used with impunity and benefit.

Ordinary spasmodic neurotic asthma is best treated by forced inspiration, or respiratory differentiation; inspiratory differentiation may be possible, but high vacuum may precipitate a seizure. This act may be made possible by the introduction of a proper anti-spasmodic agent. As to the various functional disorders of the lung, produced by pleural effusions or exudates, the non-aërating lobes and lobules following croupous and catarrhal pneumonias, regional blood stasis due to bronchial occlusion. These conditions should receive as preliminary residual air expansion, or compression, or both, followed by respiratory differentiation and then by forced inspiration, and the sitting concluded by inspiratory differentiation. The sleeplessness of anæmia, anorexia, chlorosis and the amenorrhœa dependent upon these conditions, will all receive direct benefit from inspiratory differentiation.[8] Some forms of heart disease should respond to the same act.

(*To be concluded.*)

ENTERECTOMY FOR STRANGULATED HERNIA. WITH REPORT OF A CASE.

BY N. B. CARSON, M.D.,
SURGEON ST. LOUIS MULLANPHY HOSPITAL.

Has the introduction of antisepsis into surgery improved the results of herniotomy? It is claimed by some that the mortality has been lessened by antiseptic methods. Hamilton says: "Mr. Hey states that he lost three out of every five cases upon whom he operated, but it is my impression that the mortality remains about the same as when Mr. Hey wrote, nearly one hundred years ago."

Bruno Schmidt, (Leipsig)[1] states that the mortality of strangulated hernia before the introduction of Listerism was 45.8 per cent., while the mortality since its introduction has been 36.6 per cent., a re-

[8] E. Tiegel, New Yorker Medizinische Presse, February, 1887.
[1] Verhaud. der. Deut. Gesells. für Chirurg. 12th Cong.

duction of 9.2 per cent.; an improvement not commensurate with the improvement in other abdominal operations. Schmidt accounts for this failure by the parts being already necessarily septic on account of their relations. P. S. Connor[2] reports thirty-three cases of herniotomy, with a death rate of 63.6 per cent., and in but one of these *cases did he attribute the cause of death to the wound*, and in that case tetanus was the cause. From this it will be seen that the improved methods of to day have done little for this operation.

When we examine the cause of this fearful mortality we find: Shock, peritonitis, paralysis, hæmorrhage, tetanus, erysipelas, and pyæmia set down as the immediate causes, while stricture plays its part later on. The number of deaths from shock, comparatively speaking, is not very great, while peritonitis, generally septic, plays the most active part; and why this is so can be very readily explained when we consider that the bowel is often returned into the abdomen so soon as it begins to show signs of returning circulation and while it is still in a pathological condition. The following statement clearly explains my views: "Strangulated gut returned in the condition, even if there be no openings, and although it has been well washed, is still septic, and the secretions from its surface will set up a septic peritonitis."

Another very frequent cause of peritonitis, and one that is not anticipated as likely to occur as often as autopsies prove it, is perporation after return. Most cases of strangulation come to the surgeon after the hernia has lasted many hours and often days, and after much time has been spent and much damage done in efforts at reduction. Consequently the bowel is so altered in structure that it is with difficulty recognized when cut down upon. As a result of this, if the part is not already destroyed in its entirety, it is most frequently so softened and changed at the line of constriction that little presure is necessary to cause rupture, which often occurs, as proved by autopsies, after its return to the abdomen. Personally I have not been able to verify this, but I recall two cases, one in my own practice, and one of a friend whom I assisted in the operation, wherein the condition of the bowel was such that its return seemed of doubtful propriety; but as evidence of returning circulation, in both cases, soon became apparent it was decided to return it, and as a result after some hours symptoms of rupture supervened and a fatal peritonitis followed. Here the line of constriction was marked, and no doubt if autopsy could have been made we would have found the bowel open where it had been softened by the tight and long-continued pressure. Often these openings are so small that they escape the hasty inspection made at the time of the operation. Gross says: "At the seat of stricture the bowel is usually ulcerated or pierced with apertures commonly so small as hardly to admit of the escape of gas, much less of mucus and feces." In this way many cases of peritonitis can be accounted for, as gas alone without feces is sufficient to set a septic inflammation.

Paralysis of the bowel as the result of strangulation is another cause of death that must be considered. All authorities on strangulated hernia give it as a cause of sufficient occurrence to be noticed. Connor[3] cites two cases wherein he found this condition, and as a consequence of the tight constriction paralysis of the engaged part of the bowel; the peristaltic action remained arrested, the vomiting continued, and the patient died just as if no operation had been performed. As to the other immediate causes of death little need be said, as they are so infrequent as to require no more than passing notice.

Stricture after strangulated hernia is due to cicatrization, says Mr. Treves, and follows upon ulceration, or limited gangrene of the involved bowel. He says he has found four recorded examples of this stricture, in addition to several specimens to be seen in some of the London museums. This condition may follow the relief of the hernia in from one month to some years, and may involve any part of the alimentary tract.

Having now considered the causes of death, the question naturally arises how are we to combat them? Gross says: "It has been proposed when mortification has been limited, to replace the bowel on the supposition that before the slough can separate, the parts immediately around the seat of the disease will have contracted firm adhesions to the neighboring viscera, thus protecting the peritoneal cavity against fecal effusion." He very justly doubts the propriety of such a proceeding, and says he would certainly discountenance it. An example on the part of nature to protect herself is cited by Mr. Treves, wherein Mr. Travers tied a ligature around the small intestine of a dog. The animal died on the third day, and the ends of the bowel were found to enter a kind of cyst, formed by lymph from the peritoneum. While it is true that nature makes many efforts at restoration, she does not succeed sufficiently to be relied upon, and we naturally look in what direction we can best subserve her interests. The great success attending all abdominal operations inclines us to seek in that direction, and the question is asked and answered by Mr. Sheen[4]: "Should herniotomy from within the abdomen be performed in cases of strangulated hernia? This has hitherto hardly been a question for consideration in the minds of most surgeons when about to operate, but I think that in the future it is well that it should be."

As the following case, which occurred in my own practice, bearing upon the subject in question is of more than ordinary interest, I will introduce it here.

N. R., American, aged 12 years, entered my service in the St. Louis Mullanphy Hospital December 12, 1886, with a strangulated inguinal hernia of several days' duration. He stated that on the Wednesday preceding his coming to the hospital (which was on Monday) while skating he was suddenly seized with a severe pain in the abdomen, which he did not locate definitely. He returned home, and his mother administered simple remedies which failed to bring relief. He noticed then for the first time a lump in the right groin about the size of a hickory nut. His mother's

[2] Medical News, Dec. 4, 1886

[3] Medical News, Dec. 4, 1886.

[4] British Medical Journal, February 19, 1887.

attention was called to this, but as it had been there before, and had always gone away of itself, nothing was thought of it. The next day, being no better, a physician was sent for, who ordered opiates, hot water injections and warm applications to the abdomen. From the opiates he obtained only partial relief, and the injections brought away only a few scybala. Vomiting of a dark brownish fluid, free from odor, supervened on the second day, and continued up to the time of his coming to the hospital. When I saw him, in the afternoon, after his entrance into the hospital I found him with a good expression, with a pulse of 100, regular and of good volume, temperature 98.4° F. The abdomen was distended and showed plainly the convolutions of the small intestine. There was but little pain on pressure. In the right groin was an inflamed tumor about the size of a large hen's egg, painful to the touch and pitting on pressure. The tongue was moist and covered in the centre with a thick white coating, while the edges and tip were red. The bowels had moved last on the morning of the accident. There had been no vomiting for some hours. As the symptoms were not urgent I concluded to defer any operative procedure until next morning when his parents would be present to give their consent.

The next morning his condition had not materially changed. His expression was a little more pinched, his pulse was 112, still regular, but not as good volume as the evening before. Temperature 100° F. The tongue was a little dry, but otherwise unchanged; the abdomen was a little more tense; there was no noticeable change in the tumor, and no recurrence of the vomiting. With the consent of his parents it was decided to cut down upon the tumor, and if the bowel was not already open to incise it and allow the escape of the fecal contents.

The sack was opened; there was an escape of two or three drachms of sero-purulent fluid. The knuckle of intestine was destroyed beyond recognition. When this was opened, there was an escape only of very offensive mucus and serum. The parts were now thoroughly washed with a solution of carbolic acid 1-20, and the examination proceeded with. The stricture was so very tight that I felt sure the bowel had been cut through, and if any attempt were made to divide the stricture the adhesions would be broken, and fecal extravasation result; yet if left alone with the hope that the obstruction might be spontaneously removed, the gut might be torn at the site of stricture, as happened in the case of Mr. M. Banks[6] when, after six days of favorable progress, when the bowel had been left *in situ*, it ruptured, and in an hour or two the patient was dead. After carefully considering the case I decided to open the abdomen, resect the bowel, wash out the cavity and thus give my patient, as I thought, the best chance for recovery.

The abdomen was opened in the median line, the dead part of the intestine cut off close to the external ring, and the wound again thoroughly washed with the carbolic solution, and thoroughly dusted with iodoform. I then introduced my hand into the peritoneal cavity, and my finger entered an opening in the intestine at its exit through the external ring, which doubtless resulted from the very slight manipulation necessary. I then grasped it so as to prevent the escape of its contents, and by careful traction drew it out through the median opening. I then discovered that the entire circumference of the bowel had not been strangulated, but only about four-fifths of it, while the remainder had been drawn so tightly to the border of the ring as to completely occlude it. The part above the constriction was distended, and much congested for some inches, while the part below was collapsed. An assistant held the bowel both above and below the opening, the intestinal contents having been pushed up and down, so as to prevent their escape. The abdominal opening was held together, and it and the exposed bowel were protected with hot towels. I then cut away the injured part of the intestine, being careful to reach healthy tissue, and a triangular piece of the mesentery, the free border of which was allowed to project slightly beyond the resected border of the bowel; this was done to prevent sloughing of the cut edges of the bowel, an accident which too frequently interferes with the success of the operation. The edges of the mesentery were first brought together with a continuous suture of carbolized silk No. 2. Then the intestine at its mesenteric junction was carefully adjusted and held by fine interrupted silk sutures. The mucous membrane was next sutured and subsequently the serous and muscular coats. For this the Lembert suture was used. The parts were then thoroughly washed and returned into the abdomen, which was afterwards cleansed with hot water. The opening in the groin was again washed, dusted with iodoform, a bone drainage tube introduced, and closed with catgut suture. The toilet of the peritoneum having been made, the abdominal opening was closed with silk sutures, bichloride and iodoform dressings applied, and the patient returned to bed and surrounded by hot bottles.

Reaction was complete in a few hours; and as the progress of the case to complete recovery was uninterrupted, it will be unnecessary to give it in detail. The highest pulse rate was 120; the highest temperature reached was 100°. The bowels moved spontaneously on the morning of the fifth day, a healthy stool, free from blood, being the result. The only complaint was some colicky pains which gave trouble for some days. He left the hospital six weeks after the operation, and has remained well ever since.

Considerable shock followed the cutting away of the disorganized bowel, and required the hypodermic use of brandy and ether; the pouring of hot water into the belly aided the reaction, although that had already advanced before this was done. Shock, after the cutting away of the dead bowel, is one of the chief dangers of the operation, and unless the patient is in a condition to resist this, it is better to postpone the resection of the dead part until his condition can be improved. I would advise that just before this part of the operation is reached a full hypodermic injection of brandy and morphine, or ether, be given, in order to prevent this shock as much as possible.

[6] Medical Times and Gazette, May 9, 1885.

Another danger—an insurmountable one—is the time required for the operation; in most cases two hours or more. In completing this operation I was a little less than two hours. Had I been fully prepared for such an operation I would have made it in a little over an hour. This is one of the advantages of the abdominal opening. We are thus enabled to reach the parts better, and by so doing hasten the operation.

The questions now arise, can we lessen the great mortality from herniotomy? and how can we do it? After carefully considering the causes of death in these cases, I think the questions can be answered affirmatively, by opening the abdomen and resecting at once the injured bowel in all cases where there is any doubt of the possibility of a return to a healthy condition, provided the patient is able to withstand the shock and long-continued anæsthesia. If, however, there seems a probability of healthy reaction, allow the injured portion to remain outside, covered with hot aseptic towels, until this question can be positively decided. If it is already dead and the condition of the patient unfavorable for immediate operation, open the bowel and await the improvement of the patient.

Resection for gangrene of the bowel has been performed, according to Reichel,[6] 56 times, with 29 deaths; a percentage of 51.44. Treves adds: "It will be seen that the chief cause of death in these operations is peritonitis, and it must be owned that this peritonitis is usually dependent upon some flaw in the details of the operation." After naming these causes he further says: "It is not, therefore, too much to expect that the mortality of the operation may be very greatly diminished by improvement in the details of the operation." Since Reichel's tables were published, in 1883, I have collected from journals and other sources twenty-one cases of resection of the intestine. Of this number eight died and thirteen recovered (one with an artificial anus). These cases are shown in the following table:

Analysis of the above cases shows that death was caused by shock in 3, septic peritonitis in 5. At time of operation 7 were moribund, 4 were in bad condition, 10 were in fair and good condition. Of the latter only 1 died, and that after 8 days of favorable progress, from septic peritonitis caused by ulceration of a suture. Laparotomy was done 6 times with 3 deaths and 3 recoveries. In 2 the patients were moribund, and in the third there was ulceration after 8 days of one of the sutures. In 5 the resection was secondary, with 1 death.

In regard to the treatment of gangrenous intestine: Shall we resect the dead part at once, or shall we incise, and resect later? Statistics favor the secondary operation, but I think when we examine into the causes of death, we can readily explain why it is so. It will be seen that of the 21 cases cited above 8 only were in good, and only 2 in fair condition. Of this number only 1 died, and that was a case of

Shall the constriction be divided, or allowed to relieve itself? The most rational thing to do, I think, is to allow it to relieve itself, which it will do if let alone. A relief of all distressing symptoms generally follows the opening of the bowel. Unless we intend secondary operation. Leaving the bowel *in situ* is not altogether a safe procedure, as we have already cited in a case of rupture at the site of constriction. An accident, similar in some respects, happened in one of my early operations. Finding the bowel gangrenous I opened it and allowed it to remain in place. Some weeks later the patient, having entirely recovered from the effects of the operation, after eating largely of oranges and other fruit given by friends, he was seized with cramps, followed by symptoms of obstruction, from the effects of which he died two days later.

[6] Treves: "Intestinal Obstruction."

to proceed with the operation, it is only adding fresh dangers to interfere with the bowel, or attempt to relieve the constriction. By so doing we allow septic matters to enter the abdomen, an accident which must assuredly have befallen my case had I attempted it.

In conclusion, I would advise, in cases of strangulated hernia: 1st. When the bowel has been out some hours, and when it has been constricted sufficiently to render its return to a healthy condition at all doubtful, that it should be resected at once, if the condition of the patient is such that he or she can withstand the shock of the operation. 2d. If the condition of the patient is such as not to admit of immediate resection, I would advise that the bowel be incised and left *in situ* without interfering with the stricture, until such time as the condition of the patient will allow the more radical operation. 3d. If the resection is to be made as a primary or secondary operation, I would advise that the abdomen be opened in the median line, as by so doing, I believe, we enhance many times the chances of recovery of our patient, while we do not in the least add to the dangers of the operation.

It is unnecessary here to mention the many advantages of this procedure, as any one at all familiar with abdominal surgery can readily appreciate them.

OCULAR TROUBLES OF NASAL ORIGIN.

Read before the Chicago Medical Society, January 17, 1887.

BY BOERNE BETTMAN, M.D.,
OF CHICAGO, ILL.

The close anatomical connection between the eyes and nose favors the spreading of disease from one organ to the other, by direct continuity of tissue, and also through the medium of the circulatory and nervous systems. Numerous pathological conditions of the eyes and lids are directly attributable to abnormal changes in the nose. Treatment directed to the ocular organs under these conditions will, as can well be understood, fail to influence them.

The lachrymal passage is the connecting link between nose and eye. The mucous lining of the lids and eyeballs is but a continuation of that, covering the inner surface of nose and tear ducts. This fact alone would suggest the rationality of seeking the cause of epiphora, redness of the lids and other abnormal conditions in the nose, provided the disturbances cannot be traced to local causes. Oculists have recognized this connection years ago. Mackenzie, Sœlberg Wells, Schweiger and almost all all other authorities, in enumerating the causes of dacryocystitis, do not fail to mention nasal affections. But none of them devote more than a passing notice to this subject. Not even Schirmer, Michels, De Wecker and Landolt, who have written perhaps the most exhaustive treatises on diseases of the tear passages and the lids, seem to have recognized the important rôle played by the nose in the production of the so-called reflex ocular symptoms.

It is only since the publication of Hack's[1] monograph on the operative radical cure of migraine, asthma, hay fever, etc., that the nose has been regarded as the source of certain ocular complaints which have baffled the efforts of the oculists. Hack in his introductory remarks calls attention to the fact that many persons suffering from "cold" are subject to temporary obstruction of the nose. This condition disappears often as rapidly as was its onset. An attempt to investigate the nature of this impediment to breathing will in many instances fail to reveal a pathological change. The introduction of instruments into the nose or other factors giving rise to a reflex action cause the symptoms to vanish. After repeated examinations made at various times, the physician will at last discover that the lumen of the nose is occluded by a swelling of the anterior end of the inferior turbinated bone. The mucous membrane may show a perfectly normal appearance, indicating that the cause of the swelling is due to changes underneath it, in the cavernous spaces, which become filled with blood, bulging the mucous membrane outwards until it at times reaches the septum. This swelling can give rise, as has been proven, to reflex neuroses in various organs, which can furthermore be allayed by destroying the seat of irritation by operative measures. Thus, Hack accounts for certain forms of migraine, asthma, hay-fever, supraorbital neuralgia, vasa motor reflexes of the skin of the face, epiphora, redness of the lids, turgesance of the conjunctival blood vessels and photophobia. Thickening (hypertrophy) of the mucous membrane, polypi, rhinitis, naso-pharyngitis, deviations of the septum also call forth symptoms of irritation in neighboring organs.

I desire to substantiate the above remarks by citing a few cases which did not yield to the ordinary treatment directed to the eyes, but improved immediately after eradicating the abnormal conditions in the nose.

Case 1.—Eugene F., aged 10, consulted me May 1 for an epiphora of both eyes. His mother stated that the boy's eyes were constantly "weeping" when out of doors. The slightest exposure to the wind, dust or heat would provoke a flow of tears down his cheeks, which were quite eroded from the action of the saline fluid. The eyes were bathed in tears, the conjunctiva palpabrarum thickened and congested. Both eyes were emmetropic. To determine the presence or absence of a stricture in the tear passages, I passed the nozzle of an Anel's syringe into the lower caniliculi, and was able to force the water through the nose in a stream. This indicated a perviousness of the ducts. An examination of the nose revealed an extensive swelling of the anterior portion of both inferior turbinated bones. Whenever I touched these parts with a probe, profuse lachrymation immediately set in. Light thrown into the eyes by means of an ophthalmoscope produced violent sneezing. These experiments convinced me of the reflex nature of the epiphora and conjunctivitis. In order to verify the correctness of my diagnosis I instructed the parent to apply a cocaine ointment several times to the Hack's swelling. The effect was most satisfactory. The overflow of tears ceased almost entirely. I made

[1] Dr. Gruening, of New York, was perhaps the first oculist to call attention to Hack's investigations in this country.

deep incisions into the swelling with a knife electrode, and also employed the flat burner. The slough was completely thrown off after ten to fourteen days. The boy was perfectly cured at the end of a month's treatment. I have seen him since and found no change in his condition. The eyes received no treatment.

Case 2.—Mr. J. K., aged 23, has been troubled for five years by the constant presence of "water in his eyes." It is especially annoying during the winter and on windy days and is always aggravated by sudden changes of temperature. The tear passages were pervious; the eyes normal. Both inferior turbinated bones were greatly swollen. Two applications of the flat electrode completely controlled the abnormal condition of nose and eyes.

Case 3.—Emma K., aged 28, also complained of epiphora, but of the left eye only. Eyes and tear ducts normal. The mucous membrane of the left nostril was highly congested and sensitive. She stated that owing to the pain experienced when breathing on a cold or windy day she constantly kept her muff or handkerchief to the left nostril. The right nostril was apparently normal. I recommended an alkaline solution with which to spray the nose. This relieved the difficulty in a comparatively short time.

Case 4.—Another anomalous condition of the nose, which may provoke secondary changes in the eyes, is the presence of polypi. Such a state of affairs was found in the right nostril of Herman S., aged 26. The flow of tears prevented him from performing the duties of cabinet-maker. He constantly had a handkerchief in his hand to wipe away the tears. He also complained of pain in the eyes and shunned strong light. His physician ascribed these symptoms to a cold, and prescribed two solutions, one to be instilled into the eyes, the other to be sniffed up the nose. The polypi were attached to the middle turbinated bone. I removed them with a Jarvis' snare and succeeded in effecting a cure.

Case 5.—Mrs. Catherine W., aged 35, applied for treatment on August 23, for weeping of the eyes and constant pain above the eye-brows. She also stated that the lids itched and frequently became red at the edges. I found a hypermetropic astigmatism of both eyes, also a convergent strabismus of the left one. Her error of refraction was corrected, the left rectus internus tenotimized, without relieving, however the signs of irritation. I therefore surmised that the origin of the trouble was located in the nose. This supposition was found to be correct. Both inferior turbinated bones were immensely swollen. The mucous membrane along the free edges of the middle turbinated was so thickened as to perfectly obliterate the fissura olfactoria. On inquiry I ascertained that the sense of smell was completely gone. Several applications of the cautery had an excellent effect. At home she employed the douche. When last I saw her, a few weeks ago, she no longer complained of difficulty in breathing through the nose. She sleeps with her mouth closed; her sense of smell is as acute as ever, and her eyes appear and feel perfectly well.

Zuckerkandl calls attention to the obstruction of the fissura olfactoria as a possible cause of anosmia (page 62). The subjoined case demonstrates more than any other, the reflex nature of certain ocular affections, and the immediate relief obtained by the application of cocaine to the inferior turbinated bone.

Case 6.—Emma B. aged 16, was led into my office by her mother. She kept both eyes closed, an attempt to separate the lids being followed by a violent blepharospasmus. Eventually I succeeded in obtaining a view of the eyes, which were bathed in tears and extremely sensitive to light. Every time the eyes were exposed to the glare of the light she sneezed violently. The only abnormal condition I could discover was a congestion of the palpebral and ocular conjunctiva. The girl said that her trouble was of two days' duration. She had several similar attacks during the winter months. I found a Hack's swelling in both nostrils. The introduction of the nasal speculum caused flow of tears and sneezing. I soaked two pledgets of cotton in a 5 per cent. solution of cocaine and placed them in the nose. I repeated this twice, allowing the cotton to remain *in situ* five minutes at a time. The effect of the drug was almost immediate. She gradually opened her eyes, and after a lapse of three-quarters of an hour was able to bear the light. I could not prevail upon her to have the parts cauterized. She now employs cocaine to abort attacks, which she has succeeded in doing on two occasions since.

The greater number of cases which have come under my observation during the last two years have been treated with the galvano-cautery. In every instance the heated platinum was employed; three or four applications were made during one sitting. Several patients gave a second and third sitting before satisfactory results were obtained. Applications of the cautery restricted to the anterior end of the inferior turbinated bone, frequently failed in procuring relief. In such cases I usually found a swelling of the posterior parts of the inferior turbinated bones also. John Mackenzie has shown that a sensitive area exists at the posterior end of the inferior turbinated bone, and Sajous has demonstrated another sensitive spot at the anterior part of the nasal cavity near the angle forming the anterior boundary of the vestibule. The erectil tissue covers the whole surface of the inferior turbinated bone, as was originally described by Kohlrausch and later on verified and more minutely described by Voltolini. This would go to prove that the swelling of the mucous membrane covering the inferior turbinated bone may occur over its entire surface, producing secondary irritation throughout the nose. The various forms of rhinitis and deviations of the septum are also amenable to treatment. The duty of a painstaking physician is to investigate the causes of diseases; oculists will do well to subject the nose to a thorough examination in seeking the source of numerous ocular complaints.

MEDICAL PROGRESS.

Physiological Action of Nitrous Oxide Gas.—Dr. Dudley Buxton has communicated two valuable papers upon the above subject to the Odontological Society, based upon numerous clinical observations and experiments. The effects of nitrous oxide inhalation upon the mammalian organism are, he says broadly speaking—1, a condition of anæsthesia; 2, an emotional state, provoking a sensation of exhilaration—in fact, it plays the *rôle* of a stimulant; 3, it gives rise to modifications of the respiratory and 4, circulatory systems; and 5, provokes marked muscular movements which may be classed as (*a*) rigidity and (*b*) jactitations. The anæsthesia produced by nitrous oxide is not dependent upon analgesia or loss of sensation of painful impressions of the sensory end-organs, such as that produced by cocaine, etc., or upon failure of the conducting sensory nerves, for sensation is retained until the perceptive powers themselves cease to receive; moreover, there is immedialely anterior to the loss of consciousness a hyperæsthetic stage, therefore it may be concluded that the nerve centres are acted upon. The ways by which nitrous oxide may enter the system, and is enabled to produce its special effects are—either that it gives rise to other bodies by changes in its chemical form, or by acting as an irrespirable gas and causing asphyxia, or by exercising a specific action, just as strychnine does. Dr. Frankland came to the conclusion that nitrous oxide was not decomposed during its sojourn in the body, basing his opinion upon analyses made of the air expired by rabbits when confined in an atmosphere of mixed air and nitrous oxide. In the first stage of asphyxia, that of dyspnœa, there is an increase in the respiratory movements, both inspiratory and expiratory; in the second a dominance of the expiratory efforts, culminating in general convulsions, in the last, exhaustion, with long-drawn inspirations, gradually dying out. The blood-pressure during the first and second stages rapidly rises. Dr. Dudley Buxton has never observed an increase in the expiratory movements when HO_2 has been administered, which are merely increased in number and depth, or expiratory convulsions, notwithstanding the gas has been pushed to its utmost limit, and from a large number of sphygmographic tracings the tension in the arteries has been lower than normal. In experiments upon dogs, Dr. Buxton found that where a trephine-hole was made through the skull, during the inhalation of the gas the brain pulsations became more forcible and somewhat hurried; then the brain substance was seen to swell up, until at last it actually protruded through the aperture; whereas in a similar experiment, with the trachea occluded, the brain receded, sinking away from the opening. Other experiments showed that the heart's action was but little interfered with by nitrous oxide, even when inhalations were pushed until respiration was interrupted; during asphyxia, on the other hand, a rapid and continuous increase in blood pressure invariably occurred. The dose of nitrous oxide required to produce insensibility varies very considerably in different persons—a fact which supports the view that nitrous oxide exerts a specific action on the nerve centres. Dr. Buxton also discusses many other interesting points in the action of the gas, such as the occurrence of hallucinations.—*Lancet*, April 9, 1887.

A New Substance in the Urine.—Dr. Leo's researches on sugar in urine are not less interesting, and tend to correct the commonly accepted views on the subject. Professor Scheibler, a chemist well known for his researches on sugar, has observed that the determination of the quantity of that substance contained in a liquid gives different results, according as it is done by Trommer's method or with the polariscope. As sugar now-a-days is exclusively dealt with according to the degree of polarisation, this fact is of enormous value in trade. Scheibler has isolated a substance which is more powerful in that respect than grape-sugar. Dr. Leo's researches yield analogous results, though in a different field. He has examined a great quantity of diabetic urine after three different methods, namely, Trommer's (alkaline solution of copper); by fermentation; and with the polarisation apparatus. In many cases the results agreed, while in others there was a considerable difference. He succeeded in isolating a substance corresponding in its chemical composition to grape-sugar, and also a carbo-hydrate differing considerably from grape-sugar, and turning the plane of polarisation to the left. The power of reduction of this newly-discovered substance is to that of grape-sugar as 1 :2.48. Dr. Leo found this substance in three specimens, of diabetic urine, but it was absent in normal urine, although a great amount was examined for that purpose. From this, it may be concluded that the substance does not originate outside the organism, and that it is a pathological product. The theory of Dr. Jaques Meyer, of Carlsbad, that it may be connected with obesity is negatived by the fact that, of the three persons in whom this substance was found, only one was corpulent.—*British Medical Journal*, Jan. 8, 1887.

The Treatment of Acne.—Lassar recommends the following paste for all forms of acne:

B-naphthol	10 parts.
Precipitated sulphur	50 "
Vasoline or lanolin	25 "
Green soap	āā 25 "

This is to be spread upon the skin to the thickness of the back of a knife-blade, and left on for fifteen or twenty minutes, when it will cause a little burning. It is then to be wiped off with a soft cloth, and the skin powdered with talc. The skin soon becomes inflamed, then turns brown, and finally peels off. The desquamation can be hastened by the application of Lassar's paste with 2 per cent. of salicylic acid. When the desquamation has ceased, the acne will be found to be greatly benefited.—*Therap. Monatshaft.*, 1887, No. 1.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

The Editor of this Journal would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

Subscription Price, Including Postage.

Per Annum, in Advance.....$5.00
Single Copies.....10 cents.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in registered letters.

No. 65 Randolph Street,
Chicago, Illinois.

SATURDAY, MAY 7, 1887.

HIGH PULSE-TENSION.

With our increase in knowledge and means of clinical research has been developed a disposition to undervalue the methods and ideas of our forefathers. With the multiplication of instruments for diagnosis, much of the oldtime dependence upon the eye and finger has been lost. This is particularly true with regard to the pulse. Hence it is with satisfaction that we direct attention to the Croonian Lectures delivered last month in London, before the Royal College of Physicians, by Dr. William H. Broadbent, upon "The Pulse." The speaker excused himself for venturing to consider so old a subject on the ground that there has been a great "awakening of interest" in this direction, and that, although much has been learned, there is still a great deal to be acquired. The lectures may be found entire in the *British Medical Journal*, of March 26, April 2 and 9, 1887, and the *Lancet* of the same dates. They are too long for even a cursory review within the limits allotted to this article. Hence, among the many interesting points considered, we shall direct attention to only that of high tension of the pulse.

By tension is meant the degree of intra-vascular blood pressure; "distension might perhaps be more expressive than tension, if less exact and technical." It is shown by fulness of the artery between beats, the vessel lying like a cord under the finger. The pulse is compressed with difficulty, is slow in ascent, long in duration and gradual in its decline, these characteristics being more marked, the larger the vessel. High arterial tension is chiefly due to peripheral resistance, *i. e.*, hinderance to the outflow from the capillaries into the veins. At the same time the heart's action must be vigorous. The causes of increased tension are, according to Broadbent: 1. Hereditary, as shown by the facts that paralysis and heart disease are often found in members of the same family, although of different habits of life, and that functional derangements, due to high pulse-tension, are seen in childhood and throughout life in many families. 2. Kidney disease of all kinds, except such as is attended with suppuration; being most pronounced in contracted kidney. 3. Gout and allied conditions, including almost the entire range of affections attributed by Murchison to functional derangements of the liver. 4. Lead-poisoning, with or without renal disease or gout. 5. Anæmia. This is not fully understood, nor, as Broadbent says, is it invariably the case. 6. Pregnancy. 7. Constipation. 8. Plethora. 9. Chronic bronchitis and emphysema.

The effect upon the heart of a gradual increase of arterial tension is to produce hypertrophy of the left ventricle, so commonly seen in renal cirrhosis. When, however, high tension is suddenly brought about, the heart is liable to dilatation. This explains the danger, which threatens individuals past middle age, particularly in violent or too prolonged exertion, the more if they are the subjects of gout or renal mischief.

As to whether high tension always calls for treatment, Broadbent thinks not, unless it threaten the structural integrity of the heart or brain, in which case it should be lessened. If apoplexy be imminent, blood-letting should be resorted to, and would save life in hundreds of cases in which it is now sacrificed to popular prejudice against venesection. In other instances tension may be relieved by the administration of appropriate drugs, such as the nitrite compounds and the potassium and lithia salts which latter, by promoting metabolism and diuresis, occasion the elimination of those waste products, whose presence in the blood possibly tends to keep up tension by irritating the arterioles and capillaries into contraction.

There is another condition of the circulatory apparatus in which the arteries are contracted upon their contents, while the blood-pressure is in reality low, owing to feebleness of the heart's action. This Broadbent would designate as "virtual tension," and is the characteristic pulse of cardiac dilatation. "Now, as the artery allows itself to be flattened, the pulse wave which lifts it into the cylindrical form appears to be sudden, and the pressure after lasting a certain time, seems to drop suddenly. The artery may be small or large, and the pulse varies accordingly.

We meet with the conditions which give rise to virtual tension at the two extremes of kidney disease. At the outset of acute renal dropsy, while there is obstruction in the arterioles and capillaries, the heart is rendered weak by the pyrexia and low diet, and there is more or less tendency to it throughout the attack. Again, as the heart becomes worn out in the course of chronic granular disease of the kidney, it ceases to be capable of maintaining the high tension which is characteristic of this disease, and virtual tension takes its place." In certain cases of renal disease the pulse is of low rather than high tension. This, according to the speaker, is due to absence of peripheral resistance instead of cardiac failure, and is a bad prognostic sign. It is most often encountered in connection with the large white kidney. The pulse is weak, soft, of low tension, and there is albuminuria.

Low pulse-tension often appears to be physiological and to run in families, as does its opposite. Broadbent thinks that persons with a pulse of low tension tend to accumulate fat, wear out less rapidly, but resist acute disease more feebly, than do individuals with high blood-pressure.

There are many other points in these Croonian Lectures, of which it is to be regretted space does not permit the consideration. A perusal of the lectures in full would repay the busy practitioner, since they not only contain much valuable information, but also abound in practical suggestions. They show Dr. Broadbent to be a man of intelligent observation, who has profited by his wide clinical experience.

WHAT IS THE SAFEST ANÆSTHETIC?

A discussion on the question of the selection of ether or chloroform as an anæsthetic recently took place before the New York Academy of Medicine, which may be taken as giving a fair expression of the opinion of some of the most experienced men in the country in regard to the relative advantages of these two agents. It is perhaps unfortunate that the discussion did not include other anæsthetics, such as bichloride of methyl and the A. C. E. mixture, the latter of which especially is much used at present, though not to an extent to be compared with the use of ether or chloroform.

It is noticeable that the only advocate of chloroform as the preferable anæsthetic as a rule was Dr. Sayre, who has held this view for many years, because the agent is agreeable to take, speedy in action, excites no spasmodic rigidity, and is not followed by the bad effects sometimes seen from ether. His method of giving it is peculiar, as compared with the usual methods. He uses a modification of Lente's inhaler, which by a rubber attachment can be made to fit any face perfectly: thus the patient is not allowed to breathe any air not charged with chloroform. Ten, twenty, or thirty drops of chloroform, he says, will almost always produce anæsthesia in this way; and if from any cause the heart should show signs of weakness the resort to artificial respiration will quickly cause the patient to expire the entire amount of chloroform. Given with a cone a much larger quantity of chloroform is taken into the system than is absolutely required, and when trouble arises a fatal result is more likely to ensue. But are not the large majority of Dr. Sayre's cases young children?

The views expressed by Dr. Knapp are certainly worthy of more than ordinary attention, as from 1860 to 1874 he used chloroform in more than 3,000 cases; and while he had no fatal results he had a number of critical cases. Since 1874 he has used ether exclusively, and has had no ground for complaint, and has found no contraindication for the administration of ether. He gives it by the "choking plan," though at the beginning the patient is allowed sufficient air to prevent the sensation of strangulation so often complained of. He has had no fatal cases, and has not found that the secondary effects are more unpleasant than those of chloroform. But there is one point to be considered in his experience: in several hundred of his cases the average duration of anæsthetization was one minute thirty-seven seconds; and we cannot draw absolute conclusions from an experience in these cases as to what will take place when the anæsthetic is given for long surgical operations. With anæsthetization of one or two minutes there cannot be the same risk to subsequent lung and kidney trouble as when ether is used for half an hour or an hour. And while anæsthesia of two minutes' duration in a case of renal trouble might not be followed by bad effects, it probably would if the agent were used for half an hour.

Dr. Gerster takes a more middle ground regarding these two agents than do most surgeons. While granting that chloroform is by far the more powerful agent, he does not join in the wide condemnation of it; he would have it used more cautiously. And while it is more dangerous at the time of operation, its use is not followed by the secondary affections of the lungs and kidneys seen after the use of ether. He thinks ether contraindicated: 1. When acute or chronic nephritis is present, or is supposed to exist. 2. When there is any chronic pulmonary affection,

especially in the aged, the very young, and feeble persons generally. 3. When it will not produce the complete anæsthesia and relaxation indispensable for the performance of many operations. The presence of a fatty or weak heart of course contraindicates chloroform, as does fright, probably, while it lasts. But valvular lesion is not a contraindication if there be satisfactory compensation by muscular hypertrophy, as shown by the regularity and character of the pulse. In anæmia, as a rule, chloroform is not so safe as ether, nor is it safe in marked nervous depression. But Drs. Weir, Wyeth and Thallon do not admit that nephritis is a positive contraindication to the use of ether. In regard to the pulmonary troubles sometimes seen after the use of ether, Drs. Weir and Abbe point out that these may be avoided by having the patient less exposed during the operation, keeping hot towels about him, and using greater care in transferring him from the operating room. As for the collection of mucus in the air-passages during the administration of ether, Dr. Amidon showed two years ago that it may be avoided by giving atropia hypodermatically before the operation.

It may be said that Dr. Wyeth formulated most clearly the cases in which chloroform is justifiable: 1. In children under six years of age, in whom it is less likely to cause an accumulation of mucus in the trachea and bronchi than ether; and for this class of cases it is preferable because it is more rapid and less irritating in action than ether. 2. In women in childbirth, where the recumbent position is imperative (and we may add, because it acts better than ether). 3. In an emergency when ether cannot be obtained. 4. In a patient who has previously taken ether badly. 5. In an emergency when it is necessary to perform an operation within two or three hours after the ingestion of solid food. 6. In exceptional cases of laryngeal or tracheal stenosis.

It must be said that much of the trouble from anæsthetics is due to careless or faulty administration. There is a wide-spread impression that anyone can give the anæsthetic; and there are many surgeons who still adhere to the towel-cone, giving unknown quantities of ether or chloroform, though it has been repeatedly shown that inhalers should be used. Many surgeons give morphine or atropia, or both, before beginning the anæsthetic; this is a wise precaution, but does not justify carelessness in giving the anæsthetic. Dr. Thallon uses the ordinary inhaler employed by dentists for nitrous oxide gas when giving ether, and with it he has kept up anæsthesia for hours without using more than a quarter of a pound of ether. All anæsthetics are dangerous, and become more so when administered in unknown quantities and in an unsafe manner

ABORTIVE MEDICATION.

In his *Thèse d'Agrégation* for the Assistant Professorship of Medicine, Dr. De Beurmann recently took for his subject "De la Médication Abortive" (Abortive Medication). The question has often been put, What is abortive Medication? To this the author replies that it is that which is intended to interrupt the course of a malady in its natural evolution. Strictly speaking, abortive medication ought to arrest a malady in its earliest stages, to cure it in an extremely short time, and produce the *restitutio ad integrum* of the organs affected by the morbid process; in other words, to cure in a sure and rapid manner, to diminish notably the length of the duration of the malady, or, as the author expresses it, to jugulate, should be the end of drugs and abortive means. In the present state of science, abortive medication is not yet established, nor yet is the direction in which it should be employed clearly indicated. Medical antisepsis will no doubt become in the future one of the procedures to which one will have the most frequent recourse, and the antiseptics will be placed in the front rank of abortive medicaments. De Beurmann refers to some of the diseases to which the so-called abortive treatment has been applied, the effects of which have till now been more or less satisfactory. For example, numerous drugs have been employed against blenorrhagia, as nitrate of silver, corrosive sublimate, carbolic acid, solutions of the salts of quinine, permanganate of potash, etc. The results obtained have been somewhat encouraging, but the medication may be considered inefficacious, as it is difficult to reach the micro-organisms which have penetrated to the interior of the mucous glands of the urethra. Abortive medication has rendered useful service in the treatment of furuncles, carbuncle, diffuse phlegmon, bubo, etc. Surgeons have aborted boils by a strong application of the tincture of iodine, by injections of carbolic acid; another pretends to have obtained the same result more quickly by making a deep incision at the very beginning of the malady, but this is followed by a prolonged application of spirits of camphor, which is known to possess antiseptic properties, and which should be taken into account in the result of the medication. Some surgeons employ multiple punctures at the commencement of diffuse phlegmon, but M. Le Dentu prefers large incisions which, if employed at the outset of the exudative period, will, according to this surgeon, be capable of arresting the progress of the inflammation, and even of completely preventing suppuration. It is known that the

evolution of charbon is marked by two stages: in the first the infection is local, in the second it is generalized and irremediable. It is sufficient to intervene before the second stage to make the malady abort. This may be done by the eradication of the malignant pustule, followed by deep cauterization and by iodine injections into the periphery of the œdematous zone.

By analogy, the same happy results were hoped for in syphilis, tuberculosis, and other affections. But the utility of the extirpation of the chancre is strongly combated, by a great number of authors, and those among the most competent, absolutly deny any efficacy in the operation. The question is then suggested, whether the constitutional treatment of syphilis may be considered as an abortive medication; to this, however, De Beurmann makes no reply. Another question suggested is, whether tuberculosis is a virulent malady, comparable to syphilis, generalized immediately after inoculation? This doctrine is not without its partisans, but, as De Beurmann suggests, this is no reason why the abortive medication should be neglected in these cases, as most encouraging results have been obtained by the ablation of a local tuberculous mass, anatomical tuberculosis, lupus, masses of osteitis, cold abscesses, etc. In favor of surgical interference, the author argues that certain masses of tuberculosis, local in appearance, are only manifestations of general infection, while others are truly local affections and consequently curable. In puerperal infection antiseptic injections, which have been so much vaunted in these latter times, have given the most brilliant results. Even rabies, which till now has been considered incurable, may be usefully combated by the abortive medication, now known as the method of Pasteur or the anti-rabic inoculations. Against pneumonia, typhoid fever, no abortive remedy has as yet been found efficacious, notwithstanding the daring attempts that have been made in this direction, particularly as regards pneumonia.

The antiseptic injections even in the body of a pneumonic mass are still too recent to judge of their efficacy or otherwise. Intestinal antisepsis and general antisepsis render very great service in typhoid fever, but we cannot really say that they have jugulated the malady. Fortunately the same cannot be said of the salicylate of soda in acute articular rheumatism, and of sulphate of quinine in paludal infection, which are two precious medicaments, and really abortive. It has been asked whether the medication by ether and opium in combination, recently recommended by Dr. Du Castel against small-pox is of any real use in that malady. It appears however, to have attenuated the malady, by aborting the suppurative process.

THE AMERICAN MEDICAL ASSOCIATION AND THE JOURNAL.

As we issue a large extra edition of the present number of The Journal for general circulation to members of the profession in all parts of the country, we have presented all that we could gather at this date of direct interest to members of the Association, concerning the programme of work, both in general session and in the Sections, and the reductions in railroad fares and hotel charges so far authorized. The programme is incomplete, and it is desirable that further reports of papers and contributors should be forwarded to the Chairman of the Committee of Arrangements as early as possible. The indications thus far point to a large meeting, and one of the most important that has been held in many years. The promised liberal reduction in railroad and hotel charges, and the central position of the place of meeting and its easy access from all directions, are favorable for a large gathering of representatives from every section of our country. And they will certainly receive a cordial welcome from the profession and citizens of Chicago.

The Editor of The Journal and his assistants will be no less happy to welcome the members of the Association to the publication office, where they can more readily realize the progress made during the little less than four years since the first number of The Journal of the American Medical Association was issued. At that date, 1883, and for the preceding five years, the average annual receipts of the Treasurer indicated less than 1,000 members regularly paying the annual membership dues, while since that period the number has increased more than threefold, and with the receipts from subscribers and advertisers, has so increased the income that, instead of $5,000 as in 1883, it will reach not less than $20,000, as will be shown in the forthcoming report of the Treasurer for the current year. And instead of indebtedness, as many feared, they can see a productive surplus of printing material in active use exceeding in cash value $1,058—constituting the nucleus of a printing and publication establishment which, at the end of another decade of judicious business management, will equal a working capital of $10,000, and then doing the work of a weekly journal of nearly double the number of pages of reading-matter printed at present. The present status will justify

the addition of four more pages of reading-matter at the commencement of the next volume. But it should not be forgotten that all true progress must be in the line of natural growth or well-proportioned development.

Illinois State Medical Society.—The annual meeting of this important State organization is to commence in this city on Tuesday, May 17. It is highly important that there should be a full attendance from all parts of the State. Neither the local Committee of Arrangements nor the profession throughout the State should allow the fact that the American Medical Association is to have its annual meeting in the same city only three weeks later, to lessen their interest in, and attention to the professional organization of their own State. The legitimate basis of all efficient general organization of the profession consists of the local City, County and District Societies embracing the general practitioner and specialist alike. Representatives from these make the State Societies; and on the efficiency of the several State organizations will always depend the character, scientific value, and permanency of the National Association.

Swiss Delegates to the Congress.—We learn with pleasure that the Swiss Confederation have appointed Professor Theodor Rocher, of Berne, Switzerland, and Dr. Henry A. Banga, resident in Chicago, U. S. A., as delegates to the International Medical Congress, to be held in Washington, Sept. 5, 1887.

The West Virginia State Medical Society, will hold its twentieth annual session at White Sulphur Springs, W. Va., July 13, 14 and 15, 1887. The Secretary is J. L. Fullerton, M.D., of Charleston, W. Va.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, March 21, 1887.

The President, E. J. Doering, M.D., in the Chair.

(Concluded from page 470.)

Dr. William T. Belfield read a paper on

DIGITAL EXPLORATION OF THE KIDNEY, WITH REPORT OF THREE CASES.

Of some 250 cases of nephrectomy heretofore reported, about 44 per cent. have died from the effects of the operation. The chief causes of death have been:

1. Shock (42 per cent. of the fatal cases).
2. Uræmia (14 per cent.).
3. Peritonitis (21 per cent.).

These three factors were thus responsible for 77 per cent. of all deaths. Improvement in the results of renal surgery seems, therefore, to require means for the avoidance of these three great dangers.

The chances of fatal shock are decreased by early operation, before the patient is exhausted and the damage to kidney tissue extensive through long illness. This self-evident proposition is illustrated by the fact that, while about 18 per cent. of all (250) nephrectomies have died of shock, yet of 24 nephrectomies of fairly healthy kidneys removed for wounds of loin, ureter, for mobility, etc., not a single death occurred from shock.

The greatest obstacle to the early surgical treatment of renal diseases has been *faulty diagnosis*. Such cases are usually treated as lumbago, sciatica, hip-joint disease, and (especially) cystitis, for a long time before the true seat of the lesion is detected or even suspected. Since it is not always remembered that pyelitis produces symptoms identical with those commonly ascribed to cystitis, the former is not suspected, and a diagnosis of cystitis is made; and as cystitis is still too generally regarded as an entity, a disease instead of a mere symptom requiring explanation—the patient is treated for "chronic cystitis." Finally, months or years later, a lumbar swelling or other symptom reveals the renal origin of the difficulty. Meanwhile the patient has become so enfeebled that he succumbs to the shock of an operation that could have been safely borne at an earlier period. Early exploration of the kidney—a comparatively slight operation—has, by drainage of the pelvis, in many cases relieved a difficulty which at a later stage would have required nephrectomy, a formidable operation; moreover, a preliminary drainage has been shown to be a valuable factor in diminishing mortality from nephrectomy. Thus, of seventy-three nephrectomies for suppurative lesions collected by Gross, twelve were made after previous exploration of the kidney, with but one death; of the remaining sixty-one—without previous nephrotomy—thirty-one died.

Uræmia rarely occurs after any renal operation provided the second kidney be present and in healthy condition. While commonly associated with nephrectomy, one of the annexed cases shows that uræmia may be inevitable after simple nephrotomy; hence a necessary preliminary to any renal operation should be an attempt to ascertain the functional condition of the opposite kidney. In the female this can often be accomplished by cauterizing the ureter, after Pawlik's method; in the male probably the best, though still an uncertain, means is Silbermann's instrument for compressing one urereter. (Instrument shown.) The statement that the abdominal incision, by permitting digital examination of the opposite kidney, obviates the dangers of uræmia, is fallacious; for in many cases kidneys which are indistinguishable by the finger, or even by the eye, from normal organs

are extensively invaded by disease—inflammatory, tuberculous or calculous. The pair of kidneys exhibited by Dr. Steele this evening are signal examples—normal in size, contour and consistence, yet each extensively tuberculous. Palpation through an abdominal incision could have detected nothing abnormal in either of these kidneys.

The following cases illustrate several of the principles above enunciated:

S. M., widow, 26 years old, delicate since childhood; has had dyspepsia for years; for a year past has suffered from headache, pain in back and left thigh; menstrual intervals shortened to two or three weeks. Was variously treated for lumbago, sciatica, and ovarian disease. In March, 1886, urination was unduly frequent and sometimes painful; urine contained pus and blood; was treated for cystitis.

On admission is emaciated and feeble; urination every half-hour or oftener, painful; has frequent pain in lumbar region, often shooting down to left thigh; requires morphine constantly. Urine acid, depositing blood, pus, and occasional rosettes of large uric acid crystals.

Diagnosis, calculous pyelitis, probably limited to left side; right ureter catheterized and urine appeared normal.

November 29, 1886, kidney was exposed and pelvis explored; mucous membrane rough and ulcerated, clots of pus evacuated; wound in kidney packed with gauze.

Except for persistent vomiting for a few day, recovery was without notable incident. The renal fistula was closed on the twenty-first day; patient has since been free from all her former symptoms and is regaining flesh and strength.

G. F., 30 years old, was knocked down by a cable car November 28, receiving a lacerated wound of right hand and various contusions. The hand was dressed, and patient presented no notable symptoms until December 11, when often straining at stool he passed a large quantity of blood with the urine and had severe pain and tenderness over the right kidney, with some temperature; these symptoms persisted in spite of rest, ergot, gallic acid and opium; the right loin while not swollen, felt boggy. December 22, the patient having experienced several irregular chills and sweats during the previous day, a lumbar incision was made down to the right kidney. The peri-renal tissues were found closely adherent, extravasated blood was seen under the capsule and a rent one and a quarter inches long was found in the posterior surface of the kidney extending into the pelvis; about half an ounce of a watery fluid lay behind the kidney. A large drainage tube was inserted. The temperature remained high for several days, after which recovery rapidly ensued, and January 14 the patient was discharged well; the wound entirely healed.

C. L., 48 years old, farmer, began some two and a half years ago to suffer from slight pain and stiffness in the loins; later, pus appeared in the urine; was treated for Bright's disease. About a year ago urination became frequent and sometimes painful; was supposed to have cystitis. Has lost flesh; his rest has been much disturbed by frequent calls to urinate. Six months ago he passed two small calculi after some renal colic on left side; since that time has had slight colic on left side several times, followed by expulsion of clumps of pus but no calculi.

Diagnosis, tuberculous or calculous pyelitis, probably former, bacilli were found in one examination of pus, and the lower organs were normal.

Exploration, January 26. The kidney (left) was considerably enlarged; no calculus could be detected with finger or needle. Incision through kidney showed the pelvis considerably dilated, its orifice narrowed by a thickening of upper part of ureter; mucous membrane ulcerated in several places; the pyelitis evidently tuberculous.

Nothing of note occurred until the fifth day, when the urine became scanty and tinged with blood; soon the usual evidences of uræmia became manifest, and death ensued from this cause on the eleventh day. A partial autopsy showed that the right kidney was extensively, the left slightly tuberculous; bladder and prostate normal. Evidently the right kidney, which had never caused pain, had been first diseased; the function of the left, which had latterly been performing most of the renal excretion, had been arrested not by the slight incision, but by the congestion which followed the removal of the accustomed pressure in the dilated pelvis. Similarly uræmia has followed the sudden evacuation of a habitually distended bladder.

To summarize: 1. Surgical affections of the kidneys and its pelvis are frequently masked under symptoms of cystitis, lumbago, hip joint diseases, etc.

2. Digital exploration of the kidney and its pelvis often affords the only available means for accurate diagnosis in the early stages.

3. When made with due precautions, this operation is almost devoid of danger; while saving the kidney, it may accomplish all that a dangerous nephrectomy could offer at a later stage; and if it fails to cure, it materially increases the chances of recovery from a subsequent nephrectomy.

4. An investigation into the functional condition of the opposite kidney should precede an exploratory incision into the pelvis.

GYNÆCOLOGICAL SOCIETY OF BOSTON.

Stated Meeting, February 10, 1887.

The President, H. M. Field, M.D., in the Chair.

H. J. Harriman, M.D., Secretary.

A paper contributed by Dr. Apostoli, of Paris, entitled

"ON A NEW METHOD OF TREATMENT OF CHRONIC METRITIS, AND ESPECIALLY ENDO METRITIS, BY THE INTRA-UTERINE CHEMICAL GALVANO CAUSTIC,"

To be successful in this operation the following electrical instruments are necessary:

First.—A medical galvanometer divided for intensity into milliampères.

Second.—A permanent battery of sufficient size to last for some time and to preserve practically the same strength after several successive operations. The best battery is that of Leclanché.

Third.—An intra-uterine electrode of sufficient length to reach all parts of the uterine cavity and which is not affected by acids, as platinum. It must also be provided with a muff to protect the vagina, the best being a celluloid tube.

Fourth.—A neutral or insensible electrode, which applied to the abdomen, allows a very intense current to pass without pain, without heat and without fear of burns; the best is the one invented by Dr. Apostoli in 1882.

Fifth.—Cords supple enough not to obstruct and resisting enough not be easily broken.

The details of the operation are as follows:

1. Make a tepid and antiseptic vaginal injection, placing the patient as if for an examination by the speculum.

2. Charge the battery, arrange the galvanometer and put in proper position the clay muff.

3. Introduce into the uterine cavity slowly and progressively the electrode previously singed and disinfected.

4. Cauterize the unterine cavity thoroughly and positively in all hæmorrhagic cases and less thoroughly in other cases.

Never surprise the uterus or make a too painful application, for it should be remembered that there are irritable uteri which can receive treatment only in a very mild form. After two or three applications the intensity must be increased, reaching in most cases 100 to 150 milliampères and in some cases to 200 milliampères. The intensity must at first be proportioned and regulated according to the patient's power of endurance; afterward according to the extent and gravity of the lesion and the time it has existed. The duration of the application should vary from five to ten minutes. Applications should be made every week and every second day if required. A rest of several hours should be required of all patients who have been operated upon. This rest is necessary for the safety as well as for the efficacy of the method. Vaginal antiseptic injections night and morning should be ordered. This simple and harmless treatment is only a galvano-chemical scraping, acid or basic, according to cases. It induces a formation of new mucous membrane and forms a kind of intra-uterine exudation, the action of which can be varied at will. Its beneficial effects, which Dr. Apostoli has verified in a great number of instances, does not fail to make itself felt from the first, increasing rapidly and soon restoring the patient to health. It does not condemn the woman to a forced repose and calls for no additional treatment.

Dr. E. W. Cushing did not see any advantage in the method described by the paper over the usual practice of giving ether and curetting the interior of the uterus under antiseptic precautions. He certainly regarded the latter as the shorter and safer method, inasmuch as he understood that Dr. Apostoli's procedure required, in some cases, as many as 90 or 100 applications. He did not understand from the paper whether the desired effect was produced by simple electrolysis or by galvanic cautery; if by electrolysis it was nothing new, as Dr. Cutter has used it in a similar way; if by cauterizing, its extent and depth of destructive action could not be accurately controlled, and thus its action was uncertain.

Dr. L. F. Warner understood from the paper that the action was simply an electrolytic one. He thought that it would be a dangerous method of procedure in the hands of the inexperienced or careless as the degree of effect could not be accurately known. The effect of the application might go so deep as to injure the deeper tissues of the uterus and thus set up an inflammation, or it might not reach deeply enough to remove all the diseased tissue. Unless it has the same effect as curetting it will fail to accomplish its purpose.

OVARIAN TUMOR ATTACHED TO VERTEBRA-BIFID UTERUS.

Dr. E. C. Keller presented a tumor with the following history: Patient 19 years old. Was sent to New England Hospital two months ago and was supposed to be pregnant. She stoutly denied the possibility of such a condition. Upon examination fluid was found in the abdominal cavity and external ballottement gave evidence of a solid tumor. The ascites increased to such an extent as to make relief of some kind necessary. The trocar was introduced twice but no fluid was withdrawn. Subsequent developments showed that the trocar struck the solid tumor both times, and thus prevented the exit of the fluid. The abdomen was then aspirated and four quarts of fluid removed; the remainder of the fluid leaking out after the aspiration. Peritonitis followed the tapping and the radical operation was postponed three weeks. Upon opening the abdomen a solid tumor was found attached to the fourth lumbar vertebra. This tumor had arisen from the left ovary but was attached to the right side. The uterus was bifid. The patient had never menstruated, but last May had molimen. Good recovery.

FOREIGN CORRESPONDENCE

LETTER FROM GLASGOW.[1]

The University — The Hunter Collection in the Museum—Surgery in Glasgow—MacEwen's Osteotomies — Operation for Cerebral Abscess — Radical Operation for Hernia — Cerebral Cyst—Treatment of Fractures—Subcutaneous Osteotomy versus Abdominal Section in Obstetrics.

A walk with Prof. George Buchanan through the various departments of the University of Glasgow soon convinced me that Glasgow may well be proud of her school as every branch has been supplied with every conceivable facility for teaching, regardless of expense. The buildings are located upon a hill in the western part of the city, and are surrounded by a beautiful park. We met Sir William Thompson,

[1] By permission of Drs. Fenger and Senn.

one of the most famous of scientists, in his laboratory busily engaged in his scientific investigations. The weight of advancing years appears to have no effect in diminishing his working power.

Mr. Young, the Curator of the Museum, a most accomplished scholar, very kindly showed me the most interesting specimen in William Hunter's collection. I had here an opportunity of examining the specimens and casts which had been used in illustrating the classical work of Hunter "on the Gravid Uterus." For any one who has had an opportunity to examine the wonderful book it is a great source of satisfaction to study the original specimens from which the illustrations were made. In these days of unsuccessful cholecystotomy it is interesting to look at a specimen of 1,070 gallstones, varying in size from a filbert to a millet seed, taken after death from the same patient. In the collection of urinary calculi I examined with much interest a stone corresponding in shape to the interior of the bladder, and which, as the label stated, weighed 1 pound 2¾ ounces. A number of specimens illustrate the etiological relation between renal calculi and hydro- and pyonephrosis. A number of specimens showed impaction of the renal calculus in the pelvic extremity of the ureter with extensive localized cystic dilatation of the pelvis of the kidney and its calyers. In one case the stone had become arrested near the vesical extremity of the ureter followed by immense dilatation of the tube above the point of obstruction and dilatation of the pelvis of the kidney. The anatomy of the male and female organs of generation is illustrated by numerous careful dissections, some of them have been treated with mercurial injections, which even at this time present the vascular network in a perfect manner.

In the surgical wards the antiseptic treatment of wounds is not thoroughly practiced. I was shown two cases of operation for hæmorrhoids done according to the plan devised by Dr. Lange, of New York. Excision of a circular strip of the ano-rectal mucous membrane with the eclatic veins and suturing of the wound. In one case the operation was attended by serious hæmorrhage, while in the other it was nearly bloodless. Both patients were doing well.

I called on Dr. Wm. MacEwen, whose name has become familiar wherever orthopœdic surgery is practised. He informed me that he had performed his operation of subcutaneous osteotomy with the chisel 900 times for genu valgum and varum and curvature of the leg, and out of this number of cases he never observed a bad result. He is very particular that the line of section in cases of genu valgum and varum should be made above the epiphyseal line by selecting as the fixed landmark a finger's breadth above the external condyle of the femur. The small incision for the chisel is made at a point diametrically opposite and in part of tendon of the adductor magnus, so as to avoid the anastomotica magna artery. In none of his cases had he found it necessary to resort to measures of any kind to arrest hæmorrhage. In the hands of other operators the popliteal artery had been injured, an occurrence which he attributes to carelessness of the chisel. In making the section of bone he directs that the chisel should be always directed away from the artery. In children suffering from rachitis the operation is postponed until the disease has subsided. The process of callus-formation proceeds in the same manner as in subcutaneous fractures. After osteotomy the deformity is at once corrected and the limb immobilized the same as after a fracture. He has divided as many as eight bones at one sitting and has never observed embolism or any other untoward symptoms. For genu valgum he usually applies a well padded splint with a foot board along the outer side of the limb, this splint is fastened upon a cross piece to prevent rotation.

He showed me a case in his private practice where he had operated for cerebral abscess about four weeks ago. The patient was a boy about 7 years of age who had suffered from purulent inflammation of the middle ear with perforation of the tympanum for some time. A number of weeks ago cerebral symptoms appeared, and the mastoid process was opened behind the ear by another surgeon without any benefit. When the boy came under the observation of Dr. MacEwen, he showed distinct signs of mental perturbation; the pulse was slow and the temperature subnormal. The only focal symptom was a slight ptosis on the affected side. From the history of the case and the complexus of cerebral symptoms it was concluded that the patient was suffering from a cerebral abscess. The head was shaved and thoroughly disinfected, and the trephine applied at a point about an inch above and an inch behind the external meatus. When the disc of bone was removed the dura mater appeared tense, but otherwise normal. No cerebral pulsations. A thoroughly disinfected needle was inserted and passed in a downward and forward direction towards the petrous portion of the temporal bone, the supposed seat of the abscess. About an inch from the surface pus was found. The abscess was incised and about an ounce of cream-colored pus escaped. For the purpose of securing more efficient drainage a very small trephine was applied over former site of operation, and an opening made in the floor of the abscess cavity. The middle ear, the primary seat of suppuration, was thoroughly scraped out with a Volkmann's spoon and thoroughly disinfected. The first trephine opening was closed with bone from the disc removed, an aperture sufficiently large being left for the drainage-tube. Another drain was introduced from below, thus securing efficient through drainage. An antiseptic occlusion dressing finished the operation. The effect of the operation was marvellous. The stupor disappeared promptly and full consciousness was restored in a few days. The discharge was slight, and at present the boy runs about and plays, nothing indicating the gravity of the former lesion. The defect in the skull has been almost completely repaired, a slight depression indicating the location of the trephine opening.

Dr. MacEwen places great stress on the importance of replacing the disc of bone *in toto* or in fragments after trephining, for the purpose of obtaining closure of the opening by bone during the reparative process. He is a firm believer that in an aseptic

wound completely detached fragments of bone not only retain their vitality, but take an important part in the process of repair. A number of cases which I saw in his wards would certainly tend to prove the importance of imitating his practice.

This operation for the radical cure of hernia by inversion of sac and closure of inguinal canal by stitching the pillars over each other has yielded the most satisfactory results in his hands. The inverted sac forms a cushion over the double layer of tendinous structures, conditions which necessarily offer a maximum resistance against the subsequent intra-abdominal pressure which, after the ordinary operations, tends so often to a recurrence of the hernia. He has performed the operation a great many times and has lost only one case from peritonitis and has never observed a return of the hernia.

I visited the Royal Infirmary with Dr. MacEwen, and saw another case of cerebral surgery. A little boy about 4 years of age who was running about the ward was pointed out as one of the most recent cases. The lad sustained an injury of the skull in the temporo-parietal region a few months before admission. Almost immediately after the injury hemiplegia was observed on the opposite side. The paralysis remained and was complete on his admission into the hospital. A few weeks ago, under strict antiseptic precautions, the disc of bone was removed over the fissure of Rolando at a point corresponding to the motor centre for the lower extremity. The dura mater was found tense and not pulsating. The dura was incised and several ounces of a clear fluid escaped. Further examination revealed a subdural cyst lined with a brownish membrane, a sharp fragment of bone from the internal table of the skull was found projecting into the brain and was removed. The interior of the cyst was scraped out with a sharp spoon and another smaller opening made in the skull and membranes at a lower point for more complete drainage. The large disc was replaced, only a small opening being left to secure drainage at this place. The case was explained by assuming that the injury produced a fracture of the skull and subdural hæmorrhage sufficient in amount to cause the primary paralysis, and that a cyst formed at the site of the blood clot which kept up the paralysis. The operation was performed about six weeks ago, and was followed immediately by disappearance of paralysis, so that at present both motion and sensation are nearly perfect. The bony wall at site of operation is perfect and only slightly depressed.

Another case of injury to the skull was shown which illustrates in the same striking manner the prompt effect of surgical treatment. A young man in perfect health received an injury to his skull some two years ago. No symptoms attributable to the injury were observed until six weeks ago when patient was attacked with severe headache and epilepsy. He had a hundred or more attacks daily, but never completely lost consciousness. The muscular spasms were limited to the side opposite where the skull was injured. At the point of injury a slight depression could be felt. At this point a disc of bone was removed with the trephine, which directly exposed the brain, showing that the meninges were ruptured at the time the injury occurred. Where the brain was exposed a limited circumscribed area of inflammation and softening was found, but no indications of suppuration. The diseased tissue was removed with a sharp spoon, and although the patient at this time appeared to be thoroughly under the influence of chloroform, he had a violent convulsive attack. The cavity created by the spooning was drained through a defect of the bone disc and the usual antiseptic dressing applied. Since the operation the patient has been free from pain and convulsions, and as the wound is nearly healed we can safely assume that the recovery will be complete.

The three cases related above show conclusively to what extent cerebral surgery can be practiced with success in cases which heretofore were doomed to succumb to certain death. Dr. MacEwen is taking a great interest in this modern department of surgery, and we may safely predict that a man of such ability and indomitable energy will point out new indications and methods of operation for the successful treatment of injuries and pathological conditions of the brain and its envelopes. Dr. MacEwen advocates the propriety of treating subcutaneous transverse fractures of the patella from muscular contraction, by suturing, as he claims that in all such cases bony union by any other measures is prevented by interposition of soft parts between the fractured ends, and that an apparent good result after the ordinary methods of treatment always leads to bad functional results by the gradual elongation of the cicatricial tissue between the bone ends. Fractures of the femur are treated by an outside long splint well cushioned, and short splints surrounding the thigh. After excision of the elbow joint he resorts to passive motion as soon as the wound is healed. During the day the forearm is flexed upon the arm, and supported here with an elastic band passed over the opposite shoulder, which tends gradually to increase the flexion, while at night the arm is straightened by weight and pulley extension.

He makes a very important suggestion to obstetricians by advocating the substitution of subcutaneous osteotomy for the more grave operation of abdominal section in cases of greatly contracted pelves. He claims that his experiments have demonstrated that section of the pubic bone an inch and a half or two inches from the symphysis pubis and section of the ascending rami of the ischium, would add one and one-half inches to the antero-posterior diameter of the pelvis, and that in case more room is required the ilium could be divided on each side. It would seem that this suggestion should be seriously considered by obstetricians, and as Dr. MacEwen is ready to do this operation the first opportunity that presents itself, it is to be hoped that the profession of Glasgow will call upon the master of subcutaneous osteotomy in the first case where such a procedure is indicated, so that he may demonstrate the feasibility and advisability of substituting a simple and safe operation for cases which have been until now subjected to abdominal section, which, so far, has been attended by a fearful mortality. N. Senn.

DOMESTIC CORRESPONDENCE

GALVANIC MEASURE.

Dear Sir:—You have kindly opened your valued pages to me, which I deemed necessary to protect American Electro-therapy from ridicule. I have called attention to the error, and that ends the matter as far as I am concerned, but I beg again for space, not to answer the personal attack made upon me, as that is neither of interest or importance, but to add another word to the subject of galvanic measure, that your readers may understand why I have spoken so positively.

In this progressive age it may seem bold to the superficial observer to say, "that no one ever has used, or ever will use a certain remedy without danger," but the electric current is a force so well known in certain respects, and so exactly measurable, that we can draw the line with assurance; and I am no more a prophet in saying that ten ampères of current can never be used upon the living subject than were I to say that you cannot explode a dynamite cartridge upon the abdomen without serious injury to the subject. About the same effect would be produced by ten ampéres of current. Ten ampères is the current used in the large electric lamps upon our streets; for the inside store or hotel light six ampères are generally employed. If an unfortunate fireman comes in contact with such a current for a moment, in cutting the wire, he is struck dead! The fatal shock is caused by about one-tenth of an ampère, by 100 milliampères, through the high resistance of the human body. The current used for the Brush electric light is about ten ampères; if this is sent through the human body, which, with a dry skin, represents a resistance of 30,000 ohms roughly estimated, one-tenth of an ampère (100 milliampères), strange as it may seem, would be the actual current passing through and causing the fatal stroke!

Such is the effect of 100 milliampères through 30,000 ohms resistance; what would be the effect if ten ampères of current passed through the abdomen? Granting a deep uterus and thin abdominal walls, the tissues intervening between the electrodes offer a resistance of about sixty ohms, and ten ampères through sixty ohms of resistance represent a force equal to *six horse power*! If the resistance is greater, eighty or 100 ohms, as it is likely to be, this current would mean eight or ten horse power. What what would become of an abdomen subject to this energy for five months? Six horse power represents in electro-chemical force a cautery which would burn the tissues like hot iron whatever electrodes might be used; and it is not likely that this, or any approximate intensity ever has been or ever will be serviceable or possible in the healing art. Any scientific electrician will verify these statements.

Very truly yours,

GEO. J. ENGELMANN, M.D.

3003 Locust St., St. Louis, April 26, 1887.

INTERNATIONAL CONGRESS.

NINTH INTERNATIONAL MEDICAL CONGRESS, WASHINGTON, D. C., SEPT. 5, 1887.

COMMITTEE OF ARRANGEMENTS.

The following memorandum is published by order of the local Committee of Arrangements for the information of persons desiring to attend the Ninth Meeting of the International Medical Congress, in Washington, D. C., in 1887.

RATES OF TRANSPORTATION.

Red Star Line, $100; Antwerp to New York and return.

Inman Line, $100; Liverpool to New York and return.

Hamburg Line, $90; Hamburg to New York and return.

Royal Netherlands, $80; Amsterdam to New York and return.

North German Lloyd Line, $187.50; Bremen to New York and return.

Same rates are allowed for the families of members.

Cunard Line, 10 per cent. reduction for members of the Congress.

HOTEL RATES IN WASHINGTON.

Arlington Hotel, from $3.00 to $3.50 per day.
Riggs House, from $3.00 to $3.50 per day.
Willard's Hotel, from $3.00 to $3.50 per day.
Metropolitan Hotel, $3.00 per day.
National Hotel, $3.00 per day.

Other hotels conducted on European style will furnish rooms at $1.00 to $2.00 a day. Good Lodging-houses will also furnish rooms from $1.00 to $1.50 a day.

Proper accommodations have been secured for the meeting places of the Congress and its Sections.

Transportation within the limits of the United States has not yet been determined upon, but will soon be made public. Particulars of the plan of entertainments will be published in the official programme, and all notices will be published in THE JOURNAL in due time.

Official: A. Y. P. GARNETT, *Chairman.*
C. H. A. KLEINSCHMIDT, *Secretary.*

Since the above announcement of the Committee we are informed by Dr. J. W. H. Lovejoy, Chairman of the Sub-Committee on Transportation, that the Cunard Line of Steamships have agreed to include the *families* of members of the Congress, in the reduction of 10 per cent. from their usual rates for the round trip.

Although the regular agents of the White Star Line of Steamships from Liverpool to New York, when applied to by the proper Committee at Washington, refused to make any reduction, as has been heretofore announced, we are reliably informed by Dr. James H. Parkinson, of Sacramento, Cal., that the proprietors of that line have since advertised a reduction of 10 per cent. from the usual rates, to members of the Congress and their families on the *return* trip from New York.

ASSOCIATION ITEMS.

AMERICAN MEDICAL ASSOCIATION.

The Thirty-eighth Annual Session will be held in Chicago, Ill., commencing on Tuesday, June 7, at 11 A.M., in Central Music Hall, corner of State and Randolph streets, and will continue four days. Good rooms for the several Sections will be provided as near the hall for general meetings as possible. Registration books will be open in Central Music Hall on Monday, the day preceding the meeting, for those who wish to register early. In the general meetings of each morning, in addition to the Address of the President of the Association and the Addresses of the Chairmen of the several Sections, the following important subjects will be presented for consideration:

(a) Annual Report of the Board of Trustees for the publication of THE JOURNAL, J. M. Toner, M.D., Washington, Chairman.

(b) Report of the Special Committee on Changes in the Plan of Organization and By-Laws of the Association, N. S. Davis, M.D., Chicago, Chairman.

(c) Report of the Committee on a Monument to Benjamin Rush, A. L. Gihon, M.D., U. S. N., Chairman.

(d) Report of the Special Committee on Cremation, J. M. Keller, M.D., Hot Springs, Ark., Chairman.

(e) Report of the Standing Committee on Meteorological Conditions and their Relations to the Prevalence of Disease; also concerning the Collective Investigation of Disease in Coöperation with the Committee of the British Medical Association, N. S. Davis, M.D., Chicago, Chairman.

(f) An Amendment to Create a "Section on Dermatology and Venereal Diseases, Proposed by Albert L. Gihon, M.D., U. S. N.

The work for the several Sections is not yet completed, but as far as reported is as follows:

I. *Section of Practical Medicine, Materia Medica and Physiology.*

C. N. Cooper, Cleveland, Tenn., "Glanders in the Human Subject, with a Case."

N. S. Davis, Jr., Chicago, Ill., "Value of Antipyrin in the Treatment of Rheumatism."

G. W. McCaskey, Fort Wayne, Ind., "A New Method of Intra-Pulmonary Medication," etc.

Chairman, J. S. Lynch, M.D., Baltimore, Md.; Secretary, J. B. Marvin, M.D., Louisville, Ky.

[We have received no report from the officers of this Section.]

II. *Section of Obstetrics and Diseases of Women.*

J. E. Kelly, New York, N. Y., on "Lithiasis in Pregnancy."

Charles Meigs Wilson, Philadelphia, Pa., "The Technique of Ovariotomy."

Hiram Corson, Plymouth Meeting, Pa., "The Treatment of Abortion."

Wm. T. Taylor, Philadelphia, Pa., "Eclampsia."

W. S. Caldwell, Freeport, Ill., "Intra-Uterine Therapeutics."

George F. French, Minneapolis, Minn., "The Chief Source of Danger from the Use of the Intra-Uterine Sound."

B. E. Hadra, Austin, Texas, "Hysteria and the Ovaries."

Ely Van de Warker, Syracuse, N. Y., "Laparotomy as a Cure for Tuberculosis of the Peritoneum."

John A. Miller, San Francisco, Cal., "Erosions in Ulcerations of the Vaginal Portion and their Relation to Lacerations of the Cervix, with Practical Hints when not to Perform Emmet's Operation."

John Morris, Baltimore, Md., "Treatment of Placenta Prævia."

Wm. M. Findley, Altoona, Pa., "Ante-Partum Hæmorrhage."

Papers have also been promised, more or less definitely, by H. F. Campbell, Augusta, Ga.; L. Ch. Boislinière, St. Louis, Mo.; S. S. Todd, Kansas City, Mo.; E. H. Trenholme, Montreal, Canada; W. M. McPheeters, St. Louis, Mo.; A. McLaren, St. Paul, Minn.; John M. Keating, Philadelphia, Pa.; W. H. Wathen, Louisville, Ky.; W. H. H. Githens, Philadelphia, Pa.; Howard A. Kelly, Philadelphia, Pa.; W. P. Manton, Detroit, Mich.; and A. H. Halberstadt, Pottsville, Pa.

Chairman, F. M. Johnson, M.D., Kansas City, Mo.; Secretary, W. W. Jaggard, M.D., Chicago, Ill.

III. *Section of Surgery and Anatomy.*

H. O. Walker, Detroit, Mich., "External Perineal Urethrotomy, with Report of Eighteen Cases, Instruments, etc."

N. B. Carson, St. Louis, Mo., "Injuries of the Abdomen and their Proper Treatment."

W. C. Wile, Philadelphia, Pa., "Surgical Notes from the Case-Book of a General Practitioner."

I. D. Griffith, Kansas City, Mo. "Skin Grafting."

W. D. Kearns, Pittsburgh, Pa., "Retro-flexed Splints for Fractures of the Forearm."

E. E. Glover, Terre Haute, Ind., "Operative Treatment of Non-Malignant Stricture of the Rectum."

V. P. Gibney, New York, N. Y., "The Management of Cold Abscesses."

R. Harvey Reed, Mansfield, O., "A Case of Calculi in the Appendix Vermiformis."

A. Sidney Roberts, Philadelphia, Pa., "The Mechanical and Operative Treatment of Infantile Spinal and Cerebral Paralyses."

Papers have been promised by Wm. T. Bull, New York, N. Y.; H. Tuholsky, St. Louis, Mo.; and J. McF. Gaston, Atlanta, Ga.

Chairman, H. H. Mudd, M.D., St. Louis, Mo.; Secretary, A. M. Pollock, M.D., Pittsburgh, Pa.

IV. *Section on State Medicine.*

The following gentlemen have promised to read papers upon the subjects mentioned:

Henry B. Baker, Lansing, Mich., "Scientific Collective Investigation of Disease."

Carl H. Horsch, N. H., "The Necessity of Inspection of Food Animals."

J. W. Robertson, Cal., "The Medical Climatology and Hydrology of Northern California."

Prof. V. C. Vaughan, University of Michigan,

"The Chemistry and Physiological Action of Tyrotoxicon."

T. B. Greenley, Ky., "The Hygiene of Infancy and Childhood."

P. H. Millard, Stillwater, Minn., "The Propriety and Necessity of the Regulation of Medical Practice by the State."

H. C. Markham, Independence, Iowa, "State Regulation of Medical Practice—Its Value and Importance."

Major Morse K. Taylor, Surgeon U. S. Army, "The Influence of Military Life on the Health of the Soldier."

Woods Hutchinson, Iowa, "The Physical Basis of Brain-Work."

Walter Wyman, Surgeon U. S. Marine Hospital Service, and several others, have promised papers, but have not yet announced their titles.

The Section is also instructed to submit at the coming meeting of the Association the draft of a law regulating the conditions requisite as preliminary to the study of medicine, the requirements for graduation and for the license to practice medicine, to be urged upon the several States in order to secure uniformity in method and results throughout the United States. It is proposed to discuss this question in connection with the papers of Drs. Millard and Markham above announced. Members of the Association desiring to read papers upon any subject properly coming within the purview of the Section on State Medicine, are requested to notify the Chairman or Secretary at once.

Chairman, George H. Rohé, 611 N. Calvert St., Baltimore, Md.; Secretary, Walter Wyman, U. S. Marine Hospital Service, New York, N. Y.

V. *Section of Ophthalmology and Otology.*

C. M. Hobby, Iowa City, Iowa, "Sympathetic Ophthalmia."

J. L. Thompson, Indianapolis, Ind., "Observations on Displacement of the Crystalline Lens, from Congenital and other Causes."

J. M. Ray, Louisville, Ky., "Hydrobromate of Hyoscine as a Mydriatic."

F. C. Hotz, Chicago, Ill., "Treatment of Hypopyon Keratitis with Frequent Irrigations of Sublimate."

J. W. Heustis, Pittsburgh, Pa., "Some of the Ophthalmological Clinics of Europe."

Robert Tilley, Chicago, Ill., will exhibit "A Boy of 12 years illustrating the results of either Pemphigus or Essential Shrinking of the Conjunctiva in both Eyes."

Dudley S. Reynolds, Louisville, Ky., "Nature and Treatment of Phlyctenular Ophthalmia."

Chairman, X. C. Scott, M.D., Cleveland, Ohio.; Secretary, J. H. Thompson, M.D., Kansas City, Mo.

VI. *Section on Diseases of Children.*

I. A. Larrabee, Somerville, Ky, "Epidermic and Hypodermic Medication of Infants."

I. N. Love, St. Louis, Mo., "Scarlet Fever."

S. B. Sperry, Delafield, Wis., "Aphasia in Children."

W. S. Stuart, Philadelphia, Pa., "New Method of treating Congenital Phymosis."

H. Landis Getz, Marshalltown, Iowa, "Diphtheria."

The following have promised papers: J. M. Dunham, Columbus, Ohio; W. D. Haggard, Nashville, Tenn.; Henry Jameson, Indinapolis, Ind.; J. V. Shoemaker, Philadelphia, Pa.

Chairman, J. S. Knox, 70 Monroe St., Chicago, Ill.; Secretary, W. B. Lawrence, Batesville, Ark.

VII. *Section of Dental and Oral Surgery.*

K. B. Davis, "Pathological Conditions of the Teeth, and their Systemic Effects."

G. Frank Lydston, "The Necessity of Liberal Professional Education in the Practice of Dental and Oral Surgery."

Garrett Newkirk, "The Deciduous Teeth and their Relation to the Health of Children."

A. H. Thompson, "Pathological Heredity, and Congenital Abnormalities of the Teeth."

Arthur Freeman, "Dental Lesions causing Facial Neuralgia and other Neural Phenomena."

W. H. Atkinson, "Sponge Grafting."

Subjects not announced, Chas. Payne, A. E. Baldwin, J. Taft, W. W. Allport, John Marshall.

Chairman, J. S. Marshall, 240 Wabash Ave., Chicago; Secretary, Eugene S. Talbot, 125 State St., Chicago.

VIII. *Section of Medical Jurisprudence.*

Judge Amos G. Hull, New York, "Medical Jurisprudence in its Relations to Undue Influences as Affecting Wills and Contracts."

Joseph F. Edwards, Philadelphia, Pa., "The Suppression of the Illegal Practice of Medicine."

James G. Kiernan, Chicago, Ill., two papers, "State Supervision of the Insane," and "Medico-Legal Relations of Epilepsy."

N. S. Davis, Chicago, Ill., "The Medico-Legal Relations of Alcoholic Liquors, Fermented and Distilled."

Frank S. Billings, Lincoln, Neb., "The Necessity of a Uniform Standard of Education; especially more detailed Pathological Instruction to Unity of Professional Action in Forensic Medicine."

T. D. Crothers, Hartford, Ct., "Mental Responsibility in Inebriety."

S. V. Clevenger, Chicago, Ill., "The Medical Jurisprudence of Mental and Nervous Diseases."

E. C. Spitzka, New York, "Paralytic Conditions in Relation to Testamentary Capacity."

N. E. Brill, New York, "Report on the present state of our knowledge concerning Concussion from Railway Accidents."

Alfred F. Holt, Cambridge, Mass.; W. C. Wile, of Philadelphia, Pa.; F. E. Daniels, Austin, Texas; and Herman J. Boldt, New York, have also partially promised comments.

Chairman, I. N. Quimby, Jersey, City, N. J.; Secretary, W. W. Kimball, Minneapolis, Minn.

[The above incomplete report of work for the several Sections, includes many interesting and important subjects for discussion, and indicates a very general interest in the coming annual meeting of the Association. We shall add other names and topics each week as they may be furnished us.]

RAILWAY RATES.

The following named roads will give reduced fares to all delegates, members, and their families attending the meeting. Return tickets will be issued on the certificate plan *only*. Tickets for the return journey will be sold at ⅓ the highest regular limited fare. If there is no limited fare to a desired point, the price will be ⅓ the unlimited fare. Tickets for the return journey will be limited to continuous passage by first train after they are bought. All tickets for return journey must be accompanied by a certificate signed by the Chairman of the Committee on Transportation, or by an authorized member of the Committee, showing that the holder has attended the meeting. Tickets are good for 10 days from date of purchase.

The roads which will accept return tickets on the certificate plan are:

Baltimore & Ohio (west of the Ohio River).
Buffalo, New York and Philadelphia.
Chicago & Grand Trunk.
Cincinnati, New Orleans & Texas Pacific.
Chicago, Vincennes & Cairo Line.
Chicago & West Michigan.
Chicago, St. Louis & Pittsburgh.
Cincinnati, Hamilton & Dayton.
Cincinnati, Indianapolis, St. Louis & Chicago.
Cincinnati, Washington & Baltimore.
Cleveland, Akron & Columbus.
Cleveland & Marietta.
Cleveland & Pittsburgh.
Cleveland, Columbus, Cincinnati & Indianapolis.
Cleveland, Lorain & Wheeling.
Columbus & Cincinnati Midland.
Columbus, Hocking Valley & Toledo.
Chesapeake & Ohio.
Chicago & Atlantic.
Dayton & Ironton.
Detroit, Lansing & Northern.
Dayton & Union.
Detroit, Grand Haven & Milwaukee.
Evansville & Terre Haute.
Flint & Pere Marquette.
Fort Wayne, Cincinnati & Louisville.
Grand Rapids & Indiana.
Grand Trunk.
Indianapolis & St. Louis.
Indianapolis & Vincennes.
Indianapolis, Bloomington & Western.
Indianapolis, Decatur & Springfield.
Jeffersonville, Madison & Indianapolis.
Kanawa & Ohio.
Lake Erie & Western.
Lake Shore & Michigan Southern.
Lousiville & Nashville.
Louisville, Evansville & St. Louis.
Louisville, New Albany & Chicago.
Michigan Central.
Michigan & Ohio.
New York, Chicago & St. Louis.
New York, Pennsylvania & Ohio.
Niagara Falls Short Line.
Ohio & Mississippi.
Pennsylvania.
Peoria, Decatur & Evansville.
Pittsburgh & Lake Erie.
Pittsburgh & Western.
Pittsburgh, Cincinnati & St. Louis.
Saginaw Valley & St. Louis.
Scioto Valley.
Toledo & Ohio Central.
Toledo, Peoria & Western.
Valley Railway.
Vandalia Line.
Wabash Railway.
Wheeling & Lake Erie.
Baltimore & Ohio (east of Parkersburg, Bellaire & Wheeling.)
Baltimore & Potomac.
Bennington & Rutland.
Boston & Albany (on business between common points in New England and points west of, but not including Albany.)
Boston & Lowell.
Boston, Hoosac Tunnel & Western.
Buffalo, Rochester & Pittsburgh.
Camden & Atlantic.
Central Vermont.
Delaware & Hudson Canal Co.
Delaware, Lackawanna & Western.
Fitchburg.
Lehigh Valley.
New York Central & Hudson River.
New York, Lake Erie & Western.
New York, Ontario & Western.
Norfolk & Western.
Northern Central.
Philadelphia & Erie.
Philadelphia & Reading.
Philadelphia, Wilmington & Baltimore.
Rome, Watertown & Ogdensburg.
Shenandoah Valley.
Troy & Boston.
West Jersey.
West Shore.

The following named lines offer one and one-third fare for round trip:

Burlington, Cedar Rapids & Northern Railway.
Central Iowa Railway.
Chicago & Alton Railroad.
Chicago & Northwestern Railway.
Chicago, Burlington & Northern Railway.
Chicago, Burlington & Quincy Railroad.
Chicago, Milwaukee & St. Paul Railway.
Chicago, Rock Island & Pacific Railway.
Chicago, St. Paul, Minneapolis & Omaha Railway.
Green Bay, Winona & St. Paul Railroad.
Hannibal & St. Joseph Railroad.
Illinois Central Railroad.
Kansas City, St. Joseph & Council Bluffs Railroad.
Milwaukee & Northern Railroad.
Milwaukee, Lake Shore & Western Railway.
Minneapolis & St. Louis Railway.
Minnesota & Northwestern Railroad.
Missouri Pacific Railway.
Rock Island & Peoria Railway.
Sioux City & Pacific Railroad.
Wabash Western Railway.
Wisconsin Central Lines.

[Other roads will be added as heard from. These lists have been prepared at great expenditure of time by the Chairman of the Committee on Transportation,

DR. LISTON H. MONTGOMERY,
Briggs House, 189 Randolph St., Chicago,

who should be addressed for additional information.]

HOTEL RATES.

The following hotels in Chicago will commute their rates to delegates and members and their families attending the annual meeting in June:

Grand Pacific Hotel.—A discount of 50 cents to each person per day in all rooms, except those at $3.00 per day, on which there will be no discount. By this arrangement a $3.50 room with bath may be had for $3.00, a $4.00 room for $3.50 for each person, and so on. A club room will also be placed *free* at the disposal of the Association for headquarters, if desired.

The Sherman House will give 50 cents *per capita* off regular rates, which are $3.50 to $5.00 *per diem*, as well 50 cents *per capita* off $3.00 per day rooms where more than one person occupy a room. Such committee rooms, etc., as may be required will be placed at the disposal of the Association free of cost. No cots are ever used at this hotel, and every one will be given a good bed.

The Tremont House offers 50 cents discount from

regular rates, which are from $3.00 to $4.50 *per diem*. This rate applies to each person or delegate, both included.

The Palmer House gives a rebate of 50 cents *per capita* on the American plan, when two occupy a room. On $1.00 rooms, (European plan) a rebate of 25 cents *per capita* where two occupy a room. On rooms for which the rate is $1.50 and upwards, a rebate (on the European plan) of 50 cents *per capita* is offered.

The Briggs House.—The rates will be $2.00 to $2.50 per day for their *best* rooms, meals included, a reduction of 50 cents per day on transient rates.

McCoy's New European Hotel.—The rate will be 75 cents per day for each person when two or four occupy a room. A single room for one person is $1.00 per day, or for man and wife $1.50 per day.

Clifton House.—Transient rates are $2.50 to $3.50 per day. A reduction of 50 cents per day from the above rates is offered to delegates and their families.

Commercial Hotel.—Transient rates $2.00 to $2.50 per day. For all visitors in attendance at this meeting who stop at this hotel, a discount of 15 per cent. will be allowed on all board and room bills.

Leland Hotel offers accommodations to delegates at $3.00 and $3.50 per day, *i. e.* rooms with board.

The Richelieu, on the European plan only. The rate for single rooms, is from $2.00 to $5.00 per day; suites of rooms proportionately.

All these hotels are within five to eight minutes' walk from Central Music Hall, corner State and Randolph streets.

Charles Gilman Smith, M.D.,
Chairman Local Committee of Arrangements.
Liston H. Montgomery, M.D.,
Chairman Committee on Transportation.

Rush Monument Committee.—The Rush Monument Committee will meet at Chicago, Illinois, on June 7, proximo. The hour and place of meeting will be announced on the morning of the first day of the meeting of the American Medical Association. Chairmen of local Committees are requested to send their reports of collections to the Treasurer, *Dr. J. M. Toner, 615 Louisiana Ave., Washington, D.C.*, at their earliest opportunity. It is desirable that every State, Territory, and branch of the Government Services represented should make as favorable a showing as possible in the next report of the Committee. George H. Rohé, *Secretary.*

MISCELLANEOUS.

Windham County (Conn.) Medical Society.—At the recent regular annual meeting of this Society the following officers and delegates were elected:

President—Charles J. Fox, of Willimantic.

Vice-President—F. G. Sawtelle, of Pomfret.

Secretary and Treasurer—Charles N. Allen, of Moosup.

Censors—W. A. Lewis, of Moosup, T. M. Hills, of Willimantic, E. H. Davis, of Plainfield.

County Medical Reporter—R. Robinson, of Danielsonville.

Fellows to State Medical Society at Hartford in May—T. R. Parker, of Willimantic, Lowell Holbrook, of Thompson, R. Robinson of Danielsonville, W. A. Lewis, of Moosup, H. L. Hammond, of Dayville; alternates, F. O. Bennett, of Willimantic, E. E. Gaylord, of Woodstock, N. Hibbard, of Danielsonville, E. H. Davis, of Plainfield, E. D. Kimball, of Scotland.

Nominating Committee—L. Holbrook; alternate, W. A. Lewis.

Delegates to American Medical Association at Chicago in June—E. A. Hill, of Killingly, T. M. Hills, of Willimantic, F. G. Sawtelle, of Pomfret.

Essayist for 1888—W. W. Foster, of Putnam; alternate, O. B. Griggs, of Willimantic.

The next annual meeting will be held at the Hooker house in Willimantic.

Deputy Inspector-General Lloyd, R. N., of the office of the Director-General of the Medical Department at the Admiralty, has been appointed to represent the British Naval Service at the forthcoming International Medical Congress.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 23, 1887, TO APRIL 29, 1887.

Lt.-Col. and Asst. Surgeon J. R. Smith, detailed as member of board to meet in Washington, D. C., April 28, to prepare rules and regulations for the government of the Hospital Corps of the Army. By par. 8, S. O. 92, A. G. O., April 21, 1887.

Major and Surgeon Morse K. Taylor, relieved from duty at Ft. Sill, I. T., May 10, 1887, to proceed home, San Antonio, Texas, preparatory to retirement. Par. 20, S. O. 92, A. G. O., April 21, 1887.

Major and Surgeon Chas. M. Heizmann, detailed as member of board to meet in Washington, D. C., April 28, to prepare rules and regulations for the government of the Hospital Corps of the Army. By par. 8, S. O. 92, A. G. O., April 21, 1887.

Capt. and Asst. Surgeon Fred. C. Ainsworth, detailed as member of board to meet in Washington, D. C., April 28, to prepare rules and regulations for the government of the Hospital Corps of the Army. By par. 8, S. O. 92, A. G. O., April 21, 1887.

First Lieut. and Asst. Surgeon Julian M. Cabell (recently appointed), to proceed to Ft. Omaha, Neb., and report in person to the commanding officer of that post for temporary duty. Par. 19, S. O. 92, A. G. O., April 21, 1887.

First Lieut. Chas. E. Woodruff, Asst. Surgeon (recently appointed), ordered for duty at Ft. Wayne, Mich. S. O. 96, A. G. O., April 26, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING APRIL 30, 1887.

Atlee, E. W., Asst. Surgeon, ordered to the receiving ship "Vermont."

Biddle, Clement, P. A. Surgeon, detached from the Naval Academy, and ordered to Marine Rendezvous, Philadelphia, Pa.

Ashbridge, Richard, P. A. Surgeon, ordered to the Naval Academy.

Hudson, A., Medical Inspector, ordered to the U. S. Str. "Trenton."

Decker, J. Corbin, Asst. Surgeon, detached from the receiving ship "St. Louis," and ordered to the U. S. Str. "Trenton."

Hibbett, C. T., P. A. Surgeon, ordered to the U. S. Str. "Trenton."

ABSTRACT OF A LECTURE

ON

ANTIPYRESIS AND ANTIPYRETIC METHODS.[1]

BY PROF. DR. H. VON ZIEMSSEN,

DIRECTOR OF THE MEDICAL CLINIC IN MUNICH.

In analyzing the views as to the value of antipyretics we may group authors as follows: 1. The extremists, who use only the cold bath, and reject internal antipyretics (Brand, Vogl, Winternitz and others). 2. Those who use luke-warm baths, but reject internal antipyretics (Naunyn and others). 3. Those who, according to indications, use strict and moderate hydrotherapy and internal antipyretics (Liebermeister, Jürgensen, Riess). 4. Those who imagine fever to be a kind of necessary and salutary regulation, arrangement or mechanism, and use antipyretic interference only on the appearance of dangerous conditions or complications (Heubner, Curschmann, and others). 5. Those who regard fever as necessary, reject antipyretics, and only use dietetic measures (Gläser). 6. The class who absolutely deny an influence of therapeutics on the mortality of typhoid (Port).

We thus see that all possible conceptions have their supporters, and all parties assert the correctness of their views on grounds that, in their opinion, will stand any test. It would be a lamentable state of affairs if in this way physicians should become sceptical; and especially if, after a period of active antipyresis with its satisfactory results, we should be drawn, by a reactionary movement, into the therapeutic indifference of the Vienna school. Against such a movement, all who understand the subject, and especially clinicians, must fight; and it is pleasing to know that at the IV Congress für innere Medicin those who expressed themselves against antipyresis were divided and made but little impression.

Has the antipyretic treatment of highly febrile infectious diseases, and especially of typhoid fever, a favorable influence on the individual case? Has it the same or a corresponding influence on the totality of cases of disease, and also on the mortality? Both questions we must answer affirmatively. Observations at the bedside prove the first, and the concordant statistics of the clinician the latter. We can affirm with certainty that the course of the individual case is more favorably and less dangerously shaped under judicious and antipyretic treatment; and, on the other hand, that the mortality of typhoid fever has fallen at least to one-half its former rate.

Against these propositions different objections have been raised. On the one hand (Fiedler), the decrease of typhoid (both as to number of cases and mortality) in the larger cities, is referred to their health regulations, and certainly with truth. Our observations in Munich have shown the influence of these regulations. Nevertheless, the relative decrease of mortality can scarcely depend on the healthfulness of the soil, but on the character of the epidemic, and doubtless also on the methods of treatment, as I will show later. On the other hand (Port), the ratio of mortality (the severity of the epidemic of typhoid) is connected with the state of the soil-water. From the statistics of the Munich garrison for the last ten years Port finds that the fluctuation of the soil-water is more an index of the severity than of the size of the epidemic. From this he draws the conclusion that antipyretic therapy is without any influence on the mortality, since the reduction of the former mortality from 20 to 2 per cent., as shown by the tables of the hospital of the Munich garrison, would be impossible without the discovery of a specific remedy. But Vogl, chief physician to the garrison hospital, has shown, by using the same material as did Port, that Port's hypothesis is untenable. We must wait for other material before further estimating Port's conclusions.

Such works as that of Vogl are of the greatest value for the further development of the antipyretic therapy of typhoid fever, because they are based on very similarly situated material—strong young men from 20 to 22 years under corresponding and almost similar external circumstances—with well disciplined attendants schooled to a certain method—a cold bath at 63.5° F. lasting a quarter of an hour (with a rectal temperature of 102.2° F.) about every three hours, winter and summer, in unheated rooms, with the windows opened day and night. The result of this experiment speaks clearly enough: the number of deaths from typhoid fever by this treatment, without the use of medicines, in the years 1875 to 1882 (inclusive), was 28 in 520 cases of the disease, while in the other divisions of the same military hospital, in which a more mild water treatment was used with internal antipyretics, there were 52 deaths in 610 cases in the same time. This is, then, a mortality of 5.4 per cent. by the exclusive Brand treatment, and

[1] Translated, by permission, from advance sheets by Wm. G. Eggleston, M.D., of Chicago.

a percentage of 8.5 by the combined method. From this we may perhaps draw the conclusion that in military hospitals under the given conditions the energetic Brand's cold water treatment is superior to the modified treatment, and that combined with antipyretics, and that, as a rule, it gives the best results in typhoid fever. This conclusion exactly corresponds to what has been the case in the Prussian army since 1865, since which time the mortality from typhoid fever has fallen from 25 to 8 per cent.; this, according to the report of the Prussian Minister of War, is due principally to Brand's cold water treatment, though partly also to improved hygienic conditions and better individualization in treatment. The present results in the Prussian army are entirely independent of local, temporary, and individual influences.

But though these results, taken with the former publications of Brand, Jürgensen, Liebermeister, and others, show that there is no doubt that Brand's method is best in military practice, the case is somewhat different in civil practice. We cannot introduce Brand's method directly into civil hospitals and private practice: there is a lack of trained attendants and that degree of discipline which forbids opposition on the part of the patient or carelessness on the part of the attendant; and again—and this is a most important point—the clinical material of the civil hospital and private practice is different and much less fit for such energetic cooling as Vogl carries out both by regulating the temperature of the barracks and the bath. Consider the circumstances of age, sex, anomalies of development, pregnancy, anomalies of constitution and nutrition, bad dwelling, inebriety, occupation, scrofula, tuberculosis, chlorosis, anæmia, cardiac affections, syphilis—these are the things with which, in addition to typhoid, we have to contend in our typhoid paitents in civil practice. The military physician should not forget them; he has a better mortality percentage because he has the flower of the youth of the whole country in his hands, with all uncertain and precarious constitutions excluded, while we have to treat the miserable people in all their unfavorable conditions.

With the strict Brand Vogl cold-water treatment we will now compare the results of a pure but somewhat modified hydrotherapy in a civil hospital. As representative of this method I place Naunyn before all others. He has not a large amount of material at his command, but it is large enough to cast into the scale. By his modified method Naunyn lost 10 of 145 cases, or 6.9 per cent.; certainly a favorable percentage. His method is as follows: When the axillary temperature (which is measured every three hours) reaches 103.1° F. the bath is given, usually eight baths in twenty-four hours, and in most cases between noon and midnight. Naunyn divides the baths according to temperature into: cold (72.5° to 81.5° F., duration five to ten minutes), luke-warm (from 81.5° to 90.5°, ten to fifteen minutes), and warm (90.5° to 95°). The warm baths are given in the later stages in very actively delirious patients with great restlessness and muscular weakness. For several years Naunyn has not given baths at a lower temperature than 72.5°. The diet consists of 1.5 litre of bouillon with an egg, rarely two eggs, 1 litre of milk, 1 roll, 1 litre of water or 1.5 litre of wine or sometimes 1.5 litre of grog (consisting of 0.5 litre of rum, 50 grm. sugar, and hot water).

We come now to those authors who use combined antipyresis, the combination of baths and internal antipyretics, according to the indications of the individual case. This group appears to embrace by far the greater number of clinicians and physicians. The statistics published by them correspond entirely, if we recognize the statement as correct that typhoid usually gives a less mortality in small than in large cities. With this method of combined antipyresis there is great play for modifications of the methods of treatment, and it is not impossible that the methods of the clinicians using this are all different. The cold, luke-warm and warm baths, the gradually cooled and the prolonged luke-warm bath, the cold douche, the moist pack, the cold fomentation, the simple sponging, and of internal remedies quinine, antipyrin, thallin, salicylic acid, kairin, hydrochinone, antifebrin—all these have their friends and supporters.

You will now ask: Which method of antipyresis shall we employ in our cases? What kind of hydrotherapy shall we use? And under what circumstances shall we use antipyretic measures? Our discussion of these points must begin with a consideration of those changes which antipyresis is intended to and can control. As the name shows, it was at first thought that the object of antipyretic treatment was the fever alone, and the factors from which the conception fever arises, principally the high temperature of the blood and tissue. This opinion, which was mainly defended by Liebermeister, arose from the idea that the high temperature of itself, especially if of long and uniform duration, was dangerous, and threatened life. There is no doubt as to the dangers of hyperpyrexia, but it seems that the high temperature has usually not the significance which Liebermeister at first attributed to it. The severe cerebral symptoms, the cardiac degeneration, renal troubles, the trophic disturbances, do not seem to be the effects of the high temperature, but co-effects of the dangerous process, the infection, causing the fever.

We may now answer the question as to what antipyresis should do, by saying that we must first widen our conception of the word; it is not merely a battle against fever-heat and its action, but also against the carriers of infection and their destructive products and actions in the organism. To take an exact position between the fever action and the microbe action is not possible at present. Naunyn has cleared up many points, but much is still dark. Naunyn concedes the acceleration of the heart's action and respiration as the influence of over heating. The troubles of the nervous system, of the blood and its vessels, of digestion, of tissue change and secretion, he places to the account of the infection. But the proofs which Naunyn gives are mostly of a negative nature, and there are still many doubts, especially as regards the nervous and circulatory troubles, as to the innocence of the fever. The cases of aseptic fever, in which there is no other trouble than high tempera-

ture, are very exceptional; and we must also regard as exceptional those cases in which, especially among the lower classes, the nervous system is but little or not at all affected by the fever, so that the patients continue to go around, and even to work for days after the beginning of the disease. Against these we may place those cases of extreme susceptibility to fever, usually occurring in persons of nervous constitution.

I mention these things in order to show that the absence of nervous symptoms in individual cases does not prove that as a rule there are no nervous troubles in fever as such, but that they depend on the infection. I have no doubt that fever itself affects the nervous system, and slightly or more severely according to the height of the temperature. On the other hand, I think that the cerebral troubles may be conditional upon the infection, as shown by the cases with severe prostration of cerebral function with comparatively low temperature, as in typhoid fever, for example, the early loss of consciousness and the active delirium in the first days of typhus fever, the severe nervous troubles in many cases of acute sepsis, in which there is no or but little fever. In the same way are the boundaries between the limits of action of the fever and the infection in the circulatory and respiratory troubles uncertain. That the acceleration of the heart's action and of respiration depends on the fever may perhaps be regarded as proved, as it is probably proportional to the relaxation of the vascular walls, which may be recognized by the constantly noticeable dilatation of the arteries and capillaries during fever, as well as by the sphymographic tracings. The relaxation of the peripheral vessels which is peculiar to fever can be attributed to nothing else than paralysis of the vasoconstrictor nerves, since, as Bäumler has shown, the reaction of the vasculars to irritation of the skin (stroke with the finger nail) is very prompt. If, then, the troubles mentioned are caused by the fever, we must, on the other hand, refer the nervous troubles, disturbances of organic tissue-change, of the quality of the blood, and of secretion, perhaps entirely or in the greater part to the infection: the paralysis of the heart, the reduction of the number of red blood corpuscles, the deficiency of alkali and carbonic acid in the blood, the generally increased excretion of urea (especially the large epicritical), the albuminuria, and the trophic disturbances of the muscles and skin.

We will now consider the antipyretic measures in connection with these disturbances; how and to what extent the former affect the latter. Hydrotherapy deserves to be considered first; according to the experience of all competent observers it has the first place, because it conbines in itself all the attributes of a remedial measure necessary in these cases, and its action on the fevered organism may be varied to any degree. But the mistake must not be made of supposing that the favorable action of the cold water treatment has been particularly proved in typhoid fever, whilst in other febrile diseases, such as pneumonia, erysipelas. and acute phthisis, it is shown to be much less applicable. In the last-named affection a favorable influencing of the general condition is not to be mistaken. The action of cold and lukewarm baths may perhaps be defined as follows: The bath acts on the fevered organism by cooling the blood at the periphery, and then by the return of the cooled blood from the skin to the interior of the body and to the internal organs. Whether this stream of cooled blood has an immediate effect on the central nervous apparatus is not certain, but I believe I may conclude from a personal experience (a severe attack of typhoid fever in 1874, during which I was bathed a great deal) that the immediate effect after the bath and the first effect of it is a sensation of drowsiness and cooling of the brain: and I must say that this is an indescribably pleasant effect. Following this directly cooling effect is the refreshing action on the central nervous system, which I regard as the most distinctive action of the cold bath. The excitation experienced by the sensitive nerves from the low temperature of the bath is at once transmitted centripetally, and acts to a greater or less degree on the important nervous centres. The lowered excitability of the brain is raised, and from the refreshed centre goes out a fresh innervation of the circulation, respiration, digestion, tissue change and of the motor apparatus. The effect is a restful sleep, a clear sensorium, a fresher look, active movements, and a surprising desire for food.

To speak more particularly of these effects, and beginning with the *improvement of digestion*, it must must be said that there is not only an increased desire for food, but what is taken is more perfectly digested than before. This shows that there is an increased secretion of the digestive fluids, which is probably to be ascribed only to better innervation. We can in this way feed the patient very differently; and this is of great importance in long-continued fevers, such as typhoid. The *circulatory apparatus* receives its waves of excitation from several sources: by way of the reflexes, a direct excitation from the cutaneous vessels, and finally the excitation of the heart muscle from the cooled blood circulating through it. The succession of phenomena is as follows: The first perceptible action of the bath is the contraction of the peripheral vessels (often to the extent that the pulse disappears), so far a direct action; then increase of blood-pressure and overfilling of the vessels in the internal organs, and after a time relaxation of the peripheral vessels and invariable persistence of the high blood-pressure. The heart works slowly and forcibly, the vessels show an improved tension, as recognized by the decrease of dicrotism and the return of the elasticity-elevation.

The *respiratory apparatus* is excited by the peripheral irritation to deeper and slower movements. The improved sensible innervation of the mucous membrane supplied by the vagus causes reflex cough, by which collected secretions are thrown off. In this way the formation of bronchial obstructions, atelectasis and catarrhal pneumonia, is better avoided than by the usual advice to turn the patient on the side from time to time; a recommendation which I think purely theoretical, since, on the one hand, a typhoid fever patient cannot remain on the side for

a long time, and, on the other hand, the former conception of the mechanical origin of hypostatic pneumonia is, in my opinion, very faulty. What is necessary is, not lateral decubitus, but deep respiratory movements with expansion of the lower and posterior portions of the lungs, and the normal sensib lity and excitability of the bronchial mucous membrane, so that the collection of mucus and the consequences of bronchial obstruction, atelectasis and catarrhal pneumonia, will be avoided.

The *visible secretions*, the urine, the saliva, tears and sweat, are increased by the bath treatment. The tongue is moist, the eye is bright, and the skin is soft and supple.

Finally, the *favorable action on the trophic spheres* is shown by the non-appearance of bed sores, etc. Besides the trophic innervation the conditions of the circulation (blood-pressure, rapidity of the circulation and vascular dilatation), also play an important part here.

The *form*, *duration* and *temperature* of the water-treatment is determined by the indications of the individual case. The complete bath must be regarded as the most effective, convenient and pleasant form of hydrotherapy; in this all experienced observers are agreed.

The temperature of the water and the duration of the bath are regulated by the stage of the disease, the height of the temperature, the quality of the heart's action, the condition of the nervous system and the general constitution of the patient. We may say generally, the more recent the affection, the higher the temperature, the more resistant the heart and nervous system, and the stronger the constitution, the colder and longer is the bath, and the more frequently is it to be repeated. Very low temperatures for the bath have been lately discarded by the greater number of authors, and it is seldom that a temperature lower than 65¾° is used. In most cases I use baths between 72.5° and 86°, according to the individual constitution, though in early cases, with strong constitution, baths of 63.5° to 65¾° are frequently given. The bath at the temperature of the room is very pleasant. The patient is placed, as often as necessary in twenty-four hours, in the same water, this being renewed only in the morning. As a rule, however, a temperature of 65¾° is too low.

The average duration of the bath should be from fifteen to twenty minutes. The number of baths in twenty-four hours varies according to the intensity and resistance of the fever, between two and six; I seldom use a larger number. We can best determine when the bath is to be renewed, by the tem perature. Brand's recommendation to bathe when the axillary temperature reaches 103.1° must be criticised as routine practice, but as a rule it is correct. Frequently there are cases in which we must order the bath when the temperature reaches 102.2°, and other cases in which we do not, or generally do not, bathe even at 104°. In my opinion the reaction of the patient after the first bath is an important point, and this is best determined by the condition of the nervous system, the pulse, and by the subjective condition. Of course the effect on the temperature of the body is very important, but this is not the only thing to be considered; some constitutions are but little affected by cold baths, though they are again and again desired because they are refreshing, give a good pulse, and are followed by sleep, while the temperature is lowered only slightly and for a very short time. In other cases, especially of nervous constitution, the action of cold baths is often unsatisfactory. True, the temperature goes down for a few hours 3.5° or 5°, but the patient feels uncomfortable, chilled, and has not the desired refreshed sensation.

You must consider that in private practice attention must be paid to the subjective sensation of the patient, and to the sentiments of his friends, and you must always use the mildest measures when it can be done without injury to the effect desired. The miserable condition of a patient for an hour after a too cold bath, and the frightful appearance which he presents, will not add to your reputation. And the bath has here failed of its purpose, since we wish a refreshing, an enlivening action on the nervous system, not depression or shock. For twenty years, therefore, I have recommended for private practice the gradually cooled bath, and I can now most highly recommend it after an experience with thousands of cases of typhoid fever and other infectious diseases.

The patient is placed in a warm bath of 90.5° or 86°—this is always 14° or 18° below the temperature of the body, and in proportion to it is still to be considered cool—and then the water is continually poured over him with the hands or a large sponge. While this is being done cold water is very slowly poured in at the foot of the bath tub, and thus the temperature of the whole bath is gradually lowered to 77° or 72.5°, until the patient's teeth clatter, or he declares that he cannot stand it colder. The patient must now remain in the bath as long as possible, say fifteen or twenty minutes. He is then taken from the bath and placed on a blanket, previously warmed, and he is wrapped in this without being dried. In this he remains in the greatest comfort for a quarter of an hour, when he is rubbed dry, clean linen put on, and he is allowed to sleep.

By this form of bath we have entirely in our hands the degree of reflex action desired, and at the same time as a measure of the amount of action we have the objective state and the subjective feelings of the patient. The cooling of the blood by the gradually cooled bath is not less, though the sensation of shock is absent, than by the very cold bath, because the bath can be kept up as long as desired. And I think it better to fall a little short of our purpose by the use of the warm bath than do too much by the cold bath. In regard to the individual expressions of physicians who do not recommend the gradually cooled bath, I can only attribute them to insufficient experience. But I can say that every physician who, like myself, has had personal experience with the different forms of baths, both on patients and himself, will endorse the luke-warm and gradually cooled baths.

Warm baths of 90.5° to 95,° though not much below the normal temperature of the body, are never-

theless 12° or 14° below the fever temperature, and while the reduction of temperature is not inconsiderable, it is insufficient, and the reflex action is very slight. The warm bath is therefore especially suitable for those cases which the older physicians described as febris nervosa versatilis, cases which have the character of irritable weakness to a marked extent. Such cases, in which the infection so frequently shows a malignant character — we see them in measles, scarlet fever and small-pox as well as in typhoid and other affections—bear the shock of a cold douche or a cold bath very badly as a rule, at least at first; and the subjective and objective actions of tolerable warm baths seem therefore praiseworthy. A sleep after the bath is especially important, as by it the brain has a rest which it obtains in no other way. When the extremely irritated nervous system has been quieted to some extent we can very soon follow the warm with the gradually cooled bath, and even with baths at 77° or 72.5°.

It would of course be very wrong to have the same bath-temperature for every case and for every stage. Individual indications are here very necessary in order to obtain the proper effect. Not only do different constitutions and different conditions of infection need very different temperatures and forms of baths, but the temperature of the bath should vary a great deal in the course of the same sickness. In the case of a weak, nervous woman who comes under your care in the second week of a neglected typhoid the condition of the nervous system, of the temperature, pulse, etc., will show that you can only use warm baths of 90.5° to 95,° and perhaps add a short douche or a wet-sheet. If the action on the pulse, temperature and nervous system is satisfactory, the bath temperature on subsequent days may be lowered to 86°, and later even to 77°, with from four to five baths a day. But in the third week, when there are spontaneous morning remissions, two or three baths of 90.5° may be given each day.

The indications for the temperature, frequency and duration of the bath also depend upon the needs of the individual case. *The sum of the symptoms, the whole clinical picture and the influence upon it of the first baths, but not the effect on the temperature, should alone serve as guides.*

As regards the cold douche I may remark that a short and not too cold douche in the warm bath may be tried in severe asthenic forms of the different acute infectious diseases, and is often well borne. This is especially the case in those infections whose course is rapid, as scarlatina or small-pox, and in which all therapeutic measures must be carried out in a few days.

The simple wet pack probably cannot be considered as having much of an antipyretic effect, as its temperature is very soon raised to that of the body. Ice bladders, of which we make various uses, have a marked local cooling effect, but the effect on the temperature of the body is inconsiderable. They are therefore less serviceable for antipyresis than for antiphlogosis, as in combatting pneumonia.

In regard to the value of the antipyretic drugs, I think that the opposition to them has gone too far. The more recently discovered substances of this class excel the former both in a more certain antipyretic action, which is almost without unpleasant accompanying effects, and in the much smaller dose required. As for the individual drugs, my experience is that the earlier ones, quinine, conchinine, salicylic acid, hydro-quinone, resorcine, and others, are surpassed by antipyrin, thallin and antifebrin. Antifebrin is superior to antipyrin and thallin both on account of its more certain effect (which is almost entirely free from unpleasant accompanying effects), and on account of the small dose necessary as well as its cheapness.

Of the methods of using these drugs, of their principal and secondary effects, I will speak more particularly in the lecture on the treatment of typhoid fever.

PNEUMATIC DIFFERENTIATION AND THE PNEUMATIC DIFFERENTIAL PROCESS. ITS DEFINITION AND GENERAL SUGGESTIONS FOR ITS APPLICATION.

BY HERBERT F. WILLIAMS, M.D.,

OF BROOKLYN, N. Y.

(*Concluded from page 512.*)

Recent research has simplified our classification of phthisis. Certainly as far as indications for treatment are concerned, the all imporatnt question to decide is, when does a degenerative process in the lungs become tubercular? We know that two conditions are necessary: 1. Susceptibility or soil. 2. Impregnation and germination.

The writers in the earlier part of this century recorded the clinical evidence of the liability of even the simplest bronchial catarrh to become an uncontrollable phthisical degeneration. They also recorded percentages of recovery due to what we can now ascribe as due to a continued residence in an aseptic atmosphere. It is possibly true that the bacillus of tuberculosis may find its way into the animal economy through the stomach or by the abraded mucous or cutaneous surfaces. It is absolutely sure that a tubercular person in an ordinary dwelling, theatre, church or closed vehicle, will contaminate the air to such an extent that his companions and neighbors will respire his bacilli-laden breath. All of the factors that prevent germination in such exposures are not understood, but *vital resistance* is the term that thus far conveys the answer. The ability in the subject to establish and maintain the normal equilibrium between carbonic acid and oxygen, and the intelligence and intuition with which we are endowed, lead us to acts of involuntary protection. We are told by sanitarians that the sleeping-room should be the best ventilated room in the house. In many cases tuber-

cular susceptibility is primarily instituted by persistent pulmonary indolence.

In a condition of robust health, the fatigue of the day's exertion, mental or physical, produces relaxation of our nervous energies; our respiratory power decreases, both in inspiratory length and expiratory force; we have a resultant increase of carbonic acid in our general circulation and of course in the medulla and pons, at such a time we grow sleepy, and such a condition is made manifest by our awkward attempts of revival by "gaping," and with the deeper inspiration of this act we succeed for a time in revivifying the sluggish medulla and through it the pneumogastrics, but in a short time and for the same reason our respiration becomes superficial and again we gape, until finally we retire, sleep rapidly supervenes and should we observe the phenomena of the respiration we would find the highest expression of normal breathing. The inspiratory act becomes long, deep and forcible. The air is fairly aspirated into the thorax; the expiration is short, and in the sound sleeper the vibrating nares hardly remit their sonorous rattle before the hungry lungs are again impelling the air with a faithfulness that nothing but their supreme function could demand. Sleep is "nature's great restorer" when conducted in compartments with unlimited supplies of pure air. Recent experiments prove that bacterial germs which are inevitably introduced into the air cells through the polluted air of seggregation, are annihilated by the voraciousness of the tissue cells with which they come in contact when the *vital resistance* of the cell is at the standard of health. Normal sleep then may be a virtual antiseptic process.

It is probably true that the lungs of every man, woman and child in this city have almost daily visitations from circumambient microbes. The bacillus of tuberculosis is no small minority of the sum total, but so long as the lung tissue is maintained at its normal point of *vital resistance*, the bacillis are in nocuous. Pulmonary indolence is the first step to susceptibility.

From such insidious causes down to the most sthenic inflammation that may attack the lung itself we have every gradation of power whose sequential direction is the destruction of the vital resistance. The soil is now ready, impregnation takes place, germination follows; the bacilli seize upon the stagnant lungs, invade the guarding tissue cells, gain an entrance into the blood and lymph channels and the citadel is at once in a state of siege.

From this brief outline it is plain to be seen where we must direct our treatment. I have referred to the indications for treatment in most of the simpler conditions that lead to the graver septic pathological conditions. I will now refer to that department of my subject which treats of *topical medication*.

First, is it possible? One can hardly study the mechanism of the human body and fail to discover the evidence of adaptation of ends to means. We have only to discover the function of a given part or section, when we shall surely find no bungling mechanism that permits or compels its perfect action. We are not to forget that the inexorable laws of physics find their supremest expression in the constant and ceaseless activity of our living organism. Mr. Joseph Ketchum, by a process of synthetic reasoning reached the conclusion that in respiration there must be a difference in size of the breathing aperture between inspiration and expiration before he informed himself that such a provision had been made in the physiological function of the glottis. The theory he advanced in his article upon "The Physics of Pneumatic Diffentation"[1] seems to have been unchallenged, and while it may be possible to supplement the function of the glottis, the ability to condense vapor upon the interpulmonary surface must depend upon the conditions which he clearly indicates. More than this, a close study of the function of the glottis will show that its proper action is an essential, even indispensable condition to life. In the varying humidities, temperatures and densities of our atmosphere, and in many vocations, a continually placid glottis would drown us in a moist atmosphere, or parch and crack our inter-bronchial mucous surfaces in a hot dry atmosphere. This can be shown by the behavior of the glottis in the Russian bath, where the glottis remains wide open during expiration. The respiration of dry air will cause the glottis to contract during expiration, thereby retarding the outflowing air, and keeping a sufficient amount of moisture upon the mucous surfaces. It would seem that the terminal nerve filaments which convey centric impressions from the glottidean region, are rendered obtund by moisture and the reverse by dryness. It is needless to refer to the comprehensive action of the glottis when upon a full inspiration, it is instinctively closed to effect the expulsion of abdominal contents.

In studying this unique mechanism we find it of far more importance than physiologists have ascribed to it; and to maintain its healthy action or to supplement it is the key note to the question of topical medication. I have shown how by forced inspiration and inspiratory differentiation it is possible to convey spray and vapor deeply into the pulmonary structure. It remains to describe such other means within our control as will surely condense saturated air in interpulmonary spaces and cavities.

This contemplates the principal act of the entire differential scheme, viz: Respiratory differentiation. In this act with a variation of, say one inch Hg. from minus to plus, the weight of the normal air with each inspiratory and expiratory act, we are now compelling the circulation of a corresponding increase in complemental air in the complete respiratory act. There must be in this act an assertion of the power of the physiological action of the glottis, as described by Mr. Ketchum in his study of the mechanism of the inspiratory act; but let us see how this may be supplemented.

The patient makes a full inspiration through the ordinary capacious breathing tube, breathing a saturated vapor for temperature and density of air, with the assistance of one inch Hg. minus the weight of normal air *i. e.*, rarefaction. Now, with this act, we have our ordinary quantity of inspired air, plus the complemental saturated air. At this juncture, had

[1] Medical Record, Jan. 9, 1886.

we the physical, or especially the expiratory strength, we could by closing the glottis, and making a violent expiratory effort condense our interpulmonary complement of air; but we are contemplating a measure for the cure and relief of diseased, not healthy humanity. Taking our patient, then, with his lung fully permeated with saturated air (a position he can maintain with comfort for a longer time than if furnished with his ordinary inspiratory force), we will now call upon him to give us his full expiratory power, at the same time giving him the assistance of say one inch Hg. plus the weight of the normal air *i. e.*, compression in the cabinet. We will do more —it will be remembered I said he made his inspiration through a tube of sufficient capacity to produce no obstruction to the inflow—now by the use of the artificial reversible glottis, we will restrict his expirations to a point impossible for him to expire in sufficient time, and with sufficient comfort to maintain his existence without the assistance above described. Now then, a force of one-half pound pressure per square inch is being exerted about the superficial area of the lungs, and upon the saturated air therein. This air is restricted in its outflow to a degree which will admit of the dynamic value of pressure in producing compression of the interpulmonary air, and at the same time permit a comfortable and sufficient respiration. Respiration may thus be carried on for an indefinite period with the absolute assurance of the deposition of a fixed quantity of condensate upon the interpulmonary surfaces and air containing cavities. This condensate may be increased by heating the vapor to the limit of tolerance and probably safely by covering the thorax with refrigerant bags of salt and ice. I think then, that I have demonstrated that topical application is possible.

Secondly, is it feasible? Whether feasible or not it has been the goal for unlimited professional want and endeavor. I am practically acquainted with the means hitherto within our control by which we have hoped at least, that effectual topical medication was produced. Whatever of scientific basis there may be for such a hope, the fact remains that spray introducing inhalers, nasal and oral appliances have long been used, and constitute in the estimation of many an essential element in the management of phthisical cases.

It is essential to distinguish in this connection between spray and vapor. By the forced inspiratory act, it is inevitable that the small particles of the medicament are given an impetus that carries them deeply into the interpulmonary structure; and where cavities are formed which communicate with the larger and adjacent bronchi, it is equally inevitable that agents in the form of spray can be deposited therein. When spray is finally subdivided or nebulized, such portions may the more easily spring into vapor when the atmospheric variations and temperature will permit. These variations may be found in the contrasted temperatures of the external and the interpulmonary air, and I have already referred to the means by which this can be increased; I have in other papers and discussions pointed out the evidence of the introduction of agents into the general circulation, and to those who have grown skeptical either concerning the power or the desirability of thus producing local and general medication, I especially appeal for calm judgment, lest the failure to produce a salutary effect may be as much the result of an ill chosen remedy as the possibility of its non-application. It is idle to adduce argument to prove that every professional man knows, ether, chloroform, nitrous oxide, etc., are, strictly speaking, vapors. We know that their action depends upon the fact of their entrance into the circulation through the pulmonary avenue.

Every substance is capable of being vaporized, and though those thus far supposed to be possessed of germicidal power, are of a lower specific gravity than ether or chloroform, the deficiency can be counterbalanced by bringing them to their vaporizing point before use. But in a therapeutic sense we are by no means restricted to moist agents. Chemically dry air, the various gases and smoke, may more fully suit the pathological necessity. In the selection of dry agents, respiratory differentiation, with restricted expiratory aperture should be used, for the compression so effectual in squeezing the moisture from saturated air, will as effectually disseminate air and its dry contents into such communicating bronchi and vesicles as would resist the ordinary respiratory current, and the diffusion dependent thereupon. When primary infiltration is a tubercular deposit or a neoplastic growth, of course the pulmonary structure at the seat of such disturbance has become pathological and impervious to air. It is not in the province of this paper to theorize on the etiology of tubercle, or to present such facts as may go to show the possibility or impossibility of clearing up such a deposit by any treatment medicinal, climatic or mechanical. It is my conviction, nevertheless, that any demonstrable area of lung tissue which is tubercularly infiltrated must forever remain so, or else softening, ulceration and excavation must take place. It is with a full realization of such a probability that I would urge the unremitting use of antiseptic vapors, for the purpose of circumscribing the area of deposit by rendering the contiguous lobules sterile to the bacillic germ. Ulceration and breaking down may take place. Here it is of paramount importance that antiseptic vapor be not only introduced, but forcibly introduced to secure a more thorough evacuation of the ulcerated area. It has been my good fortune to see recovery take place by such a chain of pathological and therapeutic events.

In fibrous degeneration of the lung, tubercular infection does not supervene as rapidly or as constantly as in the prodromal catarrhal inflammations. One reason for this may be that the cells of the hyperplastic tissue are as voracious for the bacilli as the normal histological tissue cells. True fibrosis of the lung is a chronic change that will resist every effort to restore its function, but such patients have normal lung tissue left, or they would not be alive, and it is the gradual involvement of these healthy areas that finally gains it the mastery of the subject. Judicious and occasional treatment with such agents

as act as emollients to the intercurrent congestions and catarrhs will save lung tissue, prolong life and render existence comfortable.

It is in these cases that over zeal in frequency, force and duration of treatment may work harm, and in the judgment of competent observers $\frac{4}{10}$ to $\frac{6}{10}$ inspiratory differentiation from five to ten minutes, once or twice weekly, will gain them all the benefit to be derived. Where respiratory differentiation is chosen $\frac{2}{10}$ to $\frac{4}{10}$ excursion is sufficient.

Little further need be said concerning the various forms and manifestations of phthisis. While the several forces of the differential process at our command enable us to manipulate and adapt the treatment that advanced disease demands—in other words to treat it—the supreme importance of bringing our skill and energy to bear at a time of more equal warfare is manifest. Nothing that experience has shown to be of benefit should be omitted, and in so far as this may apply to the dietary or as a means for the preparation for climatic sojourn, the skillful administration of pneumatic differentiation will be found a potent auxillary.

For the general manipulation of phthisis I would advise the following: *First*, residual air expansion, repeated once or twice; *Second*, respiratory differentiation with artificial reversible glottis, restricted expiratory aperture, from five to ten minutes; *Third*, the sitting may be concluded by inspiratory differentiation. In early phthisis with prolonged expiration, forced inspiration with high rarefaction one to two inches through a constricted inspiratory inlet, may be interspersed with the last act. Treatment conducted in this manner, will in a few inspirations lower the rarefaction in the cabinet. When it has reached $\frac{6}{10}$, inspiratory differentiation can again proceed; spray can be used with the forced inspiration, and the condensation of such of it, as springs into vapor may be produced by compelling the patient to make an expiratory effort through a constructed expiratory outlet, but such act is exhausting and unnecessary when the respiratory act is used. In respiratory and inspiratory differentiation spray, vapor, antiseptic gas, or air, should never be ommitted; *Fourth*, Cogwheel respiration and prolonged expiration may be treated by respiratory differentiation with artificial reversible glottis with constricted inspiratory and free expiratory aperture—(The patient simply reversing the artificial glottis in the breathing tube); *Fifth*, the duration of treatment and the length of each sitting must depend largely upon the character of the disease, and the evidence for good or evil that is gained as the case proceeds.

The acute affections will rarely require more than from two to six daily consecutive applications. Cases that demand correction of faulty development, weekly or bi-weekly expansion, covering a considerable period of time. The same for anæmia, chlorosis, amenorrhœa, sleeplessness, anorexia and assimilative deficiency.

In early phthisis daily treatment from ten to twenty minutes should be given until all adventitious sounds disappear, the sputa free from bacilli or absent altogether. The treatment can then be relaxed, but such patients should be cautioned to present themselves occasionally for inspection and treatment. This provision is as imperative as to command them to report for consultation upon the advent of any symptom which they themselves recognize as demanding treatment.

In the diagnosis of early phthisis we must have the courage of our convictions. To temporize with one small râle, to allow our sympathy and generosity to explain away a symptom like a slight hæmorrhage or a persistent anæmia, or pallor, or loss of weight, is a breach of faith as flagrant as any error we can commit.

In chronic phthisis treatment should be given daily for a week or ten days, then tri-weekly, bi-weekly and weekly, and covering a long period of time, perhaps for months and even years. As sad a mistake as can be made is to promise too much, or to allow a patient of this class or his friends to hope for an absolute restoration to health. If such a happy result is attained it can be accepted with good grace by all concerned, but opportunities for infinite good may be lost by promise or hope of impossible accomplishment. Such cases do not require the extremes of pressure and rarefaction as the earlier and acute cases. The value of climatic treatment is indisputable, but with such means within our control the failure to prepare the patient's lungs for the full advantage of any particular locality would seem as absurd as to send a man with purulent ophthalmia and conjunctivitis, to view the beauties of an art gallery, or the grandeur of a summer's sunset.

Sixth, primary hæmorrhage must be treated by inspiratory differentiation. *Seventh*, *Medication*. In the choice of agents much must depend upon our knowledge as therapeutists. While it is undoubtedly true that sedative and emollient agents will allay the excess of bronchial catarrh in chronic phthisis, there is nothing so ethereal about pulmonary tissue that shall prevent it from responding like the other tissues of the body to well chosen antiseptic agents. The general tendency in the profession now is to discard polytheraphy, and especially in the conservative measures of antiseptic surgery; and if we are to indulge the hope of the discovery of an efficient germicide against the bacillus of tuberculosis, we must select single agents and follow them to the finish. Where such agents are vaporized as by Dr. McCaskey's vaporizer[2] their doses must depend upon their point of air saturation, but when projected by spray they must bear a certain per cent. of the solution sprayed. Glycerine, cosmoline, and agents of like specific gravity make a seductive spray, and perhaps in appropriate conditions an effective one; but for a pure antiseptic effect we are not to forget that impure glycerine, the sugars and oils may be efficient cultivating mediums for bacterial propogation, and if successfully impelled into pulmonary spaces may make a rich pabulum for the microbe we are seeking to destroy.

[2]Dr. George W. McCaskey, of Fort Wayne, Ind., an earnest co-laborer in this work, has devised a vaporizer, whereby we can keep a cubic foot of air saturated with the vapor of any agent. An article descriptive of this will shortly be presented to the profession by Dr. McCaskey.

How far this may apply to moist agents of any description can only be determined by careful and continued study. If we are to reason from analogy or to act on the hints that we gain from the study of climatic treatment, we must primarily conclude that cases that should do well in warm, moist atmospheres of southern climates will do well with antiseptic vapors and spray; while those cases that should show improvement in cold, dry climates would best respond to dry dehydrating agents. The range of medication being so thoroughly under our control, it must require as good judgment and discrimination as by internal medication. I have found a hint in treating some cases, by changing as much as possible the character of the air from that in which the disease developed, and I have further found preliminary course of cabinet treatment to materially aid me in the selection of climate for individual cases. While the rapid improvement that has supervened upon a climatic change, after a preliminary course of pneumatic differential treatment may be ascribed to the effectual expansion thereby induced, I am sure I am warranted in my conclusion that a measure of the benefit is due to thorough disinfection of the lungs and the evidence gained of the patient's tolerance of moist or dry air, as the case may be.

I will mention a few of the most important agents that I have thus far used: Dry air, this can be easily furnished by attaching an U tube to the breathing faucet, and packing the tube with pumice stone and pure sulphuric acid; or absorbent cotton borated or mercurialized may be loosely packed in the tube.

The bichloride of mercury in solution of a strength of $\frac{1}{5000}$ to $\frac{1}{2000}$.

Lugol's solution 10 to 50 per cent.

Creosote 10 to 50 per cent.

Pure carbolic acid 10 to 50 per cent.

In using the last two agents I have projected the spray with the "Semple Inhaler," using equal parts of pure glycerine and water as diluents.

Oxygen gas and the per-oxide of hydrogen may be appropriately applied. I am now using C. P. glycerine as a de-hydrating and disinfectant spray.

As emollient and sedative applications I have used morphine, cocaine, atropia, stramonium, and a weak emulsion of peppermint oil.

It is unnecessary to make further reference to special agents. The list is as extensive as the materia medica, and as in other departments of medicine, each practitioner will find certain agents to behave better in his hands than in those whom he seeks to instruct, yet as there is probably but one best way to do everything, it is equally probable that there is but one best bacillicide and one best opportunity for its perfect work.

450 Classon Avenue, Brooklyn, N. Y., April 26, 1887.

BERGEON'S METHOD OF TREATING PHTHISIS BY GASEOUS ENEMATA.

Read before the Chicago Medical Society, April 18, 1887.

BY FRANCIS J. CRANE, M.D.,

OF CHICAGO, ILL.

In January last, the *N. Y. Medical Record* contained an article headed "A New Treatment of Phthisis," which gives a brief outline of Dr. Bergeon's method of administering carbon dioxide mixed with sulphuretted hydrogen gas, and referred to an article published in the *British Medical Journal*, of December 18, 1886. This described in full the apparatus and mode of using it, and stated they had been procuring beneficial results by the method, and that Professor Cornil, of Paris, had also become an enthusiastic supporter of it. This led me to write to Dr. Bergeon, and in the course of my correspondence, he presented me with an apparatus, as well as with the treatise of Dr. Morel read before the French Academy last June, and also one by Professor Cornil. These are so exhaustive that I have embodied in this paper only the essence of both, as follows:

New treatment of the diseases of Respiratory Organs and Septicæmia by the means of Gaseous Enemata according to M. Bergeon's Method. By Dr. V. Morel. It would seem from the statements of physicians who have tried either to prevent the development or the proliferation of the bacillus, or to destroy it, that it is the one thing which we have to overcome in the treatment of phthisis. In reasoning by analogy with other contagious diseases, as, for instance, cholera and hydrophobia, it might be urged that the bacillus is not the immediate cause of the morbid phenomena of tuberculous affections. It is known that, aside from miliary tubercles, which invade the lungs and are the cause of the patients' symptoms, the gravest phenomena of phthisis are due to the septicæmia, which poisons the patient, and is caused by the suppuration of the tubercles, which, brought in contact with air, undergo putrefaction and are absorbed into the system. The bacillus' work, then, by producing lesions of texture, which become fatal to the organism by rapidly destroying or, by undergoing softening and absorption, produces septicæmia. To use Darembourg's expression: "The bacillus is nothing, but septicæmia is everything."

In acknowledging that it is not necessary to ascribe to the microbe all of the morbid phenomena of phthisis, it is not less true that its presence is to the organism an incessant and real danger, and that consequently, in endeavoring to discover a remedy for the lesions which it has produced, it is necessary to destroy it, or at least to neutralize its action. For this purpose such agents as sulphuret of hydrogen, bisulphide of carbon, and other antiseptics mixed with pure carbonic acid, are employed.

Principles of Bergeon's Method.—The first mode of treatment thought of consisted in applying by inhalation some substances having parasiticidal properties. It is known that antiseptic substances are poisonous when introduced into the arterial system, either directly or by inhalation. Claude Bernard has

shown that poisonous gases introduced into the arterial system through the lungs produce toxic effects almost instantaneously. Besides, the antiseptic substances have an irritating action, and this action, operating on diseased lungs, will only increase the existing lesions, while their unpleasant odor aroused a refusal in the patients to their use; this is probably the reason why so little success has been obtained by inhalation in the treatment of phthisis, and is conclusive proof that the introduction of antiseptics by the stomach is preferable, for Cl. Bernard has shown that when a poisonous or medicinal substance is introduced into an organ distant from the arterial system; into the digestive tract, for instance, it cannot enter the arterial system, because it is expelled before reaching it. It must pass through the portal system, the hepatic veins and the pulmonary texture, there to be exhaled, or it can be expelled in the liver with the bile.

It is well established by experiments that the introduction of poisonous substances into the digestive tube may be done without danger by taking certain precautions, of which the most important consist in not injecting too large quantities at once, and not injecting more before the first has been completely eliminated. What avenue ought to be chosen? The stomach or the rectum? In both cases, the medicament will have to pass through the portal vein, the liver, the hepatic vein, the right heart and pulmonary arteries, but we think the rectal way is preferable, for the patient cannot take a dislike to the antiseptic substances on account of their disagreeable odors.

Gaseous Enemata in the Therapeutics of Respiratory Organs, Pulmonary Phthisis, Asthma, Whooping-cough, Bronchitis, Bronchiectasis, Bronchorrhœa, Pulmonary Catarrh. By M. Cornil.[1] The principle of the action of gaseous infections and of their rapid elimination by the lung, has been given by Cl. Bernard. He showed that when sulphuretted hydrogen is injected into the rectum of an animal, the gas is expelled by the lungs; he proved that we can so inject it in almost unlimited quantities, without causing harm; whereas its introduction by inhalation rapidly occasions grave accidents and the animal's death. However, to introduce sulphurous hydrogen, or any other gas or vapor, into the economy per rectum, for the purpose of destroying the microorganisms which exist in a number of diseases, it was necessary to find a gaseous vehicle, inoffensive to the economy, and easily tolerated by the bowel.

Carbonic acid gas admirably answers the purpose; it is very easily borne by the colon, rapidly absorbed and afterward expelled by the lung, with the medicinal gas which it holds. This gas itself, in all probability, plays a very important part in this new treatment of pulmonary diseases.

Dr. Bergeon, who inaugurated this method, published a few months ago the first results obtained in the treatment of pulmonary phthisis by this method. Physicians of Lyons, Paris, Geneva and Marseilles who have treated phthisis by the method, have generally obtained a very rapid disappearance of the phenomena of pulmonary suppuration, and a progress towards a state of health with all the signs of cure.

Concerning the patients I have treated by this method, I can now assert that the results I predicted three months ago have been achieved. The patients that I considered cured have no more expectoration, and give on auscultation stethoscopic signs which denote the presence of quiescent cavities, or cicatrized lesions. Some of these patients have been obliged to return to a life of labor; nevertheless their respiratory organs have stood the test, and the amelioration obtained has been permanent.

While many patients whom the expectoration once so exhausted, now have only 3 or 4 grams of sputum a day, at the beginning of the treatment it was from 250 to 300 grams. We have found bacilli, it is true, in the sputa of these patients; yet it remains to be discovered whether these bacilli which continue to exist after the return to health have kept their functional activity or not. Whatever may be the mode of action of carbonic acid introduced by intestinal absorption in the venous blood and afterward expelled by the lung, it can be said from the observation of patients, that this gas, filled with proper medicinal substances, greatly modifies the respiratory function, and makes the hæmatosis more complete and easy. It gives a sensation of well-being, followed by an increase of strength and weight, a diminution of fever and night sweats.

The following precautions must be observed in giving this treatment: 1. The CO^2 ought to be as pure as possible, so as not to inflame the bowel. That obtained by the reaction of dilute sulphuric acid on the bicarbonate of soda has always been perfectly absorbed by the bowel without producing any toxic effect.

2. The gas should be collected in a receiver from which the air has been expelled.

3. Make the injections just before a meal, or at least three hours after, and never when the patient is weary. It is necessary to be very cautious in experimenting with other medicinal substances, for if, although the sulphuretted hydrogen is inoffensive, other agents, as turpentine, chloral, ammoniæ, iodine, bromine, ether, etc., may not be, and might be the cause of an inflammation of the intestinal mucous membrane.

It is not necessary that the dose be large; by injecting twice a day 4 or 5 litres of carbonic acid gas passed through 500 grams of sulphur water, we rapidly notice the disappearance of all the phenomena of pulmonary suppuration, either in its acute or chronical state.

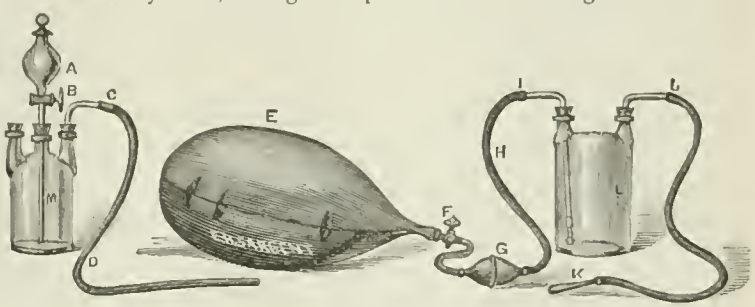
Bergeon's method has been successfully experimented with by Dr. Chantamesse, in his service at St. Antoine Hospital, during the months of August, September and October. The following are his results: "Two patients brought to the hospital suffering with violent attacks of asthma were, half an hour after the injection with sulfo-carbon vapors, entirely relieved of the dyspnœa. The treatment having been continued for a few days, the breathing was relieved, and the attacks were not repeated during the time they remained." Nine patients giving general

[1] See THE JOURNAL, January 15, 1887, p. 69.

and local signs of pulmonary tuberculosis, with tubercular bacilli in the sputa, have obtained very great amelioration from this treatment. The increase of weight has been rapid, one pound and sometimes as much as 35 oz. a week; cough and expectoration have largely ceased. We always find the bacilli in the sputum, however. These patients have been under treatment for one month and a half. One of them has increased nine pounds in weight.

I have used this treatment with four cases; two of phthisis, one of intussusception of the bowel and one of spasmodic croup. With the croup and intussusception it operated like a charm, overcoming both almost instantly. In the case of croup, I used the bisulphide of carbon, and in half an hour the little patient was sleeping, apparently as well as ever.

Case 1.—Mr. W., aged 26. Two sisters and a brother died of phthisis; he had been treating with various physicians and changing climate (having been to Colorado twice) for over three years. The right lung was nearly useless, as it contained a cavity corresponding to nearly if not quite half of its original capacity. Nowhere on this side could vesicular respiration be heard, while the left apex likewise yielded unmistakable signs of disease. There were œdema of the feet, incessant cough, broken sleep, watery stools and ravenous appetite, although he could not retain anything on the stomach; temperature 102° F. After the first injection of bisulphide of carbon, given in the evening, he slept well for three hours and was bothered very little with cough, but on rising in the morning, to use his own words, came nearly strangling for want of a cough, which he finally got, and expectorated a pint with the one paroxysm. I then used the sulphuretted hydrogen water and he improved very fast; in one week he had a normal temperature; night sweats almost entirely stopped, expectoration was much less, and he was able to wear his shoes, which he had not been able to do for over six weeks. Unfortunately, however, at the latter part of the second week he ventured out in one of our rainy March days, took cold, and his death, two days later, cut short the record of what might have proven almost a miracle.



Case 3.—Mrs. W., aged 34, widow, having lost her mother and older sister from phthisis, applied to me for some heart trouble. Complained of a dizzy sensation on rising from a recumbent position; feet swollen some, hectic flush, considerable dyspnœa, slight cough with no expectoration. *Diagnosis:* Incipient phthisis with heart complication? She had noticed, also, for about a week some night sweats, which did not last, however, after the second administration of gas. She improved so rapidly that she only made seven visits in all, and pronounced herself cured. There is, however, no doubt but she will have a return of symptoms upon the slightest provocation.

This comprises all my experience, but these are facts, and facts are stubborn things to deal with. In regard to the best mineral water, I wish to say that, after trying the Lafayette, Ind., the Blue Lick, Ky., and the Ypsilanti, Mich., mineral waters, I am satisfied that the Ypsilanti mineral water is just what we want. It contains 20 cubic inches of gas to the gallon, and is so strongly impregnated with it that I use it over the second time by having solid rubber corks to replace the perforated ones when I have got through using the apparatus. Mr. St. Clair, President of the Company at 88 Randolph St., has kindly furnished a case of 12 quarts of the water, which I have forwarded to Dr. Bergeon, in hopes that it will compare favorably with the Eaux Bonnes water which he is using. I have had an apparatus made by E. H. Sargent, of Chicago, which I think takes the place of Morel's very well, differing from it only in point of cheapness, costing but a little more than one-half the former.

The true place of this mode of treatment cannot be established until the experience of careful observers has been given us, years hence. I wish, therefore, to urge the profession to investigate the matter fairly, since time, I am confident, will prove that Dr. Bergeon has been one of the greatest benefactors of the age.

UNUSUAL METASTASIS IN MUMPS,

With Report of Three Fatal Cases.

Read before the Loup Valley District Medical Society, April 7, 1887.

BY F. D. HALDEMAN, M.D.,

OF ORD, NEBRASKA.

The epidemics of mumps which are of frequent occurrence in almost every community, present some points of interest to which it may be well to refer. But little attention seems to be given in medical literature to the consideration of this disease. Aitken, in his "Science and Practice of Medicine," three volumes of over 3,000 pages, devotes *one page* to its consideration; and that monument to the progress of medical science, Pepper's "System of Medicine," containing about 5,500 pages, devotes less than six pages to the subject; J. Lewis Smith, in his work on the "Diseases of Infancy and Childhood," of over 800 pages, devotes *two* pages to this subject; and yet it is one of our most widely extended and frequently recurring epidemics.

Mumps, as it prevails under the usual conditions, does not possess a high degree of importance, even

when metastasis to the testicle takes place. Under some conditions, however, it develops an intensity of action which is quite unknown to the ordinary course of the disease. During the winter of 1886, mumps appeared as an epidemic in and about Ord; not many children escaped, and a good proportion of adults were attacked. Among the latter were an unusual large number of metastases, and cases of violent and even alarming general derangement. From January 1 to May 20, 1886, there occurred in my practice twelve cases of metastasis in mumps. Out of this number, one died from metastasis to the right lung, and one had serious heart trouble, but recovered, as did the remaining ten cases. Two more fatal cases occurred near Ord, about the same time, under the care of Dr. Klinker, who has kindly given me the history of these very interesting cases. One was metastasis to the liver, causing abscess which opened into the right lung, producing death; and the other was metastasis to the uterus, producing death of a seven months' fœtus and premature labor, followed by the death of the mother on the second day after her confinement. A record of these fatal cases, and of one which recovered, I think of sufficient interest to give in detail.

Case 1.—A young man, 28 years of age, was taken with mumps February 25, 1886. His general health previous to this time had always been good. The disease progressed favorably until March 1, when patient complained of feeling weak and worn out; he had been up and dressed every day, and did not consider himself sick enough to be confined to his bed. On March 2 there was a severe chill, followed by high fever and sweating; patient not able to get up. On March 3 I saw the case for the first time. There was slight swelling of both parotids; left testicle tender and about twice its natural size; temperature 103, pulse 90, respiration 30. Face flushed and the skin bathed in perspiration; frequent and suppressed cough, accompanied by a scanty expectoration of glairy mucus; decided dulness on percussion over the lower lateral and posterior part of right side of chest; crepitant râle heard below the axilla of the same side; tongue coated with a light fur and bowels constipated. I directed poultices to be applied to right side of chest and sweet oil to the testicle; gave a powder of calomel and jalap to move bowels, and gr. viij doses of quinine were ordered to be given every four hours.

March 5. The swelling in both parotids had entirely disappeared; left testicle not so much swollen, but still very tender on pressure; temperature 104, pulse 110, face flushed and profuse perspiration; respiration 40, expectoration still scanty and streaked with blood; percussion and auscultation showed an increase of dulness over the right lung, with mucous râles in that region; tongue coated. The bowels had moved freely the day before; urine scanty and high-colored. The same treatment was continued, and in addition egg-nogg was ordered.

March 7. Patient's condition much worse. He was propped up in bed, as it was impossible for him to lie down. Temperature 106, pulse 150 and very weak, respiration 50 and difficult. Skin bathed in sweat; increased area and degree of dulness over right lung, with mucous râles; retention of urine; tongue covered with a dark-brown coat. Patient became unconscious; respiration more frequent and difficult; expectoration abundant; countenance livid and swollen. He gradually sank into coma, which deepened until it ended in death at 1 A.M. March 8.

This was evidently a case of embolic pneumonia, referable to the parotitis. The minute emboli, derived from the veins of the affected glands, charged with putrescent matter, being arrested in the branches of the pulmonary artery, excited a circumscribed pneumonia which caused a fatal termination.

Case 2.—On May 16, 1886, I was called to see Mr. J. V., a married man, about 28 years of age, whose prostration and general appearance indicated alarming illness. I was informed by his wife that he was taken with mumps on May 5, and seemed to be getting along all right until May 10, when the swelling began to leave the parotids and the testicle became the seat of trouble. His condition did not become alarming until May 13, when he had a sinking spell with pain over the cardiac region; the pulse was irregular and feeble. A physician was called in, and treated the case until May 16, when I was requested to take charge of the case. His condition at this time was as follows: The surface of his body was cold and drenched in perspiration; temperature 97°, pulse 50, small and intermitting; the heart's action was confused and feeble. Auscultation revealed a distinct mitral murmur. Though inspiring deeply, he seemed to suffer from apnœa, breathing hurried and anxious, but the air entered the lungs freely. There was no pain, but great agitation and feebleness, intellect clear. Both testicles were slightly swollen and quite tender. No enlargement of the parotid glands. I prescribed quinine, digitalis, and acid sul. aromatic; applied sweet oil to the testicles and ordered egg-nogg or milk-punch to be given frequently. The pulse became more regular, and his general condition gradually improved. The temperature remained below normal until May 18. The heart difficulty subsided after a few days, and patient was able to be up in two weeks. There was slight atrophy of left testicle, but no other bad results remained.

The metastasis to the heart, producing endocarditis, is an event much to be dreaded, and was caused in this case by septic infection of the blood.

Case 3.—Is one of the cases which occurred in the practice of Dr. Klinker, and the record given to me is as follows: Mr. N., aged 21 years, had an attack of mumps which dated from January 13, 1886. Both parotid glands were affected, and five days afterwards both testicles became tender and swollen. On January 19 the swelling in both parotids began to subside and a feeling of weakness, with a tendency to syncope, followed; that evening he had a chill, and soon afterwards a high fever. On January 20 Dr. Klinker was called, and found his temperature 103°, pulse 120 and very weak, profuse perspiration, pupils widely dilated, tenderness over liver with constant pain in that region; tongue coated with a light fur; *partial paralysis* of right upper and lower ex-

tremities. Did not see patient again until January 23. The temperature at this time was 104°, pulse 130, profuse perspiration, with hurried breathing; right hypochondrium tense and painful on pressure, very distinct jaundice; the paralysis had changed to the left upper and lower extremities. The right thigh became very much swollen at this time, and an abscess formed, which was not opened.

January 26. Patient semi conscious, and breathing with great difficulty. During an effort to cough, there came a large gush of dark purulent matter which filled the mouth, throat and lungs so as to produce imme diate death by suffocation.

Case 4. Mrs. D., 20 years of age, in the seventh month of pregnancy. She was taken with the mumps on April 1, 1886. April 5 the swelling suddenly left parotid glands, and she became very nervous and weak; complained of pain over the hypogastric region. Dr. Klinker reports that at this time her temperature was 104°, pulse 120 and feeble. There was pain and tenderness over the womb, with constant vomiting. Her fever continued high throughout her illness.

April 10. Active labor pains set in, and she was delivered of a seven months' fœtus, which had evidently been dead several days. The placenta came away, and with it a very profuse and *offensive* discharge. The patient became delirious, and died April 12.

I find in looking over the literature of this common disease, that metastasis to the œsophagus is mentioned by Dr. Richard McSherry, of Baltimore, Md.; to the kidneys by Dr. Croner, of Berlin; and deafness coming on during an attack of mumps has been recorded by Dr. A. H. Buck, of New York. Dr. H. V. Logan[1] gives the record of a very interesting case, in which there was double metastasis, and subsequently thrombosis occurred in most of the superficial veins. The left parotid and right testicle were involved at the same time; twenty-two days afterwards the left testicle became involved, and on the fortieth day of his illness inflammation of the right parotid gland set in. These facts indicate the serious nature of the disease, and, as I have already shown, there may be various other complications which are to be very much dreaded. There are no other examples of metastasis so complete and satisfactory as that of mumps, and bearing in mind that both testicles are not unfrequently inflamed during an attack of mumps, it seems very probable that, in many cases, the infectious material enters the circulation and, in passing through organs having a very complex circulatory apparatus, is apt to be arrested and give rise to more or less disturbance.

That mumps is a contagious as well as infectious malady has long been known, but what the nature of the contagium was, has not been so well understood. Dr. A. Ollivier, Physician to the Children's Hospital in Paris, has made some researches with a view of ascertaining the correctness of the results previously obtained by Drs. Capitan and Charrin, who had been occupied in the same line of research. Like these two experimenters, Dr. Ollivier discovered in the different liquids of the body, but principally in the blood and in the urine of patients suffering from mumps, micrococci of a special form. These results were constantly obtained in patients suffering from mumps. Similar researches were made on children in health, and the results were absolutely negative; a fact which shows that there is something specific in the disease under consideration. As it has been shown that the development and propagation of mumps is due to the presence of micro-organisms, it should be considered as an infectious or contagious malady, and should therefore be classed with measles, scarlet fever, small pox, etc.

[*Note*—Since preparing the above report, I have met with a case which shows the importance of this subject, and one of the mistakes likely to occur as a result of complete atrophy of the testicle following mumps: While in Omaha last month I was in the office of Dr. W. S. Gibbs, of that city, when a patient came in who had just met with an accident. It seems that, during an attempt to lift a ladder, he felt something give way in his right groin, accompanied by severe pain and faintness. He was taken to a physician who after an examination, found a tumor in the right inguinal region. After an ineffectual effort to reduce it, and finding that there was only one testicle in the scrotum, he pronounced it a case of partially descended testicle. The patient not being satisfied and suffering intense pain, came to Dr. Gibbs's office. We found a tumor the size of a walnut, and about as hard, lodged in the right inguinal canal; there was only one testicle to be discovered in the scrotum. After inquiring into the history of the case, we found that during boyhood he had the mumps, with metastasis to the right testicle followed by complete atrophy of that gland. The diagnosis of inguinal hernia was then made clear. Dr. Gibbs succeeded in reducing it, after passing his little finger to the seat of stricture at the neck of the sac, and by a process of tearing enlarged the opening sufficiently to allow the strangulated intestine to pass back, when he employed gentle taxis.]

My principal object in this paper has been to call attention to the seriousness of the results frequently attending these epidemics. No doubt some of the many pages of medical literature devoted to diseases which a busy practitioner might not see once in a lifetime, might profitably be given to the discussion of this most common ailment. I have availed myself of every material source of information within my reach, and deeply regret that more has not been published in an accessible form, to aid us in meeting the many indications which are frequently present in this common malady.

MEDICAL PROGRESS

Pyridine in Asthma.—Dr. Wyss, of Geneva, in *Der Fortschritt*, No. 1, January 5, 1887, commenting on the treatment of asthma with pyridine, writes: The physiological and therapeutical properties of pyridine was investigated by Professor G. Sée. His pupil, Dr. Dandien, recently published the results of his researches on pyridine and allied basic substances (collidine,) and draws the following therapeutic conclusions: 1. The pyridine is indicated in attacks of angina pectoris. Its effects are very rapid. Its use prevents other fits. 2. In asthma, be it of nervous, emphysematous, or catarrhal nature, in the pathological as well as in the symptomatic asthma, the effects of pyridine are superior to those of injections of morphia; they are of longer

duration, and perfectly devoid of dangerous consequences. Moreover, pyridine is not merely a palliative, but really a curative remedy. 3. It is equally indicated in asthmatic attacks brought on by inhalation of poisonous gases. 4. Its beneficial effects are improved in dyspnœa of bronchiectatic and and tuberculous patients, and in dyspnœa in consequence of laryngeal affections. There is no contra-indication against the use of pyridine. Its absorp tion and elimination by the urine being very rapid, no accumulative effects are to be apprehended. Germain Sée gives the following directions for its use: 4 to 5 grammes (about 4 scruples) are poured into a small plate and placed in the midst of a room of 25 cubic metres. The patient, sitting in a corner of this room inhales the volatilizing pyridine mixed with the air. In urgent cases the pyridine may be directly inhaled by pouring four to five drops of it on a pocket handkerchief, which is held before the patient's mouth and nose. Further independent observations will prove whether the properties of the pyridine bear out the extraordinary praise with which Dr. Dandien extols the efficacy of this remedy. The great drawback is the strong, disagreeable smell, reminding of rotten fish, of the slightly yellowish fluid, which will not be easly concealed. Dr. Wyss adds: I tried the pyridine in only one case of a female patient, suffering many years from asthmatic attacks, in which the remedy had unmistakably a beneficial effect. The patient, aged 44, has since December 16, regularly, daily, three inhalations of pyridine, and has since been free of fits; whilst, before resorting to this remedy, she suffered at least twice a week from very severe asthmatic attacks.—*London Medical Record*, Feb. 15, 1887.

Action of Pyridine on the Function of Respiration.—In health and in disease, says Silva, (phthisis, pleurisy, chlorosis, etc.,) inhalations of pyridine have the effect of diminishing the quantity of air respired in a fixed period of time; sometimes by 500 cubic centimètres, sometimes even by 2,000 cubic centimètres, according to the time the inhalation is given. Notwithstanding this, the feeling of need of air diminishes. The respiratory curve shows that in the healthy man pyridine produces at first an expiratory dyspnœa; the respiration then becomes less frequent, irregular, preventing true periods and sometimes long intervals of apnœa. After the inhalation the respiration remains less frequent and less full, with deep inspirations. Sometimes sleep intervenes, and the periodic respiration is then more evident. The inhalation always causes abundant salivation, preceded by a bitter taste in the mouth and roughness of the throat, with constant desire to spit; the nose also runs. The respiratory curves obtained by exciting the nostrils by the faradic current are very similar to those obtained by pyridine. The nose runs, there is salivation, expiratory arrest, the respiration is disturbed and becomes sometimes periodic, and lastly, after the excitement has ceased, there are the occasional deep inspirations, and those periods of apnœa as seen after the inhalation of pyridine. But sleep and the sense of less need of air are wanting. The author therefore believes that pyridine acts on the respiratory centre by means of the trigeminus chiefly, but that the pneumo-gastric also is affected. The influence of pyridine on the pneumo-gastric is also shown by the increased secretion from the bronchial tubes. Pyridine therefore produces irritation of the terminal nasal fibres of the trigeminus, and hence running off the nose, salivation, and expiratory dyspnœa. The action on the bulb by means of this nerve is evident, and the respiratory centre is first stimulated and then paralyxed. This is shown by the diminution of the quantity of the air respired, and by the respiration becoming periodic and superficial. But the action of pyridine is not limited to the respiratory centre in the bulb, but also extends to the higher centre of the cortex, since it produces sleep; and this again contributes to give a periodic type to the respiration and to diminish the quantity of air respired in a given time.—*Loudon Medical Record*, Feb. 15, 1887.

Atropine Injections in Hæmoptysis.—The subcutaneous injection of atropine in cases of hæmoptysis was recommended by Tacke in 1882, and Dr. Hausmann, of Meran, has found it to be a most successful means of allaying recurring hæmorrhage from the lungs. (*International Klinische Rundschau*, No. 5, 1887). The great indication is to allow of the formation of a thrombus in the bleeding vessels, as Traub explained, by diminished blood-pressure. The capillary pressure will be lowered when the smaller arteries have their calibre lessened; hence the use of digitalis, restricted diet, and rest. Reflex vaso-motor constriction may also be assisted by astringents or the application of cold. In chronic (and passive) cases iron is recommended. Ergotine, turpentine, morphine injections, and alcohol are favorite remedies. In passive hæmorrhage from congestion some recommend wine, walking about, and deep respirations; in active hæmorrhage, only rest, ice, and morphine. But there are cases which resist all these measures, and in these Dr. Hausmann has found hypodermic injection of atrophine wonderfully efficacious. The following examples are given: 1. A patient with cavities in both lungs had hæmoptysis twice daily for six days to an alarming extent. The hæmorrhage was then arrested by a hypodermic injection of 0.3 milligramme of atropine ($\frac{1}{200}$ grain nearly). After two months the hæmorrhage recurred, and was only arrested by recurrence to atropine. 2. A patient at San Remo was troubled with hæmoptysis all through the winter of 1884, in spite of every care, and it only desisted in the summer. Next winter at Meran he was again similarly affected for a long time, till two injections of atropine (of the same strength as above) arrested the attack altogether. 3. In October last year Dr. Hausmann at once stopped severe hæmoptysis in a lady who had been treated in vain for eight days by ergotine injections, turpentine, etc, The quantities of atropine recommended for hypodermic injection in cases of profuse or moderate hæmorrhage from the lungs, which resist other means of treatment, vary between 0.2 and 0.5 milligrammes ($\frac{3}{1000}$ grain to $\frac{7}{1000}$ grain.)

THERAPEUTICS OF THE UPPER AIR-PASSAGES.

How far are the topical measures at present employed in the treatment of the diseases of the upper air-passages, excluding those of a surgical nature, efficient and worthy of confidence? Such was the question discussed before the New York Academy of Medicine on April 21; and the fact that the question was brought up for discussion shows that there is some doubt in regard to the favorable influence of our measures upon the local diseased conditions of the upper air-passages. The question was discussed by Drs. F. H. Bosworth, Andrew H Smith and W. H. Thomson.

Dr. Bosworth takes the ground that when we knew little about the treatment of diseases of the upper air-passages our machinery was very extensive; but now that we finally obtain striking success in the management of these diseases he thinks he may safely say that all the machinery necessary might be carried in a small hand-satchel. As regards topical applications to the larynx, in the early days of laryngology, did any of them, asks Dr. Bosworth, ever do any good? In his opinion, in the whole history of laryngology no case of so-called chronic laryngitis was ever cured by topical applications; and as regards the more serious affections no one ever claimed that topical applications could cure them. "The condition called chronic laryngitis is merely symptomatic and secondary to disease of the nasal cavities in every case. The morbid condition is not an hyperæmia with hypersecretion, to be corrected by an astringent, but rather a perversion of the normal secretion of the part, due to the morbid lesion above." He takes the view that there is no such condition as naso-pharyngeal catarrh in the sense of its being a catarrhal inflammation of the vault of the pharynx. "This disease, which is supposed to consist essentially in an excessive secretion from the vault of the pharynx, due to chronic inflammation of its lining membrane, is a myth. This excessive secretion is in reality diminished secretion. It is a normal secretion from a healthy membrane, but undergoing subsequent change as a result of disease in the part above." Astringents are not indicated here, but some method which reaches the cause or course of the disease, which is situated in the nasal cavities.

In such conditions in the vault of the pharynx as hypertrophy of the pharyngeal tonsil, acute or chronic inflammation, neoplasms, or other diseased conditions consisting in structural changes the indications are for surgical treatment; local agents have no other than a palliative effect. Nor is nasal catarrh a hypersecretion, to be cured by the application of astringents; at least it may be said that even if it is a hypersecretion the whole list of astringents has been tried in vain. "The symptoms of so-called nasal catarrh are due to those morbid conditions of the nasal mucous membrane which interfere with the great respiratory function of the nasal passages—namely, exosmosis of serum. Furthermore, the so-called catarrh of the pharynx, larynx, and trachea are merely secondary to this condition, and not diseases in themselves, being amenable only to treatment directed to the real seat of the disease—viz., the nose."

From his point of view, then, the treatment of catarrhal affections of the upper air-passages consists in the treatment of the nasal passages—which involves the restoration of these passages to a normal condition by the removal of obstructing bone and cartilage, reducing hypertrophied membrane, and correcting hyperæmia or other morbid conditions. It consists in use of the snare, the saw, the knife and the cautery. And of these Dr. Bosworth prefers the cautery.

The views taken by Dr. Andrew H. Smith are somewhat different from those just mentioned. In regard to the doubt as to the efficacy of our methods of treating these affections, this does not exist for Dr. Smith as regards acute and subacute affections. In chronic cases he holds that surgical treatment cannot take the place of local treatment, "and that, when surgery has done all that it can do, there still remain nearly three-fourths of the chronic throat and nose cases for the treatment of which we are dependent mostly upon medicaments applied to

the diseased surfaces." Dr. Smith's statistics are taken from the report of a large throat clinic, in which it is seen that of 1351 cases 370 operations were performed. But it is not very probable that two or three times this number should have been operated upon? Is not much of the difficulty met with in treating these cases unsuccessfully due to non-interference (surgically)? "Under the most favorable circumstances," says Dr. Smith, all we can do toward promoting the resolution of an inflammation is to assist the reparative efforts of nature." But how much, if any, reparative effort is nature making in these cases?

Dr. Thomson begins his paper with the statement that in his opinion, "the treatment of chronic diseases of the upper air-passages should be directed chiefly by two principles: first, by taking cognizance of cutaneous nerve associations in the causation and in the perpetuation of inflammations of mucous membranes; and, second, local disinfection. We know that many persons with chronic mucous catarrhs are affected by external influences which are entirely inappreciable by persons in health, and can detect a draught of air, as from a keyhole, which would be unnoticed by a healthy person. For this weakness, or irritability vaso-motor tonics are needed; and Dr. Thomson knows of nothing which will compare with the local application of the cold. The cold douche to the nape of the neck on rising, care being taken that the hair of the back of the head is not even dampened by the water, and cold salt-water sponging of the throat, according to him, are measures which should be kept up for months together, in all affections of the upper air-passages. But why take care not to dampen the hair? Washing the hair every morning is a measure of cleanliness; why do away with it? When reaction from the douche is established, he says, and the skin is dried, the entire surface of the front and back of the neck and of the root of the neck, and then of the back of the shoulders, ought to be well rubbed with sweet olive oil, to lessen the tendency to perspiration, or at least to check the chilling effects of rapid evaporation of the perspiration. The sensitive surface must then be protected by special covering—the patient should even sleep in woolen night shirts and between woolen sheets. During the day a perforated buckskin shirt should be worn over the light woolen undergarment.

It is in the direction of local disinfection that Dr. Thomson looks for the greatest progress in the treatment of diseases of the upper air-passages, except, of course, in those cases dependent upon malformations, which must be treated surgically. It may be safely said, he thinks, that as pus can be prevented only by excluding germs, so all chronic mucous inflammations can be got rid of only by excluding the presence or preventing the activity of germs. This possibly may be done by improving the resisting power of the tissues, and by using the disinfectants directly; remembering in regard to the latter point, that pure ocean or mountain air is the best disinfectant, and disinfectants of the carbolic acid class probably next best, except for necrotic affections, in which the chlorine class is better (chlorine, iodine, bromine, and sulphur).

PHYSIOLOGY FOR CHILDREN.

In the *Century* for April is an article on "English as She is Taught," by that man of humor and good common sense, Mark Twain. It consists mainly of answers to questions put to pupils in public schools, and gives a very good idea of the mental training received by children in obtaining what is called "an education." It shows, in other words, the folly of filling the minds of children with fragments of subjects which they cannot understand.

Amusing as is the article, it would be more so did it not have the sad side—did it not show how much growth-force, how much brain and nerve force, how much physical strength, are actually wasted to no purpose, and dwarfed. And while reading it we are constantly reminded that adults, "children of a larger growth," are but too often carried on in the same stream, into which they are thrown in childhood, to a ripe age of miseducation. It clearly shows the truth of what has been so often said: the child, or the pupil, must first be made to see, and then to understand what he sees. Space will not permit us to notice more of the article than that containing the answers to the questions on physiology; and from these answers we can readily imagine how the subject was taught—very much as it seems that chemistry (and physiology) is taught in many academic and medical schools.

The first answer, while not sufficiently comprehensive, is fully as clear as some that we have seen: "Physillogigy is to study about your bones stummick and vertebry." The next shows that hygiene is receiving no little attention in the schools: "Occupations which are injurious to health are carbolic acid gas which is impure blood." Dermatologists must henceforth know that "We have an upper and a lower skin. The lower skin moves all the time, and the upper skin moves when we do." We must admit

that the child was not far from the truth who said that "The body is mostly composed of water and about one-half is avaricious tissue." Old as is the science of human anatomy we are constantly learning something new; it has remained for an American child to discover that "the stomach is a small pear-shaped bone situated in the body"; that "the gastric juice keeps the bones from creaking"; and that "the salivary glands are used to salivate the body." The child who gave the following had most probably had a recent séance with the dentist: "The growth of a tooth begins in the back of the mouth and extends to the stomach." Our ideas as to the functions of the cranial nerves must be revised if it be true that "The olfactory nerve enters the cavity of the orbit and is developed into the special sense of hearing."

"If a laugh is fair here," says the author," not the struggling child, nor the unintelligent teacher—or rather the unintelligent Boards, Committees, and Trustees—are the proper target for it. All through these answers one detects the signs of a certain probable fact—that a large part of the pupil's 'instruction' consists in cramming him with obscure and wordy 'rules' which he does not understand and has no time to understand. It would be as useful to cram him with brickbats; they would at least stay." We may also detect another very probable fact: that the teacher has made vain attempts to give instruction in what he himself does not understand. "Isn't it reasonably possible," says Mr. Clemens, "that in our schools many of the questions in all studies are several miles ahead of where the pupil is?—that he is set to struggle with things that are ludicrously beyond his present reach, hopelessly beyond his present strength?" It seems so.

MANIA FOR NOVELTIES IN MEDICINE.

Probably there is to be found no period in the past history of medicine, characterized by such an active strife for making new discoveries, not only in the prolific realm of bacteriology, but in new therapeutic inventions and in novel applications of old remedies, as is the present. The mania for discoveries and inventions and the thirst for novelties has become fairly epidemic. It is only necessary to invent some kind of apparatus and either some new remedy or some new combination of old ones, apply them to the treatment of a few cases of some dangerous form of disease, or, still better, to disease in such stage of advancement as had been regarded hopeless, and report some striking improvement, before time enough has elapsed to make permanent results possible, and it is at once heralded as a grand achievement. It is so important that it cannot wait for the slow circulation of the medical press, but quickly reaches the profession and the public simultaneously through the daily secular press and telegraph. And now comes the strife between the ambitious doctors to be first in the field with the new remedies, and if the more considerate would like to delay until more reliable results could be possible, their patients speedily compel them to fall into line, or abandon them for those who have succeeded in first becoming armed and equipped for the new method of miraculous healing, until the manufacturers are hardly able to supply the needed materials.

It makes no difference whatever, whether the morbid conditions to be cured are lungs containing one hundred suppurating cavities varying from the size of a pea to that of a hen's egg, and the mucous membrane of the bowels ragged with ulcerations, if a temporary improvement can be maintained for two or three weeks, it is sufficient to constitute the subject of another favorable report, and give an additional impetus to the strife. And yet, as inexorable time moves on just as many thousands of dollars have become invested in the new materials, and the hopes of many thousands of invalids have been revived, the stubborn fact remains, that cancers will not soften and disappear under the influence of condurango, nor a continued fever flee *for good* from a cold bath or a dose of antipyrin, nor a half disorganized lung be reproduced, good as new, in three or four weeks by the magic influence of gaseous enemas. The many medical friends who have written for our *candid* opinion of the value of the Bergeon treatment of consumption, as well as those who are intending to write, may gather from the foregoing our answer; which is, that it is a method of treatment as capable of doing harm, unless skilfully used, as it is of doing good; and that from the known pathological and anatomical changes involved in all the varities of pulmonary phthisis, it is not possible to determine the real value of this or any other method of treatment until a much longer time has elapsed.

PROFESSOR ZIEMSSEN'S LECTURES.—The lecture by Prof. Ziemssen which opens this number of THE JOURNAL is the first of a series of lectures on various subjects, which will appear at short intervals during the next nine or twelve months. Our readers will be pleased to know that we have completed arrangements by which we will publish them from

advanced sheets. Among others the lectures will include the following subjects: "Subcutaneous Blood-injections, Saltwater-infusion and Intra-venous Transfusion;" "Cholera and its Treatment;" "Treatment of Typhoid Fever;" "Diphtheritic Paralyses and their Treatment;" and on diseases of the respiratory, circulatory, digestive, uro-genital and muscular apparatus.

Professor Senn's Letters.—In this issue of The Journal appears the third of a series of letters from Dr. N. Senn to Dr. Christian Fenger. It may be safely said that no such review of foreign surgical work has ever appeared in this country as is being given in these letters, and that few men are so admirably fitted for writing up the subject as Dr. Senn. His tour includes England, France, Spain, Italy, and Germany, including the Congress of German Surgeons, recently held in Berlin. It is with pleasure that we acknowledge our indebtedness to Drs. Senn and Fenger for permission to publish these interesting and valuable letters. The letters will appear regularly.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, April 18, 1887.

The President, W. T. Belfield, M.D., in the Chair.

PRELIMINARY DISCUSSION ON THE TREATMENT OF PULMONARY AFFECTION BY GASEOUS ENEMATA, WITH EXHIBITION OF APPARATUS.

The President: During the last twenty-five years various specifics for pulmonary tuberculosis have been announced by enthusiastic physicians and have successively secured more or less attention from the profession, yet none of these has secured in the hands of others the results claimed by its discoverer. The benzoate of sodium treatment of Rokitansky accomplished nothing in other hands; the phenic acid injections of Déclat were powerless to arrest the disease in any but his own hands; the eucalyptol treatment of Roussel failed in the hands of other investigators. The latest method of treatment—that recommended by Bergeon, of Lyons, after two years' careful observation—has, unlike its predecessors, met with almost unanimous approval at the hands of those who have tried it, including physicians in the Paris and Philadelphia hospitals and several practitioners in our own city. Since the method not only promises well, but is also universally accessible to the profession, it has been deemed advisable to present the subject to the members of the Society in a preliminary discussion this evening. There will be presented communications from Bergeon, of Lyons, Bruen, of Philadelphia, as well as the experience of several gentlemen who have used the method in this city.

Dr. Francis J. Crane read a paper entitled

BERGEON'S METHOD OF TREATING PHTHISIS BY GASEOUS ENEMATA.

(See page 541).

The President: This method of Bergeon has been extensively used in the Philadelphia Hospital, chiefly by Dr. Bruen, who has kindly sent the following résumé of his experience with it:

The experience thus far obtained in the Philadelphia Hospital in the use of Bergeon's treatment of consumption by rectal injections of carbonic acid gas impregnated with sulphuretted hydrogen, has been highly encouraging.

In the *Medical News*, of April 2, 1887, a statement of clinical results thus far secured in my wards, was presented. These results indicated that the element of suppuration in pulmonary phthisis was usually very positively influenced. The night sweats have been controlled in twenty five cases without an exception. The temperature has been modified even in the most advanced cases, and in some instances in which the disease has been extensive it has been brought to a normal point. A peculiarity of the temperature charts seems to be an introduction of a sub-normal temperature in the forenoon. The expectoration has been lessened in all instances, and in some has disappeared. A marked impression has been made for the better on the nervous symptoms which attend the disease, and a more cheerful and sanguine spirit has followed the therapeusis.

It would seem justifiable to conclude that we have a most important therapeutic agent in the gas enemata treatment. One case of acute broncho pneumonia treated on this plan has recovered, and will be discharged from the hospital. The history of her case has been already stated in the article in the *Medical News*. Another case of phthisis with pneumo thorax under treatment for five weeks, is so much improved that the patient insists on her discharge. The râles have disappeared from this patient's chest (the pneumo thorax was local and confined to the lower zone of the right thorax), the opening into the lung has apparently closed and retraction of the chest wall is going on. This patient had been ill for a year previous to admission to the Philadelphia Hospital; the pneumo thorax was noted on admission. She has gained over nine pounds of flesh, expectoration has ceased, sweats abolished. The cough, however, continues as a modified symptom, since she is as yet merely a case of phthisis in stage of arrest, the bacilli of tuberculosis being still recognizable in the sputa.

Two cases of commencing phthisis with moist râles, dulness of percussion, harsh breathing, deficient expansion over right upper lobe, and tubercle bacilli in sputa, have recently been placed under the treatment. In these cases the gain in one week has been most material. The râles have disappeared

and the patients express themselves as benefited. The method of treatment is surely worth a careful scientific investigation.

In our hands a solution of 5 grs. sulphide of sodium and 5 grs. chloride of sodium in 22 ounces of water has proven the most satisfactory substance to produce the sulphuretted hydrogen. A solution more strongly impregnated with sulphuretted hydrogen has not only been more advantageous, but seemed injurious, apparently inducing palor, loss of appetite, and in some cases, irritation of the bowels. The gas should be introduced slowly, not less than half an hour seems requisite for each séance. From three to five quarts can be introduced in most cases, a gain in the tolerance of the necessary distension of the bowel being rapidly acquired. The absorption of the gas from the bowel is very rapid and in half an hour the distension will entirely subside. It is sometimes introduced more rapidly, but the gain is in proportion to the time consumed in giving the gas. The carbonic acid can be pumped through the solution containing the sulphuretted hydrogen by the acid of a ball with valve attachment, and a circular received from Paris mentions an apparatus made by Shet, 79 Rue Phillippe de Girard, on which an indication is placed to register the flow of carbonic acid. A convenient apparatus is now furnished by Evans, 1104 Chestnut St., Philadelphia.

We have not obtained as yet satisfactory results from the examination of urine, or breath, nor of the effect of the treatment upon the bacillus of tuberculosis.

EDWARD T. BRUEN, M.D.

1814 S. Rittenhouse Sq., Philadelphia, April 11, 1887.

DR. R. H. BABCOCK: My experience with this remedy is rather limited, but it seems to me there are several questions which should be considered in speaking on this subject: *First*, is the treatment safe? *Second*, is it applicable in all cases? *Third*, is it a cure? I have already answered these questions in an article in THE JOURNAL which appeared last Saturday (April 16). Practically the treatment is safe under the precautions which are laid down, but Dr. Osler in some remarks before the Philadelphia County Medical Society, narrates a case in which the patient almost succumbed after the first treatment, the gas being charged with a mixture of bi sulphide of carbon and sulphuret of hydrogen. We can also conceive of cases in which, on account of limited respiratory power, the rapid administration of the gas by producing distension of the large bowel would seriously embarrass the limited respiratory capacity remaining in the patient. It is also conceivable that an undue amount of distension in cases of tubercular ulceration of the bowel might be dangerous, possibly producing rupture and peritonitis; and it seems to me this is a consideration which would render us cautious about administering this treatment in typhoid fever. I have had no experience and seen no reports of cases of this disease treated in this way. In regard to its applicability in all cases; that has been partially answered in considering the previous question. It has been the experience of Geneva physicians, as reported by M. Wiss, and of De La Roche, of Lyons, that there are cases which cannot tolerate the treatment at all. One patient who had hæmorrhoids suffered from such colic that the treatment had to be abandoned. Wiss also mentions a case which the treatment has to be abandoned in the course of a month, although superintended by Bergeon himself. I was asked to administer the treatment in a case in which the lungs were so extensively destroyed that it seemed to me unwise to administer it, though perhaps a small amount of gas might have ameliorated the symptoms; but had it been possible to abate or arrest the disease, the patient could certainly not have lived with such a small amount of lung left. Of course this consideration is one which renders the indiscriminate use of the treatment hazardous. There are cases in which the recovery, or arrest of the disease has been so complete that the patients are practically well, and have been able to return to their advocations. However, if we are to estimate this thing by the disappearance of bacilli from the sputum we must say it is not a cure. No case is reported in which bacilli have entirely disappeared. As you know, M. Cornil has instituted a number of experiments on animals with reference to this question, a solution of which we are all looking for with much interest. French physicians are experimenting with a great many other substances.

I am now using the treatment upon two cases, one is bronchitic asthma, but the treatments are too few as yet for me to make any report; I would not wish to say whether the relief that has been obtained is due to the treatment or is merely a coincidence. Another case is a lady aged 34, who has been suffering from phthisis for a year and a half, and who last fall received injections of phenic acid twice daily, without any improvement, who had been taking cabinet treatments from me for six weeks, without improvement, in whom the right lung is extensively consolidated, with a large cavity; in this case the relief for the first week was certainly very surprising. The patient gained in strength and experienced a feeling of well being, or as she expressed it a clearer feeling in her head, a feeling of brightness which she had not had for weeks. She certainly coughed less and expectorated less at a time. Her stools had been clay colored in spite of everything I could do; at the end of a week they were of a natural color. The movement of the bowels was perfectly natural, her tongue also cleaned off in a remarkable manner at the end of five days. The treatments were continued at my office twice a day, and the patient had to come into the city so the improvement was perhaps not quite as great as if she had taken the treatment as home. The second week she did not do quite as well which I attributed to the quality of the mineral water. At the end of two weeks she was improved in respect to all the symptoms which have been related this evening. The night sweats had ceased, her temperature was lower, but not normal—it ranged from 99° to 100⅘°. I took her temperature at 9, 11, 2 and late in the afternoon, and the highest she had with the exception of once was 100⅘, it was repeatedly 98⅘. Her tongue did not remain clean, and her appetite did not improve as I

desired. She gained strength, but there was a complication, tubercular laryngitis, quicker than she would otherwise have done. M. Bergeon states decidedly that tubercular laryngitis has been very greatly improved by this treatment. In the case just mentioned the laryngeal symptoms have improved, but whether entirely due to the treatment I am not prepared to say, as she has had various sprays and one topical treatment to the larynx. Her case is somewhat discouraging owing to the extent of the disease since it is not entirely confined to the right lung. She has complained of no unpleasant symptoms since the first treatment when she complained of a slight burning at the anus and a desire to evacuate the rectum. Once or twice she complained of a little colic. She is now taking the treatments at home and feels very much encouraged, but the outlook to me is not what it should be. I saw her last Thursday, and I felt disappointed to learn that she is beginning to perspire again.

I think all the precautions have been taken in this case thus far, and it proves that the treatment does not give rapid improvement in all cases, and and the fact cited by Wiss, that out of four cases treated in Geneva all died within three months, shows that it does not cure in all cases. However, it is a treatment which is so admirable and furnishes such good results in many cases, that I think all physicians are justified in trying it. Another thing which recommends it is that after the patient becomes accustomed to the treatment it can be handed over to a trusty member of the family to administer. Compared with pneumatic differentiation it offers a much better chance for the improvement of the patient, although there are cases in which pneumatic differentiation will do what this will not. But thus far this method gives better prospects of benefiting a number of cases than any method which has been placed before the profession.

Dr. W. H. Weaver: A case under treatment at the Chicago Policlinic, which is making favorable progress, is one in which there is no doubt of the extent of the tuberculosis in the left upper lobe. The expectoration was quite profuse and contained an abundance of bacilli. She has been failing for two years, but very rapidly for two months. She had fever, night sweats, prostration, wasting loss of appetite, but had not taken any medicine of any sort. She came to the Policlinic dispensary where I treated her; the first time giving her an injection of only one pint of gas. Her temperature that day was 101½; the next day she returned and I gave her a quart injection and her temperature was then $102\frac{6}{10}$; the next day, the third injection, her temperature was normal and I gave her another quart. When she returned for the fourth injection her temperature was normal and she seemed better in every way; said her appetite had returned, the cough was less severe, expectoration diminished greatly, and the night sweats almost entirely relieved. At the fifth injection she had a slight temperature, she said she had had no more chills and fever for the last three days. I used a solution of about 5 grains of sulphide of potassium with 5 grains of common salt in about 20 ounces of warm water, which gives about the proper amount of sulphuretted hydrogen gas, at least the patients all say that they feel better and have no unpleasant symptoms. I have given it in three other cases, one has some pelvic trouble, and the physician who is treating her thinks that might be a counter-indication to the remedy, but she seems to be better in her general condition, has increased in flesh, and coughs less and prefers to continue the treatment. Another case of incipient tuberculosis, where the upper left apex is affected more particularly, seems to be improved considerably under treatment. He has been having the treatment one week.

Dr. L. L. McArthur: In starting in with this treatment of phthisis I saw the difficulties that were going to arise in the apparatus, and think I can make some suggestions that will prove valuable. The apparatus presented to-night is not portable, and if the patients are to be treated at home they would either require a separate apparatus for each patient or else one must run the risk of breaking the apparatus. In the first place, I thought of a method of collecting the carbonic acid gas, by taking one of those portable laughing-gas cylinders, to be obtained at any dental depot, to a soda-water fountain and having it charged with carbonic acid gas. There can be stored from one to 500 gallons of gas, equally chemically pure with that recommended. This apparatus would simply require the turning of a stop-cock in the tube or opening to permit the gas to escape at any rate desired. If found desirable to continue the use of sulphuretted water, instead of mixing the two gases together first, it could be done by using a wash bottle and a delivery tube. I believe an equally efficient method is to introduce into this cylinder a solution of sulphide of potassium, which furnishes for every ounce of the sulphide of potassium about a gallon of sulphuretted hydrogen. The carbonic acid formed liberates the H_2S from the sulphide introduced. The strength according to Bergeon's method is about half of 1 per cent. or a little less. By a little calculation it will be seen that the carbonic acid formed by the combination of the carbon dioxide and water would set free the hydrogen in combination with the sulphur in the definitely desired quantities, so that it would not be necessary to use the sulphuretted water. In that way the gas could be introduced into the measuring bag and then into the rectum. The cylinder would hold a sufficient amount of gas for many treatments, and as it is easily portable, it could be taken to the houses of patients and not require them to come to the office.

Dr. R. Tilley: I have had no experience whatever in this method of treatment, but I would like to say a word with reference to the apparatus which I think would certainly make the measurement of the gases used more definite. I think, notwithstanding the doctor's explanation of the number of pressures that may be necessary to constitute a quart, that one individual may require so many pressures and another so many less or so many more, and thus the amount would be somewhat indefinite; whereas if a bottle of the necessary size was filled full of carbonic

acid gas, and then another bottle with a tube attached full of water, the latter could be attached with the necessary tubes and elevated just the same as a siphon, and the water introduced into the bottle containing the carbonic acid gas and passed through the sulphuretted hydrogen water with the required rapidity, and thus it would come much more regularly than could be done by means of this spasmodic pressure of the bulb. I would like to call attention to the fact that there are on sale in this city large cylinders containing absolutely pure carbonic acid gas, imported from Germany.

DR. WALTER M. FITCH: For generating the gas we use a common Wolf bottle with three corks, one for a stop-cock for the acid, one for the delivery tube and one for the safety valve. This last must not be pressed in too tightly; at one time I had the stop-cock blown out and broken by putting in the acid a little too rapidly. To make the gas we use about a heaping tablespoon of bicarbonate of sodium, covering that with cold water about two inches deep. If we use hot water we make a suds that will foam up and run into the bag. We use the bicarbonate of sodium and sulphuric acid diluted one part in four. The reason for using the sulphuric acid in preference to any other is that, being absolutely non-volatile, none of it will pass over into the bag of carbonic acid gas. To make the gas the generating bottle is connected with the bag, which is emptied and tightly rolled in order to remove all the air. The generator should also be emptied of air by turning in some of the acid before it is connected with the gas bag. The bags usually hold about one-half of what they are marked—a three-gallon bag will hold about six quarts, etc. If we should over-distend it the corks would be blown out of the generator. For injecting the gas the stop-cock is turned off and the bag is connected with the bubbling tube, which extends to the bottom of the bottle of mineral water, so that the gas coming from the bag may pass down into the water and, rising up through it, be medicated by the sulphur vapor which it contains. It is injected by means of a hand bulb. In using the bulb it is important to remember that, since it is intended to be used only with water, the action of the valves is not perfect with gas, and it is therefore necessary that the bulb be held vertically, so that the weight of the valves may assist in closing them. In using it in this way we secure a perfect action which draws the gas into the bottom of the bottle and delivers it through the tube. I have now connected it as it is in use. The bisulphide of carbon has been mentioned several times. In order to use this it is necessary that the gas be washed for fear that it may contain impurities, for none of the chemicals we get are perfectly pure, and as they are most likely to contain vapors of hydrochloric acid which are easily dissolved in water, the gas is bubbled through pure water to purify it. Between the Wolf bottle and the bulb is inserted an ordinary chemical drying tube, a glass tube three-fourths of an inch in diameter, which is drawn down at one end small enough to have the rubber tube slipped over it. Into the other end is fitted a cork with a glass tube through it; in the drying tube is placed a tampon of cotton, and the requisite amount usually 1 dram, of bisulphide of carbon is placed on the cotton. In passing the gas through this cotton it becomes very strongly impregnated with the vapor and is injected in that manner. I think some Philadelphia physician spoke of an instrument for measuring the gas injected. A very simple way of measuring it when using a small apparatus of this kind, is with the bulb. The bulb will deliver at each compression just so much gas; in order to measure how much is delivered we simply take a measured bottle, invert it over the water with the water filling it, then introduce the rectal tube into the bottle and remove the water from it by displacement, the number of compressions being counted. The bulbs vary in size. I remember the capacity of six now in use: two count 15 compressions to the pint; three count 20 compressions to the pint, and one counts 25. Thus, with each apparatus the bulb must be measured, and knowing its capacity, the gas can be prescribed in as definite a way as any medicine measured out of a bottle.

THE PRESIDENT: My experience with this method, extending over less than a month, comprises the observation of one case that impressed me strongly; this was a young man suffering from the last stages of quick consumption, who had been in the care of Dr. H. A. Johnson. He was very feeble, much emaciated, had badly swollen feet and albuminous urine. His temperature ranged from 101 to 103 each afternoon, and he had profuse night sweats. In addition to these usual symptoms he suffered to an extraordinary degree from laryngeal tuberculosis. He had been unable for many weeks to lie down with comfort, and according to his own statement, had not slept fifteen minutes in three months. Cough was constant and expectoration profuse. About a month before Dr. Johnson had given him three or four weeks to live. I used gaseous enemata, employing the artificial solution advised by Dr. Bruen, twice a day. Improvement began on the second day, and by the fourth day was pronounced. The cough was less distressing and the sweats and expectoration had diminished, the patient was able to lie down and sleep for two hours continuously. He was, however, so evidently near dissolution that I deemed it inadvisable to continue a tentative treatment, and stopped it on the fourth day. Two days later he sent an urgent request for the resumption of the treatment, saying that his former symptoms were returning. However, I declined to use the injections further, and six days after their discontinuance the patient died, nearly two weeks after his physician had expected his demise.

It should be remembered that these injections seem to arrest not the tuberculosis proper, but the sepsis which is secondary thereto, and that there are numerous other septic conditions in which benefit may fairly be expected, such as surgical sepsis, diphtheria, puerperal fever, etc. The apparatus furnished by the stores is unnecessarily expensive and inconvenient for a visiting practice. I use an improvised apparatus consisting of a gas bag, double perforated cork and ordinary large wide-mouthed bottle—the whole costing $2.50 instead of $10. The entire

outfit can be readily improvised at a little cost and carried in a small handbag.

My limited experience gives me the impression that the artificial solution of the sulphide of potassium is preferable to either the Ypsilanti or the Blue Lick water, because the amount of sulphuretted hydrogen in these waters as we obtain them at the drug store appears to be extremely variable, while in the artificial solution it can be maintained at a given percentage, increased or diminished as desired, yet care should be taken to make a weak solution about such as is recommended by Dr. Bruen, since a too concentrated solution of the poison may produce very unpleasant symptoms. This method can be employed by every practitioner as well as by the most expert specialist. If it will accomplish nothing more than the relief of the distressing cough, expectoration, fever and sweats of advanced consumption, it will at least do what can be effected by no other therapeutic measure with which I am acquainted; hence it is to be hoped that it will be submitted to a general test by the profession, that we may quickly ascertain exactly its merits and demerits.

Dr. C. M. Fitch said that the first case in which he used the method was one of extreme anxiety to me. The patient, a young lady 20 years of age, had previously had exceptionally good health, was well nourished, with a muscular development that seemed to defy fatigue. She returned in July last from a visit to Colorado with a cough which was referred to the dryness of the climate and the inhalation of the alkaline dust, which causes a catarrhal irritation. This seemed a plausible explanation, and as the cough was not urgent, it received but little attention until, in November, she took a cold which resulted in chills for three or four successive days, and seemed to prostrate her greatly. I then examined her chest and, to my astonishment, found extensive and marked consolidation at the apex of the left lung; there was also irritation throughout the remainder of the lung and some moist râles. I was much alarmed by what I found, for the location of the consolidation made me fear it might prove something more than simple pneumonia. Several of our best physicians tendered their aid, but the case failed to improve. The patient lost flesh rapidly, her cough became fearfully oppressive and her temperature never fell to normal, rarely below 100°, and most of the time 101° and rising to 103°. She had daily chills and profuse night sweats, and the case presented all the features of acute phthisis. At the last examination, made by Dr. Belfield and Dr. Ochsner, both thought they detected bacilli in the sputum, although previous examinations had failed to show them.

Late in January my attention was called to an article in the *Medical Record*, giving a notice of Bennett's paper in the *British Medical Journal*, which contained an account of Bergeon's method. After considerable trouble I obtained a copy of the paper which contained this article, and went to Sargent's to have an apparatus made, and there learned that they had just made one for Dr. Crane, who kindly allowed me to appropriate it and ordered another for himself. Knowing nothing at that time of what we might expect in such a case from our different mineral waters, and knowing that Dr. Bergeon recommended bi-sulphide of carbon as the best substitute, we commenced treatment with the bi-sulphide, and the effect was surprising. The treatment was commenced seven weeks ago to day; during the week previous the temperature had at no time fallen to normal; the lowest point was 100°, and once it rose to 105½°, and night sweats and chills were constant. The first time the injection was tried very cautiously, only a moderate amount of gas being used. The effect was not specially apparent; the second day the temperature still rose to 103°. That night the gas was used much more freely and with results that to us were somewhat alarming. The next morning the temperature fell to 95°, and it did not rise above 100° during the day; the cough was almost suppressed, although it had previously been very distressing. The next day we did not use the gas quite so freely, but the day following the lung was almost entirely occluded; the mucus seemed to become viscid, and the air was almost shut out from the lung. There was so little elimination of the bi-sulphide through the lung that we soon began to have marked symptoms of bi sulphide poisoning, although in many respects she appeared better; the cough was almost gone, and there were no chills. The treatment was discontinued for about ten days, and then resumed with the Ypsilanti mineral water. From that time there has been a satisfactory improvement, and she is better than she has been at any time since her sickness began; her appetite and strength are improved, and she is evidently beginning to gain flesh; her cough is greatly lessened, and the chills have altogether disappeared. Her night sweats have been absent for six weeks, although during the last warm weather she perspired a little for three or four nights; it was not colliquative sweating, and she seems now in a fair way to recover.

The second case in which I tried this remedy seemed about as hopeless as well could be; the patient was confined to her bed, had been suffering from severe hæmorrhage, chills, night sweats, and great prostration. There was marked dulness at the apex of the right lung, and the physician who was treating her recognized softening. The husband, whose family were patients of mine, after the physician told him that nothing more could be done, came to me. I told him that I did not know that I could do anything more; the only thing I could suggest would be this new treatment which I had been experimenting with, and which might be of some value. He was anxious to have something tried, and the case was undertaken. At the end of four days this patient's chills, which had existed then about a month, ceased entirely, and have not since recurred. On the ninth or tenth day the sweats disappeared; her cough was relieved from the first, no opiate could have controlled it more completely. The expectoration was also lessened, her appetite has improved, and she is gaining in strength. In all respects I think she has gained as much in the time she has been under treatment as I ever saw a patient gain under any treatment in the same time.

Another case was a young man of scrofulous habit, who has a stiff knee from scrofulous disease of the joint. He has been under treatment about three weeks. There was marked consolidation in his case, also, at the apex of the right lung, and every indication of phthisis. He has improved materially; his cough is much lessened and he is gaining in strength. The indigestion and flatulence which had previously troubled him very much, has disappeared under the use of the gas; there has also been a great improvement in his appetite.

The other cases I have seen have not been under treatment long enough to justify me in making a report. It seems to me from what I have seen that we have a remedy that is worthy further trial. Whether it will fulfill the promise of its youth we have yet to see. I have no doubt this remedy will relieve spasmodic asthma, and there are other conditions that it would relieve. In puerperal fever I should try it, using the bi-sulphide of carbon, but using it cautiously. I also think it would be of value in malignant diphtheria and typhoid fever.

FOREIGN CORRESPONDENCE

ABERDEEN AND EDINBURGH.[1]

Alexander Ogston—Osteotomy for Pes Planum—Antisepsis in the Aberdeen Hospital—Lumbar Abscess—Fungous Osteo-myelitis of Femur—Dr. Keith—His Method of Operating—Treatment of the Pedicle—Suturing the Abdominal Wall.

Dear Dr. Fenger:—One of the principal objects of my tour through Scotland was to see in the flesh the man whose name I had so repeatedly mentioned to my class, the discoverer of the pus-microbes, Professor Alexander Ogston, of Aberdeen. While the scientific world knows but little of Aberdeen, its Hospital and its University, the name of Ogston has penetrated to all parts of the civilized world. Dr. Ogston is a man in the prime of life, tall, and handsome. Although a profound scholar, an able surgeon, and a splendid writer, he is one of the most modest men I have ever met; a good illustration that greatness is not incompatible with modesty, but rather the reverse. In my conversation with him I could not but draw a comparison between him and the average doctor in a Medical Society, who is full of experience and crammed with positive assertions. Although living in a comparatively small city, Dr. Ogston's life is an exceedingly busy one. He holds the Chair of Surgery in Marshall College, where he teaches the various branches of surgery, including otology, ophthalmology, and gynæcology; at the same time he attends to the clinical work in the Infirmary, and a large private practice. I visited with him the Royal Infirmary, a building more than fifty years old, with 300 beds, nearly one-half of which are occupied by surgical patients. Although the sanitary condition of the Infirmary is quite defective, all wounds showed that even under unfavorable circumstances good results can be obtained by strict antiseptic precautions.

One of Ogston's operations, osteotomy for pes planum, was illustrated by a number of patients in the hospital. The operation consists in the removal, with a chisel, of a wedge shaped piece of the tarsus with the base of the wedge directed downwards, so that when the osseous surfaces are brought into apposition the arch of the foot is restored. Coaptation and fixation is secured with two disinfected bone-nails and a plaster-of-Paris dressing. In all aseptic wounds the bone-nails disappear by absorption. He has done the operation forty times, and has never observed any serious results; and in only one case the deformity returned, and was permanently corrected by a second operation. He does not resort to this operation indiscriminately in every case of flat-foot, but only in such cases which do not yield to simpler measures, such as rest and fixation. About three months are required for firm bony union to take place, and he insists that the patients should not be allowed to step upon the foot before this has taken place, otherwise a return of the deformity would be inevitable.

An excellent proof of the care which is exercised in this old hospital in preventing wound infection, is the fact that all abdominal sections performed by Dr. Ogston and his colleagues, some thirty in number, recovered. For disinfection of the hands and field of operation the surface is washed with soap and warm water, and rubbed with a piece of pumice stone, after which it is washed with spirits of turpentine, and lastly with a five per cent. solution of carbolic acid. The instruments are treated with turpentine, washed with carbolized solution, and immersed in a five per cent. solution of carbolic acid. Dr. Ogston does not hesitate to walk from the dissecting room or after a course of operations upon the cadaver, directly into the operating room and perform any operation, and has never observed any ill results of such a course when the hands are thoroughly disinfected.

I witnessed two operations in his clinic. The first was for an abscess, which had evidently commenced in the lumbar region and had gravitated below Poupart's ligament. He prefers, in all these cases, to make a free incision just above the iliac crest, and drain the abscess from this point. He also called special attention to this method of operation, as it enabled the surgeon to seek for the cause of the suppuration in the lumbar region and the iliac fossa, and to remove the primary cause through the same incision should circumstances dictate such a course. He has never observed a ventral hernia after this operation.

The second case was one of fungous osteo-myelitis of the lower end of the femur, which had been operated upon some years ago, but the pain had recently returned. The femur was opened on the outer surface with the chisel, by removing quite a large piece of the compact layer. The interior was gouged out thoroughly, and after thorough cleansing and disinfection the cavity was allowed to fill with blood, after removing Esmarch's constrictor, and an

[1] By permission of Drs. Fenger and Senn.

antiseptic dressing applied. This manner of hastening the healing process in all wounds attended with loss of substance, first suggested by Schede, has yielded good results in Ogston's hands.

While in Edinburgh I called on Dr. Keith, and spent nearly two hours with him in conversation, which afforded me an excellent opportunity to become familiar with his views on hysterectomy and ovariotomy. Dr. Keith's personal appearance is striking and characteristic. Although not an old man, he shows only too plainly the effects of a life spent in the cause of his profession and for the benefit of suffering humanity. He walks with a stoop, his frail body being bent under the weight of many years spent in the performance of an arduous professional career. The wasted form and the deep furrows in his face only too plainly tell the story of the many anxieties, the hopes and the fears through which he has passed in affording relief to his many clients. A history of his life would reveal many a hard struggle which he encountered in his efforts to reach the prominent position he occupies, by universal consent, in the department of surgery, for which he has done so much in elevating it from the mire of empiricism to the dignity of a science. The unwritten history can be readily read upon his countenance, which shows only too plainly the effects of hard, conscientious work; the thoughtful and sad expression speaks of the many encounters with an ungrateful and unappreciative public, and the many sad experiences with a jealous profession. A look at his eyes, however, must satisfy any one that determination, energy and enthusiasm can live in a frail body. These qualities which he possesses will explain the mystery of the marvellous amount of work which he has accomplished, and the wonderful results he has obtained under circumstances which have discouraged even the strongest of men. When we realize the limited hospital advantages which are furnished him in the Royal Infirmary, we must admire the man who can show such results. The victories which have been so dearly bought at the expense of health, and in all probability of a portion of life itself, are the most appropriate and lasting monuments of an unselfish life spent in the interests of the profession of his choice and suffering humanity. In the Royal Infirmary he has sixteen beds and only one nurse. His son, Skene, is his assistant.

His operations are performed in a small room heated by an open grate fire, and but poorly supplied with light. Only a few students are invited to the operations. The patient is placed upon a board, to which she is fastened with a strap across the hips, and hands tied to it on each side; the board rests with each end upon a table, the operator and assistant standing one on each side between the tables. The room is disinfected before each operation with chlorine gas. The abdomen of the patient and hands of operator and assistant are washed with a strong alkaline solution for the purpose of removing the fatty substances, which, according to Keith, are carriers of the septic germs. After thoroughly washing the parts they are disinfected with a weak solution of corrosive sublimate. Sponges are used over and over, cleansing them after each operation in warm water, and subsequently in an alkaline solution; they are kept for use in a five per cent. solution of carbolic acid. During the operation they are kept immersed in a two per cent. solution of carbolic acid. The spray he has abandoned, since he has suffered from repeated attacks of hæmaturia, and if anything the results have been better since. Instruments are well cleansed after each operation, and during the operation they are kept in the strong solution of carbolic acid. All adhesions are carefully separated and each bleeding point tied with catgut. Ovarian cysts are tapped with a large straight trocar just as soon as the peritoneal cavity is opened.

From the descriptions I had read of his treatment of the pedicle I had always been afraid to adopt his method, but after I had seen the method applied I became convinced of its safety. The pedicle is firmly compressed in his clamp, and two or more cautery irons heated to a dull red heat are applied for a sufficient length of time to heat the metallic plates of the clamp sufficiently to gently cauterize the compressed portion of the pedicle. The compressed tissue must be rendered "dry," and when this has been accomplished it looks like a transparent membrane. Some practice is necessary to graduate the heat for each individual case, but when properly done hæmorrhage never occurs. Dr. Keith affirms that the tissues thus treated do not slough, but are speedily supplied with new blood vessels. He has seen new blood-vessels in the cauterized portion of the stump after twenty-four hours. Before the clamp is removed each side of the pedicle is carefully seized with forceps which do not tear, and any vessel which might contain blood is separately tied. In the many hundred cases treated by this method hæmorrhage was never observed—certainly the best argument in favor of the reliability of the method. The only case of hæmorrhage after ovariotomy which he observed was in a case where both ovaries were removed; on one side the pedicle was treated with the cautery, on the other the ligature was applied. Patient died in six hours. The post-mortem examination showed that death had been caused from hæmorrhage which had taken place at a point where the pedicle had been perforated with a forceps for passing the ligature; the forceps had injured a vein wall, and from the opening thus made the hæmorrhage had occurred.

Suturing of the abdominal wound is certainly done more neatly and thoroughly by Keith than any other ovariotomist. Medium-sized silk is used, cut in length of about eight inches, each end of a suture is mounted with a long, delicate needle, which bears the operator's name. The needles are passed from within outward, and after all sutures are in place they are picked up in a bundle on each side and the abdominal wall gently lifted so as to bring the peritoneal surfaces in accurate apposition, and while an assistant holds the parts in this position by making pressure on each side with his hands, the sutures are tied. To every inch at least three sutures are used. The skin is accurately united by applying a horse-hair suture between each of the silk sutures, thus securing the

most accurate approximation and coaptation of the margins of the wound. After excision of the breast he relies entirely upon the horsehair suture. The wound is covered with a small compress of hygroscopic gauze wrung out of a solution of 1 part of carbolic acid and 7 parts of glycerine. Over this a compress of common gauze or cotton is placed, and the whole retained in place with a flannel bandage. This dressing is allowed to remain for a time, when it and the sutures are removed. The bowels are kept quiet for a week, when a gentle laxative is administered. Catheterization is avoided whenever the patient is able to pass the urine without assistance.

N. Senn.

DOMESTIC CORRESPONDENCE

"RECTAL SURGERY MADE EASY."

Dear Sir:—In a former article in The Journal I exposed the "systems" of rectal surgery practised by numerous Western itinerants and charlatans. In that article I referred to the little rectal "pockets and fringes" or "pockets and papillæ," described by various standard authors, and well known to anatomists as existing at the base of the columns of Morgagni, just above the verge of the anus. A writer of certain lectures and essays on the subject had claimed these as being mainly his own discovery, and urged that they were "lesions," and fearfully bad ones at that; in short, that they should always be snipped out when found. I maintained, on the other hand, that these minute organs were natural, and composed of healthy mucous membrane and connective tissue. I remarked, however, that, like other organs of the body, they sometimes became diseased and required surgical attention, but were not themselves diseases requiring to be split and snipped in ordinary cases.

The *Peoria Medical Monthly* avers that, by admitting such occasional disease and need of surgical attention, I concede all that the author of the essays claims. The editor of the *Monthly* is mistaken as to what had been promulgated. The writer of the essay on "Pockets and Fringes," or "Pockets and Papillæ," as he elsewhere calls them, has shown no disposition to hide himself or his ideas in a corner. He has expressed himself fully on every possible occasion, and loudly makes the following claims:

1. That, as to these "pockets and papillæ," "no mention of them can be found in current literature;" though they are described in various works, both old and new.

2. That these little natural irregularities are "lesions," of the most fearful, health-destroying power.

3. That "they always occasion a spasmodic contraction of the sphincter ani."

4. That "their removal is invariably attended by improvement;" though many patients have got worse instead of better under the treatment.

5. He says: "I am now, as I was two years ago, in favor of removing these rectal pockets under all circumstances, and in all cases in which they are found."

6. He remarks: "I look upon these conditions as being the most mischievous of rectal disorders."

7. He emphasizes with italics the following: "*In all pathological conditions, surgical or medical, which linger persistently in spite of all efforts at removal, from the delicate derangements of brain-substance that produce insanity, and the various forms of neurasthenia, to the great variety of morbid changes repeatedly found in the coarser structures of the body, there will invariably be found more or less irritation in the rectum or the orifices of the sexual system.*" He adds in substance as he proceeds, that while piles, fistulæ, etc., do more or less injury, the principal part of all the above-mentioned obstinate diseases of every part of the body are caused by the "pockets and papillæ" of the rectum, and that the snipping of them out is "invariably attended by more or less improvement." Were good old Hahnemann alive, this etiology of one of his followers would make his hair stand on end.

The writer has made some special rectal dissections in this connection, and may have occasion at a future time to show how the peculiar banded arrangement and loose submucous connections of the thin mucous membrane of the part tend to deceive the unwary examiner.

Edmund Andrews, M.D.

6 Sixteenth St., Chicago, May 5, 1887.

GALVANIC DOSAGE.

Dear Sir:—I have no wish to enter into the controversy that seems to be raging between several of your correspondents on the subject of galvanic dosage, but a statement made by Dr. Martin in his article on the "Treatment of Fibroid Tumors of the Uterus by Electrolysis," which appeared in your issue of April 23, is so remarkable as to call for correction in the mere interest of humanity.

Really strong currents are now becoming possible by the use of direct dynamo circuits or of secondary batteries of sufficient electromotive pressure, and should some physician while using them put Dr. Martin's directions about dosage in practice, the result would be most disastrous to the patient. The particular statements referred to, which appear also in Dr. Martin's letter in the same issue, are those in which he claims to have applied currents varying from 250 to 1000 milliampères without unfavorable results, and even as much as 10 ampères (10,000 milliampères) without giving excessive pain. Since Dr. Martin takes occasion to describe a milliampère meter in his paper, which he states to be correct and evidently uses himself, the extrordinary nature of these claims remained a mystery until the last paragraph of the third section of his paper (page 450) was scanned. He there states that his 1000 ma. were obtained from a battery of 115 gravity cells. Such a thing is utterly impossible, for these cells present an internal resistance of at least 10 ohms apiece —more often 13 to 15 ohms. Placing it at 10 ohms, the total internal resistance of the battery of 115 gravity cells would be 1150 ohms, and with the electromotive pressure of each cell taken as one volt (which is rather high) the greatest amount of current

obtainable from the battery with the metallic poles brought directly together will be shown by the following calculation: 115 volts divided by 1150 ohms equals 0.1 ampère or 100 ma. But as soon as his patient is inserted in the circuit even this amount of current becomes impossible. If one electrode is large and one applied beneath the skin by puncture, the resistance of the body may possibly add only about 850 ohms to the circuit, making a total of 2000 ohms. This changes the results to the following: 115 volts÷2000 ohms=0.0575 ampère or 57 milliampères. This calculation is a simple application of the most rudimental law in electrophysics, and it is but just to suppose that the gentleman making the important blunder pointed out had forgotten about his battery resistance and its effect upon his figures, although the mistaking of 50 milliampères for 1000 is a trifle startling. But even the 40 or 50 ma. really used by Dr. Martin are strong doses when applied to the delicate lining membrane of the uterus or concentrated at a single point within the tissues, and it would seem that some words of caution might be added to both his and Apostoli's commendation of these methods respecting the dangers as well as advantages of such vigorous electrolysis. In my own practice 10 to 15 ma. have been generally sufficient.

Very respectfully yours,

G. Betton Massey, M.D.

1706 Walnut St., Philadelphia, May 2, 1887.

ASSOCIATION ITEMS.

AMERICAN MEDICAL ASSOCIATION.

The Thirty eighth Annual Session will be held in Chicago, Ill., commencing on Tuesday, June 7, at 11 A.M., in Central Music Hall, corner of State and Randolph streets, and will continue four days. Good rooms for the several Sections will be provided as near the hall for general meetings as possible. Registration books will be open in Central Music Hall on Monday, the day preceding the meeting, for those who wish to register early.

In addition to the list of papers for the Sections published last week the following subjects are announced:

Section on Practice of Medicine.

C. H. Hughes, St. Louis, Mo., will present a "Unique Case of Athetosis resulting from Railway Shock." F. C. Schæfer, Chicago, will present a case of "Complete Loss of Scalp, including the greater portion of the Eyelids and one Ear. Treatment by Skin-Grafts. New Scalp."

Section on Surgery and Anatomy.

Edmund Andrews, Chicago, Ill., "On the Solution of Necrosed Bone in Spinal Abscess by Dilute Hydrochloric Acid."

Geo. E. Stubbs, Philadelphia, Pa., "Wound Dressing—Some Notions Accepted, and some under Discussion."

Section on Ophthalmology, Otology and Laryngology.

J. W. Wright, Columbus, Ohio, "Evulsion as a Means for the Radical Removal and Cure of Pterygium;" G. C. Savage, Nashville, Tenn., "The Function of the Oblique Muscles in Certain Cases of Astigmatism;" Edward Jackson, Philadelphia, Pa., "The Effects of Obliquity of the Correcting Lens to the Visual Axis, with practical deductions; also "A New Form of Facial Frame;" Seth S. Bishop, Chicago, "Treatment of Hay Fever;" "Treatment of Chronic Suppurative Inflammation of the Middle Ear."

Section on Medical Jurisprudence.

Joseph Jones, New Orleans, La., "A Claim to Priority in the Determination of the Chemical and Microscopical Characters and Changes of the Blood in the various forms of Malarial Paroxysmal Fever, and the application of the results of their investigations to Medical Diagnosis and Medical Jurisprudence;" Marshall D. Ewell, Chicago, Ill., "Micrometric Measurements, as applied to the measurement of Blood Corpuscles in Medico-Legal Cases;" John Godfrey, U. S. Marine Hospital Service, Louisville, Ky., "Expert Testimony;" H. M. Bannister, Eastern Illinois Hospital for the Insane, Kankakee, Ill., "The Criminal Responsibility of Epileptics;" Rev. Louis Thebaud Jones, Moweaqua, Ill., "The Intimacy of the Medical and Clerical Professions, with the Supremacy of the Former in the Sociological Sense, at Least;" H. C. B. Alexander, Chicago, Ill., "Forensic Relations of the Puerperal State;" John V. Shoemaker, Philadelphia, Pa., subject not stated.

Section on Obstetrics and Diseases of Women.

W. W. Potter, Buffalo, N. Y., "A case of Pyosalpinx—Cure without Operation;" C. R. Reed, Middleport, O., "Case of Tubal Pregnancy, with Specimen of the Anomaly;" Joseph Eastman, Indianapolis, Ind., "Uterine Subinvolution and Areolar Hyperplasia."

RAILWAY RATES.

The following named roads will give reduced fares to all delegates, members, and their families attending the meeting. Return tickets will be issued on the certificate plan *only*. Tickets for the return journey will be sold at ⅓ the highest regular limited fare. If there is no limited fare to a desired point, the price will be ⅓ the unlimited fare. Tickets for the return journey will be limited to continuous passage by first train after they are bought. All tickets for return journey must be accompanied by a certificate signed by the Chairman of the Committee on Transportation, or by an authorized member of the Committee, showing that the holder has attended the meeting. Tickets are good for 10 days from date of purchase.

The roads which will accept return tickets on the certificate plan are:

Baltimore & Ohio (west of the Ohio River).
Buffalo, New York and Philadelphia.
Chicago & Grand Trunk.
Cincinnati, New Orleans & Texas Pacific.
Chicago, Vincennes & Cairo Line.
Chicago & West Michigan.
Chicago, St. Louis & Pittsburgh.
Cincinnati, Hamilton & Dayton.
Cincinnati, Indianapolis, St. Louis & Chicago.
Cincinnati, Washington & Baltimore.
Cleveland, Akron & Columbus.
Cleveland & Marietta.

Cleveland & Pittsburgh.
Cleveland, Columbus, Cincinnati & Indianapolis.
Cleveland, Loraın & Wheeling.
Columbus & Cincinnati Midland.
Columbus, Hocking Valley & Toledo.
Chesapeake & Ohio.
Chicago & Atlantic.
Dayton & Ironton.
Detroit, Lansing & Northern.
Dayton & Union.
Detroit Grand Haven & Milwaukee.
Evansville & Terre Haute.
Flint & Pere Marquette.
Fort Wayne, Cincinnati & Louisville.
Grand Rapids & Indiana.
Grand Trunk.
Indianapolis & St. Louis.
Indianapolis & Vincennes.
Indianapolis, Bloomington & Western.
Indianapolis, Decatur & Springfield.
Jeffersonville, Madison & Indianapolis.
Kanawa & Ohio.
Lake Erie & Western.
Lake Shore & Michigan Southern.
Lousiville & Nashville.
Louisville, Evansville & St. Louis.
Louisville, New Albany & Chicago.
Michigan Central.
Michigan & Ohio.
New York, Chicago & St. Louis.
New York, Pennsylvania & Ohio.
Niagara Falls Short Line.
Ohio & Mississippi.
Pennsylvania.
Peoria, Decatur & Evansville.
Pittsburgh & Lake Erie.
Pittsburgh & Western.
Pittsburgh, Cincinnati & St. Louis.
Saginaw Valley & St. Louis.
Scioto Valley.
Toledo & Ohio Central.
Toledo, Peoria & Western.
Valley Railway.
Vandalia Line.
Wabash Railway.
Wheeling & Lake Erie.
Baltimore & Ohio (east of Parkersburg, Bellaire & Wheeling.)
Baltimore & Potomac.
Bennington & Rutland.
Boston & Albany (on business between common points in New England and points west of, but not including Albany.)
Boston & Lowell.
Boston, Hoosac Tunnel & Western.
Buffalo, Rochester & Pittsburgh.
Camden & Atlantic.
Central Vermont.
Delaware & Hudson Canal Co.
Delaware, Lackawanna & Western.
Fitchburg.
Lehigh Valley.
New York Central & Hudson River.
New York, Lake Erie & Western.
New York, Ontario & Western.
Norfolk & Western.
Northern Central
Philadelphia & Erie.
Philadelphia & Reading.
Philadelphia, Wilmington & Baltimore.
Rome, Watertown & Ogdensburg.
Shenandoah Valley.
Troy & Boston.
West Jersey.
West Shore.

The following named lines offer one and one-third fare for round trip:

Burlington, Cedar Rapids & Northern Railway.
Central Iowa Railway.
Chicago & Alton Railroad.
Chicago & Northwestern Railway.
Chicago, Burlington & Northern Railway.
Chicago, Burlington & Quincy Railroad.
Chicago, Milwaukee & St. Paul Railway.
Chicago, Rock Island & Pacific Railway.
Chicago, St. Paul, Minneapolis & Omaha Railway.
Green Bay, Winona & St. Paul Railroad.
Hannibal & St. Joseph Railroad.
Illinois Central Railroad.
Kansas City, St. Joseph & Council Bluffs Railroad.
Milwaukee & Northern Railroad.
Milwaukee, Lake Shore & Western Railway.
Minneapolis & St. Louis Railway.
Minnesota & Northwestern Railroad.
Missouri Pacific Railway.
Rock Island & Peoria Railway.
Sioux City & Pacific Railroad.
Wabash Western Railway.
Wisconsin Central Lines.

[Other roads will be added as heard from. These lists have been prepared at great expenditure of time by the Chairman of the Committee on Transportation,

DR. LISTON H. MONTGOMERY,
Briggs House, 189 Randolph St., Chicago,

who should be addressed for additional information.]

A list of forty-two Southern roads which will accept return tickets issued under the certificate plan, to members, delegates and their families, who attend the coming meeting of the American Medical Association, providing as many as twenty-five delegates go to Chicago, hold certificates of the Southern Passenger Association, properly signed by the ticket agent at the starting point. The certificate entitling those to return at one-third fare, must be vouched for by the Chairman of the Committee on Transportation, certifying that said member or person has been in attendance at the meeting. Said certificate, however, is good only twenty hours after adjournment:

Alabama Great Southern Railroad.
Atlanta & West Point.
Brunswick & Western,
Central Railroad of Georgia.
Central Railroad of South Carolina.
Charleston & Savannah.
Cheraw & Darlington.
Cheraw & Salisbury.
Cincinnati, New Orleans & Texas Pacific.
East Tennessee, Virginia & Georgia.
Georgia.
Georgia Pacific.
Illinois Central (south of Ohio River).
Jacksonville, Tampa & Key West.
Louisville & Nashville (south of Ohio River).
Louisville, New Orleans & Texas.
Memphis & Charleston.
Mississippi & Tennessee.
Mobile & Ohio (south of Ohio River)
Nashville, Chattanooga & St. Louis.
New Orleans & North Eastern.
Norfolk & Western.
North-Eastern Railroad of Georgia.
North-Eastern (of South Carolina).
Pennsylvania (south of Washington).
Petersburg.
Port Royal & Augusta.
Raleigh & Gaston.
Richmond & Alleghany.
Richmond & Danville, and leased lines.
Richmond, Fredricksburg & Potomac.
Richmond & Petersburg.
Rome.
Savannah, Florida & Western.
Seaboard & Roanoke.
Shenandoah Valley (south of Potomac River.)
South Carolina.
Vicksburg & Meridian.
Western & Atlantic.
Western Railway of Alabama.
Wilmington, Columbia & Augusta.
Wilmington & Weldon.

HOTEL RATES.

In addition to the list given last week, the New Brevoort House offers rooms on the European plan to delegates at 75 cents where two or more persons occupy a room. This House is refitted and refurnished throughout with all modern conveniences, steam passenger elevator, etc.

Charles Gilman Smith, M.D.,
Chairman Local Committee of Arrangements.
Liston H. Montgomery, M.D.,
Chairman Committee on Transportation.

MISCELLANEOUS.

The American Climatological Association will hold its next annual meeting in Baltimore, May 31 and June 1, 1887, immediately preceding the days for the meeting of "The Association of American Physicians" in Washington, D. C. The Secretary is J. B. Walker, M.D., 1617 Green street, Philadelphia, Pa.

Dr. Oscar C. De Wolf, the efficient Health Officer of this City, has been reappointed by Mayor Roche.

A Public Health Conference will be held in Louisville, Ky., on May 24 and 25, under the auspices of the State Board of Health.

Regulation of Practice in Michigan.—A bill to regulate the practice of medicine in Michigan has just passed the lower House of the Legislature.

The Medical Society of the State of California met in its seventeenth annual session in San Francisco, April 20, 1887. The following were chosen officers for the ensuing year:

President—R. H. Plummer.
First Vice-President—A. H. Agard.
Second Vice-President—David Powell.
Third Vice-President—H. N. Rucker.
Fourth Vice-President—L. M. F. Wanzer.
First Assistant Secretary—J. H. Parkinson.
Second Assistant Secretary—G. W. Davis.
Treasurer—G. C. Simmons.
Board of Censors—Jules Simon, W. Anderson, J. D. Arnold, I. E. Oatman, C. G. Kenyon.
Board of Examiners—C. E. Blake, W. Lawlor, Jules Simon, C. H. Steele, T. J. Le Tourneux, C. E. Farnum, A. H. Pratt.
Alternates—H. H. Hart, C. C. Wadsworth, A. P. Whittell.

The Committee on Appropriation for the Ninth International Congress, recommended that $100 be donated. Adopted.

Regulation of Medical Practice.—The following resolution was adopted: "That it is the sense of this Society that the best interests of the public and the medical profession will be better subserved by one State Board of Examiners rather than more; and by examination of applicants rather than of diplomas; and that there should be proper provisions made for expenses of such Board."

Vaccination.—The following resolution was adopted: That it is the sense of the members of the California State Medical Society, in convention assembled at San Francisco, at its regular annual session, that vaccination should be made compulsory, and that the State Legislature should be urged to enact such laws as shall result in the protection of the entire population from small-pox.

[We are indebted to the *Sacramento Medical Times* for advance sheets of this report.]

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 30, 1887, TO MAY 6, 1887.

Major Blencowe E. Fryer, Surgeon, ordered for examination by Army Retiring Board, at San Francisco, Cal. S. O. 101, A. G. O., May 2, 1887.

Major George M. Sternberg, Surgeon, assigned by the President to the special duty, under the Treasury Department, of "investigating the merits of the method practised in Mexico and Brazil for preventing yellow fever by inoculation." Relieved from duty as attending surgeon and examiner of recruits in Baltimore, Md. S. O. 101, A. G.O., May 2, 1887.

Major John S. Billings, Surgeon, granted leave of absence for ten days, to take effect May 3, 1887. S. O. 98, A. G. O., April 28, 1887.

Major J. V. D. Middleton, Surgeon; Major J. C. G. Happersett, Surgeon; Capt. F. C. Ainsworth, Asst. Surgeon, appointed to assemble at U. S. Military Academy, West Point, N. Y., on June 1, to examine into the physical qualifications of the members of the graduating class and of the candidates for admission to the Academy. S. O. 102, A. G. O., May 3, 1887.

Capt. Leonard Y. Loring, Asst. Surgeon, sick leave of absence still further extended six months, on surgeon's certificate of disability. S. O. 103, A. G. O, May 4, 1887.

Capt. Victor Biart, Asst. Surgeon, sick leave of absence still further extended one year, on surgeon's certificate of disability. S. O. 99, A. G. O., April 29, 1887.

First Lieut. Chas. B. Ewing, Asst. Surgeon, ordered from Ft. Leavenworth, Kan., to Ft. Lewis, Col., for temporary duty. S. O. 100, A. G. O., April 30, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING MAY 7, 1887.

Shafer, Joseph, Asst. Surgeon, detached from the "Minnesota," and to the "Ossipee."

Simon, W. J., Surgeon, ordered to the U. S. Str. "Boston."

Henry, C. P., Asst. Surgeon, detached from hospital, Philadelphia, and to the "Boston."

Means, Victor C. B., Asst. Surgeon, detached from hospital, Mare Island, and to the hospital, New York.

Simons, Manly H., P. A. Surgeon, detached from Naval Academy, and to the "Constellation."

Diehl, Oliver, P. A. Surgeon, detached from hospital, New York, and to the hospital at Philadelphia.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE FOUR WEEKS ENDED MAY 7, 1887.

Goldsborough, C. B., Surgeon, leave of absence extended thirty days on account of sickness. April 20, 1887.

Devan, S. E., P. A. Surgeon, granted leave of absence for thirty days, to take effect when relieved. April 12, 1887.

Bratton, W. D., Asst. Surgeon, to proceed to Port Townsend, W. T., and assume temporary charge of the service. April 21, 1887.

Wyman, Walter, Surgeon, detailed as chairman, Board for physical examination of candidates for appointment as cadet, Revenue Marine Service. May 6, 1887.

Mead, F. W., P. A. Surgeon, detailed as recorder Board for physical examiuation of candidates for appointment as cadet, Revenue Marine Service. May 6, 1887.

ORIGINAL ARTICLES.

TWO CASES OF MALIGNANT ENDOCARDITIS.

Read before the Philadelphia College of Physicians, March 2, 1887.

BY J. H. MUSSER, M.D.,

PHYSICIAN TO THE PHILADELPHIA HOSPITAL, ETC.

Both the cases included in this report have been named malignant endocarditis, although one of them is without the warrant of a microscopical examination. The clinical course and microscopical appearances indicate such to have been its true nature, however. I venture to bring it before you thus labelled, to excite criticism, if necessary, and to ask your attention to one of the manifold phases of this interesting disease.

The case was under the observation of Dr. J. Henry Musser, of Lancaster County, and seen by my father, Dr. Benjamin Musser, in consultation. It occurred in their practice in 1878. I recall the case both from conversations and letters concerning it at the time. Unfortunately, the notes of the case in Dr. Musser's possession have been mislaid. His memory and memoranda in his case-book feebly supply the deficiency; fortunately we have the morbid specimens.

Case 1.—Rheumatism; embolism of large vessels; cardiac murmurs; gangrene; chills and fever; death. Autopsy: vegetations on mitral leaflets; emboli in brachial and femoral arteries.—H. R., male, æt. 23, laborer, consulted Dr. J. Henry Musser, June 25, on account of rheumatism. He was visited by his physician the first week in July once, the second week four times, and the third twice. On the 1st of August grave symptoms set in, and on the 3d of September he died. It will be observed, therefore, that, in July, the patient was not very ill; in fact, he continued at light work on his farm, and on the 1st of August was in the harvest field, when the first embolus manifested itself. During that month he had rheumatism, and for a short time before August 1st, chills and fever.

August 1. Sudden severe pain occurred in the right brachial artery. Could not be removed to his house at once on account of collapse. Dr. Musser saw him, and found the pulse absent at the wrist, the hand cold and cyanosed. Two days subsequently the femoral artery became plugged, much pain being occasioned at the time. The circulation in neither arm nor leg was ever restored, and gangrene ensued. Attention was at once called to the heart, and a distinct systolic murmur was heard at base and apex. During the month an irregular fever, with irregularly recurring chills, was present. Death took place from exhaustion, September 3, thirty-three days after serious symptoms set in.

At the autopsy the vessels were plugged with emboli and thrombi, as exhibited in the specimens. The heart was enlarged by dilatation, and on the posterior cusp of the mitral valve soft fungating vegetations grew. Some of the chordæ tendineæ were surrounded by vegetations. The auricular surface of one cusp was rough, and minute ulcers were present. Fibrin clung to the vegetations, and recent clots filled the cavities. The aortic valve and the right heart were normal. There was no atheroma.

Remarks.—Without doubt, in this instance, malignant endocarditis was associated with rheumatism, and the type was essentially pyæmic. One might presume, however, that the so-called primary rheumatic symptoms were pyæmic in nature, or that the cardiac lesions supervened secondarily to the gangrene. The teachings of the autopsy do not sustain either supposition. The absence of old cardiac and vascular lesions, and the general integrity of the organs, preclude the possibility of pyæmia. The normal condition of the arteries (absence of atheroma), the absence of primary blood dyscrasiæ, or of any cause, save cardiac, for the emboli, defeat the second supposition.

Case 2.—Malignant endocarditis; chills, irregular fever, sweats; cardiac murmur and pain; vomiting and diarrhœa; marked embolic phenomena; jaundice; death. Autopsy: proliferative bacterial endocarditis confined to the mitral valve; emboli of skin, mucous membrane of mouth, of stomach, and of intestines, of spleen, kidneys, peritoneum and endocardium; embolus and thrombus in left iliac vein.—M. S., female, æt. 27, white, German, married, admitted to Philadelphia Hospital August 26, 1886. At the same time her husband and children were admitted for a febrile complaint, thought to be of malarial origin. The patient had been ill about six weeks, of an irregular fever, also said to be malarial. At this time she was nursing an infant which had been born one year before. The labor was natural, and she had a good getting up. Since birth of child patient has not menstruated. Three years previous to this illness she had an attack of malarial fever, and at one time had rheumatism of the leg. She never had any other

ailment, was strong and hearty, and of temperate habits.

The family history of the patient is very good. Her parents and several brothers and sisters are living. One sister died of pneumonia; the cause of death of another is unknown. On admission it was noted that the patient was prostrated and complained of chilly sensations, she sweated profusely, and suffered from nausea. The tongue was clean and moist; the bowels loose, five movements in twenty-four hours, thin and greenish in color; the nausea had disappeared in twelve hours; tenderness of the epigastrium was observed, but none in the iliac fossæ. The spleen extended, in the axillary line, from the sixth rib to the margin of the ribs. There was no eruption. Both cheeks were flushed. The skin and mucous membranes were pale, the hands quite anæmic. She was somewhat emaciated. The mind was clear. The lungs and heart were normal; the latter rapid in action, and rather feeble. Milk diet, stimulants, and quinia ordered.

September 2. My resident, Dr. Dorland, detected a cardiac murmur two days ago, and to day the following is noted: General symptoms and appearances about the same. Apex beat of heart in fifth interspace in nipple line; impulse moderately feeble; no thrill; pulmonary second sound accentuated; high-pitched systolic murmur at apex transmitted to axilla; no murmur at aortic orifice. Pulse rapid, small, and feeble. No cough; no dyspnœa. Ulcerative endocarditis suspected.

8th. The fever has continued in spite of quinine. The patient sweats profusely throughout the day, but not at night. Her anæmic appearance is striking. She is quite cheerful, but is evidently losing flesh and strength. The diarrhœa continues. The cardiac murmur has increased in intensity during the past forty-eight hours, and can be heard loudly at the angle of both scapulæ, louder at the right. Marked tenderness on pressure, and some pain complained of in the third left intercostal space. At the base of the right lung impaired resonance, and fine, moist, crepitant râles are observed. A few râles are heard at the right apex also. Short, high-pitched, jerking inspiration and prolonged expiration is detected at the right apex, and high-pitched inspiration at the left.

12th. Two days ago two small purpuric spots were observed on each upper eyelid, and to day hæmorrhagic infarcts are seen all over the trunk and on the upper extremities, pin-head to split-pea in size, bright red, not disappearing on pressure. Hæmorrhages in the ocular and palpebral conjunctivæ of both eyes at inner and outer canthus. Rapidly losing flesh and strength. Sweats continue. Abdomen distended in epigastric and umbilical regions; large wavy impulse in epigastrium. Nausea and vomiting recurred the past five days; fluid dark, greenish tinge. The vomiting occurs in the morning. Diarrhœa continues. Spleen readily felt below the margin of the ribs, tender. Lungs have cleared up. No cerebral symptoms. Heart's action irregular. Pulse small, feeble, rapid, dicrotic. Tenderness behind the sternum. Impulse (systolic) in second, third and fourth left interspaces. In second interspace to the left of sternum very perceptible thrill. Systolic murmur not so loud as it has been at apex. Over third rib, left auricle loud, booming systole, with "grinding" murmur. In second interspace to the left of the sternum loud, rough, high-pitched murmur. Pulmonary second sound muffled. Murmur over tricuspid not so distinct as at mitral, and probably transmitted; aortic murmur low in pitch, conducted from base. No œdema. Mind clear.

13th. Physical signs as above. Cardiac dulness extends from the left edge of the sternum one inch to the left in the second interspace. It extends in the third interspace two inches, and in the fourth three inches. Apex beat in nipple line. Intensity of murmur greatest in second interspace. Chill this morning. Urine scanty and high-colored, and contains blood and epithelial tube casts in abundance, and a small amount of albumin. General symptoms the same. Extreme prostration.

14th. Chill at 7 A.M. A little more drowsy than formerly; no delirium. Murmur in second interspace not so distinct. New capillary infarcts in abundance about the neck. Vomiting and diarrhœa continue. Infarcts in lips and on end of tongue. Conjunctivæ slightly icteric. Dyspnœa severe for half an hour at 2 P.M. Partially collapsed state, with grasping and sighing; excessively rapid pulse; stimulants relieved the patient. At 11 P.M. a second attack. During the day very irritable, and latter part of day drowsy. Died at 2 A.M., September 15.

The following record indicates the daily fluctuations in temperature. The pulse record was not preserved. but from first to last it was rapid, 120 to 130 per minute.

August 25, P.M., 99.3°. 26th, A.M., 100.4°; P.M., 103.2°. 27th, A.M., 101.1°; P.M., 103.° 28th, A.M., 101.1°; P.M., 101.3°. 29th, A.M., 102.1°; P.M., 102.3°. 30th, A.M., 103°; P.M., 100.4°. 31st, A.M., 100.1°; P.M., 101°.

September 1, A.M., 102°; P.M., 101.2°. 2d, A.M., 102.1°; P.M., 102.3°. 3d, A.M., 102.4°; P.M., 99°. 4th, A.M., 99°; P.M., 101.4°. 5th, A.M., 101.2°; P.M., 105°. 6th, A.M., 99.2°; P.M., 105°. 7th, A.M., 101.1°; P.M., 97°. 8th, A.M., 97.2°; P.M., 99.3°. 9th, A.M., 101.2; P.M., 105°. 10th, A.M., 105°; P.M., 99.2° (chill at 6:30 A.M., and 9:00 A.M. temperature taken). 11th, A.M., 101.3°; P.M., 99.3°. 12th, A.M., 101.°4; P.M., 99.3° (chill 7:30). 13th, A.M., 102.3°; P.M., 102°. 14th, A.M., 100.2°; P.M., 100.4.° 15th, A.M., 99.2°.

During the course of her illness careful search was made for localized purulent inflammation. The pelvic organs were normal, the bones were evidently free from disease, and inflammation of the middle ear was not detected.

Autopsy (by Professor Osler, Dr. Musser, and Dr. Dorland).—*General Appearance.*—Medium sized body, somewhat emaciated. Skin pale, slightly icteric. Numerous petechiæ cover the face, chest, and arms; very numerous on right arm and wrist. Petechiæ range in size from a pin's head to a split-pea, and vary slightly in color from vivid red to dark

blue; one or two only present central yellowish core.

Abdomen, Thorax.—Numerous petechiæ on parietal peritoneum. Slight serous effusion in both pleural sacs; few adhesions at right base; some petechiæ in parietal pleura.

Pericardium, Heart.—Excess of pericardial fluid, numerous small petechiæ on visceral layer. Right chamber relaxed, containing fluid blood and small clot. Left ventricle, tolerably firm, dark clot. Apex of the left auricle is long, and can be seen turning round to base of pulmonary artery. Before removal of heart, fingers in pulmonary vein and pulmonary artery, both of which are free. Further dissection of heart: right auricle, little blood, staining of endocardium; a few petechiæ. Right ventricle, chamber large; tricuspid segments a little thickened; a distinct nodular thickening at angle of anterior and internal cusps. Pulmonary semilunar valve normal. Left auricle dilated. Seen from above, mitral orifice plugged by loose black clot and large greyish-white vegetations. After removal of auricle, the following conditions of valve appear: from base of posterior cusp of mitral, large irregular gray-yellow vegetations one inch in length extend into the auricle passing out at right angles to the mitral ring, and forming a sort of valve across the orifice. Entire auricular surface of this cusp covered with vegetations. Anterior cusp at free edge a large, warty vegetation projecting into ventricle three fourths of an inch. The anterior part of this cusp is free. One or two of the chordæ tendineæ are encircled with vegetations. No involvement of endocardium, other than that of valves. Aortic cusps normal. So called unprotected space below aortic ring presents deep depression, is closed, and to its base is attached a nodular thickening at angle of tricuspid cusps. Muscle substance of heart is pale, looks fatty; numerous ecchymoses Coronary arteries free.

Lungs crepitant; ecchymoses on pleura. No infarcts. Bases œdematous, somewhat congested. Pulmonary artery normal.

Spleen weighs 1 lb. 5 oz., soft, capsule closely adherent at one spot. Pulp soft, reddish-brown; four large infarcts of some age, yellowish; others recent, none suppurating.

Kidneys somewhat enlarged. Capsule free, surface irregular. Numerous recent infarcts. Unusual amount of pigment. Right kidney, same changes; not so many large infarcts; the pigmentary changes about many of these infarcts are peculiar.

Pancreas.—Few interlobular hæmorrhages.

Stomach.—Numerous ecchymoses. Many with small, central grayish spots. Mucosa about cardiac end much reddened.

Duodenum.—Bile duct pervious; in mucous membrane small, superficial ecchymoses.

Small Intestine.—One or two small infarcts in jejunum. Toward valve the ileum was much injected, and the small infarcts were numerous. *Large Intestine.*—Cæcum deeply injected; throughout the colon they are numerous, in size from two to ten millimetres. Some of larger show distinct nodular prominence, which on dissection is grayish-red, firm.

Liver.—A little enlarged. No extravasations; tissue soft and light brown. No infarcts. Weight 5 lbs. 4 oz.

Uterus.—Medium size. Os shows deep lateral laceration. Mucous membrane deeply pigmented. Muscle substance normal. Ovaries normal. Small cyst in broad ligament. Pelvic veins are normal. No trace of chronic inflammation about broad ligament. No thrombosis of veins.

Bladder.—Few ecchymoses.

In the common iliac artery a plug is seen extending into the external iliac as far as the femoral; in the internal iliac it extends for two inches. On slitting up artery the thrombus is closely adherent, and at bifurcation it has softened, and has a purulent (?) appearance. Clot in internal iliac is one and a half inches long at least. Much pigmentation about the internal coats of the artery. No evidence of any local disease. Brain, spinal cord, eyes, and ears not examined.

Microscopical examination of the fresh clot in the artery, and the vegetation on the valve, by Dr. Griffiths, revealed the micrococci common to ulcerative endocarditis, the Staphylococcus pyogenes aureus.

Sections of the organs after hardening were made for me by Dr. William Gray. He reports as follows:

Heart.—Fatty degeneration of the muscular fibre, with almost entire obliteration of the striæ; increase of the interfibrillar connective tissue, and decided increase of the nuclear elements.

Spleen.—Extensive cirrhosis; obliteration of the cellular elements by fatty degeneration and an abundance of blood crystals (section from an infarct) are seen.

Kidney.—Increase of intertubular connective tissue and tissue of Bowman's capsule. Proliferation of epithelial cells lining capsules and tubes. Cells degenerated and lumen of tubes plugged with casts. Section of infarct shows blood infiltrating into the tubules and between connective tissue fibres.

Intestine.—Increase of connective tissue in submucous layer and of adenoid tissue of villi; extensive lymphoid infiltration into mucous layer, villi, and glands of Lieberkühn. Granular degeneration of cells of villi. Infarct between and into submucous and muscular coat, blood crystals in infarct.

Artery.—Entire absence of intima, with thickening of middle coat, and infiltration of blood into media.

Unfortunately, Dr. Gray did not get any of the proliferated mass on the valves. Dr. Gray was unable to find micrococci in the sections he had cut. They were given him without proper labelling, so that he did not know the tissue he was cutting. While this is to be regretted, it is enough to learn from the early and late examinations of Dr. Griffiths, that bacteria were present. Dr. Griffiths readily found in the fresh treated preparations that micrococci abounded in the granular matter, and about the leucocytes of the vegetation.

The lesions otherwise found, were myocarditis, glomerulo-nephritis, and gastro-enteritis, with the usual histological changes about an infarct.

Remarks.—So many thoughts arise in the con-

templation of a case that represents so complete an evolution of a morbid process that one is tempted to indulge in lengthy remarks. We shall limit ourselves, however, and so be content with calling your attention to one or two prominent features.

Diagnosis.—Observe, if you please, in the first place, the perfect picture of malignant endocarditis presented by the case. There was not a moment after the manifestations of the heart lesions were studied, that the diagnosis of endocarditis was doubted. It is true that before the cardiac murmur had been detected we could only say we had to do with a septic process. Who would say otherwise in a case of a young person with irregular fever, profuse sweats, and extreme exhaustion; with vomiting and diarrhœa, and enlargement of the spleen; with an acute inflammation of the kidneys without dropsy; with the physical signs of endocardial inflammation; and with the most pronounced appearance of capillary hæmorrhages in the skin and mucous membranes, terminating in suffusion of the skin, conjunctivæ, and mucous membranes with the mild but ominous hue of icterus? It is true we considered at first whether, from the history and association with similar affections, the case was one of malarial origin. The use of quinia without result, the irregularity of the fever, the frequent pulse, the extreme sweats, and the diarrhœa, led us to abandon this idea. Typhoid fever was rightly thought of, but momentarily. The spots, the tympany, and the characteristic stools were wanting; no approach to the typhoid state was observed in spite of the high fever and rapid pulse; the peculiar features of the tongue were absent, and at no time were the faculties dull or the mind wandering. The physical signs observed in the lungs, the profuse sweats, the quick pulse, and the diarrhœa, naturally induced the question of tuberculosis to arise. The disappearance of the lung affection, the absence of hurried respiration, and of the tubercle bacilli in the discharges, were sufficient counterproofs.

Thus, by exclusion and by a careful study of the disease as it was gradually unfolded to us, we were enabled to make a diagnosis. In this, as in many instances, unfortunately, with waiting and watching, too soon the true nature of the affection was so legibly written that he who ran could read.

Class.—As far as can be ascertained, the affection was idiopathic—using the term with the modern reservation. That is, a cause cannot be ascertained for the development of the disease in this case unless the slight rheumatic attack years previously is sufficient to attach the diathesis as cause and effect.

Type.—Recall for a moment the marked symptoms present. The fever, the chills and the sweats, the clear intellect, the gastric and intestinal disturbances, clearly group the case with other examples of malignant endocarditis of the pyæmic type.

Special Symptoms.—Enough has been said of the symptoms in the history of the case. Your attention need not be called again to the vivid temperature range, the recurring chills, the grave renal symptoms, and the pronounced capillary hæmorrhages. The latter were striking—at first but a few, each day more and more appearing; confined not only to the skin but seen in the lips and the tongue and the conjunctivæ, they presented a glaring picture of the pathological process. The anæmia, which was barely noted, deserves a remark. It was profound, and the appearance due to it at once excited attention. Certainly the hæmoglobin was much reduced, yet the patient was so ill we did not care to disturb her to ascertain its percentage.

One class of phenomena deserves moré lengthy remarks—the physical signs of the cardiac lesion. At first, at the mitral orifice a systolic murmur transmitted in the usual direction was heard. It varied in loudness and pitch. Later it diminished in pitch and volume, and at the same time a very loud systolic murmur, high in pitch and grinding in character, was heard on the third left rib and in the second left interspace one and a half inches outside the sternal edge. So loud was the murmur in this situation that, especially as it was attended by a thrill, we thought the pulmonary valves were implicated in the disease. The occurrence, however, of an increased area of pulsation, most distinct in the second and third interspaces, and of an increased area of dulness in the auricular region led to the conclusion that mitral stenosis was present. A presystolic murmur was not heard, however, and probably was not present. It was not created because of the projection of the vegetation over the orifice, in all probability. For a similar anatomical reason one can infer that the ventricle fills, partially at least, prior to and independent of contraction of the auricle. For with such an effort, at once, communication would be cut of by the vegetation.

The systolic murmur was heard, in the latter weeks, loudest in the second and third interspace. Two causes can be invoked for this peculiar localization of the murmur. The projection of the mass from the auricular surface of the valve could readily throw the back flow of blood—the valve not closing from the situation of the second mass—into vibration, and thus murmur and thrill be produced and heard loudest over the auricle. While such an explanation suffices, a second cause for the murmur can be found in the position and dilatation of the auricular appendage. If such a view of the case is held, then the theory of Naunyn and Balfour to explain the mechanism of systolic murmurs in this location is well illustrated. The excessive loudness of the systolic murmur at the angle of the right scapula was very peculiar.

The case of recognition during life, and the peculiar physical signs, are the features of prominent note in this case.

FORT SILL, INDIAN TERRITORY.

BY MORSE K. TAYLOR, M.D.,

MAJOR AND SURGEON, U. S. ARMY.

The prominence given to Fort Sill as an unhealthy station by the late report of the Surgeon General, taken in connection with the comments thereon in The Journal of February 26, are such as to give a

very erroneous impression respecting the present sanitary condition of this post. That it has been in years past very unhealthy, no one familiar with its history will dispute, but that it is so now few, if any residents thereat will admit. And, as the writer has been on this station for the last three and a half years, and charged with the supervision of its hygienic affairs, he may be pardoned for feeling a little sensitive upon this question; more especially so, since under his administration the post has become one of the most healthful and pleasant stations in the West. Notwithstanding this, however, he would not write the following at this time, were it not that a lesson may be learned by a further consideration of the Surgeon-General's statistics taken in connection with others of a later date.

It may be observed that it embraces the period commencing with July 1, 1885, and ending with June 30, 1886; corresponding with the national fiscal year. In this it differs from the sanitary reports of cities and other countries. This may be noted only to invite attention to the fact that the time included by the Surgeon General's report was a part of the transition period in which the post passed from an extremely unhealthy condition to one of salubrity. How sickly it has been may be understood from the records which show that in 1876 the rate of cases per 1,000 mean strength was 3.911, and in 1877 it was 3.067.

There is nothing in the natural surroundings to make the location more unhealthy than in the best situations in the South, or elsewhere in regions of acknowledged malarial tendencies. Indeed, it may be said with truth that there are few locations as good. A hasty glance at its topography will make this apparent:

The post is situated 1,200 feet above the sea, upon an irregularly quadrilateral plateau about one-fourth of a mile in diameter, its sides corresponding in a general way to the cardinal points; and at an elevation above the surrounding lands of from fifty to sixty feet on the east, south and west; while on the north it is skirted by the bed of Medicine Bluff Creek, with a sharp declivity of seventy feet. Along this creek there is a strip of heavy timber about one-fourth of a mile in width, but beyond this, and extending in all directions for one or two miles, are open bottom lands, all of which are well drained. At a distance of a mile or so to the northwest are the foothills of the Wichita Mountains, while elsewhere beyond the bottoms are wide rolling, high, beautiful prairies. Cache Creek rises about thirty miles to the northward, and running nearly due south, passing the post to the eastward three-fourths of a mile, empties into the Red River forty-five miles away. Medicine Bluff Creek, rising in the Wichita Mountains, and taking a nearly due eastern course past the post on its northern side, discharges into the Cache within the limits of the reservation. Both are free flowing streams at ordinary stages; having dry beds, however, in many places in midsummer, in others stagnant pools, while in the rainy season they rise to the height of between fifteen and twenty feet; the Medicine Bluff becoming a turbulent mountain torrent.

From the foregoing it may be inferred that the opportunity for the successful cultivation of the Anacharis Alsinastrum, as suggested for the improvement of the health of some of the posts, is not specially encouraging here; while it also invites us to look for other causes in explanation of the large number of malarial and kindred diseases which have prevailed here since the establishment of the post in 1869.

Before entering upon the sanitary history of the station, let us consider the report briefly. From this it appears that the average length of time patients are under treatment at Sill is nine days, this being a fraction less than the average for the whole army, while there are 57 posts which exceed that number; San Diego taking the lead with 23 days, followed by Stockton, Texas, with 18 days, and Bowie, Ariz., with 17 days. In the Indian Territory Forts Supply and Reno have an average of 13 and 11 days respectively.

There is, however, another method of estimating the relative healthiness of posts better than this, or that indicated by the rate of admission. If we take the rate per 1,000 of non effectives from sickness and multiply this by the number of days they are carried on the sick reports, we get a product which gives us a better idea of severity of the disorders and the loss the Government sustains as the result. To illustrate: Fort Sill had a rate of non effectives of 58 per 1,000, which, multiplied by 9, the number of days they were under treatment, gives a total loss of time to the Government of 522 days. This method of calculation shows that there were 16 posts which exceeded Sill. The first on the list is San Diego, with a loss of 3,036 days; Stockton, 1,206; Brown, 869; Maginnis, 784; Supply, 819; Reno, 616; Columbus Barracks, 1,312; Lowell, Ariz., 624 per 1,000 mean strength, and several others, embracing Jackson Barracks, Jefferson Barracks, Ringgold, Davis, Concho, Huachuca, and Bayard.

Again, if we take the cases treated per 1,000 of mean strength, and this multiplied by the length of time under treatment, we get results differing somewhat from the foregoing, but none the less instructive. The following tabulation will make this apparent:

Posts.	Cases per 1,000 m. s.	Days under treatment.	Total loss.
Ft. Ringgold	2304	11	25.344
" Brown	2181	11	23.991
" Stockton	1121	18	20.178
" Davis	2160	10	21.600
" Schuyler	1265	18	22.770
" Reno	2004	11	22.004
" Supply	1620	13	21.060
" San Diego Bks	1000	23	23.000
" Sill	2211	9	19.899
" Willetts Point	2782	7	19.474

There are other stations that closely approach Sill in their aggregates, which are omitted.

All the foregoing relates to the condition of Fort Sill before a sufficient time had elapsed to indicate what ultimate results might be expected from the efforts being made to improve its sanitary condition. These we will now consider:

When the writer entered upon his duties as Post Surgeon the latter part of November, 1883, the com-

mand, then consisting of four companies of infantry and two troops of cavalry, was in a most demoralized condition. Of the eleven officers for duty all had been sick during the two preceding months, three others were absent on sick leave, and of the enlisted men the rate of cases per 1,000 of mean strength was 468, exclusive of injuries, for the months of September and October, according to the records. These, however, did not express the real state of the case. As there was quite a rivalry in the target practice of the respective commands, the men would take their "shakes," then their quinine, and as soon as the fever abated, their turn at the rifle grounds, without going on the sick report. From the representations of the company commanders it was evident that few men escaped. Some of the attacks were of great severity. Men would be stricken down while on parade or at guard mount and have to be assisted to their quarters. One of the more common symptoms was intense pain in the back of the neck and base of the brain. Said an officer, referring to this symptom in his own case, that it struck him almost like an electric shock, and was the most excruciating suffering that he ever endured, or could imagine one capable of enduring, and live.

At the time of the writer's assignment to this station he was made acquainted with its bad reputation and was requested to seek the cause of its unhealthiness, being assured by the department commander that every assistance should be afforded to remedy the trouble when ascertained. Entering upon his duties with this aim before him, he determined to spare no effort in the accomplishment of his purpose. Careful investigations were commenced in every direction which might afford a clue to the origin of the sickness. After examining the geology and natural environments of the post, and finding in these nothing to account for it, nor in the duties or habitations of the men, the water supply was next investigated. This came from two sources: one a shallow well situated about midway on the west side of the barrack line, which was used largely for drinking purposes by the men, and the other from a stagnant pool in Medicine Bluff Creek situated about a third of a mile from the post to the northwest. The supply from this source was obtained by driving a six-mule team and a wagon into the middle part of it, thereby stirring up all the sedimentary matters possible, and then dipping this water into the tank and delivering it to the men at the barracks and to officers in their back yards, at distances of nearly 100 feet from their dwellings; and all into open barrels unprotected from the heat of the sun, the winds, or dust. As a result, the organic matters in the water soon underwent fermentation and rendered it still more disgusting. An examination of the well water showed that it contained a large amount of chlorides, free and albumenoid ammonia, nitrites, and nitrates. Although it was situated at an elevation of 50 feet above the surrounding bottom lands and 70 feet above the creek, the water came to within 12 feet of the surface of the ground; and it was but 30 feet from the barrack buildings and 250 feet from the cavalry stables. Its water supply was clearly derived from the surface drainage of the post and contaminated in the highest degree.

The creek water was next examined. That selected for this purpose was taken from the water barrels at the hospital soon after the delivery of the water wagon, the barrels having previously been emptied. There was a large amount of sedimentary matters floating in it, and not until this had settled was the examination commenced.

The distillate of this water was most offensive, having a fæcal and urinous odor most nauseous, yet it was but an exaggeration of what had been frequently observed in the water barrels of the officers' quarters during the warm weather, after standing twenty-four hours. Under the impression that a mistake had been made, or that the water had been accidentally fouled, the water delivered the next day was distilled, but with the same results. Even the water in a moderate rise after a rain was little better. No use could be made of it in the laboratory or dispensary. The sedimentary matters were placed under the microscope, and with the revelation of too many micro organisms to be described here. The stream was running at this time, so that the water was not wholly stagnant, and represented the ordinary condition of the water supplied the post for years past. In fact, the stream had been swept by a rise of sixteen feet only a few weeks before.

Near the northeast corner of the garrison, distant about 150 yards, was a small spring from which some of the officers had obtained their drinking-water. It flowed out from the north bank of Medicine Bluff Creek fourteen feet below the surface of the bottom land and on the surface of a soft outcropping sand rock, and discharged eight gallons per minute. As a water supply it was condemned in 1877 by the Post Surgeon, and the following entry made on the post records respecting it: "This spring finds its origin in surface water which drains out of a low and somewhat marshy bottom stretching along the creek to the north. This water contains various organisms, and it is believed, if not directly productive of malarial disorders, that it favors their development in many cases who would otherwise escape." These remarks had the effect of prejudicing the officers against it, notwithstanding its physical qualities were greatly in its favor, being beautifully limpid, sweet and sparkling.

In the belief that the prejudice against it was ill-founded, the writer proceeded to make a careful analysis of it, and also to ascertain its probable geological source. The result went to show that it was one of the purest springs of water to be found in any country. That its origin was very remote, the flow being entirely unaffected by local rains or droughts, was evident.

After representing these facts to the commanding officer and urgently requesting a detail of men to examine the locality and ascertain whether the discharge could not be increased to a degree sufficient for the wants of the command, his request was finally complied with. The detail was made in March, 1884, consisting of a corporal and four men, and turned over to the writer. The work soon revealed the fact

that the water came through a bed of porphyry gravel resting on the sand rock about eighteen inches above the creek bed; and further, by lowering the outflow the discharge was increased to over 7,000 gallons per hour. On reporting the results of his efforts to the department commander, the sum of $3,500 was appropriated for introducing the water to the post. Soon after a storage basin of 7,000 gallons capacity was excavated in the rock, and a spring house of solid stone masonry, with walls four feet thick, twenty feet high, and substantially arched over, was constructed to protect the spring from the floods and drift wood of the creek, while an automatic valve was introduced in the outflow pipe to shut off the back water from the stream when it should rise above the level of that in the basin.

During that season the water was distributed by the wagons and stored at the dwellings in barrels as before; and it was not until the spring of 1885 that the water was introduced into the houses. From the time that the water supply was exclusively from this spring there was a steady improvement in the health of the post. The following comparison will make this apparent. The months of August, September, and October are taken as basis because these here, as elsewhere, are the months when malarial fevers, dysenteries, and diarrhœas most abound.

Malarial fevers, dysenteries and diarrhœas for the years of

	1883	1884	1885	1886
Rate per 1,000 m. s.	560	550	404	223

Notwithstanding this great difference in the rate per 1,000 of mean strength, the improvement has been still more apparent in the lessened severity of the attacks. Not only this, but the whole aspect of the post has been changed. The sad faces, the feeling of despondency, and the bitter curses which were hurled against it four years ago, have given place to a healthful glow, a pervading cheerfulness, and an admiration for its natural beauties, its delightful climate and its excellent sanitary condition. The bloom of nearly a thousand fruit and ornamental trees, while adding to the charms of the place, attest the interest manifested by both officers and men in its improvement. It is now one of the most desirable stations in the West, with a certainty of still further changes for its betterment when the system of drainage shall be completed, and the sewage be utilized on the gardens, so that the discomforts incident to remote stations from markets and prolonged drouths may be remedied. Moreover, it illustrates in a remarkable degree the baneful influence of impure water on public health, for the conditions of the troops, in all other respects, have been almost identical since 1882; and but little changed since the establishment of the post in 1869.

Fort Sill, I. T., April, 1887.

POISONING BY ACONITE. RECOVERY.

BY PAUL L. BRICK, M.D.,
OF LE MARS, IOWA.

Fritz Steinfahrt, a farmer, aged 28, a robust German of bilious temperament, presented himself rather unceremoniously at my office on January 13, at 3:40 P.M. A friend assisted him to stagger into the office and to throw himself upon a lounge. Mr. S. then informed me that he had taken poison and was dying. As the patient could give no information regarding the name or the quantity of the dose taken, I administered an emetic while sending an assistant to the drug store for the desired information. While the effects of the emetic (2 gr. tart. emet. and 20 gr. ipec.) kept the patient occupied, the assistant returned with the consoling news that the man had actually swallowed *seven drachms* of the tincture of aconite at 3:30 P.M., or ten minutes before entering my office. The assistant produced the vial from which the poison had been taken; it was a 2-ounce vial, then containing ℥ix of tincture of aconite. Water was heated and a quart of it administered with ℥iv fl. ext. ipecac and zinc sulph. gr. ii. Emesis followed in five minutes.

3:50. Pupils dilated, pulse full and strong, 74. I gave in each arm hypodermically, morph. sulph., ¼ gr., fl. ext. digitalis gtt. iii; *per os* whiskey and strong coffee. *Symptoms:* Burning sensation in tongue, in the throat and gullet, pressure in region of sternum, loss of sensibility. Patient could see hypodermic needle enter, but could not feel it.

4:00. Emesis; continued whiskey, digitalis and coffee; pulse became slower and smaller; patient complained of great fatigue; skin dry and cold; even the breath seemed cold.

4:15. Faradic battery stimulated circulation; pulse became stronger at once, and patient became livelier, showing influence of stimulants.

4:30. Emesis; skin dry; variable mood; felt better after vomiting.

5:00. Pulse weaker, thread like, unstable, varying from 76 to 104. A minute after I had found it at 104 an assistant found it at 82; when satisfying myself of the assistant's mistake I counted it 76; in less than five minutes it was up to 92 again.

5:30. Nervous tremors; great restlessness; throws legs about; shivers so that his teeth rattle; spasms of whole body; stretches out at full length, arms and legs rigid; feet warm; $\frac{1}{160}$ gr. strychnine hypodermically; partial loss of consciousness.

6:00. Feels better, asks to walk around, and does so without great effort; passes about three pints of clear orange-colored urine; takes freely of whiskey, coffee and digitalis.

6:30. Sleepy, but very restless. Pulse 76 to 80; almost total loss of sensibility. Gave brandy hypodermically.

7:30. Stomach rejects everything given him, whiskey, coffee, port wine, etc.; is quieted by $\frac{1}{16}$ grain cocaine.

7:45. Pulse 80 to 85; respiration 14, at times very laborious; vomited stimulants given him; pupils natural, and readily influenced by light.

8:00. Two drachms whiskey are vomited up, and cause distressing hiccough; gave cocaine and nux vomica.

8:20. Thorough emesis; hiccough disappears; patient feels better.

8:45. Pulse 72, small, compressible, thread-like; respiration 12, laborious; feels chilly, has rigors, cold, clammy sweat over the body, stupor.

9:15. Vomits freely, has profuse perspiration, drinks and retains port wine, beef tea and coffee.

9:40. Emesis; nux vomica, coffee.

10:00. Emesis; cocaine ½ gr., by mouth.

10:10. Feels easy; respiration 12, regular; pulse 106. Discontinued battery, which had been used uninterruptedly.

11:00. Emesis after ℥i beef tea and a cup of hot coffee. Brandy hypodermically, which patient feels, being first return of sensibility; skin becomes warmer, pulse stronger; perspires profusely; feels sleepy, sleeps and rests well.

1:00 A.M. Awakes, is very thirsty. P. 80, R. 17. Drinks cold water; sleeps.

2:30. Awakes, drinks cold water, has severe frontal headache and pain in region of cerebellum. Temperature 100.2°.

8:00. Feels well; has rested well for several hours; walks down stairs, urinates freely, returns and vomits without distress. Takes a dose of cocaine ($\frac{1}{50}$ gr.) and drinks some beef tea.

11:00. Has appetite; eats crackers and bologna, causing burning in stomach, which soon leaves him, after which he feels well.

REMARKS.—Emesis following so closely after taking the first emetic leads me to believe that the action of the aconite itself was the principal factor. Ten minutes after swallowing the aconite, it had affected the motor system sufficiently to seriously interfere with the patient's walking up stairs; he fell twice on the stairs, and could not rise again without assistance. When entering the office his knees gave away under him, bending forward. The sensory system was paralyzed to such an extent that he could feel neither the hypodermic needle nor the injection. The aconite was taken by mistake for whiskey, with the intention to relieve colic—and it effected a cure. Patient says that the time during which he had lost consciousness seemed like a dream to him. He suffered an undescribable agony almost instantly after swallowing the poison, which was relieved as readily by vomiting. His own story was that he would as soon die as to suffer again the agony he did before vomiting. How he got across the street to my office he does not know. The injection of brandy at 11 P.M. produced pain, the first return of sensibility; from that time I considered patient out of danger, though I watched him closely all night. On the next day the palate and throat were congested; this readily yielded to a gargle of iron and chloride of potash. On the evening of the 15th the patient was taken home in a sleigh, twelve miles, feeling well. When I saw him a few days after he told me that he never felt better in his life.

Patient took: Hypodermically, ½ gr. morphia, 6 drops ext. fl. digital., $\frac{1}{100}$ gr. strychnia, f.℥j brandy; *per os*, 2 gallons warm water, 11 pints coffee, 3 pints whiskey, 20 drops ext. fl. digital., ½ drachm ext. fl. nux vom., ½ pint port wine.

THE OPERATIVE TREATMENT OF RETROPERITONEAL CYSTS IN CONNECTION WITH MICULICZ'S METHOD OF DRAINAGE.

Remarks before the Chicago Gynæcological Society, March 18, 1887.

BY CHRISTIAN FENGER, M.D.,
OF CHICAGO, ILL.

It is not my intention to give an exhaustive review of the entire subject of retroperitoneal or parovarian cysts, but I merely wish to call attention to the subject for discussion, giving some of my own experiences, with a view of bringing out those of other Fellows of the Society. The subject is that of so-called parovarian cysts, or cysts of the broad ligament, or cysts with fimbriated epithelium, and I wish to call attention to a few facts concerning them before showing specimens.

We know that these cysts are said, in a great majority of cases, to develop from the parovarium, the rudimentary sexual remnant of the Wolffian bodies; more rarely, they are said to develop from the epoöphoron; finally, it is possible that cysts of the broad ligament may originate from hæmatomas. The canals of the parovarium being lined with fimbriated epithelium, may account for the fact that the inside of a number of these cysts is found to be lined with this form of epithelium.

Parovarian cysts are typically mono-cysts. In this respect they differ materially from proliferating cystomas or other ovarian cysts developed in or into the broad ligament. Both classes are retroperitoneal cysts, inasmuch as they are situated behind the peritoneum of the posterior wall of the abdomen, but the cysts of ovarian origin are more likely to have only a partial retroperitoneal or intra-ligamentous development; that is, part of the tumor within, part outside of the broad ligament; whilst the parovarian cysts proper are more likely to be completely surrounded by the broad ligament. From the broad ligament, and separating its two layers, they commonly develop inward to the sides of the uterus and downward toward the bottom of the small pelvis.

They are usually thin-walled, lined with fimbriated epithelium or mixed fimbriated and common cylindrical epithelium; consequently their interior surface is smooth, and they contain a thin, colorless, clear fluid of low specific gravity, with no formed elements. Between the peritoneal covering and the cyst wall there is usually a layer of loose connective tissue with but few vessels; which explains the facility with which these cysts may sometimes be separated from the broad ligament covering them, and enucleated without the use of cutting instruments, and with very little harm.

A typical cyst of this kind should have the Fallopian tube on its outside stretched out and flattened, because the cyst develops into the little mesentery of the tube. In the same way the ovary is found stretched out and flattened on the outside of the cyst near the tube. Exceptions to these common anatomical characters, however, are found. The cyst wall may be thick, may become the seat of secondary growths, such as papillæ or papillomatous

fimbriated tumors, which, having developed on the inside of the cyst, may perforate the cyst-wall, protrude on the outside, and take upon them a malignant or semi-malignant character, invade the general peritoneal cavity, giving rise to multiple metastatic papillomas.

In cases of this kind, the contents of the cyst is not a thin, clear, serous fluid, but resembles more or less the fluid of the ovarian cystomas, with numerous formed elements, viscid character, and hæmative or blood mixed with it. The connective tissue layer between the cyst and the broad ligament may not be loose and deficient in vessels, but is sometimes so tense as to make separation of the cyst here almost or entirely impossible, and it may contain numerous large vessels.

As to the symptoms: The cysts usually grow slowly, and do not cause any inconvenience unless they reach a very considerable size. They are usually not very tense. The fluctuation is very distinct and superficial. When such a mono-cyst is large, the abdomen is likely to be flat, when the patient is recumbent, as in ascites, and the percussion note is apt to change somewhat with the position of the patient, thereby sometimes making the differential diagnosis still more difficult.

The parovarian cysts are likely to burst spontaneously, but the contained fluid is so little irritative in character that peritonitic symptoms rarely follow, the thin, clear fluid being absorbed quickly and readily. On this account, these are the cysts of the abdominal cavity which best permit of puncture or aspiration, as these trifling operations are not uncommonly followed by radical cures.

In this connection I will describe a case which came under my observation in 1884. A girl 18 years of age came to me from Racine, who had a cyst extending above the umbilicus, and about the size of a uterus in the seventh month of gestation. She had been accused by her relatives of being pregnant, but knowing this was not the case, came on here. On examination I found the uterus of normal size on one side of the cyst, and in my office, with a common hypodermic syringe, I drew off and took away for examination a perfectly clear fluid, and told the patient to come down for operation. She went home to make her arrangements, and came down a month later. The cyst had entirely disappeared, without symptoms of peritonitis.

In a case like this there may, of course, be a doubt as to the correctness of the diagnosis of a parovarian cyst; but it is reasonably certain that this was the case, as one of the characteristics of this class of cysts is that rupture into the peritoneal cavity causes no peritonitis, and the fluid is absorbed without difficulty.

The method of operating on these cysts we owe to Dr. Miner, of Buffalo, N. Y., who published in 1869 his operation by enucleation.

The surface of the tumor, or, rather, the broad ligament, when exposed after the opening of the abdominal cavity, is incised down to the wall of the cyst. In the loose connective tissue layer the broad ligament is now separated from the cyst wall. By means of the finger or blunt instruments this separation can be continued, without the use of any force and without appreciable hæmorrhage, until the cyst is completely enucleated, and may be lifted out of the cavity. Evacuation of the cyst fluid after partial denudation of the wall, as a matter of course, facilitates enucleation.

In some cases of parovarian cysts, the development is to such an extent peripheral in the broad ligament that the uterine half of the latter is long enough for the formation of a pedicle. In such cases the usual operation for ovarian cysts may be performed at a sacrifice of the covering broad ligament, with tube and ovary. But such a peripheral development is not the rule, and whenever the cyst is developed down upon the uterus or into Douglas' fossa, or farther away still in the retroperitoneal space, enucleation is the only method available for its complete removal.

Difficulties during the course of enucleation arise when the connective tissue is tense and rich in vessels, necessitating dissection with the knife, and numerous ligatures. Further, if a large cyst develops deep down in Douglas' fossa, or even behind the rectum, or up into the mesenteries of the intestines, sigmoid flexure, or descending colon on the left side, or cæcum or ascending colon on the right side, we may find, in such cases, smaller or larger portions of these intestines spread over the surface of the cyst longitudinally and transversely, just the same as the Fallopian tube. It may be difficult, almost impossible, to remove the cyst wall from the intestines in such cases, and danger may arise from the fact that the intestines will not bear denudation of the muscular layers to any extent, as it easily becomes gangrenous.

The first case I met with was that of a married woman, 22 years of age, from Racine, who had a cyst which had been developing for two years. It was as large as a gravid uterus at term and contained a clear fluid. When the abdomen had been opened and the covering broad ligament had been incised down to the cyst-wall, I commenced dissection with a view to enucleation, but after working about half an hour dissecting and ligating vessels, I had advanced but very little. All that I could get out of the cyst was a piece as large as the palm of the hand. Consequently I was obliged to leave the cyst, after having united the opening into it with the abdominal wound and made use of a method of drainage of which I had intended to speak this evening, the so-called Miculicz drainage. The patient made a good recovery.

About a year ago Miculicz, of Cracow, proposed the following method of drainage, not only for retroperitoneal cysts, which can be excluded from the general peritoneal cavity, by uniting them to the abdominal wound, but also for drainage in the peritoneal cavity itself. He takes a small piece of iodoform gauze, stitches a silk thread to the centre of it, and folds it up in the form of a pouch, the silk thread being inside, that the pouch may be drawn up from the bottom by it. The pouch is now pushed down to the bottom of the cavity, and if nooks and corners

exist, it is pushed out so as to completely fill them. In the inside of the pouch is packed with iodoform gauze, as much as is necessary to completely fill up these spaces. This is the advantage claimed by Miculicz for his method of drainage as compared with the use of glass or rubber drainage. Besides the disinfectant properties of the iodoform gauze applied to the entire wall of such a cyst, Miculicz states as one of the advantages of his method that, by the capillary attraction of the gauze, everything is brought out—fluids which a glass or rubber drain could not bring out. We must remember that when we drain the peritoneal cavity with a glass drain down between the intestines or in the cavity of the cyst, we cannot always expect to get surrounding organs in so close contact with the drain as to drive the fluid out.

Further, there is this to consider: that a glass drain put down in the free peritoneal cavity has no tendency to bring out the fluid accumulated at the bottom; the intestines, filled with air, will simply swim in the fluid, and there is no pressure from without that will bring this fluid out of the glass drain, while the capillarity of the gauze is likely to help in that direction. I have had this remain in all these cases for about two weeks. As soon as the discharge ceases I commence first to pull out the loose gauze inside the sac. If a space is left after this has been pulled out I press in at that dressing a little more gauze. This is gradually removed, and the pouch itself is then pulled out by the thread gradually and finally. In all my cases it came out about the end of the second week.

The second case was similar to the first, inasmuch as there was no possibility, at least as far as my ability went, of getting the cyst out. It was a large cyst of eight years' development, in a woman fifty years of age, from Sioux City, Iowa. A prolapse of the uterus had developed during this time, and I was able to get out of the cyst, after considerable dissection, hardly more than two square inches. I used the Miculicz drain with the same result as before. The patient was operated upon October 31, 1886.

In the two above-mentioned cases enucleation was impossible, and we, with Ohlshausen, may have to class them under unfinished operations, as far as the extirpation of the cyst is concerned. But in cysts of the broad ligament, such an unfinished operation is, as a rule, followed by undisturbed and perfect recovery, and so I feel inclined rather to classify the above-named method of operating as a legitimate one for non-enucleable parovarian cysts, than to use the somewhat misleading and sinister term of incomplete operation.

The third case was a woman 50 years of age, in whom the cyst had taken three years to develop. The operation was performed February 2, 1887. The outside of the cyst looked smooth in this case because the connective tissue was so loose. It was the easiest thing imaginable to enucleate it from the retroperitoneal cavity in which it was developed. There were not two vessels to tie, and this accounts for the smoothness of the outer surface. This cyst was a typically normal one of that class, as it was covered all over with the broad ligament. The fluid was perfectly clear; no remnant of a blood clot was present.

Now, when the cyst has been enucleated, the question arises, what to do? I was afraid to leave this large retroperitoneal wound without drainage, so I used Miculicz's method, and the woman is well. It is, however, a debatable question, and in the future it is probable that in a case like this drainage will not be used. Authorities like Ohlshausen very strongly recommend, even for a cavity as large as that, not to drain at all—not even to unite the surface of the peritoneum so as to exclude the retroperitoneal wound from the general peritoneal cavity. He says that when there is no infection, no sepsis, during the operation, there will be no peritonitis, and no septicæmia afterward. He also states that he usually leaves the cavity alone after these enucleations, and that peritonitis seldom or never follows as a consequence of the operation, nor do pelvic abscesses form.

This is where the matter stands, and these are the points for discussion. I must say that I do not dare to rely so fully on entire asepsis during the operation as to leave drainage out. Undoubtedly the recovery of the patient is quicker and easier without than with drainage, as very often, in the latter case, a fistula remains which may keep open for months.

The fourth case was an old and rather anæmic patient, more than 50 years of age, but apparently 60. She was pale and emaciated, and had a large retroperitoneal cyst, located partly in the peritoneal and partly in the retroperitoneal cavity, or, in other words, of partly extra- and partly intra-ligamentous development. As a natural consequence, the enucleation was difficult, since the peritoneal cavity was at once entered. On the inside of the cyst were papillomatous masses such as are found in smaller growths, cystomas of the ovary. These, of course, always indicate malignancy. On the inside of this cyst the surface was rough, velvety from the diffuse papillomatous condition of the entire inner wall, and in some places grown out into a large papilloma, but in no place smooth.

The operation in this case was rendered more difficult, because the connective tissue surrounding the intra-ligamentous portion of the cyst was comparatively tense, and further, because it had grown up into the mesentery of the sigmoid flexure, so as to be covered by it. When the cyst was enucleated there was a portion of the sigmoid flexure that I was afraid of.

There is one other point beside the intestines which we should be careful to avoid in the extirpation of these retro peritoneal cysts; that is, the ureters. As soon as we get into the neighborhood of the large vessels in the posterior wall, we must look carefully out for the ureters and locate them by palpation, as when the ureter is adherent to the cyst it may be easily torn. Miculicz's drainage was used in this case as in the others. The first three or four days she had no untoward symptoms, but on the fourth or fifth day she commenced to vomit, and became somewhat delirious and sleepy, and died, the temperature not having exceeded 101° or 102° F. I

saw her the evening before she died, and expected, on account of the vomiting, to find peritonitis, but there were no local symptoms at all. Then I supposed it to be sepsis without peritonitis, but the autopsy showed the cause of death to be uræmia.

We found in both kidneys, from pressure of the tumor on the ureters in a state of dilatation, not exactly hydronephrosis, but dilatation and subsequent atrophy, to a sufficient degree in my opinion to account for uræmia; for we know that patients with so much degenerative disease of the kidneys of any kind as to almost reach the limit of secreting tissue, are apt to get uræmia after operation. Whether the operation or the anæsthetic is the cause, I cannot say; but it is a well known fact. After the opening of the abdominal cavity, Miculicz's drain was laid down right between the loops of intestine, and, of course, a local but aseptic peritonitis formed along the drain. You will notice on the specimen I now present the impression of the meshes of the tissue of the drain, but outside of this a perfectly clear and smooth peritoneum.

As I remarked before, the chief point for discussion is the drainage. Ohlshausen does not drain in any such cases. This may be thus explained: He says that in many cases of this kind it is impossible to finish the operation. If we accept his classification, two of my cases would be termed unfinished operations; but I am certain that with an unfinished operation and a Miculicz's drain, a radical cure may be effected just as well, perhaps, as if the cyst had been taken out. This, of course, would apply only to a thin-walled cyst of a malignant character.

MEDICAL PROGRESS.

Recent Researches in Diuretics.—To what extent the Malpighian corpuscles and the renal tubules respectively take part in the secretion of urine, is not yet accurately known, although the researches of Heidenhain, Nussbaum, and others, have added much to our knowledge. It seems likely that an investigation into the mode of action of diuretics will throw great light on the question, because a diuretic drug may act either on the Malpighian corpuscles, increasing the flow of urinary water, or on the renal tubules, increasing the amount of urinary solids, or on both structures. The great difficulty, however, in experiments on the kidney in living animals, is that of estimating how much of the effect produced by a drug is due to changes in the circulation, or in the nervous system, which has an influence on the secretory activity of the kidney, as well as on the blood-vessels. Munk has, in his recent experiments, eliminated these factors by investigating the action of diuretic drugs on an excised kidney. The organ, after excision, was nourished under a pressure of 100 to 190 millimètres of mercury, by a stream of blood and salt solution through the renal artery. The drug was added to the liquid, and its effect noted by the amount and quality of the urine, collected through a canula placed in the ureter. Before the addition of any drug, it was found that the amount of urine secreted in an hour varied from 4 to 24 cubic centimètres; that this was a true secretion, and not a simple diffusion, was shown by the fact that it contained a greater proportion of saline constituents than the circulating fluid. The addition of chloride of sodium, nitrate of sodium or potassium, caffeine, dextrose, cane-sugar, or glycerine to the circulating fluid, increased the secretion of urine three to fifteen times, the pressure remaining the same; while in the case of nitrate of potassium and of caffeine, there was an increased rapidity of flow of the circulating fluid. Diuresis of this nature and under such conditions could only result, according to Munk, from a stimulation of the secretory cells of the kidney by the drug, a conclusion which, as regards caffeine, had already been arrived at by von Schroeder. An interesting result obtained by Munk was the appearance of hippuric acid in the secretion from the kidney, when benzoate of sodium and glycocol were added to the fluid circulating through the vessels of the kidney. As is well-known, benzoic acid given to any animal appears as hippuric acid in the urine; and this result has been supposed to be due to the action of the intact blood corpuscles. But in Munk's experiment, these were absent; hence, he concludes that the transformation is probably brought about by the oxygen which is combined with the hæmoglobin.—*British Medical Journal*, Dec. 11, 1886.

Antifebrin.—Mr. J. K. Murray reports the following cases as showing the advantage of antifebrin over other antipyretics:

Case 1.—J. B., aged 3; meningitis, with a temperature ranging from 102° to 105.4° F. Three-grain doses were at first tried in the forenoon. The temperature fell from 105° to 101.4° during the first two days, but on the third evening 100.4° was registered. Five grains were then given every three hours, and the temperature fell to 99.4° after two doses, and remained thereabouts. When two doses were omitted the temperature rose again.

Case 2.—A. V., aged 2; broncho-pneumonia, with temperature from 103° to 105° F. At first three-grain doses were given every three hours, and for four days this kept the temperature below 100°. On the fifth day the temperature rose repeatedly above 102°, so five grains were given every three hours, and the temperature fell to 99.4°, and remained at that point.

Case 3.—M. L., aged 25; pyelo-nephritis. Fifteen-grain doses were used. The temperature fell to 99° within one hour and a half, and remained there for ten or twelve hours. I had the temperature taken every three hours, and whenever 101° was registered, fifteen grains were given. Quinine in ten-grain doses was tried under the same conditions. The temperature fell about 2.4°, but rose 104°, and sometimes 104.8° within six or seven hours.

Antifebrin seems much more powerful than quinine, kairin, or antipyrin. It equals antipyrin in the duration of its effects, and in this respect surpasses

quinine or kairin. It is only excelled in the quickness of its action by the external application of cold. Its effects are evident within an hour, and they last from ten to twelve hours when a full dose has been administered. When administered for a long time, the dose must be increased. It produces profuse sweating and redness of the cheeks; it diminishes the pulse-rate, and distinctly increases arterial tension. I found no depressing effects follow its administration even when full doses were given. Antipyretics belong to two great classes, namely, those which diminish tissue metabolism; and, secondly, those which increase the loss of heat. From the sweating it produces, and the rise in arterial tension, one might conclude that antifebrin belongs to the second class as well as the first one. This might explain the quickness of its action, as antipyretics of the second class act more speedily than those which diminish tissue metabolism.—*British Medical Journal*, April 23, 1887.

Conditions of Successful Production of Local Anæsthesia in Tooth Extraction.—Dr. A. Lebrun, of Brussels, and his house-surgeon M. Andries, have published the notes of twenty-nine cases in which they employed local cocaine anæsthesia for the extraction of teeth. In twenty-three cases the anæsthesia was complete, in one case partial. In the remaining five cases the procedure was unsuccessful. This is attributed by them to the difficulty of introducing the short straight needle of the ordinary hypodermic syringe in the case of the second and third molars, and also perhaps to no precautions having been taken to prevent the escape of the liquid. They point out that M. Viau, of Paris, who succeeded in producing complete anæsthesia in every one of his eighty-six cases, made use of a specially constructed syringe, with a holder by which it could be grasped firmly between the index and middle fingers, and provided with needles of various degrees of curvature; also that he surrounded the tooth with plugs of cotton-wool, and applied the finger over the puncture after the needle. Besides which he made the patient keep rinsing his mouth with cold water during the five minutes that intervened between the introduction of the cocaine and the actual operation. These precautions were not observed by MM. Lebrun and Andries. They used, however, a solution similar to that of M. Viau—viz., fifty centigrammes (seven and a half minims) of a 2 per cent. solution of carbolic acid containing five centigrammes (three-fourths of a grain) of hydrochlorate of cocaine, half of which quantity was injected into each surface of the gum. —*Lancet*, March 19, 1887.

Treatment of the Urethra after Removal of the whole Penis.—Mr. Page reports the case of man, æt. 57, the subject of phimosis, and of syphilis many years ago, who had had for twelve weeks a rapidly enlarging sore and growth on the penis, which on his admission to St. Mary's Hospital, involved the organ almost down to the root, and was obviously an epithelioma (since confirmed microscopically). He had been under the care of a legally qualified practitioner for two months, but it was not until two days before, when the ulcerated mass had attained this vast size, and the glands in the left groin were enlarged, and ulcerating, that the man had been advised to come to the Hospital. The penis was at once removed, and the scrotum having been divided through the raphé, the corpus spongiosum—rendered rigid on a staff—was dissected free from the rest of the penis, and so brought down behind the scrotum, where, ample in length, it was sutured to the skin. Reunion of the scrotum completed the operation, a drainage-tube being passed through it from above downwards, in the site, that is, of the now displaced urethra. At the same time glands were scraped away from the groin, but no dissection was made, as they seemed to dip deeply around the vessels. It was hoped that some of the enlargement might be due to inflammation alone, and this happily turned out to be the case, for much of the swelling subsided, and when, fourteen days afterwards, a solitary protruding gland had been scraped out, the wound forthwith began to heal. The scrotal wound had healed immediately, and the man had no difficulty whatever, either in retaining his water, or in passing it in a sitting posture. There is no better method than this of dealing with the urethra when, the whole penis having been amputated, the urethral orifice must of necessity be sunk and lost within the scrotum. Impressed with its value twenty years ago in a case under Professor Humphry, in Addenbrooke's Hospital, I have practised it with advantage in other instances during the past few years.—*British Medical Journal*, April 23, 1887.

The Manual Delivery of the After-Coming Head in Cases of Pelvic Deformity.—In a monograph Dr. A. Martin aims to prove the superiority of the Smellie-Veit extraction of the after-coming head over the forceps. This instrument he has had occasion to use only once in the course of an extensive practice. He tabulates thirty-eight cases in which he resorted to manual delivery in case of pelvic deformity. These thirty-eight cases concern thirty-two mothers, and in eighteen the diagonal conjugate measured between nine and ten cm., in eleven between ten and eleven cm., in three between eleven and twelve. The following were the results in previous labors: Forty were spontaneous, twenty-three required the forceps, nine version, three extraction, three perforation, two induced labor. Of the thirty-eight labors conducted by M., thirty-one children were born alive (in ten with pressure markings), seven delivered dead, six of whom had succumbed before manual delivery of the head was resorted to. In none of the living children was there any evidence that the method of delivery had been injurious, and the same remark holds true of the mothers.

These statistical data certainly speak in favor of the Smellie-Veit extraction method and are valuable in settling that vexed and constantly recurring question as to the advisability of applying the forceps to the after-coming head.—*American Journal of Obstetrics*, April, 1887.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

The Editor of this Journal would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

Subscription Price, Including Postage.

Per Annum, in Advance.....$5.00
Single Copies.....10 cents.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in registered letters.

Chicago, Illinois.

SATURDAY, MAY 21, 1887.

AMERICAN MEDICAL MISSIONARY SOCIETY.

To answer a number of inquiries in the most economical and satisfactory manner, we will state that a preliminary organization of this Society was effected at a meeting of physicians and clergymen of different denominations in this city, in March, 1885, and it was legally incorporated in July following. The experience of missionaries in all uncivilized and pagan countries had made it apparent to all interested in the spread and ultimate triumph of Christianity, that the greatest obstacle in the way, was the great difficulty of gaining access to the people of those countries; and also that the most successful mode of overcoming this obstacle, was to qualify the missionaries to perform successfully all the duties belonging to practitioners of medicine and surgery. But to acquire such medical qualifications and skill by the missionary, requires not less than three years of faithful study and a corresponding expenditure of money, while but a very small proportion of the young men and women who are willing or anxious to spend their lives in endeavoring to convert the heathen to Christianity have the pecuniary resources necessary to enable them to gain the medical education desired. Hence it becomes necessary to make adequate and reliable provision for enabling such to accomplish that object, and thereby enable them to do more both in extending a knowledge of Christianity and in relieving human suffering as missionaries among the people of Asia and Africa in ten years, than they could do in thirty without the knowledge of medicine.

It was expressly for this purpose that the American Medical Missionary Society was organized, and for this purpose only has it thus far prosecuted its work. The Society is inter-denominational and evangelical in character. It is constituted of three departments: 1st, a Board of Managers having the supreme control; 2d, a Board of Honorary Directors having advisory functions; 3d, an Executive Committee composed of the officers of the Board of Managers, having the power to transact the business of the Society during the recess of said Board. It is no part of the object of this organization to establish Foreign Missions, or to send e ther physicians or ministers into the missionary fields of labor under its own superintendence, but to furnish systematic and well directed aid in furnishing a full medical education to such young men and women belonging to any of the recognized evangelical Christian denominations as can comply with the following rules:

1. Every applicant must furnish the Executive Committee satisfactory testimonials of earnest Christian character and ability for Christian work from his or her Church, Society, or Board of Missions.

2. Every applicant must be a graduate of some college, or furnish evidence of having received a fair liberal education.

3. Every applicant must pass such a physical examination as is required by our good insurance companies.

4. Every applicant must agree to take a full medical course of three years, and to graduate.

5. Every applicant must bind himself or herself, on completion of the course of medical education furnished by the Society, to go out to the foreign field as a medical missionary, or else to pay back to the Society the cost of the medical education furnished.

It will be seen that these rules exact evidence of Christian character, and both mental and physical ability for Christian missionary work; and also guard against the tendency manifested in some quarters to send, as *medical missionaries*, men and women with only very inadequate amount of medical knowledge. It is not the intention of the members of the Society to devote any part of the money that may be received to the establishment of any medical college, as the work can be more economically and efficiently done in the best class of medical colleges already established in various parts of the country. As none of the officers receive salaries, all the money contributed can be devoted directly to the work of education, except a very limited amount for stationary, printing, etc., for the Secretary and general agent.

In the brief period since its organization, the Society has received in all eight students. Three of these entered the Rush Medical College, four the Chicago Medical College, and one the Woman's Medical College, of Chicago. Three of the above graduated this Spring, after a thorough three years' course; one having served eighteen months as house

surgeon in the Cook County Hospital of this City. Two of these go, as appointed by the American Board of Foreign Missions, to Africa, to Natal East Coast, and the other to the West Coast. The one under appointment, of the Presbyterian Foreign Mission Board, to go to China, was hindered by domestic reasons, and refunded to the Society the cost of his medical education. Rev. Mr. Mapleden, of the Baptist Board, who had been in India eight years as a missionary before he commenced his medical studies under the Society, did not complete his course, but obeyed an order of the Board to proceed at once to fill an important post made vacant by the death of a former co-worker in the foreign field. This is the first student ordered to the foreign field from this Society without a diploma, matter much regretted, as the chief aim of the Society is to insure thorough medical and surgical training, so as to furnish the varous foreign missions with worthy representatives of the American medical profession. Only such as can take the time to complete the course of three years are sought.

The Secretary has received a large number of applications, from different States of the Union, from young men and woman who are highly recommended by their Denominational Societies and Boards, as most suitable persons to make effectual, and worthy representatives of our Christian Faith and our honored profession. Hence, there is reason to believe that the number will be greatly increased by the opening of the Fall term of the medical colleges of our country. The Treasurer's book shows an income of $1514.24 and an expenditure of $1138.50. Special pledges have been given by friends of the Society to educate six students. There is no stated income except personal pledges, as no legacies of thousands are yet available. It is hoped, therefore, that the agent will receive the aid needed not only from the friends of missions generally, but from members of the medical profession who should have a special interest in the work undertaken by this Society. The two young men, sons of missionaries, born in India, set out last Fall to visit the colleges and seminaries of America, and have reported 117 colleges and seminaries visited, and 1836 students who offer themselves as willing and desirous to go to the foreign field. Here are nearly 1500 young men, and at least 300 young women, many of them to be educated as medical missionaries, with little means to aid themselves; and consequently will be needing just the kind of aid that the American Medical Missionary Society desires to give. A successful Branch of the Society is formed at Minneapolis, Min., and it is the object of the parent Society to plant Branches in as many of the States of the Union as possible, and thus facilitate the work and curtail the expenses. Two or three other States are doing something on this line, yet seemingly not quite in harmony with the broad principles of this Society.

Any further information concerning the work of the Society can be obtained from the Secretary, Dr. H. Martyn Schudder, in the Argyle building, N. W. Cor. Michigan Ave. and Jackson St., Chicago, or of the present general agent, Rev. Wm. Stoudenmire, whose office is with the Secretary.

WHY DOES BERGEON'S METHOD NOT MEET WITH BETTER SUCCESS IN THIS COUNTRY?

The American physician is essentially a practitioner of medicine, a therapeutist, a healer of the sick. He is inclined to rush at every new thing in therapeutics like a bull at a red rag. This has its advantages, to be sure; but it has also its drawbacks, as is amply illustrated by the experience of the last two months with regard to M. Bergeon's method of dealing with consumption. Gas bags and wash-bottles have hardly been produced rapidly enough to supply the demand. Mineral springs throughout the country have been called upon to furnish sulphuretted hydrogen. The press has published absurdly extravagant accounts of the marvellous cures being thus effected. The wildest hopes have been entertained by the profession and laity alike, and ill judged, premature statements uttered.

Such has been the status of affairs until very recently. Now, however, there are signs of the reaction having already set in. In this city physicians are beginning to acknowledge that they are not getting the results they looked for. The treatments have produced colicky pains and in some instances diarrhœa. The fever has not always been lowered, while cough and expectoration have not ceased. In a word, Chicago physicians are coming to regard the method as overestimated. The *New York Medical Record* for May 7, 1886, contains a report of Dr. C. L. Dana's experience, wherein he states very plainly that, in his hands, the method has not produced such results as are claimed by many others. On the other hand, there is much testimony of a trustworthy kind to its remarkable efficacy in certain cases. This is particularly true of the reports still coming from France. In other words, we are driven to the conclusion that in this country this method does not achieve as encouraging results as in the land of its birth. If such

be the case, the query arises at once, to what is this due?

From a careful perusal of the literature of the subject to the present time, as well as from personal experience and conversations with many practitioners in this city who are trying the method, we are inclined to think it is not so much owing to inefficiency of the method itself, as to defects in its administration. We have used for the most part sulphur waters without knowing the percentage of sulphuretted hydrogen they contained or gave up to the stream of carbonic acid passed through them. Take, for example, the Ypsilanti water, so extensively employed in Chicago and vicinity: It is said to contain 21.0786 cubic inches of hydrosulphuric acid to the gallon. Yet it is fair to assume that, brought from the spring in barrels and bottled here, as it is, much of its free gas has escaped. So far as we can ascertain, no analysis has been made of the two gases after having passed through the wash-bottle, with a view to ascertain the proportion of the two. If we are not mistaken, M. Bergeon charges his carbonic acid with 1 per cent. of sulphuretted hydrogen. Does any physician here know exactly what percentage of the two he himself has been using?

Again, a number of the physicians here have been in the habit of filling their gas bags with several gallons of CO_2 and depending upon this supply for several treatments on successive days. This is bad, since atmospheric air enters the rubber receptacle by endosmosis, under such circumstances, and occasions colic to the patient. Moreover, the apparatus, used in this country generally, does not admit of an accurate measurement of the amount of gas injected; the argument that one can determine this by the number of times the pressure bulb is emptied, to the contrary notwithstanding.

In the light of these and other facts, best known, perhaps, to each practitioner, is it fair to M. Bergeon to content ourselves with inexact trials of his method? Would it not also, for our own sakes, be well if some of our physicians with hospital opportunities at command, were to undertake a series of careful experiments to fix definitely the dosage of the two gases, and thereby establish this treatment upon a scientific basis? If such investigations are being conducted in this country, we have not heard of them, and shall give their results hearty welcome.

For a more careful consideration of this subject we would direct especial attention to the admirable presentation of certain facts in regard to the proper use of Bergeon's method in the letter by Dr. Babcock in another department of this issue of THE JOURNAL.

PHYSICIANS' NAMES IN NEWSPAPER ADVERTISEMENTS.

In the *Chicago Times*, of May 8 and 15, appeared an advertisement of the Ypsilanti Mineral Water as a positive cure for consumption, rheumatism, catarrh, cancer and other diseases, with extracts from an article read before a recent meeting of the Chicago Medical Society on Bergeon's method of treating phthisis, and illustrated with a cut of the apparatus made by E. H. Sargent, of this city, for administering the gas. The advertisement also contained the names of several well-known physicians of this city, and in such a manner as to show that they practically endorsed all that was claimed in the absurd advertisement.

In an obscure corner of *The Times*, of May 15, was published a protest from several of the physicians against such unauthorized and outrageous use of their names by an advertisement in a daily newspaper. But, as already said, their names were again used in a similar advertisement in the same issue.

We are authorized by Drs. Robert H. Babcock, Charles Gilman Smith, Sarah Hackett Stevenson, M. R. Brown, Wm. T. Belfield, Marie J. Mergler, C. M. Fitch, and Walter M. Fitch to state that such use of their names was unauthorized, and without their knowledge or consent; an outrage both to them and to every reputable physician in Chicago; and they do not recommend the Ypsilanti water as the best source from which to obtain the sulphuretted hydrogen for Bergeon's method—and the reason for this may be more clearly seen in Dr. Babcock's letter on Bergeon's method, in this issue of THE JOURNAL. But even were the Ypsilanti water the best source, the proprietor of that water justly deserves the condemnation of all reputable physicians for his improper methods of advertising, and for his unwarranted use of the names of reputable physicians. Nor is there any reason why Mr. Sargent should advertise his apparatus in the secular press. The public cannot and should not use the apparatus, since in hands other than those of physicians great injury to the patient may result.

We are informed by an attorney that physicians whose names are thus used can most probably stop it by legal proceedings. Is it not time that something of this kind be done? Are the names of reputable physicians private property, or do they belong to any quack advertiser who thinks he can make money by using them improperly? Here is one of the most flagrant violations of common decency to members of the profession that has occurred for some time, and it is to be sincerely hoped that the physicians of

Chicago will show that such methods will be neither endorsed tacitly (by inaction) nor patiently endured. Is it not a duty to themselves and to other physicians to stop such advertisements at once and permanently?

SOCIETY PROCEEDINGS.

CHICAGO GYNÆCOLOGICAL SOCIETY.

Regular Meeting, Friday, March 18, 1887.

The President, Chas. Warrington Earle, M.D. in the Chair.

Dr. W. W. Jaggard presented a

PUERPERAL UTERUS, SHOWING ENDOMETRITIS PUERPERALIS.

The material was placed at his disposal through the courtesy of Drs. Pickard, Hibbard and Plummer, of the Cook County Hospital.

History.—Patient 64003, Ward 14, Swede, 24 years old. I para. Labor March 13. Vertex presentation, R. O. P.: First stage, ten hours; second stage, three hours; third stage, ten minutes; male child; wt. 6 lbs., 13 oz.; condition good. Severe post-partum hæmorrhage, after expression of placenta; intra uterine irrigation with hot water, vinegar, finally mercuric chloride, 1 : 4000: perineum sutured, vaginal douche. Chill, three hours after delivery; temperature 101.8° F.; pulse rapid and feeble. Patient died four days later; temperature reaching the maximum, 103° F. a few hours before death.

The autopsy disclosed puerperal ulcers in the vagina, diphtheritic endometritis, splenic tumor, ulcerative septic-endocarditis. The ovaries, tubes and peritoneum were not involved in the inflammatory process. The case apparently corresponded to the form, described by Buhl in 1861, as "Puerperal pyæmia without peritonitis" (metro-phlebitis). The poison had apparently gained direct access to the veins, the endometritis being only a prominent symptom.

It must not be supposed that the mortality rate from child-bed fever in the lying-in wards at the Cook County Hospital is high. About 400 women are annually delivered in that institution, and less than one-half of one per centum perish from puerperal fever. Rigid antiseptic precautions, in conformity with the Semmelweis doctrine—every case of child bed fever arises from the resorption of decomposing organic matter through some local lesion in the genital track—have been instituted and carried out with commendable intelligence, skill and zeal by the internes. The only criticism that Dr. Jaggard wished to make was upon the use of mercuric chloride for the purpose of intra-uterine irrigation.

Dr. Charles Warrington Earle: I think there is evidence accumulating at this time which shows that we are not certain that the decidua comes away completely, and in a great number of cases there is not only a considerable amount of this left, but also pieces of membrane, etc., which no one, however careful, can detect. Whenever a high temperature takes place on the eighth or ninth, or tenth day, I am in the habit of washing out the uterus, and then if the high temperature continues, to curette, and in almost every case the amount brought away astonishes everybody, particularly the attending accoucheur. Sometimes 2 or 3 drams are brought away; the temperature becomes normal in twelve hours and a speedy convalescence takes place. I would like to ask what the experience and observation of the other Fellows of the Society has been in regard to the certainty which they feel that *everything* comes away.

I am getting together a series of cases in which I will endeavor to show that where there is a high temperature that comes on as late as the tenth or eleventh day, if it does not come down after a thorough intra-uterine douche with carbolized water, curetting should be resorted to, and that it will in almost every case bring away an amount of material that none of us expect. In many of these cases the temperature goes down at once.

I had a case on Hoyne street, which took place in the practice of a graduate of one of our schools, a young man of excellent record, and one who is thoroughly in accord with us on antiseptic obstetrics. On the tenth day the temperature was 103½° F.; an intra-uterine douche did not bring it down. The next day it was 105½° F. I curetted and brought away a mass of material which surprised me as well as the practitioner. The woman made an excellent recovery without a bad symptom.

Dr. A. Reeves Jackson: It seems, to look at this specimen, that the curettement would have to be exceedingly deep; especially after the infection of the walls, you could hardly get away all the septic influence. There may have been a stage in the history of that case in which it would have been a proper treatment.

Dr. Christian Fenger: In consultation last fall, I saw a case of abortion, not childbirth, where part of the placenta was left. The temperature had been down for over a week and the woman was apparently perfectly well. The doctor in charge decided to curette that part of the placenta which remained. The curettement was immediately followed by sepsis that terminated fatally within a short time. So it seems that under certain circumstances curettement may open up sepsis. He curetted to remove the placenta.

Dr. Jaggard said he supposed Dr. Earle referred to Carl Braun's practice of curettement. He did not care to discuss that subject at this meeting. Certainly, in the case presented curettement could have accomplished nothing. The poison—ptomaine, cadaveric poison or whatever it was—had already entered the veins.

Dr. A. Reeves Jackson read a report of

A CASE OF REMOVAL OF THE OVARIES AND TUBES FOR FIBRO-MYOMA OF THE UTERUS.

I present to the Society a pair of ovaries and cor-

responding tubes, which were removed for the purpose of a possible beneficial influence on the hæmorrhage caused by bleeding myoma of the uterus. The woman was single, about 40 years of age, menstruated first at the age of 13, and was always regular until three years ago, when menorrhagia occurred. At the same time there appeared at intermenstrual periods—about half way between—occasional discharges of a yellowish thin fluid. These discharges were preceded by pain in the left iliac region and some swelling. The menorrhagia increased, the other discharges continued about the same, and bleeding became so nearly constant that finally it was difficult to distinguish the menstrual period. About a year and a half before I saw her, there had been discovered a tumor in the abdomen. Ergot was then used systematically and properly, but it had no restraining influence on the hæmorrhage and she became anemic, exhausted, and had nervous headaches, cardiac palpitation and loss of appetite. I found a uterine fibroid the size of an orange and suggested removal of the ovaries, although she came for the purpose of having the uterus removed. The operation was performed at the Presbyterian Hospital three weeks ago. The left ovary was exceedingly small with no trace of recent ovulation; the tube was enlarged and contained a small amount of yellowish fluid. Possibly this condition of the tube with the previous history of occasional swelling may have indicated that the latter was from hydrosalpinx. Here are the specimens. The right ovary was enlarged and the tube normal in structure. There was a Graafian follicle which had just broken. She had menstruation two weeks before, and the condition of this follicle seemed to indicate that it had no temporal relation to that menstrual period. The highest temperature was 100.1° F., and was reached on the fourth day. The woman is now entirely well, is sitting up, and will probably be able to go to her home, a hundred or two miles distant, in the coming week. Hæmorrhage appeared on the third day after operation and lasted thirty-six hours. It was then checked by vaginal tampons. She has had no discharge of blood since that time. What effect the operation will ultimately have upon hæmorrhage and growth of the tumor cannot be determined at this stage of the history.

Dr. Christian Fenger made some remarks on

THE OPERATIVE TREATMENT OF RETRO-PERITONEAL CYSTS IN CONNECTION WITH MICULICZ'S METHOD OF DRAINAGE.

(See page 568).

Dr. A. Reeves Jackson: If I remember correctly, Dr. Miner's discovery or suggestion in regard to enucleating tumors was not originally for the purpose of removing only sub-peritoneal cysts, but to make possible the removal of ovarian and other tumors, in which the adhesions were so extensive as to make it impossible to remove them in any other way. I think his first case one in which he failed to find a pedicle and so was driven to enucleate. I think he removed very few tumors in this way, because he did not find the necessity for doing it. But when adhesions were so extensive and tense that it was impossible to remove the growth, he made a slight incision around its lower portion, and then, seizing it above, after emptying the cyst, he passed a finger or suitable instrument around until he had loosened all the attachments. It was a valuable suggestion, and operators have availed themselves of it in suitable cases.

In regard to the removal of these sub-peritoneal cysts, one of the cases related by Dr. Fenger shows clearly that the operation of enucleation is not always necessary. The tapping was followed by complete cure. Tapping has frequently been successful and these are the cases in which it is the proper method of treatment. I am aware that many hold a different opinion and advise extirpation always. If the tumor should refill after tapping and the patient's health fail, I should be in favor of removing the cyst by ordinary methods.

In regard to Miculicz's plan of drainage, it has always seemed to me that it could only succeed in removing the thinner parts of the fluid; the more dense constituents could not be carried away as well by this method as by a tube of glass or rubber. I can see an objection to it in the possibility of a long convalescence resulting from the large fistulous opening which might be left, and which would be embarrassing for months. In the last case detailed by Dr. Fenger, we have an illustration of the importance of knowing the condition of the kidneys before operating for any abdominal tumor of long standing. Many operators make it a point to know that the patient passes a sufficient quantity of urine of a proper character before consenting to operate. They insist on knowing that the kidneys can do their work, and the rule is a good one.

Dr. Christian Fenger: In regard to the remarks of Dr. Jackson, about the insufficiency of the Miculicz's drain, I will say that I forgot to state that I do not use it now, without at the same time inserting in the centre of it a glass or rubber drain. In an operation last Autumn, in which I used the Miculicz drain without a glass drain, I found the outside dressing dry and still about a pint of fluid at the bottom of the abdominal cavity after the patient was dead; so since that time I have always inserted a glass or rubber drain in the centre of the Miculicz drain.

As to the remark regarding the examination of urine: Of course we always do this. In this case there was no albumen, but I cannot say that it was examined as to quantity.

In reply to the question of Dr. Jaggard as to whether I have used the drain in pelvic abscess and acute suppurative peritonitis: I have not used it in pelvic abscess, but have used it in tuberculous peritonitis, in a case last fall which looked like a tumor; there was tuberculous peritonitis with a large localized cavity or space filled with a fluid more or less serous. I used the Miculicz drain with a glass drain, and the patient was still alive two or three months ago, and I do not know whether the drain is out yet. I have used it in other cases which show its efficiency. In a case of chylous ascites that had been tapped

and tapped and had refilled, and in which laparotomy had been performed the year before and still it had filled again, I opened and drained the peritoneal cavity, and used the Miculicz drain with a glass tube, with perfect success. I always use it in acute peritonitis, and see no reason why it should not be used in peritonitis as well as in other cases. At the time Mikulicz published his paper on this form of drainage, it was only in peritonitis that he had used it.

In regard to the similarity between labor and operation, as far as the question of eclampsia is concerned: That is one of the subjects which was brought up for discussion in the *Berliner Klinische Medicinische Gesellschaft* last fall, between Leyden and Virchow, in which no definite conclusion was reached.

I fully agree with Dr. Etheridge that vaginal drainage, mechanical of course, is the most rational method because it draws best. My own experience is limited as have only employed it twice, and both patients died. We dread the vagina as a septic cavity and the reason why we should not drain through it, is fear of sepsis from the vagina up into the abdominal cavity. But I believe with our new precautions, the vagina could be kept so aseptic that retrograde sepsis from it could be prevented, I believe also that vaginal drainage ought to be used more than it is, and we need not be so afraid of it as we are.

SUFFOLK DISTRICT MEDICAL SOCIETY.

Section for Clinical Medicine, Pathology and Hygiene.

Stated Meeting, March 9, 1887.

Dr. F. I. Knight, Chairman.

Albert N. Blodgett, M.D., Secretary.

Drs. E. W. Cushing and Morton Prince read a paper on

A CASE OF CHRONIC ARSENICAL POISONING OF SUPPOSED CRIMINAL NATURE, WITH ESPECIAL REFERENCE TO THE MEDICO-LEGAL ASPECT.

Dr. Cushing stated that the circumstances of the patient made the case specially interesting, from the evident motive which could be traced. The patient was a young man, supposed to be in possession of property to the extent of about four million dollars, and was alone in Boston. He was found at the house of a friend of his, not of his family, on Beacon street, and this "friend," with the assistance of his wife, took the sole direction of the nursing of the sick man. The medical treatment was in the hands of a so-called physician, really an apothecary and chemist. A large amount of the patient's money had been invested in the manufacture of a patent medicine, in which the "friend" at whose house the patient was staying was also interested. He said that it might be useful to members of the medical profession to know how difficult it is to bring a case before the courts, even when the evidence is apparently plain and convincing.

Prof. E. S. Wood stated that he was in a position to add somewhat to the report of the case, in the presentation of some of the results of the quantitative analysis of the vomitus and the excretions from this patient. The quantitative analysis was made, in this case, only for the personal satisfaction of Professor Wood, as the case had not advanced sufficiently far in the way of a prosecution to call for the analysis in behalf of the courts. A complete analysis is not usually made at so early a stage in the investigation of similar cases. The vomitus, which was placed in his hands on May 1st, contained one-fourth of a grain of arsenic. That of May 8th contained one-third of a grain. The urine of May 1st and 2d contained 5.4 mg. It was thought that this amount of arsenic might have been contained, as an impurity, in the medicines prescribed by the person attending the patient. These were examined, and were found to be free from arsenic. The intermediate urine, until June 1st, was not examined, but that passed on June 1st was examined, and was found to be free from arsenic. The date when the arsenic disappeared from the urine is, therefore, not yet definitely known. The only other case in which analysis was carried out in this way was that of a patient who, by mistake, took, during a considerable period, a poisonous dose of Fowler's solution, and the symptoms of arsenical poisoning were rapidly induced. In this case, analysis at the end of six and one-half weeks showed arsenic, but the urine, when examined at the end of seven and one-half weeks, did not contain arsenic. The occurrence of paralysis is not confined to chronic forms of arsenical poisoning, but may follow acute poisoning from this cause. Seligmueller quotes several such cases.

Dr. Prince said that he had made, by request, an examination of the nerves and muscles in this case. At that time the patient was almost completely paralyzed from head to foot, only a few movements being left, and these difficult and painful. Even moving the limbs passively caused great pain. There was more or less complete loss of sense of touch over all four extremities. Sense of pain was increased over some parts, but perception of it was retarded three seconds by the watch. Perception of Faradic current also diminished. Loss of Faradic excitability of all muscles of legs, forearms and hands. Triceps of right arm respond feebly, but biceps of both well. Faradic excitability of ulna and median nerves of both sides lost, also of nerves of legs. To the galvanic current there was a most exquisitely developed reaction of degeneration in all the muscles of the right forearm and hand (including loss of reaction in nerves). The same was found true of the extensors of the left forearm. The examination was not continued further on account of pain caused the patient by movement of the limbs. The same condition of affairs probably existed in all the paralyzed muscles.

The interest in this case, as indicated by the title of the paper, centred in the question of the nature of the paralysis, and the other allied symptoms. Were they due to arsenic or to alcohol? In the first place there is no question but that arsenic was given to the

man, and that, too, in poisonous doses. But on the other hand, the man was a hard drinker, was in the habit of going on constant sprees, lasting many days at a time, and had just been on a hard spree when the attempt was made on his life. Now the *paralytic* picture presented was just that of alcoholic paralysis in its most severe form. Alcoholic paralysis has only recently been thoroughly studied and understood; in fact, the best observations have been made during the last two years, and since the above case occurred. The *clinical* picture is just such a one, in almost every detail, as that which we are discussing. There is the extreme and general paralysis, the loss of sensation with hyperæsthesia, the pain and the atrophy with the reactions of degeneration. The resemblance can even be extended to the mental condition. According to Dreschfeldt[1] and Buzzard[2] there is a peculiar and characteristic delirium observed in alcoholic paralysis. A similar mental condition was present in their case.

On the other hand, the clinical picture is also like that observed in many of the cases reported of arsenical poisoning. In the severe cases there seems to have always been present the main and salient symptoms, namely, paralysis with atrophy and reaction of degeneration, loss of sensation, pain, and hyperæsthesia. Clinically and ætiologically, then, it must have been difficult, especially as a medico-legal question, to eliminate either the arsenic or the alcohol as a factor in causing the paralysis and allied symptoms.

Pathologically considered, the difficulty is as great. The pathological condition present in alcoholic paralysis is generally admitted to be a peripheral multiple neuritis. The cord is not diseased. Our knowledge, on the other hand, of the pathological condition present in arsenical paralysis is very imperfect. About the only information we have is derived from the experiments of Popow,[3] of St. Petersburg, on rabbits. According to these experiments, in acute cases, when death ensued in the course of a few hours or at the end of from three to six days, the effect of arsenic is limited to the anterior gray matter of the spinal cord. There is found a poliomyelitis. The white matter and the peripheral nerves are unaffected. In chronic cases, wherein death ensues in the course of three months, the inflammation is more diffuse, affecting the white as well as the gray matter, especially the postero lateral columns. The spinal nerves were entirely unaffected even in these cases.

Freyssig, on the other hand, claims that he has found all these changes in the spinal cord of healthy rabbits, while in six rabbits which had been poisoned by arsenic he found no pathological changes whatever in the cord. Dana, in the January number of *Brain*, states that according to Pistorius, the nervous system of rabbits and guinea pigs is very sensitive to arsenic, while that of cats and dogs is less so. Jaeschke, too, found only a few small hæmorrhages in the spinal meninges[4] of a dog which developed paralytic symptoms after a fatal dose of arsenic. Very little can consequently be inferred from experiments on animals, and we do not find that any examinations have been made on man after death to determine this point.

As has been said, the symptoms are very similar to those from alcoholic paralysis, which is known to be due to multiple neuritis. On the other hand, a diffuse inflammation of the cord would also explain the symptoms. It may be, as is most probable, that both core and nerves are affected in severe cases. At any rate, if the case we are discussing had ended fatally, and had come before a jury, whatever anyone's individual opinion might have been, it would have been very difficult to convince the jury that, notwithstanding the known ingestion of arsenic, a certain portion of the victim's condition was not due to alcohol, and even that this might not have been the exciting cause of his death. There is reason to believe that there were experts ready to take the stand and testify to this opinion. This complication is likely to arise again in other cases. A decision under such circumstances can only be arrived at by extending our knowledge of the action of arsenic on the spinal cord. It is to be hoped that pathologists and medical examiners in the future will at the first opportunity make investigation into this matter and thus increase our knowledge.

In reply to a question by Dr. P. C. Knapp as to the condition of the mental faculties, and the location of the paralysis in the patient, Dr. Cushing said that the mental condition of the patient was unimpaired, and his faculties were clear. He could remember the main events in his past life, confessed to the abuse of alcohol, remembered the jelly which had caused the relapse in his illness, and could state who had given him that delicacy. For a time he was kept in a house of ill fame on Hudson street, and from this quiet retreat he said that he was brought, on several occasions, to the residence of his "friend," on Beacon street, to dine, and was then afterward restored to the caresses of his entertainer at the before-mentioned brothel.

Dr. Bowditch asked if it were possible that the arsenic could have been absorbed into the system of the patient from the papers on the walls of the house in which he was stopping.

Professor Wood stated that the papers were examined and were found to contain no arsenic. The amounts obtained from the vomitus and from the urine of the patient were much greater than would be obtained from chronic poisoning by absorption from the wall-papers, the quantity ranging from one-fourth to one-third of a grain on the different occasions when the examinations were made, thus showing that the arsenic must have been administered at varying times, and in relatively large amounts.

Dr. Bowditch asked what is the process by which the attention of the grand jury is attracted to a case of criminal nature, and how a physician should proceed in a case in which there is reason to suspect a

criminal attempt upon the health or life of another?

PROFESSOR WOOD stated that criminal proceedings are instituted by calling the attention of the district attorney to the facts in the case, which are then carefully considered by him; and if the evidence, as presented, seems to him sufficient to secure the conviction of the person complained of, the case is submitted to the grand jury. All the experts in the case are called, and after the deliberations of the grand jury, the district attorney is at liberty to prosecute the case, if, in his judgment, it is advisable to do so. The objection to commencing proceedings of a criminal nature upon insufficient evidence is that the case first goes before what is called the petit jury, and if there should not be sufficient evidence to hold the person accused at that time, the case is at once dismissed, and cannot be again called up, as a man cannot be tried twice upon the same charge. It is, therefore, considered wiser to delay proceedings in a doubtful case, in the hope that additional evidence may be procured, which can then be used in the trial, which may be commenced at any time after the commission of the deed. This way seems better than to summarily dispose of every case by the form of a trial by jury, which would effectually prevent the admission of any new evidence after the prisoner had once been acquitted.

DR. C. P. PUTNAM presented the notes of

A CASE OF HODGKINS' DISEASE

recently under his care. The patient was about 30 years old; lawyer. He was unusually muscular, and could paddle a canoe for twenty miles without difficulty. He had had no illnesses of any importance hitherto, except eczema, from which he had suffered throughout his whole childhood, and which had been finally cured at Hebra's Hospital, in Vienna. The only remains were an irritability of the scalp and face, and he was very little disturbed by this. He first came on January 11, 1886, with one enlarged gland under the occiput, and one under the left jaw. These he had noticed about the first of January; at any rate, he was sure that, on Christmas day, he was perfectly well. Iodine was applied to these enlarged glands, and in a week they were smaller. But meanwhile, others had appeared in the same neighborhood, which, in their turn, were treated with tincture of iodine. Ten days later he returned, with the second set of glands also smaller, but with a larger crop in various places in the neck, and also in front of the ear. Then it was found that the axillary and inguinal glands were enlarged and hard. Iodide of potassium had been given, five grains, increasing to ten, three times a day. During the next two weeks he was very much better, and considered that he was getting well. All the glands diminished in size. Meanwhile, however, the whole neck had been growing gradually, but perceptibly larger, so that his collar could not be buttoned. About the middle of February this apparent improvement ceased. The glands began to enlarge again, and the skin became more red and tender. This time, a slight enlargement of the spleen and liver, and general fulness of the abdomen, was found. Arsenic was substituted for iodide of potassium, and with apparent good effect. He again seemed to improve, and was satisfied with his condition; voice husky. In March, however, he complained of want of appetite, and difficulty of retaining food; had to keep a pail near him, as he would vomit suddenly and violently. Was weak; lay on the lounge much of the time; ceased to take an interest in books, although he was an active and intelligent reader. Up to this time the pulse had been normal or slightly accelerated, and there was no rise of temperature. The vomiting was supposed, by the patient, to be caused by the arsenic, which was omitted, given again, and again omitted.

About March 18th he began to lose strength rapidly; lay on the lounge all day too ill to talk, taking little food and vomiting frequently, and yet feeling hungry from time to time. Became less inclined to get up, and from about the 20th kept his bed. His mind became less and less interested in his surroundings and occasionally it would wander. On one occasion he had a hæmorrhage from the bowels which was, however, easily stopped. During this period the action of the heart became more rapid, varying from 100 to 120. Respiration was superficial but labored. He died on the 29th, one month and eighteen days after I first saw him, and almost exactly three months from the time when he noticed the first symptoms. Autopsy by Dr. Gannett.

DR. GANNETT described the appearances found at the autopsy, made March 29, 1886. The front and lateral regions of the neck were occupied by numerous packets of gray, rounded nodules, varying in size from a filbert meat to a walnut; showing on section a homogeneous, and a somewhat translucent appearance, like that of a lymph gland. Similar nodules were found in the mediastinum and about the roots of the bronchi. The spleen was much enlarged, and contained numerous secondary nodules of lymph-sarcoma. The kidneys and liver showed the presence of very numerous secondary nodules. In the mucosa of the stomach and intestine were numerous, elevated nodules, varying in diameter from one or two centimeters, with depressed centres. Microscopically these showed the structure of a lymphoma.

Dr. Gannett stated that when he made the autopsy he was so struck with the similarity of the course of this case to the acute infectious diseases, the severe symptoms having lasted only three weeks, that he placed at once portions of the new growth in alcohol for examination for micro-organisms. Thin sections, made after hardening, of the gastric and intestinal nodules, stained with methyl-blue and examined with a Zeiss 1-12, showed the presence of well-marked micrococci, in colonies, in the new growing tissue, and no other micro organisms. Of course, such a result does not prove that the micrococci found were the specific cause of the disease; since to prove this, isolation, pure cultivation and successful innoculation experiments are necessary; but it may serve as a finger point to call attention to the possibility of lympho sarcoma being an infective disease, and to suggest the advisability of further investigation in regard to this point.

Dr. T. A. DeBlois exhibited a

NEW FORM OF PHYSICIAN'S HANDBAG,

which he had recently had made. It consists of an ordinary leather bag, of medium size, but is about one-third deeper than the ordinary bags. At one end of the bag is an opening near the bottom, which can be closed by a flap which buckles tightly. This opening displays the end of an air-condenser, with two cocks, and a pressure-gauge. In the bag can be carried a small pump, by which the air can be forced into the condenser. In the space of two minutes Dr. DeBlois was able to obtain a pressure of thirty five pounds to the inch without great exertion. The apparatus is then ready for use as a spray for the throat, the use of the Evans' inhaler, or for any other purpose to which this treatment is applicable. The bag is sufficiently capacious to accommodate all the articles usually required. The weight is not materially increased by the addition of the condenser, and the whole apparatus is not too heavy to be easily taken in the hand when walking. It is manufactured by Messrs. Codman & Shurtleff.

DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Cæsarean Section—Craniotomy—Laparo-Elytrotomy.

At a recent meeting of the New York County Medical Association Dr. Lusk reported a case of Cæsarean section, operated on by Sänger's method. The case shows the importance of operating early in labor, of proceeding with deliberation, and of using strict antisepsis, as well as the advantages of constricting the uterus with a rubber ligature to prevent hæmorrhage during the incision of the uterus, extraction of the child, and suturing of the uterine wound. The patient was 24 years old, a native of Ireland. On March 21 she was admitted to Dr. Lusk's service at Bellevue Hospital, on account of deformity of the pelvis resulting from hip disease when a child. When 11 years old she was treated for this at a Dublin hospital, and discharged cured; but during her pregnancy she noticed some suppurative discharge from the old sinus which had formed at this time. Dr. Lusk made an examination on March 22, and to his surprise he found that labor was already commencing. The pubis was a Nægle oblique, and its diameters much contracted. After consultation with Dr. Isaac E. Taylor and Dr. H. J. Garrigues, he decided to perform Cæsarean section. With the pubic diameters in this case he thought the danger from craniotomy would be actually greater than that from Cæsarean section, provided the latter were performed early enough. As the patient was already in labor, he determined to operate at once. Both the private pavilions at Bellevue being occupied, the operation was done in one of the hospital wards.

The abdominal cavity having been opened by a median incision, the uterus was turned back over the abdomen, as were also the intestines, which were held out of the way by means of towels. A rubber tube was then placed around the uterus, and an incision two inches long made in its lower segment; the opening was afterwards increased to five inches by means of scissors. Owing to the pressure of the elastic ligature, the incision was almost entirely bloodless. The child was found with the head presenting in the L. O. A., and when extracted was in a cyanotic condition from the pressure exerted by the constricting rubber; but it was successfully resuscitated. The placenta and membranes were then readily detached by the finger from the uterine walls. In closing the wound thirty-four carbolized silk sutures were used, sixteen deep, eighteen superficial. In the deep sutures the mucous membrane of the uterus was avoided. When the rubber band was removed blood slowly returned to the pallid organ, which first became of a delicate rosy hue, and finally of a deep purple. A slight oozing was then observed at one point, and after it had ceased the uterus was returned to the abdominal cavity; a drainage-tube being inserted behind it. Silver wire sutures were put into the abdominal wound, and the patient was in excellent condition at the end of the operation, which lasted 1.15 hour.

For 3 days the temperature never rose as high as 100°; then there was a little tympanites, and it went up above 101°, but a Seidlitz powder had the effect of promptly reducing it. On the 5th day the drainage-tube was removed. Immediately after the operation the discharge from it was stained with blood, but it soon became colorless. Dr. Lusk thought that the tube was not really needed in this case at all; but at the same time there was a certain feeling of security in having it. On the 6th day there was some oozing from the orifice left by it. At the end of a week the abdominal suture was removed, and at this time the temperature would usually go up to about 100.5° in the evening, falling again by morning. On the 9th day some fluctuation was discovered at one point in the line of the abdominal wound, and a little pus was evacuated; after which the temperature became nearly normal. At the end of two weeks, however, the temperature suddenly rose to nearly 103°. No trouble whatever could be detected about the abdomen, and as the patient complained of pain in the region of the right hip, an examination revealed an accumulation of pus in the site of the old sinuses. After that time the patient continued in excellent condition, and the child was in equally good condition.

In the discussion on Dr. Lusk's case Dr. Sylva, late House Surgeon in Bellevue Hospital, who had had charge of it, said that altogether the patient did better than any other case of laparotomy that he had the opportunity of observing during his service at the hospital. As regards the result of Cæsarean section when the operation was unduly delayed, he referred to the nineteen cases in dwarfs which Dr. Robert Harris, of Philadelphia, quoted in tabulating one hundred operations in 1878, and in which only one mother and five children were saved. In all these cases the operation was only undertaken as a last resort, when the patient was utterly exhausted; and the results afforded ample proof of the importance and desirability of early surgical interference.

In reply to whether it would not have been better in such a case to perform Porro's or Tait's operation, in order to prevent the woman's becoming pregnant again, Dr. Lusk said that statistics showed that with the Sänger operation (more or less modified from the original procedure) there are over 70 per cent. of recoveries, but only 40 per cent. in Porro's operation. In regard to Tait's operation, the additional risk to which it subjected the patient was by no means advisable; the extremely vascular condition of the parts constituting a serious objection to its performance.

Dr. C. S. Wood said that in the course of his experience he had had to perform craniotomy three times, and he thought that this class of cases was as disagreeable and repulsive as one could by any chance meet with. If, therefore, by this operation it was possible to save more mothers than by craniotomy, it would be a great boon. Unfortunately, however, statistics showed thus far it had saved a much smaller proportion of mothers. In two of the cases of craniotomy that he had met with the mothers recovered, while in the third the result was fatal. Yet in one of the successful cases he labored under great disadvantages from the fact that, not expecting to be called upon to perform craniotomy, he was unprovided with the proper instruments, and was so situated that none could be obtained on short notice. Under these circumstances he resorted to the device of manufacturing such rough instruments as he could from some shoemaker's tools; and he thought the case was of interest as showing what sometimes might be accomplished by very simple means in an emergency. He said he was one of those who believed that the mother should always be saved at all hazards, whether the child was sacrificed or not; and as long as it could be shown that more mothers' lives were lost by the Cæsarean section than by craniotomy, he thought the latter should be given the preference.

Dr. Lusk said that in the old Cæsarean section, the mortality was without doubt very large. In most of the cases it was resorted to only when the woman was in a dying condition, and after all other methods of delivery, craniotomy included, had been tried in vain. When it was remembered, too, that a rough and careless way of operating had also been the rule, it was hardly to be wondered at that the patients died, and that such cases militated strongly against the value of the procedure. But, even under all these adverse circumstances, a few cases had recovered. At the present time it is getting to be understood that the operation should be performed, whenever this was possible, under more favorable conditions, and in the same careful way as any other surgical procedure involving the abdominal cavity. The operator should take sufficient time to make out the pelvic diameters, and consider fully the risks to be encountered in performing craniotomy. If, having done this, he decided that the Cæsarean section offered the best chance of success, he should make his preparations as deliberately as possible and perform the operation by strict antiseptic methods. In this way the results are infinitely more satisfactory than in the old operation, as shown by the cases of Leopold, who has operated ten times, with only one death, and who states that, in the light of his later experiences, he believes that he could now have saved this case also. Very few obstetric surgeons, certainly, could show a result of 90 per cent. of recoveries in their cases of craniotomy. Within the last eighteen months Harris has collected 40 cases of Cæsarean section, with 73 per cent. of recoveries; while the best results of craniotomy in these difficult cases show only 60 per cent. of recoveries. Other operators than Leopold have reported 5 or 6 consecutive cases without a death. One great reason of the gratifying success of the modern operation is the use of the rubber ligature, which, by effectually preventing hæmorrhage from the severed uterine structures, enables the surgeon to remove the contents of the uterus in a very deliberate and careful manner, and to bring the edges of the wound together with the greatest accuracy.

In reply to a question from Dr. Gouley, in regard to his opinion of the operation of laparo-elytrotomy in these cases, Dr. Lusk said that this procedure was particularly adapted to a special class of cases, viz.: when the head was arrested at the brim and the cervix was already dilated, or in a dilatable condition. If, however, we were obliged to pass the forceps through an undilated cervix, it was a very serious operation. In case, therefore, we desired to operate early, we have to do it at a time when the conditions favorable to laparo-elytrotomy do not exist. Of the 12 cases of this operation which have been reported, 6 recovered, and 6 died; the latter being cases in which success was impossible from the existing conditions. P. B. P.

BERGEON'S METHOD OF TREATING PHTHISIS.

Dear Sir:—My object in addressing you is not to present the results of personal experience with M. Bergeon's method of treating phthisis, nor to make original suggestions for its improvement. I desire only to state a few points concerning the preparation and amount of carbonic acid to be injected, as well as the proportion of, and best mode of obtaining the sulphuretted hydrogen. These have been gleaned from *Les Nouveau Remèdes*, November 24, 1886.

But before considering them, I should like to mention the points wherein, as it seems to me, we American physicians have been at fault. The attention of the profession in Chicago was first directed to Bergeon's method by Dr Henry Bennet's paper in the *British Medical Journal*, December 6, 1886, and our apparatus has been constructed after that of M. Morel which Bennet described. We have prepared our gas in the way he suggested, and, not being able to obtain Eau Bonnes, we did the next best thing, employed native sulphur waters, chiefly that from Ypsilanti. Or, if not natural mineral waters, we have followed the lead of Philadelphia men, and used 5 grains each of sulphide and chloride of sodium in 20 ounces of water. Furthermore, not satisfied with employing the apparatus in strict accord with Bergeon's principles, as enunciated by Bennet, some of us have been in the habit of generating enough carbonic acid to suffice for several treatments, instead

of filling the gas bag afresh on each occasion. When gas is left in the rubber bag, atmospheric air enters by endosmosis and is liable to give the patients colic, an objection to the treatments of which I have heard physicians complain. Furthermore, the quantity of gas administered has not been exactly known. To be sure, it is claimed that one can ascertain this by measuring the capacity of the pressure bulb. This, I think, is an error, since when the bag is full and the gas under high pressure, it will bubble through the bulb in a steady stream. Also, as the gas grows less in the reservoir, the amount ejected by each pressure of the bulb becomes less than at first. Hence, the claim appears to me just, that for the most part, physicians have not known accurately how much gas they have injected.

Omitting for the present the fact that sulphuric acid is used in the generation of the carbonic acid, there is the source and percentage of the sulphuretted hydrogen to be considered. The great demand for Ypsilanti water reveals that in most instances it is the mineral water employed hereabouts. According to the official analysis of this water, it contains 21.0786 cubic inches of free hydrosulphuric acid to the gallon. A trifling computation shows that 1 litre of the fresh water holds about 91 cc. of free sulphuretted hydrogen, and a ½ litre, therefore, in the neighborhood of 45 cc. But does anybody imagine that the bottled water sold to us here at such exorbitant prices holds anything like as much free hydrosulphuric acid as that freshly drawn from the spring? The water is brought here in barrels and then bottled. Under such circumstances it has lost probably more than half of its free gas. But granting that it still contains the half of its original charge, a pint of the water (a pint being little less than ½ litre) would hold less than 23 cc. of sulphuretted hydrogen. Now, if 4 litres of carbonic acid be passed through half a litre of the water, it would therefore become charged with less than 1 per cent., even should the CO_2 cause the sulphides contained in the water to give up still more sulphuretted hydrogen. As will be seen later, this proportion of the two gases is too little to produce the results obtained in France. Yet, if there be a larger percentage of sulphuretted hydrogen in Ypsilanti water than I have supposed, there is still the objection that its *actual amount* is unknown. Finally, this water is so dear, and the outrageous advertisement of it in the *Chicago Times*, May 8, was of such a nature, as to lead to the inference that the dealers in the water are disposed to fatten off of the necessities of suffering humanity. Therefore, led by the considerations just stated, I have ventured to place before the readers of THE JOURNAL the suggestions offered in the French article mentioned above.

1. The gas-reservoir should be emptied of all air before being filled with carbonic acid. 2. The CO_2 should be generated by the action of a vegetable acid, preferably tartaric acid, upon sodium bicarbonate, in proportion of 16 grammes of the former to 20 of the latter. 3. The quantity of gas injected at a time should not exceed 4 litres, in some cases only 1 litre, according to the requirements of the patient. 4. An artificial solution of sulphuretted hydrogen is fully as good as, if not superior to a natural sulphur water. 5. This water should consist of a solution of sodium sulphide of such strength as will furnish a definite quantity of hydrosulphuric acid. 6. The rectal nozzle should not be introduced until the medicated gas has begun to flow out of its extremity, thus precluding the entrance of atmospheric air.

Tartaric acid is preferred to a mineral acid on the ground that the latter generates vapors which may render the CO_2 irritating to sensitive, ulcerated bowels. Personally, I have found my CO_2 would make my nostrils sting even after it had been passed through the mineral water. Hence, although tartaric acid is dear, I shall advocate its use. A sufficient quantity to charge the gas bag for a single treatment would cost about five cents.

Eau Challes is stated to be the strongest sulphur water in France, containing an amount of sulphides capable of evolving in the presence of tartaric acid 150 cc. of sulphuretted hydrogen to the litre of water. In order, therefore, to produce an artificial water of equal strength, the two following solutions are used at Cochin Hospital, Paris: No. 1, of pure sulphide of sodium, 10 grammes; of distilled water, 100 cc. Solution No. 2, of tartaric acid, 25 grammes; salicylic acid, 1 gramme; distilled water, 100 cc. The sodium sulphide must be *pure* and *fresh*. The salicylic acid does not all dissolve, but is added to prevent the development of fungi. When 1 cc. of the second solution is added to 1 cc. of the first, exactly 10 cc. of pure sulphuretted hydrogen are generated. Therefore, if 15 cc. of each solution are poured into a litre of plain water, 150 cc. of hydro-sulphuric acid are set free, and an artificial sulphur water of equivalent strength to Eau Challes is produced. Now, elsewhere in the article referred to, it is stated that 250 cc. of the sulphur water are put into the wash-bottle through which the CO_2 is to pass. This amount, one-fourth of a litre of water containing 150 cc. of free sulphuretted hydrogen, would yield to 4 litres of CO_2 sent through it, one-fourth of 150 cc., or about 40 cc. of the medicament; and this is 1 per cent.

The question may here be asked: Does the carbonic acid absorb all of the free sulphuretted hydrogen in the water? But, whether it does or not, this appears to be the proportion of free hydrosulphuric acid held in the water employed at the Cochin Hospital. In order to obtain the required amount, then, for a single treatment, one should proceed as follows: After having filled the gas bag with 4 litres of CO_2, pour into the wash-bottle 250 cc. of warm water, and then add separately 4 cc. of each of the solutions given above. You will then pass 4,000 cc. of carbonic acid through water holding in solution 40 cc. of sulphuretted hydrogen, which is 1 per cent. of the latter.

Here, then, is something approaching accuracy; and if these directions, as furnished by *Les Nouveau Remèdes*. are followed, it is to be hoped we shall soon have more satisfactory results to report in this country. As yet I have not had time to report the effect of treatment carried out according to these suggestions. In closing let me thank H. C. Wood's con-

tribution to the *Therapeutic Gazette* for having put me on the track of the article in the French journal, although it would seem that I have drawn widely different conclusions from its statements than those given by him. In another letter I may describe a simple apparatus by which the quantity of carbonic acid injected may be accurately measured. Very respectfully, Robert H. Babcock, M.D.

70 Monroe St., Chicago, May 14, 1887.

BOOK REVIEWS.

The Science and Art of Obstetrics. By Theophilus Parvin, M.D., LL.D., Professor of Obstetrics and Diseases of Women and Children in Jefferson Medical College, Philadelphia, and one of the Obstetricians to the Philadelphia Hospital. Octavo, pp. xv, 701. With illustrations. Philadelphia: Lea Brothers & Co., 1886. Chicago: A. C. McClurg & Co.

Few books issued from the American press during the year, have been awaited with the same degree of expectancy as "Parvin's Obstetrics"—a fact not at all remarkable, in view of the author's well earned reputation and great influence as practitioner, teacher, and writer. Then, too, the subject is one of intense interest to every member of the profession. Accordingly, we turn over the pages with unusual attention, and venture with diffidence to express a brief opinion as to the value of a master's work.

"The first necessity of a book," says Edward E. Hale, "is that it shall be entertaining. If, therefore, the book do not interest me, I consider that I have, *prima facie*, a right to put it on one side, before it puts me to sleep." Parvin's book is entertaining. No one can go to sleep over it. From introduction to end it chains attention. In the choice of words, their number and arrangement, the acute student of verbal criticism is at once apparent. Clearness, force and elegance are the essential qualities of his style. Passages of unusual beauty are constantly recurring, *vide* "Diagnosis of Pregnancy," p. 178; "Management of Pregnancy." p. 210; "Lactation," p. 539; "Induction of Abortion," p. 601; "Embryotomy," p. 650. Traces of a refined and delicate sense of humor pervade the book, but the dignity of the subject is never lowered by coarse or unseemly jests. It is not a little annoying, however, to note numerous and important typographical errors in a piece of literary work of such a high order. Ben Jonson wrote *Bartholomew Fair*, not "Vanity Fair," *vide* p. 156. Then, Littlewit's[1] words were, "O yes, Win: you may long to see, as well as to taste, Win: how did the pothecary's wife, Win, that longed to see the anatomy, Win? or the lady, Win, that desired to spit in the great lawyer's mouth, after an eloquent pleading?" The elevated tone of discourse becomes at times a trifle more ecclesiastical than is consonant with the canons of good taste or the requirements of a scientific treatise. Grammatical lapses, although infrequent, do occur. "Case where," instead of "Case in which," disfigures the appearance of many an otherwise fair sentence, pp. 178, 441. On page 284, the author states that hydramnios, or hydramnion, is an incorrect term, polyhydramnios being preferable. He persists, however, in the use of the alleged incorrect term, pp. 284, 384.

Let us pass on to the matter of the book. Parvin has attempted "to present the most recent information relating to obstetrics, at the same time not overlooking important truths established by past experience"—truly a difficult task, never, up to the present time, adequately performed by any American or English writer. In the execution of this object, he has drawn too exclusively from French literature, while he has neglected, to an utterly inexcusable degree, the teachings of the Germans in general, and of the Vienna School, in particular. The Vienna School is very generally and very justly regarded as a sort of ultimate court of appeal, in all matters pertaining to the science and art of midwifery, and its teachings are in a high sense mandatory.

This defect constitutes an essential weakness that cannot be remedied, the severest criticism that can be passed upon the book. It may be said in palliation of this fault, that most Americans are familiar with German modes of thought, while they are comparatively ignorant of French notions. In the utilization of the work of other men Parvin thoroughly maintains his own individuality. He never sinks to plagiarism,—by no means a negative virtue. His book can never be mistaken for a translation of Spiegelberg's magnificent classic. The results of his own observation and experience are recorded with becoming modesty.

Let us examine the book in detail. Parvin still insists that the sacro-iliac and pubic articulation are symphyses, and not true joints (p. 25), the results of the investigations of Luschka, Strauss, Müller, Budin, to the contrary notwithstanding. The important subject of velamental insertion of the cord (pp. 131, 132) is disposed of in twenty-seven words—conveying an erroneous notion of the condition—and is illustrated by a cut of a "battledore" placenta! He does not mention the important function of the mammary gland, *in utero*, in the production of the *vernix caseosa*.—an activity that explains in part the "painful swelling of the breasts" with the secretion of colostrum in the new-born, male and female (pp. 88, 545). The chapter on the behaviour of the *cervix uteri* during pregnancy and labor—a subject of great theoretical and practical interest—is totally inadequate. Hegar's so-called new sign of pregnancy is worthy of more distinct recognition than the scant inaccurate allusion on page 184. Rasch's[2] sign of uterine fluctuation, detectible through the anterior uterine wall as early as the eighth week, is not mentioned. Mediate auscultation (p. 189) with a stethoscope "not less than six inches, about fifteen centimetres, long," is urged for the reason, among others, that "the direct application of the ear to the abdomen is indelicate!" A remark not unlike that of the Philadelphia lecturer, who said that the man

[1] William Gifford: The Works of Ben Jonson. London, 1870, p. 325.

[2] British Medical Journal, Vol. ii, 1873.

was lacking in fine feeling, who would practice immediate auscultation, and take advantage of a poor woman, when the cry of shame was hidden by the cry of pain. Mediate auscultation, unless the bell of the instrument be very large, is practically useless in the recognition of the sounds of the fœtal heart, as a very limited experience will convince the most casual observer.

On the treatment of *placenta prævia*, Parvin remarks: "If loss of blood be slight, and especially if the fœtus be not yet viable, the expectant plan is indicated" (p. 319). Experience teaches that there is no expectant treatment of placenta prævia, and that the evacuation of the uterine contents is urgently indicated as soon as the condition is discovered. As a matter of fact, however, unavoidable hæmorrhage seldom occurs before the latter part of the second half of pregnancy, and the induction of premature labor—not of abortion—comes up for consideration. The cotton tampon, as a means of checking hæmorrhage until the os is sufficiently dilated to admit of version or the forceps, is discussed at length, but no allusion is made to the far simpler, safer, and more effective method of colpeurysis, proposed and practiced by Carl Braun. Then in the employment of the cotton tampon, there is no necessity for stuffing the vagina to its maximum capacity, as illustrated in the cut on page 322. The Vienna method of perineal protection—effective in the large majority of cases—is inadequately described on page 411. The balloon catheter of Gustav Braun and Hüter is not mentioned in the paragraph on "Insufflation through a Tube passed into the Larynx" (p. 420). The prophylaxis of puerperal fever is disposed of with a single page (593) of vague generalizations, a subject. in the light of the discovery of Semmelweis, that justifies, demands the use of dogmatic aphorisms.

The weakest part of the book is the chapter on "Obstetric Operations" (p. 601). Wright's method of version is not at all identical with Braxton Hicks' method, as intimated on page 607. We look in vain for a discussion of the "conditions" and "indications" for version—an unpardonable omission. The weight of professional opinion is so opposed to the application of the forceps to the pelvis, that the description of the mode of application, on page 646, is unnecessary. Cephalotripsis is practically an obsolete operation, yet it is fully described and well illustrated. Cuts of old-fashioned instruments mar the pages devoted to craniotomy. Levret's murderous perforator and Meigs' craniotomy forceps seem in the mind of the author to be adequate substitutes for Carl Braun's curved trepan and cranioclast! The Smellie-Veit method of "extraction" and "manual aid" in pelvic presentations is not mentioned. In speaking of "Decollation or Decapitation" (p. 659), Parvin says: "This operation can be very quickly done by means of a piece of strong twine, which is thrown around the neck, then used as a saw, to-and-fro movements given it, burying it deeper in the cervical tissues, until finally the section is completed." This sentence really requires no comment. It is utterly absurd. It presents *prima facie* evidence that the writer himself has never performed the operation, nor seen it performed by others. It would also seem to indicate that he had read very little on this topic,—aside from Playfair's Treatise, Fifth Edition, 1884, vol, ii, p. 224. It is unnecessary to add that decapitation is justly regarded by authorities on operative obstetrics as the most difficult, and one of the most dangerous procedures, in this special department of surgery. These are only a few of the sins of omission and commission, but they are sufficiently grave in nature to imperatively demand that the chapter be re-written.

Viewed as a whole, we regard "Parvin's Obstetrics" as the best exposition of the subject, issued from the American press, up to the present time; and we know of no book, equal to it in all respects, that has emanated from an English source. It must be admitted, however, that the work is very faulty. The author has not given us that which his distinguished ability entitled us to expect. W. W. J.

ASSOCIATION ITEMS.

AMERICAN MEDICAL ASSOCIATION.

The Thirty-eighth Annual Session will be held in Chicago, Ill., commencing on Tuesday, June 7, at 11 A.M., in Central Music Hall, corner of State and Randolph streets, and will continue four days. Good rooms for the several Sections will be provided as near the hall for general meetings as possible. Registration books will be open in Central Music Hall on Monday, the day preceding the meeting, for those who wish to register early.

In addition to the list of papers already published, the following are promised:

Section of Diseases of Children.

C. E. Briggs, M.D., St. Louis, Mo., "On Spasm of the Larynx and Œsophagus."

L. Duncan Bulkley, M.D., New York, "On Infantile Feeding, Especially with Reference to Subjects with Infantile Eczema."

Section on Practice of Medicine, Materia Medica and Physiology.

L. Duncan Bulkley, M.D., New York, "On the Treatment of Felon Without Incision."

Byron H. Daggett, M.D., Buffalo, N. Y., "On a Convenient and Practical Method of Administering Bergeon's Treatment."

Section on Obstetrics and Diseases of Women.

Henry O. Marcy, M.D., Boston, Mass., "Cystitis in the Female."

W. H. Wathen, M.D., Louisville, Ky., "Rupture of the Uterus."

Section on Surgery and Anatomy.

Alex. Y. P. Garnett, M.D., Washington, D. C., on "The Surgical Treatment of Suppurative Pleuritis in Children."

Robert Newman, M.D., New York, "Synopsis of the Second Hundred Cases of Stricture of the Urethra Treated by Electrolysis."

E. A. Wood, M.D., Pittsburgh, Pa., "A Deformity and Disability following a Form of Injury to the Ankle Joint."

J. McFarland Gaston, M.D., Atlanta, Ga., "On the Pathology, Diagnosis and Treatment of Perforation of the Appendix Vermiformis."

Joseph Jones, M.D., New Orleans, La., "A New Method of Testing the Relative Value of Certain Antiseptics, Disinfectants and Germicides Employed Internally and Externally in the treatment of Wounds and Syphilis."

S. T. Armstrong, M.D., Memphis, Tenn., "Trephining in a Case of Intermingeal Hæmaturia with Hemiplegia."

A. H. Wilson, M.D., Boston, Mass., "The Prostate Gland; a Review of its Anatomy, Pathology and Treatment."

Section on Ophthalmology, Otology and Laryngology.

J. J. Chisolm, M.D., Baltimore, Md., "The Results of a Year's Experience in the Abandonment of Eye Bandage."

Wm. Porter, M.D., St. Louis, Mo., subject not announced.

W. F. Montgomery, M.D., Chicago, Ill., "After-Treatment of Cataract Extraction."

Geo. E. Frothingham, M.D., Ann Arbor, Mich., "A Case of Epilepsy Apparently Cured by Correcting Hypermetropia." "Two Cases of Tumor of the Optic Nerve."

Section on Medical Jurisprudence.

Wm. C. Wile, M.D., Philadelphia, Pa., "On Expert Testimony."

FACTS REGARDING RAILROAD RATES.

[The following letter sufficiently explains itself, which we cheerfully publish, as under.—ED.]

TO THE EDITOR:

My Dear Sir:—Kindly afford space in this week's issue of THE JOURNAL, and until June 4, please, by publishing the subjoined valuable information, as to those who anticipate attending the coming meeting of the American Medical Association, it will be of much practical interest—as well also, that it will be a REPLY in full to inquiries of many physicians, whose valued favors have unavoidably remained unanswered, simply because a number of our good friends have written substantially in the same manner from various parts of the country, desiring information regarding railroad rates, etc. And by your publishing a statement of the facts herein contained, it will be accepted by the Committee on Transportation as a favor personally to each of its members, and at the same time it will also be an answer to the many questions thus far received by this Committee, and which we have not had the time to respond to individually, as well as a reply to those who contemplate writing to the Committee upon the points enumerated above, and greatly oblige, Yours truly,

LISTON H. MONTGOMERY, M.D.,
Chairman Com. on Transportation.

189 Randolph St., Chicago, May 18, 1887.

Upon all railroads within territory bounded as follows:

On the East, by the western termini of the Trunk Lines, which termini are: Toronto, Canada; Suspension Bridge, Niagara Falls, Tonawanda, Black Rock, Buffalo, East Buffalo, Buffalo Junction, Dunkirk, and Salamanca, N. Y.; Pittsburgh and Allegheny, Pa.; Bellaire, Ohio; Wheeling and Parkersburg, W. Va.; and Ashland, Ky.

On the North, by the line of the Grand Trunk Railway from Toronto to Port Huron, including the points thereon, thence via the Great Lakes to Chicago.

On the West, via the west line of Cook Co. Ill. (the county in which Chicago is located) to, and via the Illinois and Mississippi Rivers to Cairo, including St. Louis, and all other points on said lines and rivers, the extensions of the Wabash, and Toledo, Peoria & Western Railways westward from said boundary—as well as *on the South* by the Ohio River.

Delegates, members, and their families are instructed that at time they purchase their tickets going to Chicago, the Agent will furnish you with a certificate or receipt at time of said purchase, stating that you have paid full fare to place of meeting. This certificate or receipt is positively necessary for you to get from the ticket agent, which will afterwards require to be endorsed by the Chairman of the Committee on Transportation at Chicago, stating that you have been in attendance at the meeting. This will enable you to get your ticket for the return journey at *One-Third the Lowest Regular Limited Fare.*

In case there is no limited fare to the point desired, one-third of the regular unlimited fare will be used.

Tickets for return journey are limited to continuous passage, and should be used on first train after they are purchased, although the certificates will be good *three days* after the Association adjourns. And no certificate or receipt will be honored at Chicago which was procured from agent at starting-point more than *three* days prior to date of meeting. Thus it will be seen the certificates are good until used within the above described territory, ten days, and include all those lines that have not already been published in former issues of THE JOURNAL.

For delegates, members and their families who reside at points in Trunk Line territory (study the list of roads embraced therein) blank certificates will be furnished you by the Chairman of the Committee on Transportation at Chicago, if in good time you requisition me for the necessary number. This can be done on, and after May 24. These blank certificates will be furnished parties from points east of Niagara Falls, Buffalo, Salamanca, Pittsburgh, Petersburg or Wheeling, which will be certified to by the agent at starting-point, stating that you have paid full fare through to Chicago. It is absolutely imperative that certificates for this territory be in the hands of parties at the time of purchasing their "going" tickets, to get the ticket agent's receipt, and will require to be endorsed by the Chairman of the Transportation Committee at the meeting, to enable the holders to get the concession returning, which will be *one-third the lowest regular limited fare.* These certificates are also good three days after the Association adjourns, or ten days altogether.

Regarding the Western Roads, specific knowledge cannot at this time be given as to the plan each of them will pursue. Ticket Agents for the Chicago, Milwaukee & St. Paul Railway will give each person a receipt who has purchased a ticket, stating that full fare has been paid to Chicago. This receipt will be endorsed as described above, thus entitling the holder to return at *one-third the lowest limited fare*, and applies to all parties in attendance at the meeting; in all cases, however, the return rate will be made one-third the regular fare. The Chicago & Alton simply requires for its protection, a certificate as per form prepared by the "Committee." having this matter in charge, properly endorsed at Chicago, to secure the reduced fare of one-third the regular rate, etc., for each person in attendance.

The Illinois Central will also honor tickets in the same manner as will the Chicago & Alton when vouched for in the same manner.

The Chicago, Burlington & Quincy has adopted the same plan as that of the C. M. & St. P. Road.

The Chicago & Northwestern will pursue a similar plan, that of giving to each purchaser a receipt for the amount of full fare, going, as will, doubtless, most of the other lines within the territory leading west, southwest and northwest from Chicago, as far at least as the Mississippi and Missouri rivers. Tickets over the lines west of Chicago will not be honored after June 12. Negotiations are not yet completed, but from present knowledge, the indications are, that the following roads will also give the reduced rate, amounting to a fare and one-third, for the round trip to delegates and their families:

Union Pacific.
Burlington & Missouri River.
Atchison, Topeka & Santa Fé.
Denver & Rio Grande.
Gulf, Colorado & Santa Fé.
Houston & Texas Central.
Texas & Pacific.
Missouri Pacific.
Southern Pacific.

St. Louis, Arkansas & Texas.
St. Louis & San Francisco.
Iron Mountain.
Atlantic & Pacific.
Northern Pacific.
St. Paul, Minneapolis & Manitoba.
St. Paul & Duluth.
As well, too, as the following Steamboat Lines:
Goodrich.
Lake Michigan and Lake Superior.

In all cases, except where stipulated otherwise above, it is advisable that you get from the Ticket Agent at the time you procure your tickets to Chicago, a receipt from Agent, stating that you have paid full fare going, and which must invariably be shown the Chairman of Transportation Committee at place of meeting.

Upon the forty-two Southern Roads enumerated (see list), you are required to procure a certificate, similar to that required of parties who live in territory occupied by the Trunk Lines, viz., by sending to the Chairman of Transportation Committee, at Chicago, for the necessary number, etc., which you can procure on and after May 24.

Certificates are good to return on these Southern Lines only, twenty-four hours after adjournment, *i.e.*, good until June 11. And in every instance upon all the roads named, you are required to return the same route as upon going.

It seems as though the above information embraces every possible inquiry that can be propounded, and we trust a largely representative meeting will be held, in which we are joined by the hearty wish and co-operation of the entire profession of Chicago. Further particulars may be obtained by addressing

DR. LISTON H. MONTGOMERY,
Chairman of Committee of Transportation.
Briggs House, No. 189 Randolph St., Chicago.

The roads which will accept return tickets on the certificate plan are:

Baltimore & Ohio (west of the Ohio River).
Buffalo, New York and Philadelphia.
Chicago & Grand Trunk.
Cincinnati, New Orleans & Texas Pacific.
Chicago, Vincennes & Cairo Line.
Chicago & West Michigan.
Chicago, St. Louis & Pittsburgh.
Cincinnati, Hamilton & Dayton.
Cincinnati, Indianapolis, St. Louis & Chicago.
Cincinnati, Washington & Baltimore.
Cleveland, Akron & Columbus.
Cleveland & Marietta.
Cleveland & Pittsburgh.
Cleveland, Columbus, Cincinnati & Indianapolis.
Cleveland, Loram & Wheeling.
Columbus & Cincinnati Midland.
Columbus, Hocking Valley & Toledo.
Chesapeake & Ohio.
Chicago & Atlantic.
Dayton & Ironton.
Detroit, Lansing & Northern.
Dayton & Union.
Detroit, Grand Haven & Milwaukee.
Evansville & Terre Haute.
Flint & Pere Marquette.
Fort Wayne, Cincinnati & Louisville.
Grand Rapids & Indiana.
Grand Trunk.
Indianapolis & St. Louis.
Indianapolis & Vincennes.
Indianapolis, Bloomington & Western.
Indianapolis, Decatur & Springfield.
Jeffersonville, Madison & Indianapolis.
Kanawa & Ohio.
Lake Erie & Western.
Lake Shore & Michigan Southern.
Lousiville & Nashville.
Louisville, Evansville & St. Louis.
Louisville, New Albany & Chicago.
Michigan Central.
Michigan & Ohio.
New York, Chicago & St. Louis.
New York, Pennsylvania & Ohio.
Niagara Falls Short Line.
Ohio & Mississippi.
Pennsylvania.
Peoria, Decatur & Evansville.
Pittsburgh & Lake Erie.
Pittsburgh & Western.
Pittsburgh, Cincinnati & St. Louis.
Saginaw Valley & St. Louis.
Scioto Valley.
Toledo & Ohio Central.
Toledo, Peoria & Western.
Valley Railway.
Vandalia Line.
Wabash Railway.
Wheeling & Lake Erie.
Baltimore & Ohio (east of Parkersburg, Bellaire & Wheeling.)
Baltimore & Potomac.
Bennington & Rutland.
Boston & Albany (on business between common points in New England and points west of, but not including Albany.)
Boston & Lowell.
Boston, Hoosac Tunnel & Western.
Buffalo, Rochester & Pittsburgh.
Camden & Atlantic.
Central Vermont.
Delaware & Hudson Canal Co.
Delaware, Lackawanna & Western.
Fitchburg.
Lehigh Valley.
New York Central & Hudson River.
New York, Lake Erie & Western.
New York, Ontario & Western.
Norfolk & Western.
Northern Central.
Philadelphia & Erie.
Philadelphia & Reading.
Philadelphia, Wilmington & Baltimore.
Rome, Watertown & Ogdensburg.
Shenandoah Valley.
Troy & Boston.
West Jersey.
West Shore.

The following named lines offer one and one-third fare for round trip:

Burlington, Cedar Rapids & Northern Railway.
Central Iowa Railway.
Chicago & Alton Railroad.
Chicago & Northwestern Railway.
Chicago, Burlington & Northern Railway.
Chicago, Burlington & Quincy Railroad.
Chicago, Milwaukee & St. Paul Railway.
Chicago, Rock Island & Pacific Railway.
Chicago, St. Paul, Minneapolis & Omaha Railway.
Green Bay, Winona & St. Paul Railroad.
Hannibal & St. Joseph Railroad.
Illinois Central Railroad.
Kansas City, St. Joseph & Council Bluffs Railroad.
Milwaukee & Northern Railroad.
Milwaukee, Lake Shore & Western Railway.
Minneapolis & St. Louis Railway.
Minnesota & Northwestern Railroad.
Missouri Pacific Railway.
Rock Island & Peoria Railway.
Sioux City & Pacific Railroad.
Wabash Western Railway.
Wisconsin Central Lines.

A list of forty-two Southern roads which will accept return tickets issued under the certificate plan.

Alabama Great Southern Railroad.
Atlanta & West Point.
Brunswick & Western,
Central Railroad of Georgia.
Central Railroad of South Carolina.
Charleston & Savannah.
Cheraw & Darlington.
Cheraw & Salisbury.
Cincinnati, New Orleans & Texas Pacific.
East Tennessee, Virginia & Georgia.
Georgia.

Georgia Pacific.
Illinois Central (south of Ohio River).
Jacksonville, Tampa & Key West.
Louisville & Nashville (south of Ohio River).
Louisville, New Orleans & Texas.
Memphis & Charleston.
Mississippi & Tennessee.
Mobile & Ohio (south of Ohio River)
Nashville, Chattanooga & St. Louis.
New Orleans & North-Eastern.
Norfolk & Western.
North-Eastern Railroad of Georgia.
North-Eastern (of South Carolina).
Pennsylvania (south of Washington).
Petersburg.
Port Royal & Augusta.
Raleigh & Gaston.
Richmond & Alleghany.
Richmond & Danville, and leased lines.
Richmond, Fredricksburg & Potomac.
Richmond & Petersburg.
Rome.
Savannah, Florida & Western.
Seaboard & Roanoke.
Shenandoah Valley (south of Potomac River.)
South Carolina.
Vicksburg & Meridian.
Western & Atlantic.
Western Railway of Alabama.
Wilmington, Columbia & Augusta.
Wilmington & Weldon.

MISCELLANEOUS.

THE AMERICAN LARYNGOLOGICAL ASSOCIATION will hold its ninth annual session in the Hall of the New York Academy of Medicine on May 26, 27 and 28, under the Presidency of Dr. E. Fletcher Ingals, of Chicago.

DR. SELIM PACHA.—From the *British Medical Journal* we learn that the Khedive has nominated Dr. Selim Pacha to represent Egyptian Medicine in the approaching International Medical Congress.

DR. ROBERT BARNES, of London, has been elected an Honorary Fellow of the Chicago Gynæcological Society.

THE ASSOCIATION OF MEDICAL EDITORS will meet at the Palmer House, Chicago, at 8 P.M., on the Monday evening preceding the meeting of the American Medical Association. The President, Dr. Shoemaker, will deliver an address on "Some of the Present Abuses of Medical Literature." This organization is permanent, and largely social, and it is desired that medical editors who can attend the meeting will do so. Those who expect to be present should send their names as soon as possible to Dr. Wm. Porter, 3137 Lucas Ave., St. Louis. Dr. J. L. Gray, 70 Monroe St., Chicago, is Chairman of the Committee of Arrangements.

KENTUCKY STATE MEDICAL SOCIETY.—The next annual meeting of this Society will be held in Paducah, on the 15th, 16th and 17th of June, 1887. Dr. W. N. Wathen, of Louisville, is President, and Dr. Steele Bailey, of Stanford, Secretary. A full attendance is expected.

THE CONGRESS AND TRANS-ATLANTIC STEAMSHIP FARES.—The London *Lancet*, of May 7, 1887, says: "We understand that Messrs. Henderson Bros., managing owners of the Anchor Line of Steamships, from Glasgow to New York, have decided to offer to members of the medical profession desirous of attending the International Medical Congress to assemble at Washington, in September next, return tickets to New York for £20, giving the best accommodation at this low rate."

ENGLISH SOCIETY FOR THE STUDY AND CURE OF INEBRIETY.—The Council of this Society have called an International Congress, to be held in Westminster Hall, London, July 5 and 6, 1887, for the purpose of discussing the problems of inebriety medically. Papers have been promised from a number of eminent men in different countries, and the meeting will doubtless be a profitable and interesting one, under the Presidency of Norman Kerr, M.D., F.L.S., London. T. D. Crothers, M.D., of Hartford, Conn., is the American member of the Committee of Arrangements.

NEW YORK STATE MEDICAL ASSOCIATION.—The Fifth District Branch will hold its third annual meeting in Brooklyn, at Remsen Hall, 190 Remsen St., on Tuesday, May 24, 1887. An interesting meeting is expected.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 7, 1887, TO MAY 13, 1887

Lieut.-Col. C. T. Alexander, Surgeon, granted leave of absence for four months, with permission to go beyond sea, to take effect May 23, 1887.

Capt. P. F. Harvey, Asst. Surgeon, granted leave of absence for four months, with permission to go beyond sea, to take effect June 10, 1887. S. O. 105, A. G. O., May 7, 1887.

Capt. Victor Biart, Asst. Surgeon, ordered for examination by Army Retiring Board at Ft. Leavenworth, Kans. S. O. 107, A. G. O., May 10, 1887.

Capt. F. W. Ellery, Asst. Surgeon, ordered for examination by Army Retiring Board at Washington, D. C. S. O. 109, A. G. O., May 12, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING MAY 14, 1887.

Gravatt, C. N., Surgeon, detached from the U. S. Str. "Michigan."

Lumsden, G. P., P. A. Surgeon, ordered to the U. S. Str. "Michigan,"

Ashbridge, Richard, P. A. Surgeon, detached from the Naval Academy, and to the practice ship "Constellation."

Streets, Thos. H., P. A. Surgeon, promoted to Surgeon.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE WEEK ENDED MAY 14, 1887.

Fessenden, C. S. D., Surgeon, detailed as chairman of Board for physical examination of cadets, Revenue Marine Service. May 13, 1887.

Stoner, G. W., Surgeon, to proceed to Delaware Breakwater as inspector, and to New York and Philadelphia to inspect unserviceable property. May 12, 1887.

Irwin, Fairfax, P. A. Surgeon, detailed as recorder of Board for physical examination of cadets, Revenue Marine Service. May 13, 1887.

Fattic, J. B., Asst. Surgeon, relieved from duty at Baltimore, Md.; ordered to Marine Hospital, St. Louis, Mo. May 13, 1887.

THE CURE OF HERNIA.

Read in the Section on Surgery at the Thirty-seventh Annual Meeting of the American Medical Association, May, 1886.

BY HENRY O. MARCY, A.M., M.D.,

OF BOSTON, MASS.

Temerity born of ignorance would seem the only judgment to be passed upon one who would offer any further contribution upon the cure of hernia. The eighty closely printed quarto pages of the "Index Catalogue" of our National Library, giving only titles and authors, would presuppose an exhausted subject. Notwithstanding, from the Fathers to the present, the cure of hernia has remained in large degree an unsolved surgical problem, and the sale of supports and trusses increases with each decade. This paper is of narrow limit and has but the one definite object—that of teaching a single method of cure which the writer would commend in operative cases; yet, the importance of the subject demands brief notice.

Although hernia in all classes and ages, from infancy to old age, is a matter of daily observation by our profession, the statistics of Dr. J. H. Baxter, giving 5 per cent. of the total population as subject to such a disabling and dangerous affection, will surprise most who are not special students of the subject. This gives nearly three millions of people, of all ages and conditions, in the United States alone, who are sufferers in a greater or less degree from this affection. One English firm manufactures over 50,000 trusses a year, chiefly for home supply. As quoted by Mr. Spanton in 1881, as referable to Great Britain, "the mean annual rate of mortality for the year 1879 was 45 deaths to every 1,000,000 living; and to make the significance of this more manifest, I may point out that while calculus killed 237 persons in the year 1879, and all malformations (except spina bifida) put together, 219; gout 662; and all uterine diseases only 1,068, hernia caused the death of 1,119 in the same period." Table II shows that out of 1,870 cases of operation, in hospitals, etc., for strangulation, there occurred 782 deaths, giving 41.80 per cent. of mortality. This has been greatly lessened by modern methods of wound treatment, but the injury to the intestine by the constriction still remains a danger to the patient, often far exceeding those incident to operative measures. We can do no less than second with all earnestness the plea so ably set forth by Mr. Spanton in England and Dr. Joseph Warren in America, to effect by operative measures a cure in a large class of these sufferers, especially in the young, rather than condemn them to lifelong discomfort from support and a perpetual risk of disability and death. The revolution in abdominal surgery, during the last decade, renders less imperative the need of enforcement, by argument, of proper antiseptic precautions by which peritoneal wounds are rendered almost devoid of danger; rules enforced in my earlier writings upon hernia, as a duty of religious exactitude; now, however, like the church dogmas, accepted in theory, but obeyed with a laxity which brings discredit upon the faith.

The etiology and causation of hernia cannot even be referred to here; but the fact that about one-eighth of the entire number occurs in childhood, renders it probable that a congenital lack of proper development is a fundamental factor in its production.

My first operation for hernia which involved the essential principles now advocated was done seventeen years ago. The year previous, I had returned from Edinburgh, a convert to the teachings of Prof. Lister. The omentum with a loop of the intestine was incarcerated, stercoraceous vomiting had ensued, and the patient was *in extremis*. The hernia was old, the ring large, the pillars weak; and the patient, advanced in years, had a very troublesome bronchial cough. The operation was antiseptic in method, and, owing to the cough, the deep pillars of the ring were stitched together with large catgut sutures and the wound closed, to prevent a prolapse of abdominal contents, rather than with any thought of cure. The cough continued severe until the patient's death, six years later, but there was no return of the hernia.

I first published an article on hernia in 1871, advocating this method, with a report of this and one or two other cases. In 1878, I reprinted from a communication offered to the Association, a paper giving a considerable series of cases and a study of the histological metamorphosis which tendinous structures undergo when incorporated into the tissues. These observations were made upon two cases of the human subject in which I had operated some months previous and death had supervened from acute disease; also a series of studies upon rabbits and puppies. In 1881 I communicated to the International Congress in London further observations upon the same subject, with a list of cases, and emphasized the removal of the peritoneal pouch as important in preventing return of the affection.

There can be no doubt but that many cases which are reported cured by any of the various methods of operation, in the end prove failures; since a very considerable period must elapse before one can be at all sure of results. This should cause hesitation in tabulating cases until they have continued for a considerable period under observation. Only recently have I seen a case of double hernia, where I witnessed a very skilful operation by injection, and examined the patient with great care one year after without detection of a weakening ring; but now, four years having elapsed, the hernia has returned, and the patient must again resort to a truss. I am led to believe that, in a very considerable class of cases reported cured, especially in the blind operations of subcutaneous sewing and injection methods, the hernia returns, because the deeper tendinous structures remain unclosed and the peritoneal sac unobliterated. Since the days of Morgagni, it has been repeatedly claimed that hernia was often produced by the elongation of the mesentery and a consequent prolapse of the intestines. This error is repeated even in our best text-books: as, for example, Bryant. The frequency with which the small intestines are found, at autopsies and in abdominal operations, in the pelvic cavity, would refute this supposition.

Mr. Treves' observations[1] are of much interest in their bearing upon this subject. He found the mesentery of the jejunum on the left side longer and looser at a point from six to ten feet from the duodenum. Here the mesentery attains a length of from nine to ten inches. In the right iliac fossa, at the lower part, the mesentery attains only about one-half this length. In one case out of the hundred examined, Mr. Treves found the intestines, in a woman of 70, could be drawn down eight inches below the crest of the ileum, and yet there was no hernia. If it is true that, in a majority of cases, the small intestines find easy lodgment as low as in the pelvic basin, the bearing of these considerations upon the cure of hernia becomes apparent. The pinching of the peritoneum over a weakened ring gives an effective lodgment of abdominal contents. The elongated omentum is continually slipping into the depression and acts as a wedge, driving the supporting walls apart, and often cases occur where it is wiser to remove an elongated, thickened mass rather than to replace and leave it to act as a future source of trouble. In a number of cases, I have removed considerable portions of omentum, for this reason, without bad result.

Interesting as is the anatomy of hernia, we can only refer to the inguinal canal, as a passage from the deep to the superficial ring, one and one-half to two inches in length, doubly oblique in direction, and closed in a valvular way, by close apposition and by connective tissue attachment of its walls. In congenital cases, the tunnel-like projection of the peritoneum of pre-natal formation has not been obliterated, and the walls of the canal have become stretched and torn, until the valvular action of the canal is lost. Cure is effected by obliterating the peritoneal folds and closing from the very bottom the walls of the canal. In most instances, the sudden production of hernia is only the final yielding to forces which have been of indefinite duration. I have operated upon every variety of hernia, and with considerable modification of detail. The usual method is simple and is outlined as follows: A careful shaving and cleansing of the external parts, using carbolic acid or mercuric bichloride solution. Soap containg ½ of 1 per cent. mercuric bichloride is very convenient. Each step of the operation is taken with strict antiseptic detail, usually under irrigation. If the abdominal cavity is opened spray is used. In inguinal hernia, in no instance have I made the incision in the scrotum as advocated by Mr. Wood, and it is usually parallel with Poupart's ligament and a little, perhaps half an inch, higher on the abdominal wall than the opening through the ring. The elasticity of the tissues allows of easy manipulation of the parts, and brings the external wound a little way from the fold of the groin, which facilitates a safer dressing and causes less irritation in the subsequent wearing of a support. The incision should be free and sufficiently long to insure easy inspection and ample room. Secure, of course, any vessel which bleeds—and yet, my experience does not confirm Mr. Wood's views in his recent lectures published in the *British Medical Journal*.[2] He says: "With respect to the supposed advantages of the open method, enabling the surgeon to see the parts on which he operates, I have myself found that, after the first cut and the application of the sponge, the parts became so bleared with blood, that I was obliged to rely mainly upon the sense of touch, before I ventured to pass a needle through Poupart's ligament, the conjoined tendon, or the pillars of the ring. My experience is that this operation can be all done, and has been very frequently done by me, when the sac to be removed is not very large, through a scrotal incision two inches long reaching up to the superficial ring."

Having divided the external tissues to a sufficient extent, draw up the peritoneal pouch quite sufficient to cause its obliteration upon the inner side and sew it evenly with fine tendon sutures by the so-called shoemaker's stitch. This encloses all the peritoneum and occludes it, while it has the advantage of a double thread and only one knot. Then cut away the redundant pouch and allow the peritoneum to drop back, in order not to include it in the deep suturing of the tendinous structures. In some cases, where the ring has been very large and the pillars much attenuated, I have folded the sac upon itself and incorporated it in the deep suturing, as a reinforcement to the tissues. However, I can but regard this as a doubtful measure; usually I have felt it wise to refresh the pillars before suturing as more likely to secure a firm union. The method of Mr. MacEwen, of suturing the peritoneal pouch in such a manner that it can be introflected upon itself—pursed up, so to speak—is, to say the least, ingenious; but it appears open to the objection of making an obstructive thickening of the peritoneum, over which normally

[1] Hunterian Lectures on the Anatomy of the Intestinal Canal and Peritoneum.

[2] June, 1885.

the pelvic contents should easily glide without obstruction or lodgment. It cannot strengthen the ring, since it is returned through it. This method appears to be offered as a substitute for opening the peritoneum, and appeals to the earlier fear entertained in regard to the surgical treatment of these tissues. Sewing through the peritoneal pouch and its excision is easier, equally safe and, in my judgment, offers promise of a better result.

The proliferation and repair of the tendinous structures, under favorable circumstances, are much greater than was earlier supposed. Formerly I used catgut, but for a number of years have preferred the tendon suture. That from the tail of the kangaroo is the best, since the fibres are more parallel and do not readily fray out as those of the ox, deer, or whale. With the finger within the ring, to protect the peritoneum and guide the needle, I introduce it quite one-half inch from the outer portion of the ring, and enclose the tissues to this width deeply to the peritoneum. The stitches are repeated at distances of about one-third of an inch, including both pillars of the ring, until the opening is securely closed—in the female completely and a little within the inner border; in the male, the parts are closed so as to carefully protect and secure the cord from injury. The suturing is simple, and I first devised it for the sewing of the large pedicle of uterine myoma and in the excision of the uterus. The needle is set in a firm handle and is without a cutting point, with the eye near the end. A half to three-quarter curve is preferable. The needle, threaded, is introduced, and the end unthreaded, the opposite end is threaded and withdrawn; this is continued until the seam is complete in as many and as fine stitches as may be thought best. A little care is necessary not to overconstrict the tissues and thereby cause necrosis. I have deemed this method of sewing important, since the great objection to the animal suture is the knot, which in this way is reduced to one, no matter how many stitches are required. Moreover, thus applied, the pressure on the enclosed tissue is equalized and injury therefrom reduced to a minimum; and if it is true, as my experiments lead me to believe, that the tendon suture is replaced by a proliferation of connective tissue, this method of reinforcement is doubly important. I have also used with satisfaction the over and over suture with the Hagerdorn needle, which possesses certain advantages now well known to the profession. A twisted horsehair is generally used for drainage, and the external wound closed by a fine continuous suture. Iodoform dressing is carefully applied, but the great danger is the infection of the wound during manipulation rather than after its closure. Care to avoid over-strain should be exercised for a considerable period, A water pad truss is advised to be worn for some months, but too much pressure is injurious.

The above procedure is simple, effective, and safe; when properly done, in the great majority of cases, the cure will be permanent.

A brief review of our literature will show that the operative measures for hernia, like all other surgical procedures involving the abdomen and its contents, are being rapidly modified. The operation known by my name has had a varied experience. It was at first condemned on theoretical grounds as dangerous, unscientific, and more radical in method than the cure sought. A few surgeons tried it and gave it up, reporting to me that the catgut which they used yielded in a few days.

The first case of cure reported in Great Britain was by Mr. Charles Steele, of Bristol (*British Medical Journal*, November 7, 1874), three years after the publication of my cases. Mr. Steele stated to me in 1881 that the cure of his case remained permanent. He used catgut antiseptically. As might naturally be supposed, Mr. Lister has repeatedly operated with good result. Prof. Annandale, of Edinburgh, operates in this manner. He prefers to remove the sac when easily done. Prof. Stokes, of Dublin, returns the sac unopened, believing the excision of the sac unjustifiable because of danger. Mr. Banks and Mr. Alexander, of Liverpool, report cases and advise removal of the sac; also Prof. Buchanan and Sir William McCormac.

Prof. MacEwen, of Glasgow, reported cures in 1880 from the use of chromicized sutures; also Mr. J. Whitson, in the *Medical Times and Gazette*. Prof. Czerny published in 1883 a paper in which he advocates the closing of the ring with sutures. Dr. Porter, of Boston, reports two cases thus cured, also L. Champonnière, of Paris, and others.

Subcutaneous wire suturing is of very ancient date. It fell into disuse and was condemned as dangerous, until within the present generation. Prof. J. C. Nott published a case of cure in 1845 from the use of the lead suture. Prof. John Wood, of London, a quarter of a century ago received a prize for an essay on the cure of hernia. His method is a subcutaneous closure by wire, the originality of the method dependent upon the way of introducing the wire. The remarkable skill of the operator, together with the shape of the needle, enabled Mr. Wood to secure and occlude the canal.

In that day, when septic infection of wounds, in hospitals, was the rule rather than the exception, subcutaneous surgery, even if blind, bungling, and imperfect, was commendable. With the record which Mr. Wood presents of a majority of cures, it is no wonder that he still, in large degree, advocates his methods, and it is very creditable to his spirit of enterprise that he is willing to adopt the tendon suture, instead of wire. "Latterly," he says, "I have used a stout piece of kangaroo, deer, or ox tendon, well antisepticized in carbolized oil, and softened just before using by soaking it in 1 to 40 carbolized lotion. The advantage of this is, that there is no necessity for disturbing the wound by the removal of the buried suture, as in the case of the wire and other methods."

From this it is apparent that he recognizes only the coaptation and constriction of the ligature, and not the re-enforcement claimed by the development of surrounding connective tissue.

The late Dr. McDowell, of Texas, by an equally ingenious method, using a needle of peculiar construction, subcutaneously wired the rings together,

and reported a large percentage of cures. Shortly before his death he informed me that, in his judgment, his operation left little to be desired. Mr. Spanton, whose paper has already been referred to, has devised an ingenious modification of subcutaneous suturing, combining the needle and constricting material in the same instrument, which closely resembles a cork-screw. This is introduced so as to incorporate the rings, and is left for a period of time sufficient to secure a large exudative mass about the ring, and is then withdrawn. No serious results have followed the operation in his hands, and he reports a very large percentage of cures.

The injection methods of which Dr. Warren, of Boston, is the world-wide known advocate, aim at a somewhat similar result. A very large exudation into the surrounding tissues follows, and undoubtedly many cures have thus been obtained.

The criticism pertains, in a large degree, to all these subcutaneous methods, that they belong to blind surgery; at the best, depend upon the tactile sense which, cultivated by the long experience of a Wood or Warren, may be trustworthy; but an operation which is to become general must be based upon a few simple, well understood factors, to be safely entrusted to the general surgeon. Prof. Tilanus, of Amsterdam, reported to the International Congress of 1878 a collection of 100 cases by Continental operators, by the open method of dissection, for the cure of hernia, both under and without antiseptic precautions, with a mortality of about 11 per cent. Prof. Annandale, of Edinburgh, has more recently reported 71 cases with 4 deaths, by various operators, but all under antiseptic precautions; 66 cases are claimed as cured.

The inaugural Thesis of Victor Cuenod, published in Lausanne in 1881, gives a detailed list of the cases operated on by his master, Prof. Socin, of Basle. He tabulates 34 cases, all of which were under repeated observation during many months; 22 cases remained cured, twelve failed in from six weeks to twenty-two months. He attributes failure, in most cases, to imperfectly prepared catgut and silk; following the use of the latter were very troublesome abscesses, although the silk was carbolized. In the entire list of failures (and the cases were all improved) there was not a single death. The catgut which was chromocized, or prepared in oil of juniper, proved satisfactory. The method was the open dissection with deep suturing of the pillars of the ring, under careful aseptic care and dressing.

In thirty operative cases recovery followed without serious symptoms. I have had two deaths; one a strangulated umbilical hernia, where I removed seven inches of gangrenous small intestine and joined it with a double row of fine tendon sutures. Death ensued about seventy hours after, from exhaustion, as the most probable cause, since there was no peritonitis and the edges were agglutinated by lymph exudation, so that the closed section held water. The other was a case of strangulated crural hernia, where the autopsy showed a slough of the returned constricted intestine, with the escape of its contents. These two cases are thus fairly excluded from the list.

In conclusion, I would advise operation by the above method:

1. In all cases of operation for strangulation.
2. In all cases where the abdominal contents are imperfectly retained by an instrument, unless the age and condition of the patient prevent.
3. In that large class of children when the conditions do not warrant a spontaneous cure.

This opinion is based upon the rigid enforcement of the aseptic principles of operative wound treatment.

THE USE OF A PLUS CYLINDER IN SIMPLE MYOPIC ASTIGMATISM OF LOW DEGREE;

And the Occasional Necessity for Changing the Axis of the Cylinder for Distance to a Different Axis for Reading.

Read before the Chicago Society of Ophthalmology and Otology, February 8, 1887,

BY W. FRANKLIN COLEMAN, M.D., M.R.C.S., Eng.

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY, CHICAGO POLICLINIC.

Errors of refraction assume so many forms and are so variously treated that I could wish very much to hear the whole subject discussed. This evening I wish to give examples of two classes of cases, in one of which I have more recently adopted a method of treatment, the merits of which entitle it to more general recognition. These are cases of simple myopic astigmatism of low degree (say $\frac{1}{40}$ to $\frac{1}{12}$). Whether they be due to spasm of accommodation or not, I am inclined to think it would always be best for near vision to substitute a plus cylinder, with its axis at right angles to that of the minus cylinder found for distance.

Dr. Culbertson asserts[1] that in non-spasmodic myopic astigmatism, a plus cylinder used as just stated will, in many instances, correct the ametropia, and he proceeds to illustrate the manner in which the ciliary asthenopia is relieved by the plus glass. I will quote only one passage as a sufficient reason for not coinciding with his explanation. He says: "By this minus glass for distance, the myopia in proximal vision has been simply transferred from one to the other plane, and the foci of the two planes are not of the same length." Now if an eye is made emmetropic for remote vision (by correcting its myopic meridian or otherwise), it is certainly emmetropic for proximal vision, and the foci of all the meridians must then be of the same length; and it will require accommodation only to receive a clear image of the near objects.

The reason of the advantage of a plus cylinder does not seem to me far to seek. The total accommodation (not "the unequal contraction of the ciliary muscle") is relieved by a plus glass. For example: Let us suppose an eye with a myopic astigmatism in the vertical meridian of 2.D (or $\frac{1}{20}$) to be corrected by a — 20c axis 180°, and now without accommodation to be adapted for remote vision or parallel rays. If the object be brought to 20" and

[1] American Journal of Ophthalmology, October, 1885.

a + 20s glass be placed before the eye corrected with the cylindric glass, the eye will still receive parallel rays, and, hence, an image without the necessity for accommodation. It follows that at whatever proximal distance the object is viewed with this + 20″ glass the ciliary muscle is relieved, an effort equal to + 20″ (or 2.D). Now the combined + 20s — 20c axis 180° is equal to a + 20c axis 90°.

This + 20c is perhaps preferred to the — 20c for the additional reason that it gives a larger image. Again, as in myopes, the ciliary muscle of the astigmatic myope may be reasonably supposed to be poorly developed and unequal to ordinary use. In other words, I would not give a weak minus cylinder in myopic astigmatism, for the same reason that a weak minus spherical is not given in myopia for reading.

Formerly I prescribed the minus cylinder, which the patient certainly preferred to astigmatic vision, and as a rule was satisfied with the improvement as compared with no glass. Recently I have given the option of a plus or minus cylinder, and in every instance (not a few) the plus was preferred. That is, with the latter the type was more distinct and reading more comfortable. What I supposed theoretically to be true the test of trial has verified. It is this: A simple myopic astigmatic (1) might read 1 Jaeger at 12″ imperfectly; (2) with a + spherical glass would read it still better; (3) with a minus cylinder still better; (4) and with a plus cylinder at right angles to that required by the minus the type could be read best and perfectly. In (1) the astigmatic image is indistinct; in (2) the astigmatic image is magnified; in (3) the image is clear; in (4) the corrected eye, the image is also clear and larger. This I think is preferred for the reasons previously mentioned. I will cite a few cases in illustration:

Case 1.—Hortense H., æt. 13, has had during the past year frequent attacks of phlyctenular conjunctivitis, and the edges of the lids have been red and swollen. After recovery from the conjunctivitis,

Under atropine R. E. V + 36c 180° = $\frac{20}{20}$.
Under atropine L. E. V — 36c 90° = $\frac{20}{30}$.
With accommodation R. E. V — 48c 90° = $\frac{20}{20}$.
With accommodation L. E. V — 36c 90° = $\frac{20}{30}$.
R. E. V = 1 J 12″ with — 48c 90° = 1 J 12″, better.
with + 48c 180° = 1 J 12″, best.
L. E. V = 1 J 12″ with — 36c 90° = 1 J 12″, better.
with + 36c 180° = 1 J 12″, best.

Glasses were ordered R. E. + 48c 180°; L. E. + 36c 180°.

Three months subsequently the lids recovered, and the patient prefers reading with the glasses, which completely relieve her of asthenopia.

Case 2.—Mrs. R., æt. 21. Since childhood her eyes have been more or less red and sore, and she has been unable to read, sew or paint longer than ten minutes at a time without straining her eyes.

R. E. V = $\frac{20}{30}$ = 1 J 12″ with difficulty.
L. E. V — 48s — 48c 180° = $\frac{20}{20}$ = 1 J 12″ imperfectly.
L. E. V + 48c 90° = 1 J 12″ better but imperfectly.
Under homatropine R. E. V = $\frac{20}{15}$ (Em). L. E. V = $\frac{20}{20}$ with + 60c 90°.
At 20′ adduction = 10°, abduction = 6°.
R. Glasses R. E. + 60s ◯ prism 2° base in. L. E. + 60s + 60c 90° ◯ prism 2° in.

A month later all redness of the conjunctiva had disappeared. Mrs. R. can use her eyes with the glasses all day, for near work, with perfect comfort.

At one time I seldom used atropine in testing refraction, but mistakes convinced me of the errors of my ways; and now I get the full effect of atropine whenever practicable, and when not so I substitute, if possible, the less efficient homatropine. This case (of Mrs. R.), it seems to me, shows that spasm of accommodation produced a myopia of $\frac{1}{48}$; and changed a hyperopic astigmatism of $\frac{1}{60}$ into a myopic of $\frac{1}{48}$, by advancing the focus of the hyperopic meridian to the retina and the focus of the emmetropic meridian to $\frac{1}{48}$ in front of it; showing an excess of ciliary contraction in the vertical meridian of the muscle = $\frac{1}{48} - \frac{1}{60}$. Dobrowolsky has demonstrated that this unequal contraction of the ciliary muscle sometimes occurs. The case illustrates also the necessity of a mydriatic to determine the best glass for near work.

Case 3.—Mrs. W., æt. 36, is unable to read longer than fifteen minutes without feeling her eyes fatigued.

R. E. V —10c 15° or + 18c 105° = $\frac{20}{60}$ = 1 J 8″.
L. E. V —10c 165° or + 10c 75° = $\frac{20}{60}$ = 1 J 7″.

With the above plus glasses the patient read for an hour without any inconvenience, and they were ordered.

In this case, with the accommodation active the right eye accepted for distance a plus 18 cylinder, and apparently by unequal ciliary contraction (the excess = $\frac{1}{10} - \frac{1}{18} = \frac{1}{22}$) the eye also accepted a — 10 cylinder with axis at right angles to the former, and vision was the same with either glass. Here even in so high a degree of myopic astigmatism as $\frac{1}{10}$ a plus glass is preferred for reading. Granted that the myopic astigmatism occurs during active accommodation and is probably spasmodic. In the left eye the change of a hyperopic astigmatism of $\frac{1}{10}$ to a myopic of $\frac{1}{10}$ is easily due to a ciliary contraction equal to overcoming a minus 10 spherical lens.

Case 4.—Miss S., æt. 16, was sent to me October 7, 1886, by her physician, on account of her headaches, which he thought had some connection with an error of refraction. Miss S. is a large, rapidly growing, neurotic, and not very vigorous young lady, who has suffered daily from headache since childhood, and during the past two years she has been unable to read longer than twenty minutes without pain in her eyes and forehead, lachrymation, and blurring of the type. The eyes have been painful also several times during the day. They are sensitive to pressure.

R. V = $\frac{20}{40}$ = 1 J 12″ + 48 = $\frac{20}{40}$ = astigmatic card.

L. V = $\frac{20}{30}$ = 1 J 12″, refuses any glass.

At 6′ { adduction = 13° / abduction = 10° } V. d = 8° divergence.

Upon fixation within 12″ the eyes diverge.

After atropine three days R. V + 36c 90° = $\frac{20}{30}$.
L. V + 36c 90° = $\frac{20}{30}$.
At 8′ adduction 24°, abduction 15°.

At 12′ adduction 45°; abduction 24; V. d = 12° divergence.

October 14.—With accommodation restored R. V —36c 180° = $\frac{20}{30}$; L. V 36c 160° = $\frac{20}{30}$.

November 14.—After constant current of electricity to the eyes daily for two weeks, the tenderness of the eyes is much less, but the pain and inability to read remain the same. The headache is not relieved.

November 19.—Upon trial can read only five minutes with + 48s ◯ prism 2° base out or in before each eye.

Ordered to wear for distance + 48s ◯ 2° base out each eye, and to read with these glasses every second day. On the alternate days to read with + 36s. To read after each meal, commencing with one minute, and increase each trial by one minute, until reading becomes fatiguing, then to return to half the maximum time attained and increase as before. Prescribed arsenic and fat food.

Three weeks later. Reads twenty-seven minutes with comfort, and equally well with the adducting prisms or with the + 36s glasses. Was told to try reading on alternate days with the prisms reversed, or bases in, and the 36s as before.

Six weeks later. Now reads fifty-four minutes with ease, and equally well with either pair of glasses. The headache is not relieved.

With accommodation R. V — 60c 180° = $\frac{20}{30}$. L. V — 60c 180° = $\frac{20}{30}$. R. or L. V = 1 J 12″ + 60 = 1 J 12″ better — 60c 180° = 1 J 12″ still better, + 60c 90° = 1 J 12″ best.

For the first time in testing binocular vision is shown at 20 feet and adduction = 24°, abduction = 6°, V. D = 4° convergence.

After atropine (grs. viij and ℥j) six times in two days, R. V + 48 + 60c 90 = $\frac{20}{30}$. L. V + 48 + 60c 90° = $\frac{20}{30}$. Was given prisms 2°, 6°, 8°, 10°, 12°, with which (by combining) to exercise the internal and external recti muscles.

Case 5.—Countess de B., æt. 35. Asthenopic.

With atropine R. V — 16s — 48c 90° = $\frac{15}{30}$. L. V — 16s — 48c 90° = $\frac{15}{30}$. These glasses were ordered for distance. With accommodation intact R. or L. V — 48c 90° = 1 J 12″. These glasses were ordered for near work. In a month the patient reports the glasses afford great relief, but her eyes still tire in reading. Her ladyship is advised to rest her eyes when they get tired. Possibly a + 48c 180° might have afforded more relief, especially if near work was usually done within sixteen inches.

Case 6.—J. H. B., æt. 20, school teacher, seen in January, 1882. During the past six months has had pain in his eyes whenever he read for five minutes.

R. V + 48c 90° = $\frac{20}{20}$. L. V + 48c 90° = $\frac{20}{20}$.

With these glasses he read half an hour with ease.

In February Mr. B. reports: A little reading affects the left eye for two to three days; and in September presents himself, saying he can read comfortably with the glasses for only fifteen minutes..

Glasses + 60s + 48c 90° each eye were prescribed, with which he reads without any unpleasantness for an hour and a half.

A year later the patient again returns and reports that the last glasses relieve him more than the previous ones. Still he can read only ten minutes without pain in the left eye. Under homatropine, R. V — 30c 180° = $\frac{20}{20}$. L. V 30c 180° = $\frac{20}{20}$. When accommodation was restored abducting prisms of 2° each were added to the above glasses. With these Mr. B. reads one and a half hours comfortably. These glasses were ordered.

Nine months later: "I can use the spectacles if I do not look away from the book." Recommended to consult Dr. H. Derby, of Boston, as he wished further advice.

Nine months later Mr. B. said Dr. Derby prescribed + 40c 90° ◯ prism 6° base in for each eye. He had tried these glasses for ten minutes only, and thinks he read with more comfort than with the last prescribed by myself.

Case 7.—Frank F., æt. 12, complains that his eyes get tired in five minutes reading. R. V — 42c 90° = $\frac{20}{20}$ = 2 J 5″ to 12″. L. V — 48c 90° = $\frac{20}{20}$ = 2 J 5″ to 12″.

Under homatropine, R. V — 36c 90° = $\frac{20}{20}$. L. V — 60c 90° = $\frac{20}{20}$.

At 20′, convergence = 15°, divergence = 5°.

With accommodation, R. V — 36c 90° = $\frac{20}{20}$ = 1 J 8″. L. V — 60c 90° = $\frac{20}{20}$ = 1 J 6″.

Read with these glasses comfortably for one hour.

A month later Frank reports the eyes give him no trouble in reading. In this instance the astigmatism of the right eye is less before than after the mydriasis, and that of the left eye greater. The crystalline astigmatism of the right under accommodation may compensate for that of the cornea, as Donders pointed out is usually more or less the case. It is noticeable that the findings under homatropine prove to be the best reading glasses.

Case 8.—Mr. R., æt. 37; auditor; asthenopic. Under homatropine, R. V + 36c 75° = $\frac{20}{20}$. L. V + 36c 80° = $\frac{20}{20}$.

Two days later, with restored accommodation, R. V —36c 180° = $\frac{20}{20}$. L. V — 36c 170° = $\frac{20}{20}$.

R. V = 1 J 12″ with difficulty, + 36s better, — 36c 170° still better, + 36c 75° best and well. L. V = 1 J 12″ with difficulty, + 36s better, — 36c 170° still better, + 36c 80° best and well. The above + cylindric glasses with which the patient could read best were given.

A year later Mr. R. says he likes his glasses very much, and is quite relieved of asthenopia. In this case the right eye prefers for reading the + cylinder at an angle of 75°, which was accepted with paralyzed accommodation. This glass varies 15° from the same glass that would have been selected for reading by the oculist from the result of testing remote vision with accommodation intact.

This change in the axis of the cylinder determined for remote vision to a different angle for near vision, is not mentioned so far as I have seen in literature. After first noticing this peculiarity I looked for other instances, and soon found a few. Since then I confess to having neglected to test for it, so cannot say whether the phenomenon is rare. If an eye is tested for distance both with and without atropine, and neither cylindric glass proves satisfactory in reading,

it would be well to test the effect of changing the axis of the cylinder.

I will cite one very typical case in illustration:

Case 9.—In November, 1883, Mrs. G., æt. 37, had been unable for twelve years to read more than half a column of newspaper at a time without producing pain in her eyes. After homatropine, R. V + 60c + 36c 15° = $\frac{20}{20}$. L. V + 60s 36c 165° = $\frac{20}{20}$.

With accommodation, R. V — 48c 120° = $\frac{20}{20}$. L. V — 48c 60° = $\frac{20}{20}$.

The patient can read only five minutes with the latter glasses, and half an hour with the former plus glasses with comfort. The glasses that prove most satisfactory in reading are: R. E. + 36c 180°. L. E. + 36c 150°. Two months later the report is: "The spectacles afford perfect comfort."

In this instance the axis of the reading cylinder varies 15° from the axis of the distance cylinder determined with the right eye under homatropine, and varies 30° from the axis determined with active accommodation. In the left eye the reading glass varies 15° from the distance glass selected with homatropine, and corresponds with the glass selected without a mydriatic. In the above I of course assumed that the plus cylinder for reading would be at right angles to the minus cylinder, *i.e.*, R. E. + 48c 30°, L. E. + 48c 150°.

The change in the reading axis we might assume to be due to the accommodation in which the excessive contraction of the ciliary muscle in the special meridian so alters the figure of the lens as to change the meridian of the real astigmatism of the cornea. In this instance it seems more probable that the eyeball rotates on its visual axis during convergence, possibly on account of excessive tension of the superior oblique. That active accommodation does not account for the result, seems the more probable, since the reading glass for the right eye corresponds more nearly, and for the left eye perfectly, with the distance glass selected during active accommodation.

THE IMPORTANCE OF HYGIENIC MEASURES IN THE TREATMENT OF NASAL CATARRH.

BY THOMAS F. RUMBOLD, M.D.,
OF ST. LOUIS, MO.

Chronic catarrhal inflammation of the mucous membrane of the nasal passages and the cavities connected with them, requires a very different management from that given to other diseases, for the reason that the effects of dress, customs and daily habits of patients have a controlling influence on both the production and prevention of the complaint.

In the early part 1868, I treated a number of patients for catarrhal inflammation of the throat and nasal passages. They were in the habit of frequenting a skating-rink from two to four nights each week. After exercising violently they became exhausted and seated themselves on a bench in the cold air, thus becoming chilled. I was but partially successful in the treatment of their catarrhal complaint, being unable to do more than alleviate their most prominent symptoms, and these only temporarily. These circumstances led me to consult a record I had kept of the history and treatment of a few observant patients who had, at different times during the five years previous, been under my care for the same complaint. These last named patients had noted many of their symptoms and had taken special pains to maintain their general health. I made a record of these cases at different times, but had not, until on this occasion, read them through in succession. After a careful reading and comparison one with another, I was struck with the marked similarity of their statements regarding the causes they ascribed to the aggravation of their catarrhal complaint. The similarity did not end here, but included the care that experience had taught them to take of themselves; the amount as well as the kind of clothing that proved sufficiently protective, and the best means they found to relieve a fresh attack of cold in the head and throat.

The reading of this record deeply impressed me with the paramount importance of hygienic laws in the management of this disease. The humiliating fact that I had failed, time and again, since 1855 (the date of my first systematic attempts to treat this complaint according to our text books), to do more than give a little relief, proved to me that some very important matter in the management of this disease had been overlooked. Indeed, I had made the records spoken of, because of this impression. Under these circumstances, as I reflected on the effects of colds upon the mucous membrane, repeated year after year, and re-called to mind remarks that a large number of other patients had made on this same subject, I was more thoroughly convinced that I had found what had been overlooked by all who had preceded me, namely: that a strict observance of the laws of health was indispensible to a successful treatment, as well as to the prevention of the renewal of the cause of the inflammation, namely, colds. It was not difficult now to see why I had failed in the "skating-rink cases." Since that time I have made it a point to require my patients to strictly observe the laws of hygiene. If they do not do so, I discontinue the treatment at once.

In 1868, I made a series of observations concerning the causes of sickness and death among men and women between the ages of 20 and 40 years. I soon found that most of the ailments and deaths of men arose from the *results of excesses* of various kinds, and the chief of these, was the use of tobacco and stimulants. In the case of women, their sickness and death arose from the results of exposure of various kinds, but principally owing to insufficient clothing. While this is far from being complimentary to man's strength of will to control his appetites, it is as far from being flattering to woman's judgment of her own endurance or ability to resist the injurious effects of inclement weather. One is an evidence of a determination not to be deprived of any pleasure at whatever cost, and the other denotes either a great state of ignorance or an indifference to a very common cause of disease and death.

Every physician who expects to treat chronic catarrhal disease of the nasal passages successfully, must keep in mind the proneness of male patients to commit excesses, and the certainty that almost every female patient is insufficiently and imperfectly clad.

Patients suffering from any kind of disease should so assist their physician as to insure as speedy and permanent a recovery as possible; but with those suffering from catarrhal inflammation of the nasal passages, this assistance is absolutely indispensable; a recovery without it is impossible. A majority of these patients appreciate this, when the subject is fully presented, but the most of them are ignorant of many of the details of the laws of health, or they do not consider them of sufficient importance to give them strict attention. For this reason each patient should, on his first visit, receive instructions on such hygienic laws and sanative measures as are suited to his particular case. These instructions should refer to the following points of conduct:

The importance of avoiding any exposure liable to produce a cold; the best method of protecting the head, neck, body and extremities; the danger of exposure to night air; the course to pursue when a cold has been taken; the proper temperature and ventilation of the sleeping room; the kind of food that should be used; physical exercise and the time it may be taken; the injury resulting from not controlling a gloomy mind and an irritable disposition; the danger arising from cold feet and the way to maintain them warm if they are habitually cold; the necessity of maintaining the nasal and aural passages free of catarrhal secretion, and the most effective and non-irritating means to be employed; the kind of bath that may be used and the manner and time in which to use it; the necessity of abstaining from the use of tobacco and stimulants; the importance of having diseased gums and decayed teeth properly treated by a dentist, and any other hygienic and sanative measures that will tend to regain and preserve health. It will seldom happen that any one patient will need to be instructed in all of these matters, but the greater portion of them must be given to every patient.

The successful treatment of chronic catarrhal inflammation of the superior portion of the respiratory tract, may be likened to the successful suspension of a chain. If any one of its links is broken the chain drops. So with the treatment of this disease. It may be said that one link of the chain is called protection of the head, neck, body and extremities; another link, danger of draughts to night air; another, injury resulting from not controlling an irritable disposition and a gloomy mind; another, abstainance from the use of tobacco and stimulants; and so on through the whole list of hygienic and sanative measures. Two other links belong to this chain, namely, therapeutic and operative measures. If any one of these links is broken, it matters not which one it is, the chain is broken and falls, and the attempt to bring about a recovery is unsuccessful, whether it be the patient's or the physician's fault. My experience leads me to affirm positively that unless patients take such care of themselves, by proper attention to their dress, habits and daily customs as will lessen to a great degree the severity of recurrent colds, the disease cannot be controlled by either local or constitutional treatment, or by both. It is only during the observance of hygienic and sanative measures that therapeutic measures can be successfully employed. It should not be expected that a chronic disease originating solely from repeated violations of the laws of health, can ever be ameliorated while the patient continues to violate these laws.

It is a characteristic of chronic nasal catarrh to establish a susceptibility to renewed attacks of cold in the head. That is, past colds have so weakened the mucous membrane, that it becomes inflamed on the patient being but slightly exposed, while at an earlier stage of the complaint, or when it was still in the acute form, this exposure would not have produced an injurious effect. In the still more chronic stages, the patient will often realize this important but very unpleasant fact. Past experience proves that in the treatment of patients who have been afflicted so long as to acquire this character of susceptibility, the dependence upon medicines alone must result in failure, as it is evident they cannot ward off colds. This is to be done by conforming to rules pertaining to the general health. But it is equally evident, that the observance of these rules cannot give immediate relief to an irritation caused by morbid secretion, or to a pain occasioned by a local congestion; this relief must be the result of remedies locally applied.

Such therapeutic and operative measures must be instituted as will prevent the continuance of the diseased action already set up. If the therapeutic measures are non-irritating and alleviating, and the patient lives in conformity to hygienic principles, the reparative processes of nature will, in a longer or shorter period of time, according to the age and temperament of the patient, restore the inflamed membrane to its normal condition, or to such a condition that the patient will not be conscious of the existance of the disease. Of course it would be preposterous to think that this restoration could be effected in a few weeks or even in a few months, except in young persons. The changes in the mucous membrane, the result of long standing inflammation, are too great for a cure to be effected in so short a time. Time was required for the congestion to produce the disease, and time will be required for the reparative processes of nature to undo or eradicate it, that is, proper care, non-irritative therapeutic measures and time will do it. For this reason, the strictest observance of hygienic measures must not cease with the termination of medical treatment, but must be continued for several years thereafter, or so long as there is susceptibility to take cold. Some patients complain of the severity of this—what they call—rigid mode of life. Can any man or woman give a good reason for not living continually in conformity to well-known and easily obeyed laws of health.

From the foregoing it will be readily perceived,

that, according to the writer's views, the observance of hygienic measures is of far greater importance to the successful issue of a case than are therapeutic measures. From close and careful observation extending back to 1862, I am satisfied that more can be done for these sufferers—including all ages—by the proper observance of hygienic measures alone, than can be cured by therapeutic measures alone, especially if the latter causes the least irritation. I say this to show the high estimation I place on the value of the proper observance of the laws of health.

CONSERVATISM IN GYNÆCOLOGY.

Read before the Gynæcological Society of Boston, February, 1887.

BY HORATIO R. BIGELOW, M.D.,
OF WASHINGTON, D. C.

Over two years ago, I wrote a paper for the Boston Gynæcological Society on "The Conservation of Energy and Conservative Gynæcology," every point of which I can now emphasize with double force; and some time prior to this, I also made a plea for patience in the treatment of oöphoritis and salpingitis. While my own personal experience in surgical gynecology is exceedingly small, I have seen, perhaps, as many operations as most men of my years, and have assisted at a large number. In the conservative treatment of the diseases of women I have had quite an intelligent experience. What I write is based upon a long series of observations, and upon two years of hard work upon the Continent. I have, too, the courage of my convictions; for what I have seen, that do I believe and know. The surgeon, with his brilliant results, lays up for himself treasures upon earth, and brings about him all the luxuries that wealth, reputation and social prestige can give. The patient plodder in conservatism is often out of pocket; goes to his home with many a misgiving and many a heartache. I hope for his sake, at least, that there may be a real, actual heaven, in which his treasures may be laid up, for scientifically, if he has rescued his patient from suffering, he has done more than the surgeon who, in half an hour, has rid her of pain at the expense of some of her organs, and at the risk of her life.

And first, I wish to say a word in regard to uterine tumors: I hold it as axiomatic that *no tumor calls for surgical interference unless it is immediately endangering life.* This brings in the question of hæmorrhage and early operations. Hæmorrhage does endanger life, it is true, but not in the sense which I mean. I hold a hæmorrhage to be *dangerous*, only when it fails to yield to conservative principles of medicine — ergot, etc. Therefore, a myoma that bleeds presents no indications for removal, unless the bleeding be beyond the control of other well known measures. Primary, simple hæmorrhage, of itself does not endanger life, unless it be beyond the control of the medical man. Tumors only bleed when associated with endometritis fungosa, or with a predominant glandular endometritis, or with a glandular endometritis on one side, conjoined with an interstitial endometritis of the other side. It may not be impossible to modify these conditions by local treatment, at the same time that we act upon the capillaries by the internal administration of ergot. At all events, only a small percentage of myomata *endanger life* from *any cause whatever*, and a plea for an early operation cannot possibly find a logical foothold in these cases. In rapidly growing cysts, which endanger life by pressure, and by interfering with those functions which are necessary to life, the question is one of quite another nature. A myoma may endanger life by rapid development (rare), or by blocking up the pelvis and so interfering with the functions of the bladder and rectum, or by undergoing degeneration—but even in these cases, electricity and ergot should be given a fair trial. Every woman who has her abdomen opened subjects herself to a certain fatal risk. The responsibility of a fatal issue no surgeon has any conceivable right to assume, until he has satisfied himself that all other means are useless, and that the woman *must* die unless operated upon. Now a myoma, without alarming hæmorrhage, that grows slowly, and that occasions no discomfort from pressure, surely does not demand a dangerous operation; and yet I have seen many such cases die after a laparotomy, when they probably would have lived many years had they been left alone. Any woman would much rather live on for years as a sufferer, than to have the tumor taken out at the risk of her life. Even in the earliest stages of their development in which a diagnosis is possible, a laparotomy is *always* a dangerous operation, and no surgeon can possibly say beforehand whether such a tumor will assume an alarming form or not. I am convinced that many myomata have been operated upon unnecessarily, and I am equally sure that the careful use of ergot and electricity by intelligent men will render the necessity of laparotomy for uterine myoma an exception. The mania for surgical renown has become such an epidemic that medical men forget that there are tumors and diseases which do better under conservative handling. The mistakes that are made, and the results that are obtained, should be lessons pregnant of thought. But they are not. Death follows death; mistake follows mistake; and still the crowd rush madly on.

I cannot conceive of anything more pernicious than the advice urged by an eminent surgeon: "When in doubt, open the abdomen and find out." It reminds one of Dr. Panglos: "When in doubt take the trick." In the first place, there are few cases in which the competent gynecologist cannot map out the disease—approximately at least. In the second place, he has no right to relieve his ignorance at the slightest risk of a human life. Fortunately for us all, a beneficent one, has prevented any general acceptance of such a doctrine. I have seen some splendid results following upon the use of ergot, and have read of others equally good in Chicago. Apostoli and others are doing first-rate work with electricity. Certainly, with these facts patent, it is simply uncalled for (I dislike using a stronger word) to open the abdomen, unless this practice has failed, and the *woman's life is in immediate danger.*

These thoughts are impressed upon me by long

and close observation. I know of no cure for rapidly growing cysts, or for malignant growths, or soft myomata, but the operative treatment, and it is in these cases that an early operation is demanded—the earlier the better. Here surgery is truly conservative. Another class upon which surgery has gloated, is that in which the adnexa are involved. I have written so much, and at such length, upon this topic, and I have so often demanded a hearing for less "scalpel" and more patience, that I almost hesitate to add anything further. I will not go over the field which I have already traveled, because other men, abler than myself and of more experience, have lately urged the same plan of conservative handling. It is sufficient to say that many cases in which the operation is advised *will* get better by patient, persistent, vigorous treatment. Local applications, rest, treatment, exercise, electricity, Turkish baths, and a subjective condition of environment directed toward the patient's psychic symptoms, will surely, but slowly, bring about an amelioration. I have seen this plan work well, and I know it to be true, even were I not supported by such men as Goodell, Ball and others. This line of treatment is troublesome and is best carried out in a private hospital; and unless the patient has some means, it is quite impossible to practice it properly. It has become almost a conviction with me, that the instances in which a laparotomy is necessary for disease of the adnexa are exceedingly rare.

My experience with these cases, and with this treatment, has been sufficiently ample to allow of my forming an opinion which is entitled to respect. Most earnestly, then, I urge upon the profession to rid themselves of their skepticism, and to try at least such regular, constant surveillance and care. The field is wider than pure surgery, just as praiseworthy and brilliant, and more immortal in its results. Couple with surgery a thorough knowledge of conservatism, and the end must crown the labor.

Leipzig, November 6, 1886.

A CASE OF CARIES OF THE PATELLA FOLLOWING FRACTURE AND WIRING OF THE FRAGMENTS.

BY GEORGE R. FOWLER, M.D.,

SURGEON TO ST. MARY'S GENERAL HOSPITAL, BROOKLYN, N. Y.

The subject of the present report entered St. Mary's General Hospital on October 24, 1885, with the following history: About twenty years ago she fell and suffered a transverse fracture of the patella. The fracture was treated in the ordinary way, and in due course of time union by ligament resulted, with a distance of about two inches between the fragments. Three days prior to her admission to the hospital, she again fell and ruptured the ligamentous connecting band between the fragments, at the same time breaking up a partial anchylosis of the knee-joint of a fibrous character, which had existed ever since the first accident, twenty years ago.

At the time of her admission, there existed some synovitis and considerable effusion in the knee-joint, the result of the recent injury. When this had subsided it was decided to open the knee-joint, remove the fibrous connecting band, and, after freshening the opposing bony surfaces, to bring the fragments together and secure them in position by means of the wire suture. This was done on October 26. Full antiseptic precautions were observed in the performance of this operation. The wire used was annealed iron, which was brought out of the transverse incision made for the purpose of exposing the fragments, and twisted over a bridge of hard rubber. Drains of soft rubber were employed, these being passed through the soft parts upon the lateral aspects of the joint only, and protruding but slightly into the joint cavity itself. Wood-flour dressings were applied, and the limb placed in a fracture box made of heavy wire cloth.

Everything went well for the first fortnight, when the dressings were removed for the purpose of removing the drainage tubes. The parts were found to be in an aseptic condition, and were re-dressed in the same manner employed at first. At the end of forty-eight hours there appeared a discharge through the dressings which necessitated their removal. An extensive cellulitis of the limb had occurred in the neighborhood of the knee-joint, and suppuration was already in progress. No union of the fragments had taken place, and on removing the bridge over which the wire had been twisted, the underlying soft tissues were found to be in a condition of ulceration, seemingly from the pressure of the bridge. The latter was removed, and the wire twisted closely to the bone through the opening produced by the ulcerative process. The parts were thoroughly irrigated by means of a one to one thousand solution of mercuric bichloride, and again redressed as at first. The cellulitis continued to extend, however, and the parts required re-dressing each day. During this time, however, the temperature was but slightly elevated, although the local distress was considerable. Incisions were made, and soft rubber drainage tubes introduced from time to time in places where pocketing of pus threatened, and thorough antiseptic irrigation practiced once or twice daily, in addition to the use of absorbent antiseptic dressings.

Under the above line of treatment the cellulitis gradually subsided, but no union of the fragments could be made out. On the contrary, as the swelling subsided, it became evident that the patella itself was diseased and the lax condition of the lateral ligaments of the knee-joint led to the belief at one time, that the head of the tibia had become separated from the shaft of the bone. The wire was removed at the end of the sixth week, at which time the drainage tubes were likewise dispensed with, the openings from which the latter emerged becoming reduced to mere sinuses. The point of ulceration over the patella obstinately refused to heal, and the probe detected indubitable evidences of carious bone at the bottom of the opening caused by the ulceration over the patella. On February 15, three months and a half following the receipt of the injury, an incision was made over the patella and the greater portion

of the latter gouged away, it being found to be extensively diseased. In this operation the knee-joint was unavoidably opened, but it was thoroughly irrigated with the bichloride solution. The sinuses, as well as the surface of the ulcer over the patella were curetted by means of Volkmann's sharp spoon.

Nothing further untoward occurred in the history of this case. The sinuses, as well as the ulcerated surface overlying the patella healed readily under the same antiseptic dressings heretofore employed, and the patient left the hospital on May 31. She was able at that time to walk unaided. There was some fibrous anchylosis of the knee-joint, yet motion was possible, to a limited extent. Upon this latter point the patient was perfectly sure that no greater amount of disability was present than had existed prior to the last injury, and following the first fracture of the bone.

Several points present themselves for notice in reflecting upon the history of this case. In the first place, it may be asked with propriety if it were a justifiable procedure, this opening of the knee-joint, and dissecting away the old connecting band of fibrous tissue and wiring together the fragments. My reasons for doing so were, in the first place, the fact that there had existed great disability for twenty years following the fracture in the first instance, and this was in a great measure due to the long ligamentous union existing between the fragments. The patient belonged to a class in whom it was very desirable that as near an approximation to the normal condition of the members of the body as possible should obtain, on account of the necessity of earning their living. The patient was a widow, and relied solely upon herself for support. It was thought that her condition could be made no worse by an attempt to obtain bony union of the fragments, and their could be no question as to the desirability of obtaining the latter. In the second place, it was my intention to search for, and remove if found, any adventitious bands within the joint which might be held accountable for the anchylosis previously existing. I omitted to mention that no such bands were discovered at the time of the operation for wiring the fragments.

It has been my practice to use heavy silver wire for the suture, instead of iron, but in this instance such was not at hand, and the iron was substituted. Whether the oxidizing of the iron could have acted as an irritant is an open question, which I am not prepared to discuss at this time.

The use of the bridge of hard rubber upon which the wire was twisted is a device to which I have resorted upon previous occasions, and have not heretofore thought that it produced trouble by making undue pressure upon the soft parts. I am free to confess, however, in this instance at least, that the ulceration beneath its under surface was a direct result of the pressure of the bridge.

The wisdom of the course pursued in the matter of the treatment of the capsule of the joint, namely, a separate suture of the same, is illustrated in this case. This structure was carefully sutured with a fine continuous suture of catgut, independently of the suture which closed the external portion of the operation wound. To this, no doubt, is due the immunity from destructive inflammation enjoyed by the knee-joint, in the midst of the conflagration, so to speak, which swept over that portion of the limb during the first few weeks following the operation. Immediate and perfect union of the wound in the capsule took place, thus shutting it out from the irritating fluids which infiltrated the tissues surrounding the joint.

Although great care was exercised in the removal of the carious portion of the patella, yet in spite of this the cavity of the knee-joint was invaded. The condyles of the femur, as well as a portion of the head of the tibia, were brought into view. Notwithstanding this, the antiseptic measures were so far efficient as to entirely protect this important articulation from infection, and no harm came from this exposure.

MEDICAL PROGRESS.

Diagnosis of Brain Diseases.—Nothnagel, in a recent article read before the College of Physicians of Vienna, gave the following diagnostic points of brain disease:

1. In brain tumors headache is of very little value in diagnosis; the cerebral substance is not sensitive; the pia mater but little sensitive and the dura mater only, of the cranial contents, is sensitive. Headache in cases of cerebral tumor is explained by tension on the dura caused by the bulk of the tumor.

2. Headache is present in inflammatory processes in the meninges, and more frequently in lepto-meningitis than in pachymeningitis; in lepto-meningitis the headache frequently changes its character.

3. Headache is present in chronic cerebral hyperæmia and chronic anæmia; it is questionable whether anæmia alone is the important element in chlorosis, as most marked cases of pernicious and intensive anæmia are caused by carcinoma in which headache is absent. Headache is rare in insular multiple sclerosis; in cerebral abscess its presence and character are variable. The location of the headache gives no certain diagnostic point as to the location of the lesion, though in general it may be said that usually the lesion is where the headache is.

Vertigo, though common in various cerebral diseases, is of little importance; when it is excessive and accompanied by incoördination, as in diseases of the crura cerebelli, it has decided import.

Vomiting is rarely of much value in diagnosis; it aids chiefly in the location of lesions. It may be present in cases in which the amount of blood in the brain is abnormal, and an irritation of the centre of emesis in the medulla oblongata exists. We are aided by this symptom in diagnosticating lesions of the tissue in the posterior fossa of the skull; *e.g.*, tumors originating in the cerebellum press upon the medulla; or tumors of the medulla or pons.

Fever is an important symptom in but few cerebral

diseases. The highest temperature is present in meningitis, especially in its infectious form. But as peritonitis without fever is often seen, so meningitis may run its course without marked rise of temperature. Fever occurs in cerebral abscess and septic phlebitis of the cerebral sinuses; it has then more often the characteristics of septic fever with pyæmic chills, and does not depend directly upon the phlebitis, but upon pulmonary embolism. Fever also occurs in the course of progressive paralysis. The pulse gives no certain criterion for the diagnosis of a given cerebral disease. It is often, however, of value in the abnormalities of its rhythm in beginning meningitis, in the form of regularly occuring arythmia (first described by Nothnagel), where a certain periodicity in the variations of the pulse frequence occurs; the increased number of beats endures but a few moments, and is caused by an irritation of the pneumo-gastric nerve. The respiration gives no information in the diagnosis of brain diseases.

As to disorders of speech, aphonia is seldom present and the location of the lesion which could cause it, in the medulla oblongata, is such that death generally results speedily in these cases. Speech is affected most often in progressive bulbar paralysis, and frequently in multiple sclerosis in patches. Speech is also implicated in progressive paralysis when the origin of the hypoglossus is affected; also in cortical disease of the lower portion of the central gyrus.—*Wiener medizinische Presse*, No. 13.

Antifebrin.—Eisenhart (*München. Med. Woch.*, No. 47, 1886), tested the therapeutic action of this drug in thirty cases in the medical clinic of Ziemssen. The activity of the drug usually manifested itself two hours after its administration, sometimes with appearances of collapse, in more than half of the cases with copious perspiration, and in a few cases produced no lowering of the temperature. The apyrexia produced by it lasted generally six hours. It acted as readily when administered by enema as by the mouth. In a single case of typhoid fever it produced over the entire body a papulose eruption of moderate size, which disappeared after two or three days' duration under the continued use of antipyrin, only to break out anew. Cahn and Hepp (*Berlin. klin. Wochensch.*, 1887, No. 1 and 2), have published the results of a new series of tests of antipyrin in sixty cases of various kinds of fever. They reaffirm that it is a strong and sure antipyretic, one that can be used in small doses and is relatively free from coincident undesirable effects. Of these undesirable effects they have observed, at times, a fall of temperature below normal, a chill as again the temperature rises, and sometimes after its effects pass off a rise of temperature above that previously observed in the case, also occasionally, a red miliary eruption and sometimes a cyanotic appearance. They noticed a decided increase in the quantity of urine and fall in its specific gravity, together with increased thirst in severe cases. Parallel with the fall in temperature occurred a lessening of the pulse frequency and an increased tension of the vessels. Moreover they call attention to the quieting effect of the drug. By all observers the dose most frequently used is 25 gms. (gr. iv). When this dose did not give satisfactory results Cahn and Hepp repeated it at intervals of one-half to one hour; .5 gms. (grs. viii) doses they gave in the same way, and administered the drug in single doses of 75 to 1 gm. (gr. xii to gr. xv). Small repeated doses appeared in rather severe cases useless, while single large doses produced prompt effects. They never used per day more than 2 gms. (grs. xxx), but think that much more might be given with safety. The drug was administered in watery solution, in urine or wafers. In regard to the undesirable coincident effects of antipyrin Heinzelmann (*Münchener med. Wochenschr.* 1887, No. 3) adds that he has observed after sweating, once partial deafness, once mydriasis, but never vomiting or eruptions upon the skin.—*Centralblatt für klin. Med.* 1887, No. 17.

The Value of Hæmorrhage in Treating Wounds.—Taruzza publishes a note to show that hæmorrhage from wounds, unless due to lesion of large vessels or in excess, does not interfere with primary union. He does not think it necessary to follow strictly the rule to secure complete arrest of hæmorrhage and to apply firm compression. He relies on perfect disinfection of the bleeding surface, as far as possible, by means of weak solutions of carbolic acid or mercuric chloride. After this he leaves the cavity of the wound full of blood, the edges being accurately sutured, and without fear that primary union will not result. From his experience he formulates the rule: "In wounds perfectly disinfected and free from foreign substances effusion of blood is not a source of danger, but the reverse, as the effused blood fills the wound-cavity perfectly, preventing the formation of empty spaces, and making compression and drainage superfluous; and the organization of the clot favors union." He is opposed to the drainage tube, thinking that it increases risks of sepsis, and may remove from the wound fluids which, when aseptic, may be useful by reabsorption.—*Gazetta degli Ospitali*, April 13, 1887.

Albuminuria in Diabetes.—Dr. A. Pollatschek, of Carlsbad, has published (*Zeitschr. f. Klin. Med.*, xii., 4) some statistical results of the systematic examination of diabetic urine for albumen, with a view to determine whether the occurrence of the latter varies in proportion with the amount of sugar. He found that out of 1187 specimens containing sugar, in amounts varying from traces to as much as 5 per cent., there occurred more or less albumin in 437. The percentage (37) was almost the same, when reckoned on the cases examined in 1885, as on those of 1886, showing a curious uniformity. By grouping the specimens of urine according to their richness in sugar, he shows that there is no constant relation between the amount of albumen and of sugar—the lowest number of albuminurics (29.1 per cent.) occurring in cases of urine with a minimal quantity of sugar, and the highest (43.8 per cent.) in urines having from 2 to 3 per cent. of sugar.—*Lancet*, April 23, 1887.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

The Editor of this Journal would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

Subscription Price, Including Postage.

Per Annum, in Advance.....$5.00
Single Copies.....10 cents.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in registered letters.

RESPIRATORY THERAPEUTICS IN PHTHISIS.

As the active treatment of phthisis is now attracting so much attention, some notice of a valuable contribution to the subject made by Dr. Lawrence J. McNamara, at the May meeting of the New York County Medical Association, will no doubt be received with considerable interest. His paper was entitled, "Respiratory Therapeutics in the Treatment of Phthisis Pulmonalis," but he limited his remarks to one division of the subject: the local treatment of phthisis by medicinal agents applied to the interior of the respiratory tract in finely divided particles. While he may be thought too sanguine, Dr. McNamara thinks that from his experience with this plan we now have a proper and scientific method of treating phthisis, especially in hospitals.

To Laennec's insistance on the essentially tuberculous nature of phthisis is to be ascribed the determination of its specific character; and Koch's isolation of the bacillus seems to be but the legitimate outcome of the work of Laennec and his followers. The importance of the bacillus and the infectious nature of the disease being admitted, the necessity of using means to retard the further development of the organism, or of destroying it, and the placing of the exposed person in an atmosphere devoid of its presence, at once become apparent. The acceptance of this idea of infection by the profession in general would be the dawning of a new day in the treatment of phthisis. The possibilities of relief and cure are greater, and the idea of prophylaxis assumes prominence. The changing of an infectious pulmonary discharge to one devoid of dangerous elements is the logical sequence of putting the theory into practice. But Dr. McNamara does not consider the antiseptic treatment of phthisis the only form of treatment worthy of application to the diseased lung. He believes that it is at present a necessary and most important means of modifying the course of the disease; but the physical conditions caused by the extension of the inflammatory irritant naturally call for other methods of treatment.

While the greater number of appliances for producing sprays are of no use, it must be admitted that we can obtain a spray sufficiently fine to pass the larynx and penetrate beyond the larger bronchi. For almost two years Dr. McNamara has used an apparatus which has given him great satisfaction, a description of which is to be found in our New York letter. The spray produced by this apparatus consists of a central stream of very great attenuation, the larger particles of the atomized fluid being projected against the sloping sides of the globe, and being condensed fall as drops into the original solution, so that they do not escape through the mouth piece. The mist which passes through the mouth-piece has not sufficient momentum to cause its entire condensation, and does not wet the hand when placed before it. Ordinary inspiratory efforts will carry the spray into the lower respiratory passages. The results obtained with this apparatus certainly warrant a more general use of the method. But, though the patients were relieved of their symptoms, and the evidence in many cases pointed to a cure of the process, the scanty expectoration still contained bacilli, except in one case, in which the vesicular murmur returned, and both the râles and bacilli disappeared.

There are a number of difficulties in the way of a systematic use of such methods of treatment in private practice, and when possible the patients should be treated in special institutions, where the methods can be combined with the pneumatic method, when the physical condition of the patient calls for the use of the latter. Again, as remarked by Dr. Janeway in the discussion of Dr. McNamara's paper, it is difficult to carry out any plan of antiseptic treatment that will fully reach the affected parts, and it is also difficult, in many instances, to appreciate the amount of disease present. By inhalation methods we may be able to benefit a certain proportion of cases; but the conditions present are often such that the application is carried to the sound tissues of the lung rather than to the affected parts. It is well known how much difficulty there is in favorably affecting a case of tuberculosis when the parts involved can be readily reached; as, for example, in tuberculous ulcers of the mouth, gum, tongue or legs; and the

difficulty must necessarily be much greater when the diseased part is as inaccessible as the lung. But inhalations may do good by arresting the process from their effect upon the neighboring sound tissue. Again, in cases of chronic phthisis attacks of capillary bronchitis and broncho-pneumonia sometimes occur, making them appear like acute tuberculosis; and under these circumstances the violent symptoms usually subside in a short time. There are, then, many cases in which one might be led to suppose that the tuberculous process is much more advanced in the lungs than is really the case; and it is possible that some of the cases reported as being so much benefited by the Bergeon treatment are of this character.

While it may be objected that such measures do not destroy the bacilli, or cause them to disappear, the counter-objection may be raised that, so long as the other symptoms improve and disappear, we need not concern ourselves too much with the bacilli; and at present it may be fairly questioned whether the bacilli will not finally disappear from a case which is kept at a high standard of improvement. And certainly, with our present knowledge of germicides, it would not be wise to make vigorous efforts to destroy the bacilli at the risk of injuring the patient by irritants. And while it may still be true that our main reliance in the treatment of phthisis is in constitutional remedies, including the selection of a suitable climate, other measures are not to be neglected; and in a large number of cases change of climate is, for pecuniary reasons, out of the question.

THE INFLUENCE ON LABOR OF PRESSURE OVER THE SACRO-SCIATIC FORAMEN.

Can we influence the mechanism of labor by external pressure over the sacro-sciatic foramen? is the question asked by Dr. A. F. A. King in a communication in the *American Journal of Obstetrics*, of May. While examining some cadavers he found that such pressure produced an elevation or protrusion at the same point in the interior of the pelvis. Having removed the uterus and appendages, he anointed the pelvic cavity with vaseline, and placed in the pelvis a good-sized, recent fœtal head, also anointed with the vaseline. The head was placed low down in the pelvic cavity, with the occiput towards an acetabulum, and the forehead towards the opposite sacro-sciatic synchondrosis. Pressure with the finger-ends over the sacro-sciatic foramen towards which the forehead was directed easily caused the head to rotate, bringing the forehead to the sacrum and the occiput to the pubis.

Could the same thing be done on the living subsubject? When rotation fails to take place during labor can we expedite it by this pressure? asks Dr. King. Such external pressure would cause the part of the fœtus in contact with the foramen to move in a *posterior* direction towards the hollow of the sacrum. "If it is found to be of any value, the pressure should be made in the left occipito-anterior position of a *head* presentation, and in the left mento-anterior position of a *face* presentation only upon the right sacro-sciatic foramen, so as to cause the *occiput* in the one case, and the *chin* in the other, to come towards the pubis; while in the right occipito-anterior and right mento-anterior positions of the same presentations, respectively, the pressure must be made upon the *left* sacro-sciatic foramen; and so of the other positions and presentations." When the vectis or forceps was applied on the dead subject it was easy to feel the end of the blade on the outside, through the tissues covering the foramen; and pressure upon the instrument at this point would distinctly move the handle and cause rotation. It was also found that when the lower extremities of the cadavers were bent back as far as possible, thus bringing them into the same relation with the trunk as would occur in kneeling, the heels just reached the sacro-sciatic foramina; and when they were firmly pressed against the tissues over the foramina the same elevation was made on the interior of the pelvic cavity, and the same movement of the head was produced as by digital pressure. It is then fair to ask—Would a kneeling posture during labor, with the heels at the points indicated, expedite labor by promoting rotation?

While it may be said that the tonicity of the muscular and other structures covering the foramina differ in the living and dead subjects. Dr. King states that pressure over the foramen in the *living* will also produce an impulse perceptible by the hand placed over the abdomen, and even by the eye, if the abdominal muscles be sufficiently relaxed. He also states that a moderate degree of rotundity does not make any great difference in the result as compared with the experiment on emaciated subjects.

Verification in actual cases of labor of what these facts lead us to hope for will be awaited with interest. It is certainly possible that the conversion of the soft internal depression of the sacro-sciatic space into a solid elevation, and maintaining this during a few labor pains, may have a great deal of influence in promoting the normal movement of the presenting part.

MEDICAL LEGISLATION.

The bill before the Illinois State Legislature proposing several amendments to the law for regulating the practice of medicine that has been in force since 1877, has been defeated. Precisely what the nature and scope of the proposed amendments were, we do not know, not having seen a copy of the bill.

There is another bill before the Legislature, having for its leading object such amendment of the existing law in this State, as to secure a more humane and rational mode of proceeding for the commitment of the insane to asylums, or otherwise depriving them of their personal liberty. It is well known that the State of Illinois enjoys the unenviable honor of having a law which requires every person supposed to be insane, to be arrested and brought before a court and jury, for the purpose of determining their sanity or insanity, before they can be received in any asylum or institution for the cure of the insane, in this State.

The law makes no exceptions, and the mother who becomes insane during her confinement after childbirth, and all other cases of acute general insanity, are compelled to go through the same inhuman process of exposure in open court and the mockery of a trial before a jury of six or twelve men, only one of whom is required to have any semblance of medical knowledge. The medical profession of the State have not ceased to protest, on all proper occasions, against the law, since it was enacted several years ago, under the delusion that it would lessen the danger of having parties fraudulently deprived of their liberty by the collusion of friends. This earnest and persistent opposition to the law as it exists, arises from no personal interest that the physician has in the matter, but from the instinctive horror he feels seeing men and women phrenzied with maniacal delusions arrested, sometimes locked in cells two or three days waiting for trial, and then brought into a court-room, subject to the gaze of a crowd of spectators; all the time conscious, as he is, that the proceeding not only does not add one particle to the safety of the patient, but often adds to the danger of making the insanity permanent or early fatal in its results. Three years since the Illinois State Medical Society, through an able committee, framed a Bill proposing to so amend the law that cases of acute general mania could be committed to proper asylums by the Judge of a court of competent jurisdiction on the sworn testimony of two physicians, as is done in all other civilized countries, while the trial by jury in open court was still left for all such parties as might ask for the same, or any one of whose friends might ask it for them. The Bill was presented to the Legislature then in session, but was not acted upon. We understand that a bill is now before the two branches of the Legislature with the same amendments regarding the proceedings on commitment of the insane, with some additional sections relating to other points that we have not seen. At the recent meeting of the State Medical Society, May 19, in this city, the following resolution, offered by Dr. N. Bridge, was passed unanimously:

Resolved, That this Society heartily indorses the provisions of the bill now before our Legislature providing for the commitment of the insane in certain cases without trial by jury, and asks the Legislature to enact these provisions at least.

It is to be hoped that the members of the present Legislature will not allow a final adjournment without complying with the reasonable and humane request contained in this resolution.

Professors M. Semmola and Durante, of Italy, have been designated as representatives in the International Medical Congress to be held in Washington, in September next.

SOCIETY PROCEEDINGS.

AMERICAN SURGICAL ASSOCIATION.

Eighth Annual Session held in the Army Medical Museum, Washington, D. C., May 11, 12, 13 and 14, 1887.

WEDNESDAY, FIRST DAY.

MORNING SESSION.

The Association was called to order by the President, Dr. Hunter McGuire, of Richmond, Va., who delivered the *President's Address* on

THE NEED AND VALUE OF COÖPERATIVE WORKS IN SURGERY.

Nearly every advance in whatever is accomplished by human enterprise is secured by coöperative effort. Advance in surgery can be more surely made by Associations such as ours than by any individual efforts of man. The difficulties which beset us are numerous. Disease presents problems difficult of solution. We cannot apply to the human machine the fixed rules by which inanimate bodies are governed. Besides this, it is necessary to get rid of the rubbish with which we are too often flooded by ignorant, but ambitious contributors. This is an easy task, but it is more difficult to know when to reject the material presented by skillful but unscrupulous workers, who to gratify their own personal vanity, make false returns of their labors. For the developments yet awaiting us, we must be indebted to the contributions which every patient and conscientious laborer may bring to the common stock of ascer-

tained knowledge, and we shall accomplish this best by the cultivation of a broad and generous appreciation of each others work, from which every particle of envy at the success of others has been eliminated; by the hearty commendation which we give to all who have enlarged the boundaries of surgical science, or who have improved its art.

In concluding his address the President made the following suggestions:

1. The formation of a business committee to prepare the work of the Association. The committee should select two general subjects in surgery to be discussed at the morning sessions of the first and second days.

2. The address of the President should be limited to half an hour; readers of papers to the same length of time, and those who take part in the discussions to fifteen minutes.

3. I venture to suggest the abrogation of Article 9 of the Constitution. This will allow us to admit to fellowship some men in this country who are really needed in the Association. While I believe in the rigid observance of the Code of Ethics of the American Medical Association, and the absolute necessity of its enforcement in that body, there is no need for it in our Association. The only code that we should have is scientific work.

4. That the report of the committee with reference to the American Congress of Physicians and Surgeons be adopted.

5. That the Conststitution be so amended that propositions for membership shall lie over for one year. The qualifications for fellowship should be age, experience in surgical work, and scientific attainments with general culture.

A committee of five was appointed to take into consideration the suggestions offered by the President. The committee consists of Drs. S. A. Gross, C. H. Mastin, D. W. Yandell, Moses Gunn and C. Johnston.

The Association then went into Executive Session.

Afternoon Session.

Dr. F. S. Dennis, of New York, read a paper on

Exploration of the Bladder, by the Supra-pubic Method.

The time is not far distant when practically the only two operations will be supra-pubic lithotomy and litholapaxy. Supra-pubic lithotomy is simple in technique, safe in execution, free from injury to the reproductive organ, radical in results, curative in application and brilliant in statistics. The many serious accidents attending the lateral operation are avoided.

Technique of Operation.—For a few days before operation a milk diet should be employed. The day previous to operation the bowels should be moved with castor oil. The morning of the operation an enema should be used so as to empty the rectum for the introduction of the rubber bag. The parts should be washed with antiseptic solution. After the patient has been etherized, the surgeon should introduce a rubber bag into the rectum so as to be above the internal sphincter. Into this twelve ounces of warm water is to be introduced. This quantity will have to be increased or diminished according to circumstances. The danger of rupture of the rectum in elderly people and young boys should be borne in mind. The urine should be withdrawn and six ounces, more or less, of an antiseptic solution introduced into the bladder. The catheter may be left in the bladder and stopped with cork, and this will serve as a guide to cut upon. The distension of the rectum and bladder increases the distance from the pubes to the anterior cul-de-sac of the peritoneum to three inches. The incision should be made in the median line, and should extend for three or four inches above the pubes. When the transversalis fascia is reached its use of retractors on the principle of the eye speculum facilitates the operation. Having divided the fascia the end of the catheter can be felt and cut upon as a guide. The bladder may then be seized with two tenacula and opened. Where free exploration is desired, sutures are introduced on each side of the incision. The stone is removed either with the fingers or forceps. The bladder may then be washed out. A catheter should be introduced through the urethra, but not left longer than twenty-four hours, on account of the danger of exciting traumatic urethritis. In the majority of the cases the wound of the bladder should be left open. In cases of calculi, the condition of the tissues is such that primary union is unlikely. In certain other conditions, such as rupture, the wound may be closed, for here the condition of tissues is different. The abdominal opening is to be closed and a tube introduced.

This operation is indicated (1) for hard, large calculi, and in persons suffering with paraplegia and deformities rendering lateral lithotomy difficult; (2) for removal of certain foreign bodies such as hair-pins, etc., and for the treatment of chronic cystitis; (3) in cases of tight stricture, fibroma of prostate, tumors of the bladder and for rupture. In its extraordinary simplicity, its reduced mortality, its freedom from danger and safety for the general practitioner, it compares well with litholapaxy.

Dr. Dennis had collected 124 cases of supra-pubic operation for stone done since 1879. Previous to this date, the rate of mortality was 30 per cent. Since then the mortality has been reduced, there being eighteen deaths, a mortality of 14 per cent. Seven of these deaths may be justly excluded, giving a mortality of 9 per cent. According to Sir Henry Thompson's statistics, the death rate from the lateral operation is 12 per cent. According to the same authority the mortality of lithotrity is 6 per cent. In considering the mortality of this operation, two facts are to be considered. The mortality may be improved by more rigid antiseptic precautions. The second fact is, that the operation has been limited to the largest stones. When the smaller stones are included, the death rate will be reduced.

Dr. John H. Packard, of Philadelphia, read a paper on

SUPRA-PUBIC CYSTOTOMY FOR OTHER PURPOSES THAN THE REMOVAL OF CALCULI.

In 1883 he removed, by supra pubic cystotomy, a piece of shawl pin five inches in length, which had been passed through the urethra. Since then he has done this operation a number of times. In cases of retention of urine from stricture, where a fair attempt to pass an instrument fails, he draws the urine by aspiration. In a short time an instrument can usually be passed. He did not recall a case in which it was necessary to repeat aspiration. The following cases were cited: July 7, 1855, Mr. G., 85 years old, had retention due to large prostate. The bladder was greatly distended. The urine was drawn off with a long catheter, but he desired more permanent relief. Supra-pubic cystotomy was performed, and a glass ovariotomy tube bent like a tracheotomy tube, was introduced. The patient improved decidedly, but suddenly died July 9, from heart failure, the result of sudden exertion.

J. C., age 43, came under observation January 21, 1885, at the Pennsylvania Hospital, with a history of retention, the result of old stricture. The bladder was greatly distended and no instrument could be passed. There was frequent chills and profuse sweats. The next day Dr. Thos. G. Morton made a perineal incision, opening an abscess; the catheter then passed into the bladder. The following day the bladder was again distended. Supra pubic incision was then done. A catheter passed through the abdominal opening and the neck of the bladder escaped through the perineal wound. On February 7 a large mass of slough came from the abdominal wound. The patient then rapidly improved, and was discharged cured April 21st.

H. F., 43 years old, had retention for four days. The penis, scrotum, and skin of abdomen were swollen and rigid. Free incision was made. The bladder was opened and a tube introduced. On June 4 an instrument was passed by urethra. On July 13 the patient was discharged and has continued well.

Mr. S., age 63, admitted with enlarged prostate and frequent attacks of retention. August 13, 1886, supra-pubic incision was performed and the bladder opened. Although the condition was improved, the patient died of exhaustion August 29.

W. E., age 70, was admitted April 24, 1887, with retention due to enlarged prostate. Supra-pubic cystotomy was performed and a large quantity of putrescent urine removed. A rubber tube was passed into the bladder. The urine contained albumen to the amount of one-half its bulk. Granular casts were also found. A typhoid condition developed and the patient died on the fourteenth day after admission.

R. M., age 40, was admitted the same day. He had double inguinal hernia and double hydrocele. He had passed no urine for fourteen hours. Catheterization was attempted without success. Supra-pubic incision was then performed and a rubber tube introduced. He has done well since then and is beginning to pass some water by the urethra.

Method of Procedure.—The fullest antiseptic precautions should be observed in these cases. In most of the cases on which the author had operated the question whether or not the bladder should be distended had not presented itself, as the bladder was already over-distended. The bladder should never be more than moderately distended, not more than six or eight ounces of a boric acid solution being employed. To retain the water in the bladder a convenient method is to bend the urethra on itself and hold it in this position. There seems to be more advantage and less risk from distension of the rectum. Many writers recommend that the bladder be steadied by an assistant, but this was regarded as needless and objectionable. The incision through the skin should be free enough to give ready access to the deeper parts. When the bladder is reached it is desirable to secure it in some manner before puncturing. For this purpose a small double hook may be used; a small tenaculum may answer. When a large opening is to be made a double ligature is perhaps the best device. In cases of retention the curved trocar and canula should afterward be substituted by the tube. The speaker's custom is to make the opening in the bladder just large enough for the tube. The proper point for making the opening seems to be about at the middle of the exposed portion of the wall of the bladder, which would be about one inch or one and one-half inches above the pubes. The drainage tube should go well into the bladder and have lateral openings only near its extremity. The external end may be closed with a cork or clip, or by bending it. In old men with atonied bladders he had sometimes used glass tubes. If a large opening has been made in the bladder it may be closed around the tube with a few catgut sutures. The tendency of the wound is to close quickly except where the tissues as well as the general system are in bad condition. The edges of the wound in the skin can be apposed with sutures of catgut or silk-worm gut.

In concluding the speaker asked "If the supra-pubic section had been first tried, as generally adopted, is it likely that the perineal operation would have been afterwards performed on account of its greater ease, simplicity and efficiency?"

Dr. A. Vanderveer, of Albany, N. Y., read a paper entitled

TO WHAT EXTENT CAN WE CLASSIFY VESICAL CALCULI FOR OPERATION? WITH A REPORT OF CASES, AND REMARKS ON THE DIFFERENT METHODS EMPLOYED.

He gave the detailed histories of forty-one cases which he had operated on. There were seven cases of perineal lithotomies with two deaths and five recoveries, the former being very old men with large stones. Of attempted litholapaxies and an immediate perineal lithator there were two cases, both resulting in death, one occurring in the speaker's practice, the other in the practice of a friend. Both were severe cases of large stone, the patients presenting a history of much suffering through many years. Of dilatation of the urethra in the female and washing out of fragments or removal of stone entire, there

were six cases, all recovering with no complication whatever. Of urethral calculi in the male there were four cases, all recovering. Of simply lithotrity in the male, there was one case, followed by recovery. Of attempted litholapaxies, but not completed, there were four cases, three ending in death, and one, the stone hiding in a sac, later underwent perineal lithotomy and recovered. One was probably complicated with some form of tumor of the bladder and a history of chronic disease of the kidneys. One was a case of chronic alcoholism, one was complicated with sacculated bladder, and the last two were cases of surgical kidney of the very gravest kind. Of the litholapaxies in the male there were eighteen patients having twenty-two operations, four requiring a second operation. Of the number, sixteen recovered and two died. Of the latter, one after the first and one after the second operation.

With reference to supra-pubic lithotomy, the author said that with the excellent results we are ever likely to obtain from rapid lithotrity, the operation must necessarily deal with severe cases of large, and in some instances sacculated, stone. He did not believe that we should ever expect from it as great a per cent. of recoveries. A table of reported cases of supra-pubic operations was given, showing that in 142 adult cases, a mortality of 22 per cent.; in children under 15 years of age, 113 cases gave a mortality of 10.5 per cent.

The operation of litholapaxy is certainly indicated where the stone is small or of moderate size, and, contrary to the teachings of a few years since, can be done in very young male children with proper instruments. In male adults, if there is severe chronic cystitis, no matter what is the size of the stone, the supra-pubic or some other form of perineal lithotomy seems best. The cystitis can then be successfully treated and there is less danger of a reformation. The speaker thought that it would be found by future statistics that cystitis has much to do with the necessity for a second or third operation. He thought that contracted bladder in the male with adhesions had not received the attention which it demanded. This must in some instances embarrass supra-pubic lithotomy. On anatomical grounds the supra-pubic operation will be much simpler in the youth, as the bladder is much higher in the pelvis at this time of life. In girls rapid dilatation or supra-pubic lithotomy will undoubtedly reach all cases. In adult women vaginal lithotomy may be added.

The discussion of these papers was postponed until Thursday morning.

Thursday, May 12.—Second Day.

Morning Session.

The committee of conference with reference to the

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS

reported that they had attended the meeting of conference held in Washington, September 24, 1886. At their meeting the following resolutions were adopted:

Resolved, 1st, That it is desirable that the following special Societies, the American Surgical Association, the American Ophthalmological Association, the American Otological Association, the American Neurological Association, the American Laryngological Association, the American Gynæcological Association, the American Dermatological Association, the American Climatological Association, with the Association of American Physicians, shall arrange for a conjoint meeting in the city of Washington, September, 1888, and subsequently at intervals of three years at the same time and place.

2. That this arrangement shall not interfere in any way with the autonomy of each special Society, and that each Society shall retain the right to withdraw at any time from this conjoint scheme.

3. That the special feature of the meeting shall be the conjoint assemblage of the special Societies on two evenings during the session; on one of which there shall be an address delivered by the President of the conjoint meeting, and on the other there shall be communications by a referee and co-referee on some subject of general professional interest.

4. That each special Society approving this report is invited to appoint one representative (with an alternate), and that the representatives so appointed shall constitute an Executive Committee to serve for one year, with power to select such officers for the first conjoint meeting as may be deemed necessary; to propose a programme for said meeting; to make all other arrangements, and to prepare and submit a plan or organization for future meetings.

5. That all expenses connected with the conjoint sessions shall be apportioned equally by the Executive Committee among the special Societies participating.

Owing to the views entertained by the committees of the Ophthalmological and Dermatological Associations with regard to the interval of times of meeting, they abstained from voting upon the first resolution. The report was adopted, and Dr. C. H. Mastin, of Mobile (with Dr. J. Ford Thompson, of Washington, as alternate), was appointed as the representative of the Association.

The discussion of papers read on Wednesday was then taken up.

Dr. W. T. Briggs, of Nashville, said that one of the speakers in his paper held that the time would come when supra-pubic lithotomy and litholopaxy would practically be the only operations performed for the removal of stone. The surgeon should have all operations at his command and should select the one adapted to the particular case. In certain cases, such as large stones or deformities of pelvis and lower extremities, supra-pubic lithotomy is undoubtedly the best operation. There is, however, no reason why, in ordinary cases of medium stones, the perineal operation should not be adopted. The best operation, he thought, was one through the median line. The neck of the bladder is usually resistant, but by making a lateral incision of three lines on each side of the prostate gland, with gradual dilation, the opening can be enlarged to an extent sufficient to permit the removal of any stone that should be removed through the perineum. There is no reason why fragmentization of a large stone should not be combined with the medio-lateral operation. He held that incision in the manner mentioned with the removal of all stones at once, would have a less mortality than litholapaxy. His first seventy-four cases were operated on by this method without a death. He then had two deaths, in one a pelvic abscess complicated the case, and in the other there was scrofulosis. Forty-six cases were then operated on with one death. This case died three months after operation of general tuberculosis, with wound

ununited. In the last two years he had operated on six old men with an average age of 66 years, all recovering.

Dr. D. Hayes Agnew, of Philadelphia, said that we cannot commit ourselves positively to any one operation. The median operation is undoubtedly the safest operation through the perineum. The only damage likely to be done is in extraction, but this can be avoided by nicking the neck of the bladder which admits distension to almost any extent. Where the stone is large, and yet is one which should come through perineum, an incision may be made on each side. Drainage is more readily effected by the perineal operation. In cases of large stone the high operation is the best.

Dr. J. R. Weist, of Richmond, Ind., said that he had performed the operation described by Dr. Briggs in eight cases, all of which recovered. With one exception all the patients have been old. One case was 20 years of age, and a mulberry calculus weighing 520 grains was removed. The next youngest age was 59 years old, eight stones being removed. In another case 72 years old, twenty-two stones were removed. From the accounts of the supra-pubic operation given yesterday, he inferred that the operation is more difficult of performance than the one described by Dr. Briggs.

Dr. H. H. Mudd, of St. Louis, said that the use of litholopaxy in the majority of cases takes the place of perineal operation. The supra pubic operation is of service for the removal of certain large stones and for exploratory purposes. It must be borne in mind that the existence of contracted bladder with adhesions will render the supra-pubic operation difficult or impossible.

Dr. J. Collins Warren, of Boston, had seen two cases of the supra-pubic operation during the past year, both in the practice of others. One was for stone and the other for tumor. There seemed to be no difficulty in the operation. Both cases recovered without a bad symptom.

Dr. Theodore Varrick, of Jersey City, operated two years ago on a boy 14 years of age, who had symptoms of stone for seven years. He began with the left lateral operation, but had to carry the incision to the right side. The stone removed weighed seven ounces and two scruples. There was no perceptible laceration and the boy recovered completely.

Dr. David W. Yandell, of Louisville, said that he had performed ninety-two operations by the perineum, eight by lithotrity, and six by litholopaxy. He had seen two supra pubic operations, but thought the operation no easier or better than those mentioned. There were seven deaths from the lithotomies. In none of the cases was there any return of the stone. In the eight lithotrities there was a return of the stone in two cases. In the six Bigelow operations there was a return in two cases.

Dr. John B. Roberts, of Philadelphia, considered the high operation as certain to be a very important one. If we wish to make a free exploration of the bladder the high operation is better than the one through the perineum. In cases of stone operated on by a surgeon without special experience in this direction the supra-pubic operation is the safer. With reference to Dr. Packard's suggestion to treat retention of urine from stricture by supra-pubic cystotomy, he said that his view was that persistent efforts should be made to introduce a filiform bougie which will drain off the urine. Simple aspiration above the pubes will give a chance for the passage of an instrument through the urethra in two or three days.

Dr. J. E. Michael, of Baltimore, said with reference to retention due to stricture or prostatic disease, that supra-pubic aspiration seemed to be all that was necessary, and under proper precautions is safe. Then, in prostatic cases the use of a soft catheter will accomplish all that can be done, without some radical operation is attempted. In cases of stricture this must be treated. As to the advisability of the supra-pubic operation for exploration, for some cases of prostatic enlargement, and for exceptional cases of foreign bodies, there can be no question.

Dr. J. Collins Warren, of Boston, read a

STUDY OF THE PROCESS OF REPAIR AFTER RESECTION OF THE INTESTINES AND SOME OF THE COMPLICATIONS WHICH OCCUR.

A number of experiments made upon dogs were described. The operation consisted in removing a portion of the intestine and a V-shaped portion of mesentery, and then bringing the parts together. The Lembert suture was the one used. After the operation the bowel was replaced in as near its normal position as was possible. The dogs were killed at varying times after operation from three to eight days. In these cases the intestines were found matted together around the seat of operation, but a current of water flowed freely through the gut. In one case the abdomen was opened a few days after operation and this matting together of the various coils of intestine found. The intestine was replaced and the wound again closed. Six months later most of the adhesions were found to have disappeared.

Dr. Charles B. Nancrede, of Philadelphia, read a paper entitled

SHOULD LAPAROTOMY BE DONE FOR PENETRATING GUNSHOT WOUNDS OF THE ABDOMEN INVOLVING THE VISCERA?

The chief object in presenting this subject to the consideration of the Association was a medico-legal one. He asked that after a consideration of the subject the Association, the highest surgical tribunal of the country, express an authoritative opinion upon this question. Reference was made to the experiments of Wegner and Grawitz, showing that the healthy peritoneum can dispose of air, serum, bile, and healthy urine. When, however, air and putrescible fluids in greater amount than could be disposed of in a short time were introduced, decomposition occurred, and septicæmia resulted. A notable exception was that living defibrinated blood never decomposed under these circumstances. This seems to prove the truth of the suggestion of the author that the presence of fibrin-ferment, and probably its absorption, is one of the dangers of peritoneal trau-

matism. The ordinary micro-organisms produce no evil effects, provided the quantity of putrescible matter does not exceed that which may be disposed of in a short time. In small quantities the pathogenic micro-organisms produce no harm. Suppurative peritonitis is produced by these micro-organisms when stagnant fluids are present, capable of nourishing the bacteria, when the surface of the peritoneum has been destroyed by caustic fluids, and when there is a wound of the peritoneum. The practical application of these experiments teaches that all blood and serum should be removed and free drainage provided; every wounded surface must be coaptated; if a tube is used, the opening must be carefully guarded; the depression of the circulation present during shock must be removed; and the vascularity of the peritoneum must be kept as near the normal as possible.

When visceral wounds do undoubtedly exist, the tendency of these cases is invariably towards death. Hæmorrhage, in itself, is rarely fatal, but a very small collection of blood may be followed by fatal consequences, either through the induction of sapræmia or by furnishing pabulum for the development of organisms productive of suppurative peritonitis. In nearly every case, death is due to septic peritonitis caused by extravasated matters. Of those attacked with septic peritonitis 90 per cent. die within twenty-four hours. When recovery ensues, the effused matter is absorbed and a limited adhesive peritonitis glues the injured organ to the abdominal walls or to a neighboring viscus. This process is successful in about 8 per cent. of the cases. Shock, and the risk of rendering a peritonitis septic and diffused, which might have remained local and simple, are the dangers of the operation; but as we have the power of rendering the inflammation resulting from the manipulations innocuous, shock is practically the only result to be dreaded. If these facts and the deductions from them be true, all ball wounds of the abdomen involving the stomach, intestines, bile, or urinary bladder should be treated by suture, or by resection and suture. Injured omentum should always be excised and the serous surfaces carefully sutured. Wounds of the liver and pancreas are to be treated in the manner to be described. A wounded spleen or kidney is to be removed, provided certain contra-indications do not exist. Even penetrating wounds of the abdomen without involvement of the viscera are better treated by exploratory section than by the expectant method. In many instances, unsuspected injuries of the blood-vessels and viscera will be found and appropriately treated. The speaker laid but little stress upon most of the symptoms said to be diagnostic of wounds of the viscera, and held that the diagnosis should be made by the eye alone. The track of the ball should be enlarged, under aseptic precautions, until it has been determined whether or not the peritoneum has been opened. Then median section should be performed to ascertain the existence of and repair any damage that may have been done. The above remarks can only apply to wounds of the anterior and lateral walls of the abdomen. When the posterior wall is involved, it is unadvisable to ascertain the fact of peritoneal penetration by direct exploration. In these cases, a correct opinion is almost always difficult, and often impossible, without laparotomy.

The rational signs of peritoneal or visceral lesion were briefly mentioned. The escape of bile, fæces, or the contents of the stomach, at once determines the question of visceral penetration. These signs, however, are rare, even when visceral lesion is present. Repeated vomiting of considerable quantities of blood almost certainly points to peritoneal or vssceral penetration. This symptom is unlikely to be present, even when there are numerous wounds, unless one involves the stomach or upper portion of the small intestine. The passage of blood in quantity by the bowel is strong presumptive evidence, but it rarely occurs early enough to be of practical diagnostic value for operative purposes. The presence of fluid within the abdomen within an hour or two after the injury is a positive indication of peritoneal penetration and probable visceral injury, for only intra-peritoneal hæmorrhage could produce such rapid accumulation of fluid. The rapid accumulation of intestinal gas in the general peritoneal cavity is a sure sign of wound of the peritoneum and of the gut. To be of much value it must appear within a short time after the injury. Finally, an amount of hæmorrhage which cannot be accounted for after a careful examination of the parietal wounds, indicates penetration and vascular or visceral lesion.

Profound shock, if not due to hæmorrhage, is a contra-indication to operation. The surroundings should not contra-indicate operation in a proper case, provided the operator is an expert in abdominal surgery. Most cases will do better if left to nature than they will if operated on by a bungling surgeon. If well advanced peritonitis exists, laparotomy is contra-indicated. Where there is no visceral complication, operation under these circumstances may sometimes be justifiable. Laparotomy, if done at all, should be done at the earliest possible moment that the condition will admit of it. Shock is the only thing that should delay the operation, and this should not do so if the condition is produced by hæmorrhage. In operating, strict antiseptic precautions should be carried out. The incision should always be median, extending from a short distance above the umbilicus to two inches above the pubes. Unless there be free hæmorrhage, the small intestines should be carefully gone over, keeping them constantly enveloped in towels wrung out of hot water. Afterwards the stomach, spleen, kidneys, bladder, etc., must be carefully examined. The sources of a severe hæmorrhage must at once be sought for. Wounds of the bowel should be secured with the Lembert suture and dusted with a little iodoform. Wounds of the liver, if occupying its free border, should be coaptated, if possible, with dry antiseptic catgut, which will soon swell and fill the track made by the needle. If this cannot be done, the hæmorrhage may possibly be arrested by the thermo-cautery; or if the bleeding is free, the wound should be plugged with an iodoform gauze tampon. If, at the close of the operation, the bleeding is almost completely checked, the

cautery may be used as a further protection and the tampon removed. If, however, the bleeding is still free, the tampon should be replaced and allowed to remain permanently. Wounds of the pancreas, spleen, and kidneys are to be treated in a similar manner. If these measures fail, the spleen or kidney is to be removed. Wounds of the bladder had best be united with dry catgut. Contused portions of the bowel should be excised. Wounded or contused omentum or mesentery should also be removed. In removing a portion of the bowel, the cuts should correspond to the distribution of a large mesenteric branch. Should the pulse fall during the operation, flushing the abdominal cavity with hot water is often of service. The peritoneal toilet is most quickly and effectively made by irrigation with warm sterilized water and subsequent removal with sponges. Wounds of the peritoneum should be united. In closing the abdominal cavity, the peritoneum should be sutured with fine silk or catgut. The muscular, aponeurotic, and cutaneous structures should then be united with strong silk. The wound should be dusted with iodoform, and the dressing completed by the application of a pad of absorbent cotton and a flannel bandage.

Alimentation should be carried on by the rectum for forty-eight hours, when possible. Where peritonitis comes on after the operation, the treatment will depend upon whether it has developed rapidly or gradually. In the former case there is often evidence of shock from vaso-motor paresis; and in these cases small doses of morphia with atropia will be of service, while large doses of opium may prove fatal. This should be continued until pain is relieved and the patient falls into a quiet sleep, from which he is readily aroused. In the latter stages of peritonitis, one or more hypodermics of atropia will at times save otherwise hopeless cases. For the control of the vascular processes involved in peritonitis we have two powerful measures in the ice coil to the abdomen and in the use of leeches, if applied early and the patient has not lost much blood. If the temperature continues to rise despite treatment, it is probable that ptomaines are being absorbed, producing sapræmia. In such cases, irrigation with safe antiseptic fluids is indicated.

In concluding, the speaker stated that everything advanced was to be viewed as more or less provisional, since sufficient experience in the operative treatment of these cases has not been accumulated to warrant positive statements.

(*To be concluded.*)

CHICAGO SOCIETY OF OPHTHALMOLOGY AND OTOLOGY.

Stated Meeting, February 8, 1887.

THE PRESIDENT, E. L. HOLMES, M.D., IN THE CHAIR.

BOERNE BETTMAN, M.D., SECRETARY.

DR. W. FRANKLIN COLEMAN read a paper on

THE USE OF A PLUS CYLINDER IN SIMPLE MYOPIC ASTIGMATISM OF LOW DEGREE.

(See p. 592.)

DR. GARDINER said he preferred to give the same minus cylinder glass for reading as for distance. He wished to have the eye use the normal amount of accommodation, and does not care to give two pairs of glasses; one for distance (the minus cylinder) and one for reading (the plus cylinder).

DR. BETTMAN had always prescribed the minus cylinder for reading. Since Dr. Coleman had mentioned the substituting a plus cylinder for a minus he had tried it in four cases, and in two of them without a good result.

DR. HOLMES had tried the plus cylinder as above described, and found the minus cylinder more satisfactory.

DR. GRADLE has always found the minus glass more satisfactory than the plus. He has frequently noticed that the axis of the minus cylinder determined with homatropine differs from that determined when the accommodation recovered, but the patient always accepted the former in reading.

DR. GARDINER said he had frequently noticed the patient in reading change the axis of the distance cylinder.

DR. COLEMAN, in reply, said that in his experience, patients with low degrees of myopic astigmatism did not care to wear glasses for distance. He was pleased to hear the experience of these members, though it differed from his own.[1]

DR. J. ELLIOTT COLBURN read a paper on

GALVANIC CURRENT IN THE TREATMENT OF CERTAIN FORMS OF CATARACT.

(which will appear in an early issue.)

Stated Meeting, February 12, 1887.

THE PRESIDENT IN THE CHAIR.

DR. F. C. HOTZ reported a case of

PARTIAL TRICHIASIS RELIEVED BY STELLWAG'S METHOD OF REVERSING AND TRANSPLANTING THE CILIARY BORDER.

(which will appear in an early issue.)

THE PRESIDENT presented a

CATARACT GLASS, DOUBLE CONVEX CYLINDRICAL,

axes at right angle and equivalent to + 12, D. spherical, ground by Meyrowitz Brothers, New York. He stated that such lenses had been long in use by watchmakers and in the construction of certain optical instruments. His attention was called to the subject more than a year ago by a friend, a distinguished surgeon of New York, upon whom had been performed a successful cataract operation. The usual glasses, if he remembered correctly, gave perfect satisfaction. After a secondary operation for capsular remains, the patient found difficulty in adjusting spherical glasses. He then experimented with cylindrical lenses with great satisfaction. There is reason to believe that this patient is one of the first who ever wore such a combination as being superior to spherical lenses. The patient, after visiting some of

[1] Since the above was written Drs. Noyes and Roosa (New York) express an experience similar to Dr. Coleman's in the substituting of a plus cylinder glass in simple slight myopic astigmatism.

the European clinics, was led to believe that few, if any, of the teachers knew, by practical experience, that such cataract glasses were advantageous to some patients. Experience must determine whether the slightly less spherical and chromatic aberration and the somewhat enlarged field of the cylindrical lens, such as was here presented, can be of special benefit to cataract patients, and those requiring strong positive lenses.

The President also presented a small

INSTRUMENT FOR INCISING SECONDARY CAPSULAR CATARACT,

in cases in which iridectomy had been performed. The instrument is practically a very narrow Græfe's knife, bent on the flat at about half an inch from the point, making a right angle with a square shoulder. The metal portion of the handle is round and small, not unlike that of a cataract needle. The handle of the instrument, in operating, is held in position as in making the corneal incision for extraction of cataract. The point is carried through the periphery of the cornea into the anterior chamber, the plane of the knife being in the plane of the perpendicular meridian of the globe. A slight rotation of the handle carries the cutting edge of the instrument through the opaque capsule. Dr. Holmes had used this instrument in three cases with great success. In the fourth case, the very tough membrane was simply torn from its attachments and displaced. The wound in the cornea produced by the instrument is somewhat larger than that made by a stop needle. There is less violence, however, to the tissues than in cases in which it is necessary to make extensive motions with the handle of a stop needle or of Knapp's knife needle to ensure rupture of the membranes. An instrument right or left is required for each eye.

FOREIGN CORRESPONDENCE

LETTER FROM EDINBURGH.[1]

Skene Keith—Ovariotomy—Tapping Cysts of the Broad Ligament—Myo-fibroma of the Uterus—Professor Chiene—Resection of Knee and Ankle—Amputation of Thigh—Resection of Hip—Professor Annandale—Resection of Knee—Tuberculosis of Knee—University of Edinburgh.

Dear Dr. Fenger:—I had the pleasure of witnessing an ovariotomy by Mr. Skene Keith, assisted by his father, Dr. Keith. Young Keith has inherited many of the good qualities of his father, and promises to become one of the most successful ovariotomists. I doubt if ever a man of his age could show such a record of cases as he has recently published, and it is only just to say that the statistics published by the Keiths can always be relied upon.

The patient was 74 years of age, and the tumor had been growing for two years and had been several times tapped. The cyst was large, and in the pelvis a number of hard nodules could be felt. The operator and assistant were in shirt sleeves and wore an apron. Ether was used as an anæsthetic. The abdominal incision was about three inches in length, and the cyst was tapped and, as its contents escaped, it was drawn forward into the wound. When nearly empty it was freely incised, the hand introduced and a number of smaller cysts crushed, which diminished the tumor sufficiently in size so that it could be brought out of the wound. The pedicle was treated as above described, and after the removal of the clamp the compressed cauterized portion looked like a dry translucent membrane. A number of firm adhesions to the abdominal wall were carefully isolated, tied on each side and cut between the ligatures. The operation was done slowly and carefully, and afforded a good illustration of what is meant by conscientious scientific surgery. A number of convalescent patients were shown where abdominal section had been done for different indications, and all of them were doing well. An old lady 78 years of age had an ovarian tumor removed three weeks previously, and now insisted on leaving her bed, as she insisted that she felt stronger and better than before the operation. In one case the pelvic adhesions were so extensive and firm that only part of the tumor could be removed; the remainder was fixed in the wound and drained, and the patient was doing well and the tumor becoming smaller in size. Dr. Keith has observed numerous permanent cures after simple tapping of cysts of the broad ligament, and is in favor of resorting to this simple procedure in all such cases as a preliminary or tentative measure before exposing the patients to the increased risks of an abdominal section. In spite of his unparalleled results in the operative treatment of myo-fibroma of the uterus, he assured me that as his experience increased with this class of tumors the more he dreaded a radical operation. Dr. Keith is a representative conservative surgeon, but he can never be accused of possessing a "statistical conscience," as when the indications for an operation are clear to him he will never shrink from the responsibility of an operation, no matter how desperate the case may be, for the sake of improving his statistics. His fame is established, his record is made, and whatever his statistics in the future may be, the scientific world can rest assured that it is the result of honest, conscientious work. The second evening in Edinburgh I spent in the family of Dr. Keith, as I had been invited to dinner. I felt that I was surrounded by the blessings of a truly Christian home, and the evening was spent in discussing abdominal surgery. Although the weather was cold and a drizzling rain rendered out-door exceedingly unpleasant, the doctor insisted on accompanying me to the hotel, where he bade me an affectionate farewell, and I retired with pleasant thoughts of the many profitable hours spent in his genial presence.

While in Edinburgh I attended a lecture by Professor John Chiene, on Resection of Knee and Ankle-joint, and Amputations of Thigh. After resection of knee-joint he does not resort to any immediate measures to secure coaptation and immobilization, but relies on extension by means of weights and pulley,

[1] By permission of Drs. Fenger and Senn.

to prevent posterior displacement of tibia. Only a moderate degree of extension must be applied, so as to overcome the contraction of the hamstring muscles without effecting diastasis of fragments, which might lead to pseudo-arthrosis. Carden's transcondyloid amputation was clearly described, and a comparison drawn between it and Syme's amputation through the ankle-joint. In Gritti's amputation the bone is divided higher up, so as to make room for the patella, and this operation resembles Pirogoff's amputation through the ankle-joint. In this operation the great difficulty that presents itself is the tilting of the patella, which, when it takes place, interferes in obtaining a satisfactory result. The patella must hang loosely over the sawn surface of the femur, and when this is not the case it will become necessary to divide the insertion of the quadriceps femoris from within with a tenotomy knife. In amputations at the hip-joint in children, and in adults who have become greatly emaciated, he prevents hæmorrhage by circular elastic constriction applied at a point corresponding to the perineum and above the tip of the trochanter major. After making the flaps and ligating all visible vessels, the constriction is removed and the upper portion of the femur laid bare by a longitudinal incision and disarticulated. In fleshy people he recommends the use of Spence's skewer, which is passed through the hip joint in the same manner as the amputating knife in the old operation, and after transfixion the tissues anteriorly and posteriorly are constricted separately by winding over the ends of the skewers a rubber cord in a figure of 8. The anterior flap is made first and the large vessels are tied; after disarticulation the posterior flap is carefully examined and all visible points tied, when the constrictors are removed separately and additional bleeding points secured. By resorting to this simple procedure the lecturer claimed that hæmorrhage could be reduced to a minimum.

In excision of the hip-joint he has tried the more conservative method of removing only the head of the femur, but experience has taught him that this method of operation does not afford adequate drainage, and he has been obliged to come back to complete excision, so that at present he always removes the trochanter major. To prevent muscular contraction after amputation of the thigh he resorts to a novel device. Sheet lead is moulded to the shape of the stump and applied over the dressings; the weight of this splint, it was claimed, would suffice in preventing undue muscular contractions. Professor Chiene is a fluent speaker and most excellent teacher. Almost every member of the large class listened with undivided attention and took full notes of the lecture. In a small but well supplied laboratory Prof. Chiene, with the help of his assistant, Dr. Edington, important and valuable work is done in bacteriology. Here specimens are examined and diagnoses are made, and all known germs are cultivated, and a considerable enthusiasm prevails for the detection of new microbes. It seems to me that every teacher of surgery should imitate the example of the Glasgow professor of surgery in making observations and researches independently of the teacher of general pathology, as in doing so the student's attention is constantly called to the importance of surgical pathology.

I had the pleasure of accompanying Professor Annandale through his wards, and of witnessing several important operations. Prof. Annandale is a perfect type of a Scotch or English surgeon, a good anatomist, skilful with the knife, a dexterous but careful operator. An immense clinical experience enables him to diagnosticate surgical lesions and injuries almost on sight, and with remarkable accuracy. He has abandoned typical resections of the knee-joint in children in favor of arthrectomy and atypical or partial excisions. The details of antiseptic wound treatment he considers superfluous, and relies mostly on dry dressings, as sublimated cotton. After excision of the knee-joint, he applies a hollow posterior wire splint, with an opening for the heel. This splint is well padded and covered with Mackintosh cloth, so as to render it impermeable to fluids. It is applied immediately after the operation and fixed to limb with a plaster of Paris circular splint extending from toes to near the perineum, with an open space for the knee. This dressing completely fixes the limb, and at the same time permits changes of wound dressing without removing the splint.

His method of treatment of affections of the knee-joint which call for operative measures, was illustrated on a boy about 18 years of age, suffering from tubercular disease in its earlier stage. The joint was only moderately swollen and the operation could certainly be designated an early one. Volkmann's incision was made and the patella divided transversely with a saw. The synovial membrane was dissected away with the knife and the articular cartilage was partially removed in slices with the same instrument. A fungous osteitic depot was found in the internal condyle of the femur, and was gouged out, as well as a similar but smaller focus in the head of the tibia near the articular cartilage. After irrigating the wound with a weak solution of sublimate and arresting hæmorrhage, the patella was united with one silver wire suture, the ends of which were cut short and hammered down upon the bone. A small drain was introduced at the most dependent point on each side as far as the bone. Protective silk and sublimated cotton constituted the dressing. The limb was immobilized in the manner described above. The next case was a resection of the wrist for a suppurating tubercular lesion of the joint, in a female 35 years of age. A single long incision was made over the middle dorsal aspect of the wrist, and after opening the radia-carpal articulation the lower end of the radius was brought into the wound and the whole articular surface removed with the saw; all of the carpal bones were removed, as well as the articular surfaces of the metacarpal. The wound was repeatedly irrigated, and drainage established anteriorly by pushing a dressing forceps through the tissues, cutting the skin and widening the tract by distending the blades of the forceps a drain was introduced and the wound closed by suturing. Wound-dressing the same as in previous case. The hand and fore arm were fixed upon a pistol-shaped splint.

I visited Greenfield's laboratory, where I had an excellent opportunity to study a great variety of bacterial cultures. One of the favorite culture substances in this laboratory is bread paste. Although the microbes do not show so well upon this substance as gelatine or agar-agar, the cultivations were very large and could be readily recognized. The Medical Department of the Edinburgh University contains, as I was told, nearly 2000 students, and to judge from the crowded condition of the lecture rooms and the crowds in the halls rushing from one room to another, the estimate cannot be far from being correct. Although the system of instruction is perfect and the means for demonstrations excellent, and most of the teachers have more than a local reputation, I could not but think that the students injure their own interests by congregating in such numbers, and that it would be advantageous to them if at least half of the number would seek places of instruction where the same facilities are offered and where the teachers can devote more time to each individual student. N. SENN.

DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Tuberculosis of the Joints—Respiratory Therapeutics in Phthisis—Death of Dr. E. Darwin Hudson.

At the May meeting of the New York County Medical Association, Dr. Ira B. Read read a paper on *Tuberculosis of the Joints*, in which he related in detail the history of a case now under his care which he believed to be of this nature, in which, during the past five years, a number of joints have been successively attacked; the patient (at the present time 60 years of age) having, up to the beginning of this trouble, always enjoyed excellent health.

At the same meeting Dr. Lawrence J. McNamara read a paper on *Respiratory Therapeutics in the Treatment of Phthisis Pulmonalis.* About four years ago Dr. McNamara's attention was attracted to an inhalation apparatus consisting of a funnel-shaped glass globe with two openings; one for the attachment of the metallic disc holding in its centre the spray tubes, and the other, immediately opposite, terminating in a long mouth-piece. The fluid to be atomized was placed in the globe, and a rubber tube used to connect the fluid with one of the spray-tips, while the other tip was connected with a cylinder of compressed air. The globe rested on a bracket capable of being raised or lowered as required. The patient, standing with head elevated, took the mouth-piece in his mouth, and inspired; allowing the expired air to escape through the nostrils.

His first impression was that this apparatus was of similar nature to many others tried before, and found wanting; but experience in its use had convinced him of its practical utility. The compressed air is made to pass through a large cylinder into a smaller one before reaching the spray-tubes, and by this means, the valves being kept partly opened, constant, steady pressure could be maintained in the smaller cylinder; with the effect of constantly producing the same character of spray.

Dr. McNamara has used this apparatus for nearly eighteen months, having begun to employ it with the idea that he could no doubt relieve many of the distressing symptoms in a considerable proportion of his phthisical patients; but, noticing the marked amelioration of the condition in the majority of instances, he determined some months ago to keep more exact records of temperature, pulse, respiration and expectorating, noting especially the presence or absence of bacilli, and the effect of the treatment upon them. All the cases were in private practice, and the whole number treated was between fifty and sixty; but, as nearly one-half had the treatment but a few times and at irregular intervals, they are excluded from the account. The cases considered embraced almost all the forms of phthisis except the disease in the stage of excavation, and the patients remained under treatment from one week to nearly eight. Under this method of treatment the cough and expectoration diminished, and in those treated the longest the cough quite disappeared. The bacillus was found in every one of these cases, and was always present, even to the termination, with the exception of one instance; although the number of bacilli was visibly diminished. When the treatment was discontinued, however, the symptoms had in most cases disappeared. One illustration can be described in detail; that of a young married woman 23 years of age. He placed her on iron, quinia and strychnia, and gave her daily inhalations of the following solution:

℞. Sodii bicarb. .....
Sodii biborat. ..... āā ℥i.
Acid carbolic. ..... gtt. xx.
Glycerinæ. ..... f℥j.
Listerine ..... f℥ij.
Aq. destillat. ..... f℥xvj.
M.

When this treatment had been continued for nearly two weeks the expectoration was found to have increased, but its purulent character had changed to one more mucoid. The severity of the cough was lessened, and the general health had begun to improve. She was then placed on an inhalation of the dark extract of pinus Canadensis, with Lugol's solution (1 to 5 drops to the drachm), carbolic acid and distilled water. She remained under treatment regularly for about three weeks longer, and then refused to continue the daily inhalations, although consenting to come to the office two or three times a week. At the time the daily treatment was discontinued repeated examinations, made with the greatest care, failed to discover any evidence whatever of the presence of the tubercle bacillus. Three months afterward, also, the same rigid search for bacilli gave a negative result.

The sudden and untimely death of Dr. E. Darwin Hudson, the popular professor of medicine at the New York Polyclinic, at the age of 43 and in the midst of his active labors, is severely felt by the profession here. He was held in the highest esteem by

all, and no man of his years had achieved greater success as a consultant and clinical teacher; his position as physician to Bellevue and St. Elizabeth's Hospitals affording him special opportunities for study and instruction, of which he availed himself to the fullest extent. P. B. P.

GALVANIC MEASUREMENT.

Dear Sir:—I have before me copies of THE JOURNAL of April 23 and May 7. The former opens with "Treatment of Fibroid Tumors of the Uterus by Electrolysis, with a Description of Apostoli's Method," by Franklin H. Martin, M.D. Both numbers contain articles under *Domestic Correspondence* entitled "*Galvanic Measurement.*" That of the former being also by Dr. Martin, and of the latter by Dr. Engelmann, of St. Louis, Mo. I have also carefully read a paper by Apostoli, describing his method of treating uterine fibroids by powerful electrolysis, and a subsequent paper by the same author "On a New Method of Treatment of Chronic Metritis, and especially Endo-metritis, by the Intra-Uterine Chemical Galvano-Caustic." This is a translation as it appeared in the *Boston Medical and Surgical Journal* of April 21, in which currents as high as 200 milliampères are mentioned.

A careful consideration of some of the statements which are to be found in the above-mentioned papers, I believe to be of the greatest importance to physicians in general, especially to those who employ the galvanic current in their treatment of certain cases. Ohm's Law, which is as well established as the multiplication table, and which enables us to locate exactly a fault in an ocean cable, expresses the following fact: Electro-motive force divided by resistance equals current—Electro-motive force in volts, resistance in ohms, and current in ampères; these being the electrical units, the formula being $\frac{E}{R} = C$, and by deduction $E = C \times R$ and $R = \frac{E}{C}$. Thus, knowing any two of these factors, the third is easily obtained.

Electro-motive forces of batteries vary with the materials employed, and not with the quantity of material; for example, E. M. F. of the Law cell is 1.4 volts, of Leclanche 1.5 volts, of chloride of silver cell 1.06 volts, of gravity 1.079 volts; whether the cells be an inch high or a mile high. E. M. F., however, increases directly as the number of cells connected up, in series. Resistance includes internal resistance of the battery, the resistance of connecting wires, milliampèremeter, tissues, etc.; in fact, whatever is in the electrical circuit. Current is equal at all parts of the circuit.

Dr. Martin's article says: "The current of electricity used in electrolytic therapeutics should be one of moderate quantity compared to the intensity." He is here making use of obsolete terms to express the idea of currents derived from sources of high or low electromotive force. The facts are these: The effects of equal currents are equal. To obtain the same current through double the resistance, double the E. M. F. is necessary.

Again he says: "The maximum current that can be safely passed through the body, consistent with our present experience and knowledge, is about 1,000 milliampères. To get this power I use a battery composed of 115 gravity cells" In another place he says: "The results of my experiments have led me to adopt for office purposes the ordinary crowfoot gravity cells." In a note to the "1,000 milliampère" paragraph he states: "Since writing the above I have been able to use still higher currents in special cases;" and also states that "These cells are coupled in tandem," by which I judge that he means connected in series. I am afraid he has been deceived by the indications of his absolute milliampèremeter; for if his patient was constituted of pure copper in abdominal section, and in possession of a uterus of the same material, the impossibility would still remain of passing a current of 1,000 milliampères, even with a thousand cells of ordinary crowfoot battery gravity, connected in series.

But when, in the article on "Galvanic Measurement," page 472, Dr. Martin states that he had used on one tumor with very great depth of uterus, a current of 10 ampères, I can only say, "The cake is his'n, because he took it." It seems to me like a bad case of extra-uterine astigmatism!

In the article on "Galvanic Measure," by Dr. Geo. J. Engelmann, in THE JOURNAL of May 7, I notice the following: "Granting a deep uterus and thin abdominal walls, the tissues intervening between the electrodes offer a resistance of about 60 ohms." Also in the article in the *Boston Medical and Surgical Journal*, translated from Dr. Apostoli, where 200 milliampères are said to be obtained by employing 30 Leclanche elements, which would indicate a resistance between electrodes of about 200 ohms, and this without counting resistance of milliampèremeter. To the writer these resistances seem too small, though his opportunities for making these measurements have been very limited. A contact resistance alone of a flat platinum uterine probe properly inserted amounted to over 600 ohms. Undoubtedly a great variation in resistance will be observed with different subjects, as well as character of both electrodes.

Very truly yours,

H. L. BAILEY, *Electrician.*

112 Liberty Street, New York, May 10, 1887.

BRANCHES OF THE AMERICAN MEDICAL ASSOCIATION.

Dear Sir:—In view of the fact that at the coming meeting of the Association, a special Committee on the "Branch question" will submit its report, it seems strange that members who may not be present should refrain from expressing their opinions beforehand. The question is open for discussion, yet, from the silence in your columns, it would appear that the last words on this subject had been written. Your correspondents last year were more engaged in devising the means by which a change could be made than in demonstrating its fitness or advisability. This is the least advantageous method of bringing the question to an issue; the first point should be the establish-

ment of a case. Those who advocate the change do so in the expectation of extending the power and influence of the Association; of rendering possible a thorough and practical organization; and of affording a means through which an expression of opinion, or a policy, could first be shaped within the body, and then authoritatively projected beyond. The question at the bottom of this matter is medico-political rather than scientific, and the end to give the profession status as a vital factor in political life. There is no country where organization is more respected or has greater practical influence than in the United States, and when a plan can be devised which is in harmony with existing institutions and the system of representative government, its adoption will hardly fail to be advantageous. Instances have been cited in which the influence of the Association has been successfully employed in the past to great professional advantage; yet we are forced to believe that these successes were due more to the personality of the advocates than to the weight of a resolution or series of resolutions passed at the annual meetings of a scientific body. Cannot these achievements be taken as an earnest of what may be done when the means are provided? The Association now possesses within itself the elements necessary for a progression which would be unequalled in professional annals. With the assistance of The Journal it has already demonstrated a renewed vitality; and it only requires a system of organization to make it what it might be, the most powerful medical association in existence.

It is a mere matter of theory that affiliated local and State societies contribute more than moral strength or support. Their members are not members of the Association in fact, nor is the treasury enriched by a single direct contribution. If the financial aspect of this question of reorganization could be placed upon a sound and equitable basis, most of the fancied objections to real progress would be removed.

It has been claimed that the present system of representation by delegates who *alone* have the power to vote, accomplishes all that is sought from representatives duly elected by Branches; yet it appears that practically the suffrage is not so limited. A letter from an "Old Member" of the Association which appeared in *The Sacramento Medical Times*, of May, 1887, gives evidence of a different character. The writer says: "Where the necessity arises for legislative action, both registered and unregistered delegates, as well as Permanent Members who have no right to vote, indiscriminately exercise it, thoughtlessly or indifferently." Presuming that the writer knows whereof he speaks, it would seem that the delegate representation system is not by any means the safeguard that it purports to be. Admitting, however, that this is a rare occurrence, a grave and inseparable disadvantage still remains—and one which has been keenly felt by the Association very recently. The writer adds: "Moreover, with a system where a numerical attendance dependent upon locality has legislative power, there can be no fixed policy, as the conclusions of one year may be contrary to those of preceding years, or may be overruled at some subsequent place of meeting." I trust that, during the interval which still remains, those who believe in the innovation will place their side of the question before your readers. The age is one of progression, and this occasion demands that steps should be taken to furnish means of attainment commensurate with the broad prospects of the American Medical Association.

Westward Ho.

INTERNATIONAL CONGRESS.

NINTH INTERNATIONAL MEDICAL CONGRESS.

Section 9, of Pathology, Microscopical and Pathological Exhibit.

In connection with the Section of Pathology at the approaching meeting of the International Medical Congress to be held in Washington, D. C. (U.S.), commencing on September 5, 1887, there will be an exhibit of objects relating to Microscopical Anatomy and Pathology, including Bacteriology, and illustrations of Ptomaines and Leucomaines, and whatever else may throw light upon intimate Pathological processes.

In order to make the exhibit as complete as possible, the loan of Microscopical preparations, the instruments and agents for preparing them, and the apparatus for Bacteria Culture are solicited.

The means illustrative of the following subjects are desired:

a. Human and Comparative Histology, morbid and healthy, as illustrating Pathology.

b. Morbid Growths, benign and malignant.

c. Embryology, human and comparative.

d. The development and Pathology of Nervous Matter, of Brain, Spinal Cord, and Peripheral Nerves.

e. Epizoa and Entozoa.

f. Pathogenic Microbes, both discovered specimens and culture preparations.

g. Impurities in water liable to be used for drinking.

h. Miscellaneous objects of interest to the Pathologist and Microscopist—such as test objects to illustrate the working powers of particular lenses, Microscopical appliances, Bacteriological apparatus, etc.

i. Pathological specimens of moderate size to be examined without the microscope, are desired.

Competent persons will be secured to assist in the proper exhibition of objects. Those who forward objects for exhibition and intend to be present at the Congress, are requested to take charge of their own specimens during the hours of exhibition. Others, who are willing to take charge in the same manner of such specimens as the Committee in charge of the exhibit may assign them, are requested to notify the Chairman as early as possible.

All preparations and apparatus will be regarded as loans, and care will be taken to secure their proper preservation and safe return.

All persons willing to contribute to the exhibit are requested to forward a list of the objects, they propose to display, at as early a date as possible, to the address of Edward M. Schaeffer, M.D., Washing-

ton, D. C. (U. S. A.), Chairman of the Committee in charge of the exhibit.

All preparations may be sent to the same address, and on receipt will be at once acknowledged by the Committee, and those selected for exhibition will be included in the catalogue of the exhibit. The Committee can only be responsible for exercising proper care of articles received.

The President and other officers of the Section of Pathology request further contributions to the Section on any pathological subjects, but are particularly desirous of articles on the Pathological Relations of Ptomaines and Leucomaines, the Morbid Anatomy and Pathology of Alcoholism, the Etiology and Pathology of Cholera and Yellow Fever, the Pathology of Tubercle and Tuberculosis, the Influence of Inhibition in Inducing and Modifying Pathological processes; and, in connection with the exhibits, descriptions and essays which may go into the records of the Section.

A. B. Palmer, M.D., L.L.D.,
President of the Section of Pathology.
E. M. Schaeffer, M.D.,
Chairman of the Committee on the Exhibit.

Transatlantic Rates.—In the *Revue Générale de Clinique et de Thérapeutique*, we notice the following in regard to special rates for physicians coming from France to the International Congress: "In a letter addressed to various journals, M. Dujardin-Beaumetz announces that the Compagnie Transatlantique will carry French physicians to the International Medical Congress in America at a reduction of 30 per cent., making the fare 700 francs ($140) over and return, first class.

ASSOCIATION ITEMS.

AMERICAN MEDICAL ASSOCIATION.

The Thirty-eighth Annual Session will be held in Chicago, Ill., commencing on Tuesday, June 7, at 11 A.M., in Central Music Hall, corner of State and Randolph streets, and will continue four days. Good rooms for the several Sections will be provided as near the hall for general meetings as possible. Registration books will be open in Central Music Hall on Monday, the day preceding the meeting, for those who wish to register early.

In addition to the list of papers already published, the following are promised:

Section on Practice of Medicine, Materia Medica and Physiology.

R. W. Seay, Pilcher's Point, La., on "Aids in the Prevention of Fevers;" Wm. B. Fletcher, Indianapolis, Ind., "Diseases of the Dura Mater Producing Motor Paralysis, Facial Spasm, and Neuralgias, etc."

Henry J. Reynolds, of Chicago, "A New Method of Producing Local Anæsthesia of the Skin."

John V. Shoemaker, of Philadelphia, "Geranium Maculatum."

E. C. Spitzka, of New York City, "Acute Fatal Delirium; Its Differential Relations."

Section on Obstetrics and Diseases of Women.

A. McLaren, St. Paul, Minn., "The Relationship between Puerperal Fever and Erysipelas in Both its Acute and Dormant Forms."

L. Ch. Boislinière, St. Louis, Mo., "The Management of Occipito-Posterior Positions."

E. W. Cushing, Boston, Mass., "The Use of the Buried Continuous Animal Suture in Laparotomy and in Perineorrhaphy."

Fayette Dunlap, Danville, Ky., "Sudden Death in Labor and Childbed."

Section on Surgery and Anatomy.

Henry C. Bœnning, Philadelphia, Pa., "On Some Points in Human Anatomy."

Section on Ophthalmology, Otology and Laryngology.

J. E. Harper, Chicago, Ill., "The Causative Relation of Ametropia to Ocular Disease;" E. Fletcher Ingals, Chicago, Ill., "On Suppurative Inflammation of the Antrum of Highmore."

Railway Rates.—Arrangements have been made by which delegates living on trunk lines may apply for blank certificates to Dr. Liston H. Montgomery, of Chicago, Chairman of Committee on Transportation. Delegates should name the line of railway over which they will travel when making the request. Dr. Montgomery will sign all return certificates, and no deviation in this matter can be permitted. Some member of the Transportation Committee will be always present at the meeting to give information.

Liston H. Montgomery,
Chairman Com. on Transportation.

RAILROAD RATES.

Dr. Liston H. Montgomery, Chairman of the Transportation Committee, has received the following communication from the General Passenger and Ticket Agent of the Northern Pacific R. R.:

I have received your favor of the 17th, and in reply beg to say, that to members of the American Medical Association in attendance at the convention in Chicago from June 7 to 10, we will issue *Return Tickets* from St. Paul or Minneapolis to points on our line *in Dakota only*, at *One-Fifth Fare* for the return trip. These delegates, in going to Chicago, must be instructed to purchase of Northern Pacific agents first-class tickets from *starting-point to St. Paul*, and take receipt therefor of our agents. Attached to this receipt is a certificate which certifies to their attendance at the convention. These you must fill up, and attach your signature thereto.

On presentation of such receipt and certificate to our agents at St. Paul and Minneapolis Union Depots, or to B. N. Austin, No. 19 Nicollet House Block, Minneapolis, or C. E. Stone, 169 East Third St., St. Paul, return tickets at one fifth fare will be issued as above.

We cannot make delegate excursion rates returning from St. Paul to points in Minnesota under the Minnesota State law.

Please advise me if fully understood, and if you will see that delegates to the convention from points on our line are fully instructed as to the method of procedure. Yours truly,

Charles S. Fee,
Gen. Passenger and Ticket Agent.

The St. Paul, Minneapolis & Manitoba R. R. has agreed practically to the same concession as its competitor, the Northern Pacific, viz.: that of one-fifth fare to return; but it is believed, in this instance, to apply to Minnesota delegates as well.

N. B. In any case, however, delegates must take receipt of agent of whom going ticket is purchased. Ticket agents along this line will be supplied with a combined certificate and receipt,

to be issued upon application of the passenger purchasing one-way unlimited ticket.

Only those in *actual attendance* at the meeting of the American Medical Association will be given certificates to return, the aggregate of which must at least be twenty persons who pay full fare "going," along this line.

The Committee on Transportation appreciate the above courtesies, and trust our Minnesota and Dakota friends will find it convenient to avail themselves of same.

Liston H. Montgomery,
Chairman Com. on Transportation.

MISCELLANEOUS.

The St. Charles Co. (Mo.) Medical Society was organized at Wentzville, Mo., on May 17. The following were chosen officers for the ensuing year:

President—J. A. Talley, Wentzville, Mo.

Vice-President—J. C. Edwards, Cottleville, Mo.

Secretary—H. H. Vinke, St. Charles, Mo.

Treasurer—M. D. Carter, New Melle.

The most interesting part of the proceedings was a report by Dr. Edward Talley, of Wentzville, on "The Treatment of Tuberculosis by Bergeon's Method." Dr. Talley is unfortunately suffering from phthisis himself, but stated that since the employment of Bergeon's treatment cough, expectoration, night sweats and other distressing symptoms have been materially improved, and that he is in hopes of being perfectly cured.

State Medical Society of Arkansas, will hold its next annual session at Little Rock, June 1, 2 and 3, 1887. President, James A. Dibrell, Sr., M.D.; L. P. Gibson, M.D., Secretary.

Ohio State Medical Society, will hold its next annual meeting at Toledo, June 15, 16 and 17, 1887. Thos. McEbright, M.D., President; G. A. Collamore, M.D., Toledo, Secretary.

Yellow Fever in Florida.—A dispatch from Key West, of May 23, says: Mr. Baker, who was declared Saturday to be suffering from yellow fever, died this morning. His wife, who contracted the disease a few days later, also died to-day and was buried a few hours after her husband. Both developed the most malignant symptoms. A sister of Mrs. Baker, who lived in the same house, which is in the principal street in the heart of the city, is also down with fever, but her case is not hopeless. The disease is undoubtedly traced to some bedding recently brought from Havana. Several other suspicious cases are said to exist.

Health in Michigan.—For the Month of April, 1887, compared with the preceding month, the reports indicate that tonsilitis, erysipelas, measles, diphtheria, and influenza decreased in prevalence. Compared with the preceding month the temperature in the month of April, 1887, was much higher, the absolute humidity was much more, the relative humidity was much less, and the day and the night ozone were slightly less. Compared with the average for the month of April in the nine years, 1879–1887, intermittent fever, diphtheria, remittent fever, scarlet fever, pneumonia, consumption of lungs, influenza and bronchitis were less prevalent in April, 1887.

For the month of April, 1887, compared with the average of corresponding months for the nine years, 1879–1887, the temperature was slightly lower, the absolute and the relative humidity were slightly more, the day ozone was about the same, the night ozone was considerably less. Including reports by regular observers and others diphtheria was reported present in Michigan, in the month of April, 1887, at twenty-five places, scarlet fever at thirty-nine places, typhoid fever at eight places, and measles at thirty-six places. Reports from all sources show diphtheria reported at twenty-one places less, scarlet fever at thirteen places less, typhoid fever at five places less, and measles at one place more in the month of April, 1887, than in the preceding month.

The Practice of Medicine by Apothecaries in Pennsylvania.—At a meeting of the Philadelphia County Medical Society, held February 23, 1887, it was resolved to address to the Senators and Representatives from Philadelphia County, and to the Governor of the Commonwealth, a communication signed by the President and Recording Secretary of the Society, requesting them to oppose and to disapprove of the passage of Section 10 of the proposed Pharmacy Law now pending before the Legislature of Pennsylvania. This section so far repeals the Registration Act as to permit druggists to engage in the practice of medicine, provided that they conduct only an office practice.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 14, 1887, TO MAY 20, 1887.

Major Morse K. Taylor, Surgeon, retired from active service, May 14, 1887. S. O. 111, A. G. O., May 14, 1887.

White, R. H., promoted to be Surgeon with the rank of Major, to take effect from May 14, 1887.

Capt. Jno. D. Hall, Asst. Surgeon, granted leave of absence for one month, with permission to apply for one month's extension. S. O. 74, Dept. Col., May 11, 1887.

Suter, William N., appointed Asst. Surgeon, U. S. Army, with the rank of First Lieut.; to rank as such from May 16, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING MAY 21, 1887.

Curtis, L. W., P. A. Surgeon, ordered to the "Quinnebaug."

Baker, J. W., P. A. Surgeon, ordered to the hospital, Chelsea, Mass.

Price, H. F., Surgeon, ordered to Board duty, Annapolis, Md.

Gravatt, C. N., Surgeon, detachment from "Michigan," revoked.

Lumsden, G. P., P. A. Surgeon, orders to the "Michigan" revoked.

Siegfried, C. A., Surgeon, ordered to the "Quinnebaug."

Persons, R. C., Surgeon, detached from the "Saratoga."

Farwell, W. G., Surgeon, ordered to the "Saratoga."

Dixon, W. S., Surgeon, ordered to special duty, Baltimore, Md.

Rogers, B. F., Surgeon, ordered to the Marine Rendezvous, New York.

Wells, Howard, P. A. Surgeon, ordered to the "Jamestown."

Wise, J. C., Surgeon, detached from the "Jamestown."

Harvey, H. P., Surgeon, ordered to the "Iroquois."

Waggener, J. R., Surgeon, detached from the "Iroquois."

White, Stuart S., M.D., of Frederick, Md., commissioned Asst. Surgeon in the Navy, May 19.

THE

ORIGINAL ARTICLES.

OUR POSTERITY.

The Address of the Retiring President before the Allegheny County Medical Society, April 19, 1887.

BY JOHN M. BATTEN, M.D.,

OF PITTSBURGH, PA.

The constitution of this Society makes it obligatory upon the retiring President to deliver an address on medicine or one of kindred topics. The subject of my address has been treated of before more ably than I could even hope to do; but the good results from frequent presentment of a subject will as surely follow as will the wearing of the granite stone follow the constant falling of raindrops upon it. The subject which I wish to present for your consideration to-day is

OUR POSTERITY.

The question, What shall we do to be saved? is just as pertinent a question now as it was two thousand years ago. My object principally, in this address, is to make a few remarks, briefly, bearing upon the laws of heredity, upon the great importance of proper selection, and upon a correct system of education of the people's physical, intellectual and moral powers.

It has been, I believe, truthfully asserted that in each generation, in all civilized countries, there have risen to the surface a few men who are the ideals of perfection, physically, intellectually and morally. If the ancestry of such men were traced, it would be found that they were the offspring of parents for several generations who presented just such qualities with which their descendants were endowed. Suppose A. was one of these ideal men; it is likely that his father and mother were persons above the average physical, intellectual and moral development, and that their parents were blessed with the same attributes. We have had many instances in our own country where an A. rose to a position of eminence, power and trust in which he exercised a mighty influence in church or in State, and justly so, by having inherited a good moral, intellectual, and physical development. It has also been noticed that his descendants have exercised the same influence for several generations, and then lost sight of entirely. It would seem to be adhering to the laws of heredity that like begets like, and therefore A.'s children, if he made proper selection, morally, intellectually and physically, would be on the ascending scale of development; and, other things being equal, would be stronger physically, intellectually and morally than their parents, and so on *ad infinitum*. And such would be a fact, but some of A.'s descendants make improper selection, and consequently their children fall below the plane of development of their parents; and once below this plane of development it requires many generations, even though proper selection were made, for the descendants who had thus fallen below A.'s plane of development to ascend again to that plane.

Suppose A. to have selected a wife whose plane of development, morally, intellectually and physically, was far below his own plane; it would follow that his children would be also below his plane of development, and so on indefinitely, or until A.'s posterity would become extinct, provided his descendants continued to make improper selections. Sometimes, however, a few of A.'s children, who inherit the constitutional development of the father, may possibly not descend below the father's plane of development, but his children and his grandchildren who inherit A.'s wife's inferior physical, intellectual and moral development will, according to the laws of heredity, descend below A.'s plane of development. The question might be asked: Would it be possible for any of A.'s descendants, who had thus fallen below his plane of development, to ascend again to the plane from which they had descended? I believe the answer to this question might be made truthfully in the affirmative; that is, if a wise vigilance was exercised in their selection. For example, suppose A. and B. (brothers), being both equal in moral, intellectual and physical development, should each make a selection—the former of C. and the latter of D. The plane of D.'s development is far below that of C.'s. The law of heredity would place B.'s children on a plane of development far below that of A.'s; and consequently, in order that B.'s children should rise to the plane of development of A.'s children, it would require many generations, even though wise selections were made.

An exception to the above law might be when B.'s children would inherit the constitution of the father, in which case some of B.'s posterity, through proper selection, might not be affected, but B.'s children who inherit the constitution of the mother would be the most affected, and would require the longest time, through proper selection, to ascend to the plane of development of A.'s children.

By our present custom of selection, there must

naturally be a sort of zigzag or shuttlecock scale of development—some families are on the ascending scale of development, whilst others are on the descending scale. Some of those families' descendants who are on the ascending scale may place their descendants on the descending scale by improper selection, whilst those on the descending scale may rescue a few of their descendants from such a scale of development by proper selection; but the posterity of many families who are placed thus on the descending scale of development are never rescued from such a scale of development by proper selection, but so continue along the downward scale of development till their posterity becomes extinct. So, too, occasionally along the ascending scale of development there may be found an offspring of weakly development; and, on the other hand, along the descending scale there may be found quite a perfect development physically, intellectually and morally; but on the latter scale of development there is more likely to be found a feeble body, possibly with a good development intellectually and morally.

There are many other causes besides improper selection which may place families and their descendants fon the downward scale of development, only a few ol which causes we have time at present to refer to, name y: acquired disease, our present system of education, together with the high pressure education of women. I have taken it for granted that both acquired and hereditary diseases are the prime factors in the cause of the physical, the intellectual and the moral disability of those on the descending scale of development, and such should be avoided in selection.

Our present system of education has a tendency to develop the intellect at the expense of dwarfing the development of the body. We should have such a system of education as would develop simultaneously the physical, the intellectual and the moral powers of the child. Dr. Charles K. Mills says: "Education should be so arranged as to develop the brain by a natural process—not from within outward; not from the centre to the periphery; not from above downward—but as the nervous system itself develops in its evolution from a lower to a higher order of animals, from the simple to the more complex and more elaborate. Any system of education is wrong, and is calculated to weaken and worry an impressionable nervous system, which attempts to overturn or change this order of the progress of a true development of the brain. To develop the nervous system as it should be developed—slowly, naturally and ev enly—it must also be fed, rested and properly exercised." It might be added that the same scrupulous care as recommended by Dr. Mills in the development of the brain ought also to be exercised, at the same time and in the right direction, in the development of the moral and physical powers.

HIGH-PRESSURE EDUCATION OF WOMEN.

To be convinced of the fact that this high-pressure education of women will be conducive to weaken them as a class physically, and prevent them from being healthy mothers, and finally affect the health of their offspring, one need only open the door of any institution of high-pressure education of women, and there observe, too frequently, the pale faces, the sunken cheeks, the flat breasts, the wasp waists, and the stooped forms among many of its inmates. Even Napoleon, with his keen perceptive mind, nearly a century ago observed the evil tendency of high-pressure education of women; when he was asked the question, by a high-pressure educated French lady: who was the greatest woman then living? although the latter expected a different reply, Napoleon curtly answered: "The mother of the greatest number of children." A better reply would have been: the mother of the greatest number of healthy children. The first requisite to success in life, says Mr. Herbert Spencer, is to be a good animal, and to be a nation of good animals is the first condition to national prosperity. In order that children be good animals it is necessary for their mothers as well as their fathers to be good animals. A woman who throws herself in the current of competition either for higher literary honors, or in the professions, or in business, cannot for a long time remain a healthy animal, and therefore cannot be a healthy mother, and consequently cannot bear a healthy offspring. Hence Napoleon's reply to Madame De Stäel was correct, when he stated that a woman's proper sphere in life is to be a mother. If Napoleon's answer was correct—and we have no reason to doubt the correctness of the answer—then it follows that to be a mother is the proper sphere of woman, and any education that would lead a woman to be other than a healthy mother, will be not only detrimental to her own offspring, but will finally affect the offsprings of the nation. Dr. Emmet says that one effect of this higher education of women, of which we hear and read so much, will be to hinder those who would be good mothers of men from being mothers at all. In its full sense, says Herbert Spencer, the reproductive power means the power to bear a well developed infant, and to supply that infant with the natural food for the natural period. Most of the flat-chested girls who survive their high-pressure education are unable to do this. Were their fertility measured by the number of children they could rear without artificial aid they would prove unable to do this. It might be added parenthetically, that one effect of this higher education of women in this country is the increase of the number of nursing-bottles. It might be interesting to the advocates of such an education to know how rapidly the nursing-bottle is gaining admittance for use in families of America. According to a Paris letter, since his recent centenary celebration, M. Chevreul has received hundreds of letters from all parts of his country asking him for the secret of his strength, with minute inquiries as to what he eats and what he drinks; when he goes to bed and rises; how he exercises, and so on. To all these inquiries the old scientist replies through the Paris press that the secret of his long life consists of two words: "good health." For this gift he says he is indebted to his parents, for which he thanked them in the dedication of his works published in 1870.

The descendants of those now living in large cities will be ultimately placed on the descending scale of

development if they and their descendants continue to remain denizens thereof, for it has been said, and I believe observation bears out the truthfulness of the assertion, that if an embarriment were placed around a large city preventing healthy, robust recruits from the country, the inhabitants of such a city would become extinct before many generations.

In these times of such a craze for wealth, and power, and fame, the powers of the intellect are so pressed at the expense of the body that endurance ceases, causing in many wrecked constitutions, if not premature deaths. With such there should be called a halt, and less work and more recreation before it is too late, if they would prevent themselves and their posterity from being placed on the descending scale of development. The great importance of proper and wise selection in marriage should be indelibly impressed upon the young, soon to become fathers and mothers not only of this, but of all future generations, at the home firesides, at the schools of education, and from the pulpits. It is a question which is of vastly more interest and value to the American citizen, if he wishes to have transmitted to America's posterity America in the ascending scale of development, than all the mathematics and languages that might be taught in our schools of education, and all the dogmas and isms that might be proclaimed from our pulpits. Dr. Samuel D. Gross, shortly before his death, in an address at the dedication of the McDowell monument, after discussing the importance of skilful and successful laparotomy operations, skilful and successful operations for stone, and skill and success in other capital operations, said: "But the question of skill and success in capital operations sinks into insignificance compared with the great problem of the people's welfare." He further said: "The day has arrived when the people must be aroused to a deeper and a more earnest sense of the people's welfare, and suitable measures adopted for the protection as well as the better development of their physical, moral and intellectual powers. This is the great problem of the day, the question which you, as the representatives of the rising generation of physicians, should urge in season and out of season upon the attention of your fellow citizens; the question which alone and beyond all others should engage your most serious thoughts and elicit your most earnest coöperation."

Consequently, no father should suffer his son or his daughter to marry a person who could not present him with a satisfactory certificate from a competent physician as to the physical fitness of that person for marriage. No license should be granted by county or State officials to any individual without a like satisfactory certificate. In fact, the State Board of Health, in each State, composed of competent physicians, after careful examination, should issue such certificates to applicants. The family history of candidates for matrimony should be well studied by parties most interested, and by physicians granting such certificates. If more attention were paid to proper selection, and to a correct system of education of the people's physical, intellectual and moral powers, there would be no need for so many eleemosynary institutions, which are now dotted thickly all over our land; there would be fewer courts of justice needed, and consequently fewer prisons. Much suffering would be prevented; there would be happier homes, and in the end America would be populated by a more robust, a more intellectual, and a more noble people. By our present mode of selection, I might say, as I wrote on a kindred subject six years ago, that if it were not that every birth is a regeneration, and were the constitutional diseases which diseased parents transmit to their offspring not modified by an inalienable bequest of an older world, and by the redeeming instincts which our All-Mother grants to every new-born child on earth, the people of the world long ere this would have become extinct. Are we not aware of the fact that a powerful people once inhabited this fair land of ours, known as the Mound Builders? We do not know that the Indians, a powerful race, did inhabit this country in years gone by. Where are the Mound Builders now? and where is the Indian race? Then, since these two once powerful races have disappeared from our land, does it not behoove us to use all proper means, to throw out all possible safeguards that God and nature have placed in our hands, to preserve this great American people from eventually being placed on the descending scale of development, and consequently following in the footsteps of their predeccssors, the Mound Builders and the Indian races?

THE GALVANIC CURRENT IN THE TREATMENT OF CERTAIN FORMS OF CATARACT.

Read before the Chicago Society of Ophthalmology and Otology, February 8, 1887,

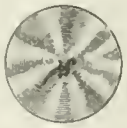
BY J. ELLIOTT COLBURN, M.D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN THE CHICAGO POLICLINIC; ASSISTANT SURGEON TO ILLINOIS CHARITABLE EYE AND EAR INFIRMARY, ETC.

The following extract is from Erb's "Handbook of Electro-Therapeutics:" "Among diseases of the lens, cataract has been drawn recently into the field of electro-therapeutics. Neftel created no little excitement in the ophthalmological camp by a report of two cases of undoubted beginning cataract, in which all the symptoms of the cataract were relieved by methodical galvanic treatment, and visual power restored completely. After a sharp criticism of these statements by Hirschberg, Neftel acknowledged that the opacities of the lens, demonstrable with the ophthalmoscope, had not disappeared entirely, and explained the undoubted improvement of the eyesight to a removal of a molecular opacity, which was not recognizable upon ophthalmoscopic examination. He adds also that galvanic applications exert an influence, though not to any great extent, upon the opacities of ripe cataracts."

This subject is, therefore, still in its infancy, but its importance justifies further careful experiments, mainly with reference to beginning cataract. In 1879, or before, my attention was called to the use of electricity as a remedy for the treatment of cataract. The following case came under my observation:

Mrs. G., aged 53, consulted me for general debility, loss of vision, and catarrhal conjunctivitis. She had been in poor health for seven years, following the climacteric period. There was no evidence of organic disease of the viscera. Her family history was good, with the exception that one aunt, a brother and an older sister had cataract, the brother's cataract following an injury, not of the eye, but a fracture of both limbs; the sister's, at the age of 57 years, following an operation for fibroid tumor. One year before consulting me Mrs. G. had a severe attack of acute bronchitis, which left her greatly debilitated, and from which she had not fully recovered. Right eye, vision equals Snellen No. 8, at 12 inches with correcting glass; left eye, vision equals Snellen No. 5, at 12 inches with correcting glass. Two months before she was able to read with the left eye and thread a needle. The right eye had been out of use for some time, and had been slightly irritated and "weeping." Examination with the oblique illumination gave the results indicated in the following diagram:



No. 1.

As she had for a long time been under the careful management of a good practitioner, and the whole range of tonics and stimulants had been exhausted, I concluded to try central galvanization, as recommended by Beard and Rockwell in their first edition. To my great satisfaction my patient responded to the treatment, and in three months had gained fifteen pounds in flesh and greatly in general vigor. While attending to another member of the family I found my former patient reading, and much to my astonishment found it to be Milton's Paradise Lost, in small print. I again made an examination of the eye under atropine, with the oblique illumination, giving the results as in sketch No. 2.

No. 2.

Soon after this case had passed from my observation my attention was called to the papers of Neftel and others, with the discussion. This and the doubt that these papers engendered, has tended to make me slow in giving to the profession the results of my limited experience and study in the treatment of incipient cataract by the use of the galvanic current of electricity. I doubt if I should have done so now, but for reasons which I cannot here mention, and to prevent being misunderstood by my professional friends and associates. The following are the cases as taken from my notes. I have arranged my cases in the following groups:

Group 1 includes those cases in which there was no improvement, as follows:

Case 1.—1881. Mrs. La L., aged 49. R. V. = $\frac{15}{80}$, L. V. = $\frac{15}{100}$. Peripheral cataract both eyes. Long narrow spikes extending to centre of lenses, no nebulæ. No change in vision for two years. Previous health good. Three years previous had fracture of right arm and amputation of hand at wrist. Treated one month, fifteen sittings, no improvement. Recent letter from son states that, one year ago, glaucoma developed in right eye.

Case 2.—Mrs. K., aged 53. R. V. = 20, L. V. = $\frac{20}{80}$. Right eye + $\frac{1}{10}$ reading V. = Snellen No. 8. Left eye + $\frac{1}{10}$ V. = Snellen No. 3. Peripheral cataract. Many long spikes in both lenses, no nebulæ. Occasional sittings for two and a half months. No improvement. Lately successfully operated.

Case 3.—1883. Mr. H., aged 54. R. V. = $\frac{20}{80}$. L. V. = $\frac{20}{40}$. Peripheral cataract. Two long spikes and many short ones in each lens, also what seems to be a calcareous deposit at the periphera of lenses, much nebular matter. Has atheromatous degeneration of arteries and valvular heart-lesions. Could get no definite results with the ophthalmoscope. Treated six weeks, eighteen sittings. R. V. = $\frac{20}{20}$. L. V. = $\frac{20}{40}$. Six months later R. V. = $\frac{20}{100}$, L. V. = $\frac{20}{80}$.

Group 2 includes cases that have been under observation from four to seven years, in which the improvement has been permanent.

Case 1.—1879. Mrs. McC., aged 50. R. V. = $\frac{15}{100}$, L.V. = $\frac{15}{60}$. Peripheral cataract. Dense nebulæ about lines. Vision had diminished slowly for past 4 months, following carbuncle of the neck; in other respects health good. Under treatment two months, R. V. = $\frac{20}{30}$., L. V. = $\frac{20}{20}$. Six and one-half years later there was no perceptible loss of vision.

Case 2.—1880. Mrs. G., aged 52. R. V. = $\frac{15}{40}$, L. V. = $\frac{15}{60}$. Peripheral cataract. A few short lines and nebulæ extending far toward centre of lenses. Vision had diminished rapidly for two months. Had noticed "weeping" in left eye for six months. Nine months previously had pneumonia. Treated two months, R. V. = $\frac{15}{30}$, L. V. = $\frac{15}{15}$. Extensive spot of choroidal atrophy just at junction of right and left lower field, near ciliary region. Four years later reported no loss of vision.

Case 3.—1880. Mrs. L., aged 57. R. V. = $\frac{20}{60}$, L. V. = $\frac{20}{100}$. L. V. with reading correction + $\frac{1}{10}$ = Snellen No. 10. Peripheral cataract. Long lines and dense nebulæ. Has been in poor health for past four months. First noticed loss of vision two months ago. Under treatment four months, forty sittings, R. V. = $\frac{20}{60}$, L. V. = $\frac{20}{60}$. With correction reading vision equals No. 3, Snellen. Eighteen months later, vision and health improved.

Case 4.—1881. Mr. D., aged 63. R. V. = $\frac{15}{100}$, L. V. = $\frac{15}{200}$. Peripheral cataract. Three long lines and many short ones, with dense nebulæ in each lens. Cannot read with correcting glasses. No change in vision for six months previous. In better health than during preceding winter. Treated two months, R. V. = $\frac{15}{40}$, L. V. = $\frac{15}{100}$. Can read with correcting glasses. Two years later, no perceptible change in vision.

Case 5.—1883. Mrs. B., aged 70. R. V. = $\frac{15}{100}$, L. V. = $\frac{15}{80}$. Left eye with correction reading vi-

sion equals No. 5, Snellen. Right eye, two long lines meeting at centre of lens form a V, and many short lines, all the lines surrounded by nebulæ, more or less dense; left eye, one long line and many short ones. Had malarial fever nine months previously, three months after recovery noticed disturbance in eyes, which was followed shortly by loss of vision. Treated four months, R. V. = $\frac{1}{3}\frac{5}{0}$, L. V. = $\frac{1}{2}\frac{5}{0}$. With correcting glasses reads Snellen, No. 1; can thread a fine needle and do fine sewing.

Case 6.—1883. Mr. H., aged 54. R. V. = $\frac{2}{8}\frac{0}{0}$, L. V. = $\frac{2}{1}\frac{0}{0}\frac{0}{0}$. Could not read with glasses. Peripheral cataract, more marked in left eye than in right. Was examined in January, 1883 (six months previous), with diagnosis of cataract in left eye. Had malarial fever in March, and when convalescing noticed failure of vision in right eye. Under treatment three months, thirty sittings, R. V. = $\frac{2}{5}\frac{0}{0}$, L. V. = $\frac{2}{1}\frac{0}{0}\frac{0}{0}$. Four years later, R. V. = $\frac{2}{9}\frac{0}{0}$, L. V. = $\frac{2}{1}\frac{0}{0}\frac{0}{0}$.

Group 3 includes cases in which there has been complete removal of short lines and nebulæ.

Case 1.—1881. Mr. J. L., aged 49. R. V. = $\frac{2}{4}\frac{0}{0}$, L. V. = $\frac{2}{3}\frac{0}{0}$. Correcting lens for reading + $\frac{1}{8}$. Peripheral cataract in both eyes. Right eye, three long spikes reaching nearly to centre of lens and surrounded by dense nebulæ. Left eye, one long spike reaching to centre of lens, and many short ones; slight nebulæ. General health fair; lately developed large varicose ulcer. Two and one-half months under treatment, twenty three sittings, V. = $\frac{2}{2}\frac{0}{0}$ in both eyes, with + $\frac{1}{1}\frac{1}{2}$ correction reads Snellen, No. 1. Two and one-half years later there was no change in vision.

Case 2.—1883. Mr. L., aged 54. R. V. $\frac{1}{4}\frac{5}{0}$, L. V. $\frac{1}{3}\frac{5}{0}$. Short lines and nebulæ in both lenses; much depressed from loss of property; has labored hard for last four years. Regular daily treatment for three weeks and occasional treatments for two months; at end of two months no lines and no nebulæ visible. Vision normal in both eyes. Two and one-half years later, stronger correcting glasses gave normal vision. No sign of degeneration of lens.

Case 3.—1883. Mrs. B., aged 63. R. V. = $\frac{2}{2}\frac{0}{0}$, L. V. = $\frac{2}{5}\frac{0}{0}$. With correcting glass reads Snellen, No. 2. Had noticed loss of vision R. E. after protracted confinement to house, from injury, L. E., following chicken-pox. After daily treatment for three weeks, could see no lines nor nebulæ in left eye; in the right eye nebulæ had cleared, leaving lines unchanged. Four years later no appreciable change in either eye.

Group 4.—Recent cases in which there has been complete absorption of opacities.

Case 1.—June, 1886. Mrs. M., aged 63. R. and L. V. $\frac{2}{2}\frac{0}{0}$. Reading vision, with + $\frac{1}{8}$ correction, equals Snellen, No. 8. Peripheral cataract both eyes. Consulted for excessive lachrymation, and rapid change of glasses, being able to read but a short time. Three months previously had consulted Dr. ———, who also had diagnosticated cataract. Treated one month, ten sittings, R. and L. V. = $\frac{2}{3}\frac{0}{0}$. No lines nor nebulæ visible; reads Snellen, No. 1, with + $\frac{1}{1}\frac{1}{4}$ correction. Nine months, vision equals $\frac{2}{2}\frac{0}{0}$, and no sign of opacities.

Case 2.—July, 1886. Mrs. F., aged 68. Myopic. R. V. = $\frac{2}{1}\frac{0}{0}\frac{0}{0}$, L. V. = $\frac{2}{2}\frac{0}{0}\frac{0}{0}$. Reading glasses, R. + $\frac{1}{1}\frac{1}{8}$, L. + $\frac{1}{2}\frac{1}{2}$. Slight cataractous radii in both lenses. Has much trouble from loss of sleep, uses chloral at times. Under treatment one month, twenty four treatments, only one or two lines visible at end of treatment. November, 1886, fully recovered; can see no lines nor nebulæ.

In all cases in which I have suggested galvanism as a possible remedy, I have steadily avoided encouragement as to the result, and had it fully understood that the remedy was on trial; though I had long considered it a legitimate treatment. In my first cases I did not make the discrimination that Wells offers as to the rapidity or stasis of development of catatact, for I had not learned to fully measure the change that was produed in conjunction with improvement of vision. It was soon manifest that the great change which took place was not in the already degenerated lens structure, but in that portion which was in a metamorphosic state, *i.e.*, the nebulæ that enveloped the lines and filled the more transparent portion of the lens; this nebular matter is slowly absorbed, leaving the former gray portions of the lens clear and transparent, and the lines clearly marked. I have never seen radii that were already fully degenerated, become absorbed or changed more than could be accounted for by the clearing of the nebulæ. In those cases where we would expect arrested development, there was absolutely no change nor improvement of vision, except in one case; and that was due alone to the improvement of the choroid and retina.

As to the etiology of cataract or opacities of the lens, there can be but one opinion; that it is the disturbance of nutrition, through functional and organic changes in the uveal tract, nerve and retina, and that these changes may be associated with, and are usually due to, some general disturbance of nutrition. In thirty-one cases which I have tabulated from my private work, and twenty-six from my outside or dispensary practice, I have found in more than 90 per cent. of the cases that there was a history of acute disease or an acute exacerbation of a chronic disease, or an exhausting mental depression or depression preceding the disturbance of vision, and in many cases attributed to it by the patients. In thirty per cent. of the cases there was evidence of choroidal degeneration, neuro-retinitis or retinal atrophy; showing that it was not the lens alone that had been or was suffering from disease. Wells says: "It appears most probable that the causes of the loss of transparency of the lens are to be sought in the impairment of nutrition, due to some morbid alterations in the vitreous humor and inflammatory changes in the lens itself."

The therapeutic action of electricity is threefold: Mechanical, tonic, and catalytic. We have to deal in this connection only with its tonic and catalytic actions. It is tonic from its action on the pneumogastric and sympathetic; catalytic from its electrolytic action, as manifested by the rapid changing of the nebula long preceding the manifest results in the general system.

Beard and Rockwell say: "Indirect constitutional effects result from localized electrization of nervous centres, especially from galvanization of the brain, spinal cord and sympathetic of the cervical region." The physical effects of electricity passing through the body, are heat, transference of substances from one pole to the other, and modification of endosmosis and exosmosis. In the structural changes which take place, we have the effects of the catalytic or chemical most markedly manifested. Electrolysis of organic substance starts a process that continues long after the current has ceased to flow. Dr. F. H. Martin, in his paper on "Electricity in Gynecology," page 10, says: "I have worked on the principles enlarged upon in the first part of this paper, viz.: 1. That a galvanic current of moderate quantity, passed through a soft tissue of the body, produces electrolytic action all along its course. 2. That a process of rapid absorption is produced in the parts so acted upon. 3. That normal tissues, while the least susceptible to the current, and therefore least liable to be chemically decomposed, are, if decomposed and absorbed, almost immediately replaced by the inherent property of healthy tissue to reproduce itself. 4. That pathological tissue is usually of lower vitality than normal tissue, is more easily decomposed by the current, and when it is decomposed and its absorption accomplished, it has not the power to reproduce itself."

By one who has used electricity in general practice and noted the continuous improvement of patients months after the treatment has been discontinued, it can readily be understood why frequent séances are not required in a large majority of cases.

My experience would lead me to associate the improvement in vision directly with the visible local changes. If the cataract is due to the disturbance of nutrition or change in the vascular supply, and in a large number of cases preceded by a marked disturbance of the general health, is it not fair to suppose that in those cases cited by Bull and others, where there is arrested development, delayed maturing or spontaneous absorption, that the cause for the change may lie in the improvement of nutrition? That the remedy fails in a certain percentage of the cases, or in fact all the cases under treatment, may not be the fault of the remedy, but in the selection of the cases to be treated. *In all cases in which the disease is progressive*, as indicated by the fat granules and nebula, where electricity is well borne, where the choroid and retina are not greatly degenerated, and where there are no complications of cirrhosis of kidneys or liver, diabetes or organic disease of the heart or lungs, *improvement may be expected.* The cases in which improvement is not to be expected are those in which vision has remained stationary for some time, and where there are structural changes in the choroid and retina. The opacities of the lens treated by me with electricity, are of the senile forms of cataract, commencing at the periphera and extending towards the centre in the shape of radiating lines or spikes. In the progressive form the lines are surrounded by, and the inter-space more or less filled with, an aggregation of dots and nebula of gray matter. In one case there was marked yellow deposit under the anterior capsule.

The battery to be used should consist of a number of medium sized cells, giving a steady, constant current. The special battery manufactured by McIntosh & Co., or the battery invented by Felton, I think are the best adapted to this purpose.

The treatment may be given in this way: The electrode should be first freely moistened; the negative placed over the eye, the positive at the nape of the neck, at the angle of the jaw or over the stomach. Three or four cells should first be turned into the circuit, followed by one, two, three or four more, until a slight vertigo is experienced. then gradually reducing the number of cells; the whole sitting not occupying more than five to ten minutes. The treatment may be at first given daily, and gradually decreasing to once or twice a week. In some cases I have been obliged to use a very mild current, and in others as high as eighteen elements, and in a few cases the galvanic current was not well borne at first, but a few daily treatments with the induced current rendered my patient less susceptible or sensitive, and I was enabled to use the galvanic current with good results.

PERINEPHRITIC ABSCESS; OPERATION; RECOVERY.

BY U. O. B. WINGATE, M.D.,

OF MILWAUKEE, WIS.
(FORMERLY OF WELLESLEY, MASS.)

FELLOW OF THE MASSACHUSETTS MEDICAL SOCIETY; MEMBER OF THE AMERICAN MEDICAL ASSOCIATION; MEMBER OF THE GYNÆCOLOGICAL SOCIETY OF BOSTON, ETC.

Acute inflammation resulting in suppuration in the connective tissue surrounding the kidney must be a rare disease. The literature in the medical journals is exceedingly scant, and but brief mention is made of the affection in the books. Yet we can hardly expect it to be infrequent when we consider its etiology. Injury is supposed to be the most frequent cause; next, exposure to cold, which is questioned by some, but undoubtedly is a cause; previous suppurative nephritis or pyelitis; extension of pelvic cellulitis; operations on the rectum; inflammatory affections about the bladder; psoas abscess; typhlitis and perityphlitis. Well authenticated cases have been reported in children, although by some this has been denied.

The symptoms are said to be local pain, shooting downwards; chilliness, followed by fever; malaise; nausea; anorexia; coated tongue; rigors and profuse sweats; emaciation; obstinate constipation. Deep-seated fluctuation may be detected, but it may be very late. There may be a tumor, but that may appear very late. Pus usually points in the lumbar region, or it may rupture into the bowel, or into the peritoneal cavity, in which case death would soon follow, unless the condition was early diagnosticated and abdominal section resorted to at once.

The differential diagnosis is to be made from hydronephrosis; from echinococcus; from cancer; and from pyelitis with pyonephrosis. In the early stages the diagnosis is extremely difficult, especially in children;

and by good authority is pronounced impossible in the absence of a tumor. My experience with this disease is limited to a single case, and its history, difficult diagnosis, course and termination seem to be worthy of a pretty full record, and especially so as but a very few cases can be found to which more than a passing notice is given.

Miss P., of Massachusetts, aged about 30 years, was first seen by me as a patient on August 28, 1883. She was a tall, spare brunette, and had always had fairly good health. She had been ill several days before I was called. Nearly a week before she had been on an ocean excursion, had been in the ocean bathing and was chilled at the time—came home and was taken ill. There is a constant dull pain, uninfluenced by motion or position, in the upper part of the right lumbar region, and inclined to the front. Slight tenderness over this region and extending over the abdomen. Bowels quite regular. Marked anorexia. Tongue coated white. Slight nausea; no vomiting; no urinary symptoms; no chills. Menses have been regular and normal. Pulse 100; temperature 101° F. Patient sits up part of the time.

August 29. Bowels moved by a cathartic to-day. All the symptoms the same.

September 1. Side more tender and painful, requiring an opiate. Anorexia is a marked symptom. Pulse 100; temp. 99.5° F.

September 4. Not as well. Pain shooting down right thigh, and there is some tenderness in the right groin. Anorexia. Pulse 100; temp. 101°.

September 6. Menstruating at regular time. Despondent; tired. There is less pain, no opiate required. Anorexia marked. Tenderness still a prominent feature over the right side and in the right groin; no swelling anywhere. Pulse 80; temp. 100.5° F.

September 7. Less tenderness of abdomen—otherways the same. Pulse 88; temp. 101.8° F. As I was to be absent from town for a few days, I placed the patient under the care of my neighbor, Dr. G. J. Townsend.

September 12. I resumed charge of the case again. Tongue cleaner and patient appears some better generally. There is some pain complained of in the right hip. She cannot walk well on account of the pain in the hip. Less pain in the side. Sweats profusely and complains of weakness; anorexia still marked. Pulse 80; temp. 100° F.

September 14. Slight icterus, more prominent about face and neck than elsewhere. Tenderness over side and abdomen; pain in right hip when walking. Pulse 80; temp. 100° F.

September 17. Patient still sits up part of the time. Tongue quite clean and moist, but anorexia as marked as ever. Skin less yellow; tenderness of right side and abdomen still prominent; pain in the hip on motion; sweats profusely nights. Afternoon pulse 100; temp. 102° F.

September 21. Slight chill last night for the first time. Pain in the hip and groin. No swelling could be found. Bowels moved quite regularly. Pulse 90; temp. 101° F.

September 25. Pain in the hip is constant—she says it is "inside the hip." Pulse 100; temp. 100.1° F.

September 27. One month after my first visit patient rode out, it being a pleasant day; she thinks she feels better for it. Pain in hip some less. Pulse 90; temp. 100.5° F.

September 30. In addition to the other symptoms the right thigh is beginning to be flexed, and cannot be fully extended. There is more tenderness over the right kidney, and I think some little fulness in that region. Up to this time no satisfactory diagnosis has been made. My notes at this time read: "Abscess? malignant disease? tumor? floating kidney? What?

October 2. A consultation was held with a gentleman of large experience, and the physician who officiated at the birth of the patient. A careful examination was made, and the following symptoms summed up in their order of prominence: 1. A long-continued, persistent anorexia. 2. Tenderness in the right lumbar region, first extending over a greater part of the abdomen, later becoming more marked over the right kidney, with some fulness in that location, accompanied by a constant dull pain in the right hip and groin, and flexion of the thigh. 3. Fluctuating, low, but persistent fever, accompanied with but one or two very slight chills, but with profuse perspiration at times. 4. Emaciation quite marked. The urine, which has been free and without abnormal qualities before, is now three pints in quantity in twenty-four hours, S. G. 10.20, contains a trace of albumen, a small amount of pus and a few epithelial casts. Diagnosis hinges between deep-seated abscess and malignant disease, the consultant inclining to the latter, as I perhaps would have done had I not watched the case carefully from day to day. Prognosis guarded. Treatment continued, namely: opiates sufficient to relieve pain, with quinia in tonic doses, and all the nourishment she could be made to take, with some alcoholic stimulants.

October 3. Much pain in the hip, with a "twinge" down the limb at times, a spot over the right kidney very tender. Pulse 104; temp. 102.1° F.

October 4. Pulse 112; temp 103.5° F.; other symptoms the same.

October 5. Patient looks haggard—is restless; asks if she can get well; cannot lie on left side, decubitus mostly dorsal with limbs drawn up. Vomited once this morning. Pulse 91; temp. 101.6° F.

October 7. Had a restless day yesterday; perspires profusely when asleep. Is taking many eggs for nourishment, which are forced. Pulse 100; temp. 100° F.

October 8. Much pain caused by defecation, which is assisted by enemas. Bowels tender and somewhat tympanitic. Pulse 96; temp. 101° F.

October 9. Has a sharp pain in the right lumbar region; cannot lie on the right side on account of a pulling sensation. Pulse 88; temp. 101.8° F.

October 10. Slight puffy appearance about face and eyes noticed for the first time, but urine is free. Slight chill yesterday, followed by flushed face; seems dull and low-spirited. Pulse 104; temp. 102° F.

October 11. Perspires much of the time; tongue clean and red; anorexia as prominent as ever. The

fulness over right kidney is decidedly more prominent and very tender, but I can get no fluctuation. Percussion flat. Less pain in the hip, but requires opiates. Pulse 101; temp. 101° F. A large flaxseed poultice was applied over right kidney.

October 13. Consultation was again held. Night sweats are profuse. The enlargement over right kidney is more pronounced, but fluctuation could not be obtained. Pulse 95; temp. 103° F.

At this point I suggested aspiration, but the consultant was in favor of waiting, and was inclined to the diagnosis of very serious if not malignant disease of the kidney, and a grave prognosis. We agreed to wait a few days longer before resorting to surgical measures.

October 14. I can get a slight wave of fluctuation, and am more convinced than ever that there is deep-seated pus. Patient very tired; there is considerable pain. Pulse 105; temp. 103.9° F.

October 15. Forty-eight days since my first visit. Consultation again—patient much the same as yesterday. Fluctuation being evident, it was decided to explore the tumor, which was now quite prominent over the right kidney. Patient was etherized, and I passed an aspirator needle well into the swelling and obtained pus; it was too thick to be evacuated through the aspirator, and I withdrew the needle, made a longitudinal incision over the most prominent part of the swelling, dissected carefully down about one and a half inches and came to the sac, then passing in a director made a free opening, and evacuated about eight ounces of pus. A drainage-tube was inserted and the opening dressed as near antiseptically as the circumstances and surroundings would permit. Patient rallied from ether well, but was very weak.

October 16. Comfortable, but weak. An enormous amount of pus has been discharged. Pulse 110; temp. 102°. The cavity was well syringed out with a 1–40 solution of carbolic acid, and the opening redressed as before.

October 17. Pus discharging very freely; patient quite comfortable. Pulse 100; temp. 99.6° F. Opening dressed with oakum.

October 18. Some diarrnœa; abscess discharging freely. Pulse 92; temp. 100° F. Redressed as before.

October 19. Discharge of pus diminishing. Diarrhœa checked with bismuth and morphia. Thigh can be extended to full extent. Syringed cavity and redressed with oakum.

October 27. Since last note patient has been doing well. Abscess has discharged a large amount, but discharge is now growing less. Opening has been syringed daily and dressed with oakum. Patient's strength has been well sustained on iron and quinine in tonic doses, with all the liquid nourishment she could bear. Last night had a chill—cause obscure. Pulse 120; temp. 103.2°. A larger drainage tube was inserted, cavity thoroughly syringed out with carbolized solution, 1–40. In the afternoon a consultation was again held, but no cause of the chill was apparent. The pulse had fallen to 100 since morning, and temp. to 101.8° F.

October 28. A slight erysipelatous blush was present around the opening, which undoubtedly accounted for the chill and rise of temperature and pulse. Pulse 116; temp. 102° F. Opening syringed as before, and dressed with a lead and opium solution carbolized.

October 30. Erysipelatous blush gone, abscess discharging but little; cavity much smaller. Pulse 100; temp. 99.5° F.

November 3. Very slight chill this morning; abscess redressed. Pulse 100; temp. 100° F.

November 4. Pulse 80; temp. 98.8°. Very little discharge.

November 7. Drainage-tube removed. Patient improving fast.

November 13. Slight discharge yet. Patient sits up some of the time. Pulse 80; temp. 98.5° F.

November 23. Opening completely closed. Patient discharged well, nearly three months from my first visit. I have no doubt that the chill and erysipelatous blush were due to a want of asepsis, and although it did not prove a very great obstacle to overcome, a greater neglect might have proved disastrous.

IMMOBILIZATION IN HIP-JOINT DISEASES.

BY B. M. GRIFFITH, M.D.,
OF SPRINGFIELD, ILL.

Mr. A. A. B., aged 32 years, Canadian parentage, about four years ago received a severe fall upon the right hip when alighting from a moving train. To all appearances he soon recovered from the immediate effects of this injury, About two years afterwards his hip-joint commenced paining him upon excessive exercise or fatiguing use of the limb, and in the course of another year he complained of pain in the knee-joint. This was the history of the case when I first saw it in August, 1886. The right limb was apparently three-fourths of an inch longer than its fellow, and the right foot slightly everted. He complained of excessive fatigue in the joint on walking, especially if the ground was rough, and if he accidentally stubbed his toe the pain in the joint was quite severe. Upon sneezing, he would instinctly seize the affected limb in order to lessen the pain caused thereby.

No hereditary taint was discovered by examination of the patient's history. The general health was quite good. On manipulating the limb, the hip-joint was found rather sensitive; inversion limited. When lying on his back the patient was unable to place the heel of his right foot on the toes of his left; the pelvis was also tipped considerably, and the pain was quite marked when the limbs were fully extended in this position. The pain was lessened by flexing the thigh on the abdomen at an angle of about twenty degrees, and slightly everting the foot; and by so doing placing the pelvis flat on the floor. At no time was pain produced by striking the heel of the foot while the limb was extended.

The plan of treatment entered on was one suggested to the patient by Dr. Alfred Bray, of Minneapolis, Minn., *i.e.*, the application of a plaster of-Paris cast to the pelvis, and thereby immobilizing

the joint. The cast was applied as far up the body as the xiphoid cartilage, and extended down the affected limb to the knee, making it especially strong on the groin. The cast was applied by having the patient stand on a stool, with the limb slightly everted and somewhat advanced, thereby placing the limb in a comfortable position. The patient was afterwards placed on a canvas cot, and a double inclined plane and a slight weight used. In this position he was entirely comfortable, and commenced improving from the start, cod liver oil and comp. syrup wheat phosphates being the only medication.

Patient was kept on the cot for twelve weeks, when the cast was removed. He complained terribly of muscular soreness for several days. The limb can now be moved in all directions, flexion and adduction being slightly compromised. No pain in either knee- or hip joints. The movements, while slightly limited, are more powerful than formerly, and are getting stronger. The pelvis is also improved in position. It has been four months since the cast was removed, and neither pain nor any of the old sensations have been felt in the joints; and the patient walks with an almost imperceptible limp, while he was very lame before the treatment.

This case I offer as an illustration of the most effective method of treating hip-joint troubles when seen under such conditions, believing it to be more efficacious than the use of braces.

235 S. 5th Street.

MEDICAL PROGRESS.

Antiseptic Midwifery.—In a report by Dr. K. Inoieffs of the work done in the Lying in Institution in connection with the Golitsinski Hospital, in Moscow, for the year 1886, the advantage of antiseptic midwifery, which is strictly carried out there, is evident, as out of 541 cases there were but two deaths. Some of the statistics, which are very carefully kept, may be of interest. The largest number of births occurred, as it is popularly believed they do, at night, 145 taking place between midnight and 6 A.M.; the numbers corresponding to the remaining three-quarters of the twenty-four hours being 131 from 6 A.M. to noon, 107 from noon to 6 P.M., and 144 from 6 P.M. to midnight. There were fourteen abortions and nine cases of twins; three births took place in the street. Of the remaining 501, 478 were vertex presentations, fifteen breach, and eight transverse. In nine of the fourteen cases of abortion the ovum was removed mechanically. When there was considerable hæmorrhage and the os was not dilated, a hot vaginal injection of carbolized water was given which was, as a rule, successful. Twice, a plug consisting of a long strip of cotton-wool moistened with glycerine and iodoform was introduced by means of the speculum, as much as possible being inserted into the cervical canal, and subsequently, when the os was sufficiently patent, the finger was introduced and the uterine contents removed. In one case there was a slight amount of perimetritis, and in two a single rise of temperature. In one case a spatula was cautiously used to assist the irrigation, and once the contents were removed with the help of a sharp hook. Apart from cases of placenta prævia and abortion, there were twenty-nine cases of hæmorrhage, six of these occurring in primiparæ; six took place during the first and second stages of labor, the rest in the third stage and post-partum. The treatment adopted was, during the first stage, to plug, and when the os was sufficiently dilated to rupture the membranes. If there was rigidity of the os, narcotics were given. When uterine atony was the cause, massage, the application of ether to the abdomen, hot injections, and (after the birth of the placenta) ergot was resorted to. As to operations, episiotomy, or a double V-shaped incision of the perineum was performed five times, no sutures being inserted afterwards. Twice the os uteri was incised; twice the prolapsed cord was replaced; perineal sutures were required in twenty cases. In the performance of the operation the most careful antiseptic precautions were taken; in sixteen cases the union was complete. Retention of membranes required the introduction of the hand into the uterus once, but in fourteen cases the placenta had to be artificially extracted, being completely adherent once, and partially so thirteen times. Labor was induced prematurely for contracted pelvis three times, twice by the injection of water at 28° R. (95° F.) through a tube passed into the cavity of the uterus, between the uterine wall and the fœtal membranes; in the third case it was induced by the introduction of an elastic sound into the uterus. Podalic version was performed eleven times, and the forceps applied fifteen times. Craniotomy was performed twice.—*Lancet*, May 7, 1887.

Physiological Action of Spigelia.—Dr. H. A. Hare, of the University of Pennsylvania, in a study of physiological action of spigelia, or pink-root, says: On the cardiac muscle it acts as a direct depressant poison, for if it be injected into the jugular vein in such a way as to come suddenly in direct contact with the heart the movements of that viscus almost instantly cease. Further than this, if the excised heart of the frog is dropped into a strong solution of the drug its movements are almost immediately stopped in a condition of diastolic arrest, although the relaxation is not very marked. When a frog receives as much as twenty minims of the extract of spigelia, the heart is slowed to a considerable extent, as much as ten or fifteen beats per minute, and diastole, while not increased in length, is nevertheless very full and marked. The change from systole to diastole is abnormally rapid, so that the heart in one moment in systole springs with a quick movement to its full diastolic condition. Systole, however, gradually increases on diastole, in much the same manner as in digitalis poisoning, until finally the greater portion of the ventricle fails to dilate, the apex being tilted more and more forward while the ventricular walls are powerfully contracted. As the systolic pauses increase, the diastolic movements decrease in volume, until finally the heart dilates no more than it does

normally. At this time the powerful and heretofore spreading systolic contractions seem to lose power and the heart shortly stops all movement in a semi-relaxed state. Experiments on the warm-blooded animal show that on the injection of one drachm, or less, of the drug, the action of the heart is very rapidly slowed in its movements, and that this slowing is chiefly due to central inhibitory stimulation is shown by the fact, that if the vagi be cut before the drug is given this slowing does not occur, and also if after the drug has slowed the heart the vagi be cut, the inhibition no longer remains. That the fall of arterial pressure produced by this drug is due in great part to the cardiac depression which it produces is proved, since asphyxia will cause a rise in pressure, and that the pressure returns nearly to normal as soon as the heart gets rid of the drug which has been suddenly injected into it. On the respiratory centre the drug seems to have a still more depressing influence, respiration ceasing some moments before the cardiac arrest.—*Medical News*, March 12, 1887.

LIGATURE OF THE EXTERNAL CAROTID ARTERY.—In a paper describing three cases of ligature of the external carotid artery, in two of which both vessels were tied simultaneously, DR. JOSEPH D. BRYANT draws the following conclusions:

1. Ligature of the external carotid artery, together with dependent ligature of the branches arising from the first inch of its course, is a safe and commendable operation.

2. When the facial and lingual arteries do not arise singly, or by a common trunk from the first inch of the course of the external carotid, the branches arising at the point of bifurcation of the common carotid should be tied.

3. Simultaneous ligature of both external carotids is a rational preparatory measure for operations involving the parts supplied by their branches when dangerous hæmorrhage is feared. If the pharynx be involved, the ascending pharyngeal branches should be ligatured also.

4. Simultaneous ligature is advisable as a final expedient to diminish the rapidity of the development of extensive malignant growths when they are nourished by the branches of the external carotids.

5. Ligature of one or both of the external carotids for the cure of aneurismal formations of the branches of the same is not feasible as an independent curative measure.

6. Ligature of the common carotid should not be done for the cure or for the arrest of morbid conditions involving the external carotid or its branches, except as a final resort.—*Medical News*, May 14, 1887.

CARBOLATE OF MERCURY IN SYPHILIS.—DR. KARL SHADEK, of Kieff, being anxious to try the effects of carbolate of mercury, which has been strongly recommended in syphilis by Professor Gamberini, requested M. H. Brandt, a pharmacist in Kieff, to prepare some for clinical use. This he did by precipitating a very dilute solution of bichloride of mercury with a concentrated alcoholic solution of carbolate of potassium. A yellowish precipitate was obtained, which, after being frequently agitated with the liquid for twenty-four hours, assumed a whitish appearance. It was filtered and washed with distilled water till the washings showed no traces of chloride. It was then transferred to a fresh filter paper and dried under a bell jar. In this way a nearly white tasteless amorphous substance was obtained, which was scarcely acted upon or dissolved by cold, but was readily soluble in boiling, hydrochloric acid. The name given to it by Dr. Shadek is "hydrargyrum carbolicum oxydatum," and he has been using it in his private practice for several months. At first he gave it in the form of pills, one of which, containing about an eighth of a grain, was ordered three, or occasionally four times a day. It was well borne, and did not interfere with the digestion. In some cases the treatment was continued for six or eight weeks, without producing colic or other disagreeable symptoms. The total number of syphilitic cases in which it was given internally was thirty-five (twenty-six men, six women and three young children). In five of these there was swelling of the gums and salivation. Mercury was found in the urine after the third dose. Its therapeutic value was especially remarkable in macular and tubercular syphilides and in syphilitic psoriasis of the palm and the sole. Syphilitic rash and slight relapsing forms yielded to the treatment in from two to four weeks; in syphilitic affections of the mucous membrane, and in papular and pustular eruptions, from four to six weeks were required. Multiple enlargements of glands were but little affected by it. In the case of children from 2 to 4 years old, doses of about the fifteenth of a grain were well borne twice daily.—*Lancet*, May 7, 1887.

TRANSPARITONEAL NEPHRECTOMY.—At a recent meeting of the Paris Surgical Society, M. TERRIER communicated a note on a new method of performing transperitoneal nephrectomy. The abdomen is opened in the middle line, and the intestine pushed aside so as to uncover the peritoneal membrane covering the kidney A verticle incision is then made in the membrane, the edges of which are held back with clamps. After removal of the tumor, the pedicle and the ureter are tied and brought forward through the peritoneal incision to the abdominal wound, where they are secured. In this manner the peritoneal cavity is closed on all sides. M. Terrier claims that this operation does not necessitate drainage through the loin, as has generally been supposed. *British Medical Journal*, May 7, 1887.

XYLOL IN SMALL-POX.—OTVOES has used xylol in 315 cases of small pox with excellent results. This substance is recommended by Zuelza as an antiseptic; it coagulates albumen. Otvoes administered it in wine, in doses of 2 to 3 grammes a day. The total amount given was sometimes 24 grammes. Otvoes gives the following formula for the administration of xylol: R. Pure xylol, 3 grammes; menthol water, distilled water, āā 50 grammes; cinnamon syrup, 10 grammes. One spoonful every two hours. *British Medical Journal*, May 7, 1887.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address
JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS.

SATURDAY, JUNE 4, 1887.

PUBLICATION OFFICE OF THE JOURNAL.

We again remind the members of the Profession who may be in the city during the meeting of the American Medical Association next week, that the business office is at No. 65 Randolph street, corner of State, in which they will find a clerk at all hours ready to wait upon them. Also, that THE JOURNAL printing office is at No. 68 Wabash avenue, only one square from the Central Music Hall, in which the Association will meet, where the extra volumes of the Transactions, published prior to 1883, are to be found and are for sale. Mr. White, in charge of that office, will be prepared to give any information concerning them that may be desired.

MECHANICAL TREATMENT OF HIP-JOINT DISEASE.

Of late years the attention of the profession has been so much directed to the operative treatment of hip joint disease, that the more conservative method of treatment of the affection has not received the attention merited by the attainable results. It is with pleasure, therefore, that we notice an interesting paper read before the New York Academy of Medicine, on May 5, "On the Ultimate Results of the Mechanical Treatment of Hip joint Disease. An Analysis of Fifty-one Cases, occurring in the Service of the New York Orthopædic Dispensary and Hospital," by Drs. Newton M. Shaffer and Robert W. Lovett, which may be found in the *New York Medical Journal*, of May 21. The cases upon which the report was based were all *dispensary* cases, no hospital, private, or other cases being considered, and no cases in which the hip affection has been treated by other than mechanical means. It will be seen at once that the most difficult of all cases, dispensary, were selected. With the results obtained it is the object of the paper to show that it is not only possible but comparatively easy to treat hip-joint disease successfully, and satisfactorily with proper facilities; by which is meant a well-equipped shop and a corps of mechanics to make, repair or alter the necessary appliances, and the coöperation of out-door visiting surgeons. A further object of the writers is to show that it is exceptional that homeless or illy cared for children require *prolonged* hospital care in hip-joint disease; and to show that a well-equipped orthopædic dispensary, if properly conducted, can do the work of several large hospitals at far less cost.

In order to arrive at positive and ultimate results when the investigation was begun, no case was to be considered which had not been under the care of the institution from the time of entry to that of final discharge; none which had been entered as "discharged cured" after a final examination; no case which had not been "discharged cured" at least four years prior to the investigation; none except those which presented unmistakable signs of the disease at the first examination; none which had not been at least two years under treatment; none which were not seen or examined after investigation was begun; and all cases within these exclusive conditions were to be classified and reported. These conditions, of course, excluded many interesting and valuable cases, but had the latter been included the facts brought out might have had less value. The general plan of treatment was as follows: In each case reported a long Taylor traction-splint was applied soon after the first examination, and the parents or some friends of the patient were instructed in the use of the apparatus. Unless recumbency was necessary to overcome a malposition of limb, or unless the symptoms were so acute as to demand rest (in which case the patient was visited at home by the visiting surgeon) the patient was allowed almost unlimited exercise in the open air. He was seen at the dispensary every week or two for observation and readjustment of the apparatus, etc. If the condition required recumbency for a month or more, and his home was inadequate, he was placed in one of the wards of the institution, to be removed and returned to the dispensary service as soon as possible.

The aims of the treatment were to: 1. Overcome

by mechanical means any acquired deformity existing before treatment was begun. 2. Protect the diseased joint from traumatism. 3. Permit the patient to have almost unrestricted out-door exercise. 4. Maintain that position of the limb which would reduce deformity to the minimum if ankylosis occurred. Except with the occasional opening of an abscess no operative measures were undertaken in any case. "As a matter of experience abscesses connected with a suppurating hip-joint did no better under antiseptic measures than those opened by simple incision, and neither did so well as those which were allowed to open spontaneously. Cold abscesses were allowed to take their own course, unless they were in a location which interfered with the use of joint protection." The patients were carefully watched, and when they failed to report at the dispensary, they were requested to call, or were visited.

What were the results? Of the 51 cases treated 4 had died, 2 of meningitis, and 2 of pneumonia. Six had relapses, after being under treatment 2½, 4, (3), 5, and 7 years. The remaining 41 were seen and carefully examined, except 2, who were reported to be in excellent health. The 39 were carefully examined and measured. These 39 had been discharged as cured between 1875 and 1882. They had been under treatment from 2 to 8 years; they had had hip-disease from less than 6 months to 9 years (2 for an indefinite period) before treatment was begun. Abscess occurred in some stage of the disease in 27 cases. From this paper which is worthy of the most careful study, it appears that the amount of shortening of the leg is not dependent on the presence or absence of abscess, that it is less in children who are cured before 10 years, and that it apparently increases after that age is passed. It also appears that shortening increases slightly after the joint disease is arrested, which seems to prove that the affected limb did not grow so fast as its mate.

Muscular atrophy is always present in hip-joint disease. It persists after the disease is arrested and the apparatus is removed, and it may often improve after treatment is stopped, but never wholly disappears.

The amount of motion in the joint when the disease is arrested and the apparatus is removed is very apt to diminish somewhat in the course of years; but recovery with perfect motion is not impossible, or indeed unlikely. The presence or absence of abscess has no apparent effect on the amount of motion obtained.

Ankylosis being the result most likely to occur, it is important to study the ultimate position of the limb, so that, if ankylosis occurs, the most useful position will result.

Adduction, rather than flexion, is the ultimate position to be avoided, and adduction is apt to occur after the joint seems to be free from inflammation and the apparatus is removed.

Non-deforming club-foot, or even a considerable degree of acquired talipes equinus, may occur when there is much shortening of the leg with flexion of the thigh.

True lateral curvature with rotation occurs very exceptionally, if at all, as the result of even great inequality in the length of the lower extremities, only one case being found in the series, and that not a true rotation curve.

A comparison of the results reported with the published results of excision of the head of the femur leads the authors of the paper to the conclusion that the conservative methods of treatment here described promise much better ultimate results than excision of the joint, aside from the greater mortality attending the operation.

The authors summarize the results of their investigations as follows: Of 51 patients discharged as cured over four years ago, 4 have died, 6 have had relapse, and 41 have apparently been cured of the disease. Of the 4 who died, 2 only had presumably tubercular disease, the other 2 dying of an acute lesion. Of the 6 who had relapse, 2 are now under active treatment with a prospect of a speedy cure, and 2 have been cured a second time. One has been in bed a year after excision of the joint, the other is on crutches. Of the 41 who recovered there is not a single individual who is incapacitated from doing a full day's work at his or her trade or occupation. Only one, a boy who had suffered from both Pott's disease and hip-joint disease, used a cane, and none used crutches. There are, among those who recovered, printers, glaziers, machinists, errand-boys, shop girls, dress-makers, and many children attending the public schools—all at their work and none with evidences of active tubercular disease or any serious incapacity arising from the condition for which they were treated years before.

CLASS MORTALITY IN THE UNITED KINGDOM.

The causes which govern the mortality among different classes and ranks in the United Kingdom form the subject of an interesting paper which has just been read before the Statistical Society by MR.

Noel Humphreys, a well-known authority upon topics of this character. The marked decline in the English death-rate during the last eleven years is accepted as proof that the public health is better cared for now than formerly, and that the large expenditure upon sanitary works is bringing substantial return for money in the shape of improved health and a prolongation of human life. The death-rate in the City of London a few weeks ago was almost down to vanishing point, the mortality per thousand of the population being the lowest the city has yet known. Taking the whole country, however, not only are there local variations in the death rate, but the mortality varies according to the grade of society to which the statistics refer.

What may be termed a simple inquiry on the subject has been made in the case of Dublin, and the facts which have been brought to light reveal such startling contrasts between the death rates of the several social classes as to make it obviously desirable to discover whether the phenomenon repeats itself in the case of English towns. Already some facts bearing on the question are forthcoming, and these tend to show, in regard to England, "sufficiently wide contrasts between the rates of mortality among the professional and independent and the working classes to supply material for the gravest consideration of politicians, as well as sanitary reformers." Concerning the distribution of diseases, the Dublin inquiry is replete with results which appear almost anomalous on the surface, sometimes showing that the poor enjoy a greater immunity than the rich. Thus it was found that diphtheria was only slightly prevalent among the laboring classes; the artisans had more of it, and the professional class still more, while the middle class suffered most, and also had the highest death rate from enteric fever. This particular experience is not confined to Dublin, but has also been noticed at Glasgow, and the only available explanation is one which says little for the value of some of our modern sanitary works. On the whole, the Dublin statistics indicate that the poor are the principal sufferers from zymotic disease, notwithstanding the remarkable exceptions just mentioned. The zymotic death rate was found to be three times as great among the general service class—that is to say, the mass of the working population—as among those engaged in professional pursuits. The mortality from measles was nearly ten times as great in the general service class as in the professional and independent class, and from whooping-cough more than four times as great. It is worthy of note that the death-rate from phthisis during the period of observation was 70 per cent. more in Dublin than in London, and was more than four times as fatal among the general service class as among persons of professional standing. Mortality from lung disease followed a similar law, though in a somewhat less degree.

The investigations of Dr. Ogle show that the mortality of males between the ages of 25 and 65, occupied as agricultural laborers, gardeners and nurserymen, is not much greater than that of clergymen. It is even considerably less than that of barristers and solicitors, or of medical practitioners. Thus poverty and hardship appear to play a very subordinate part in shortening human life, and classes far removed from each other in the matter of social status enjoy equal vitality. On the whole, there is a marked difference between the death-rate of the upper and lower classes, yet there are instructive exceptions to the rule. That which kills is not mere poverty or hard work; there must be the accompaniment of dirty homes, impure air, and more especially intemperance, to render life precarious. Neither will the possession of ample means and apparently healthy surroundings give all the security that might be expected, if judged by the fact that barristers and solicitors die earlier than the poor cottagers of the rural districts. Still, these professional classes make their appearance among those who have the lower death rates. The truth remains that, on the whole, the poor die first. The untoward influence of poverty appears in the large towns. Laborers may be healthy in the country, but in London they have a high mortality. Work in the open air is not sufficient to counteract adverse influences of another sort, as shown by the high death rate of those engaged in the cab and omnibus service. These die twice as fast as the gardener and agricultural laborer. Still more severe is the mortality among costermongers, hawkers and street sellers. Curiously enough, the mortality among hotel servants is nearly four times as great as that of the clerical class. Hotel service seems to be more fatal to human life than the occupation of the Cornish miner. One of the apparent anomalies connected with the rates of mortality is the high and increasing death-rate among medical men. This has been recently made the subject of a special and interesting paper by Dr. Ogle. It certainly calls for remark, and indeed for regret, that while the mortality of the population is on the decline, those who are more directly concerned in curing disease and preserving life, are themselves the peculiar victims of that fate which they are instrumental in averting from others.

In estimating the relative mortality of different classes in the community, regard has to be paid to

the proportion of children. This varies greatly in the different parts of the social scale. Thus Dr. Grimshaw found that a thousand of the professional and independent classes included only seventy-five children under five years of age, while a thousand of the artisan class contained one hundred and twenty-one such children. The Dublin statistics further prove that the annual mortality among children under five years of age is five times as great among the working population as in the professional and independent classes. Further on in life the balance keeps in the same direction, though in a less degree. Special attention is drawn to the enormous waste of infant life among the working population. It is a striking fact that this "wholesale slaughter of the sickly and weakly children under five years of age" does not verify the favorite theory of many vital statisticians, that those who survive are capable of living long. That the children of the poor need not die so young is proved by the statistics of the Peabody Buildings, situated in various parts of London, and housing some twenty thousand persons belonging to the artisan and laboring classs. The low rate of child mortality in that instance shows that one cause of early death is to be found in the character of the dwellings, though to this must be added the habits of the people themselves. The Peabody population is assuredly living in a higher scale of civilization than the mass of the London poor, so far as personal conduct is concerned. There is abundant scope for the saving of child life among the poor, it is however a painful thought that the lives thus spared may help to swell that enormous mass of indigence which hangs already as a burden on the state. The solving of the sanitary problem will leave other problems to be faced, and will rather add to the complexity of some of these.

THOMAS F. ROCHESTER, M.D., one of the most eminent members of the profession in the western part of New York, died at his home in Buffalo, May 24, 1887. He was born in Rochester, N. Y., in 1823. He graduated in medicine in 1848, and in 1853 accepted a professorship in the Medical Department of the University of Buffalo, and removed to that city, where he soon won a high reputation as a practitioner and teacher of medicine, and sustained it until his death.

DR. MORELL MACKENZIE AND THE CROWN PRINCE OF GERMANY.—For several days reports have reached this country of the serious illness of Prince Frederick William, who is suffering with a serious affection of the throat. A dispatch of May 30 says that Virchow determined by a microscopical examination that the growth is not carcinomatous. Dr. Morrell Mackenzie was called to Berlin to see the Prince, and it is said that his early arrival averted a thyrotomy. He removed about two-thirds of the growth. Dr. Mackenzie will go to Germany again in a few days. His call to Germany to see the Crown Prince is a merited honor, and shows that scientific worth is not estimated by geographical boundaries.

NEW YORK STATE MEDICAL ASSOCIATION—*Third District Branch.*—This Branch of the State Association will hold its next meeting in Odd-Fellows Hall, Elmira, N. Y., Thursday, June 16, 1887, commencing at 10 A.M. The programme embraces a large number of interesting papers, with a banquet in the evening.

DR. EDMOND FELIX ALFRED VULPIAN, widely known as the Dean of the Faculty of the French Academy of Medicine, died in Paris, May 18, 1887, aged 60 years.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Regular Meeting, March 23, 1887.

THE VICE-PRESIDENT, D. S. LAMB, M.D., IN THE CHAIR.

DR. J. B. HAMILTON gave the history and presented a specimen of

CANCER OF THE STOMACH AND PANCREAS.

The patient was a lady, 69 years of age, who first came under observation about three months ago, suffering from an injury to the hip joint. He found evidences of an old contusion, but there was general debility and anorexia. On palpation, there was found a perceptible tumor in the left hypochondriac region, which seemed to be enlargement of the spleen. There was some pain, a little jaundice, but no vomiting. The patient was not seen again for about a month, when the jaundice had deepened, the pain had become more constant, there was complete anorexia, the patient had become greatly emaciated, and the tumor was projecting in the left hypochondrium. The symptoms intensified until last evening, when the patient died. There was considerable vomiting in the last two or three days of her life, and for the last twenty-four hours, there was characteristic black vomit, previous to which time it had not been positively demonstrated that the stomach was involved. The specimen showed carcinoma of the pancreas, and a large cancerous mass occupying the posterior wall of the stomach involv-

ing the inner coats. The mesenteric glands in the vicinity were infiltrated, and the stomach was adherent to the abdominal parieties. He had been surprised to see so much disease of the stomach, with such negative symptoms, and accounted for the absence of vomiting by the fact that the pylorus was not involved, and the passage consequently unobstructed. The spleen was greatly atrophied.

In reply to a question by Dr. McArdle, he said there had been some diarrhœa at intervals, and within the last three or four days, but it had not been a prominent symptom.

Dr. S. C. Busey said that the absence of vomiting was probably accounted for as Dr. Hamilton says. The absence of pain, however, which is not uncommon in cancer of the stomach alone, is very unusual when both stomach and pancreas are involved.

Dr. Samuel S. Adams read a paper on

CIRCUMCISION FOR THE CURE OF ENURESIS.

He said that several years ago he had advocated circumcision for the cure of incontinence of urine only under certain conditions in a small class of patients. Further experience had convinced him that the views then held should be modified in order to broaden the scope of the operation. After the eighteenth month a healthy child should pass urine voluntarily; passing it involuntarily he deemed due to pathological cause and not to carelessness. Instead of accepting the popular belief that incontinence is due to laziness, he had been able to detect a specific pathological state in all his cases. Boys have been repeatedly and unmercifully punished for bedwetting when they were powerless to control the sphincter on account of disease. Again, others let the disease run on, hoping that education and refinement will effect a cure, or expect it to be relieved by the establishment of puberty. In too many cases the disease is not treated, and finally psychical changes take place. The boy's whole disposition is altered, and he presents a striking likeness of the onanist.

The disease is divided into three classes: In the first there is a constant dribbling of urine day and night. This is infrequent, and is associated with some serious pathological state; consequently it does not fall within the scope of this paper. In the second class, the incontinence is intermittent in character and occurs in the day as well as at night.

The urine is retained for a short time when the desire to void it comes, but before the child reaches a convenient place the sphincter relaxes and the child soils his clothes. But our interest is in the third class, because of its frequency, its nocturnal character, its possible concealment for years, and the promptness with which it yields to treatment.

It is the children of this class who are so frequently punished for bedwetting when they are as powerless to control the sphincter during the night as those of the two preceeding classes during the day. Dr. Adams thought he could safely add another class, although it might be claimed that it properly belonged to vesical hyperæsthesia. In these the urine is only held for a short time when there is an incontrollable desire to void it. Clinical observation warranted him in making such a classification. This position is strengthened by the fact, that the treatment applicable to this form is similar to that in the others and is equally as successful.

Formerly he did not advocate circumcision in all cases of elongated prepuce, because he believed that if the adhesions were broken up, thus rendering the prepuce capable of retraction, the incontinence would be cured. He had learned by more extended clinical experience that there are a great number of cases that will not be cured as long as the redundant prepuce remains. In a large majority of cases destruction of the adhesions will only afford temporary relief. Where phymosis exist there seems to be no question about the surgical procedure. It is in those with the retractible prepuce that the propriety of circumcision is called in question. In children under 8 years physicians operate without hesitancy; after this age there is a tendency to delay operative measures until the child's health is impaired.

Dr. Adams then gave the clinical histories of the classes and described the methods of treatment that had been applied, and finally abandoned. The disease becomes so bad and the person so filthy, that the child is brought to the surgeon. He finds the prepuce projecting from one-fourth to one-half inch beyond the meatus; the opening is small and its margin is irritated; and on retracting it he finds an ichorous, foul-smelling collection behind the corona, and the glands irritated and injected.

The nerve-supply of the penis is derived from the pudic nerve, giving branches to the musculi-bulbo and ischio cavernosa, and then passing to the glans where it breaks up in sensory filaments. A portion of these final branches possess a special kind of end-bulb, discovered by Kraus, and called genital corpuscles. It also receives branches from the hypogastric plexus. The upper part of the bladder receives its supply from the hypogastric plexus and the base and neck from the fourth sacral nerve.

It seems reasonable that an irritation of the terminal filaments of the pudic and hypogastric distributed on and around the glans penis, being of sufficient intensity to overcome their spinal gangliomi termination, will also expend its force on the centre of urination and the bladder will be emptied. If the prepuce covers the glans in the adult, the greatest care has to be taken to secure cleanliness and prevent inflammation. The natural secretions soon become offensive and irritating, causing a vesicular inflammation of the corona and adjacent mucous membrane, which is characterized by intense itching, burning, foul odor, painful erections and frequent micturition. This condition is seldom seen in those who have the glans uncovered. Such conditions must occur frequently in the child, that even by the strictest supervision will not regard the hygiene of its person. In only one instance had he known enuresis to continue after circumcision. This child he had previously treated for gonorrhœa so that the continuance of the incontinence might be due to stricture; however, this was only presumptive as the boy would not permit another examination.

DR. T. C. SMITH said that according to his experience the majority of cases of incontinence of urine had been in females, and he would like to ask Dr. Adams what he would do in such cases?

DR. G. L. MAGRUDER stated that he had been interested in the subject for several years, and was glad to hear Dr. Adams express himself so positively in favor of this operation. He is in accord with what he has said, and even goes further and believes in the operation as a means of relieving constant dribbling.

His service at the Central Dispensary has confirmed the opinion he expressed so early as 1879, when he first advocated circumcision for the relief of this class of troubles. In his experience enuresis is cured at once by circumcision if the parts heal by first intention; if not and there is some inflammation, the trouble may continue until it subsides. His experience as to the relative frequency in the sexes does not coincide with Dr. Smith's. At the Central Dispensary the proportion is about ten boys to one girl with incontinence. He often finds, however, a vulvitis, a vaginitis, or a constriction about the clitoris, which last he breaks down by passing a probe around the organ. He also finds that females respond to medicinal treatment more readily than do the males.

In this connection he has found strychnia the most valuable drug, with belladonna next, and where there is a bad state of health, syrup of the iodide of iron. He is not an enthusiast about this last, in all cases, but in females he considers it especially valuable.

DR. T. C. SMITH said that he has never had a large experience with circumcision for enuresis, but he considers it a valuable operation, and one that is not often enough done. If some dynamic force could be found which would compel the whole male population to allow their penis to be examined by some doctor, what a variety of pathological conditions we should find. The other day a man came to his office with a picture of his own penis and asked him what could be done with such an organ. Dr. Smith persuaded the patient to let him see the original of the picture, when he found a pin hole prepuce with a portion of the glans penis sticking through it like a polypus. Years ago he had treated this man for asthma, and after months of treatment he was no better. The patient went from one to another doctor without being benefited of his asthma. Dr. Smith said that he was positive that if he had known of the condition of the prepuce when he first attended the case for asthma, he could have cured his patient by circumcision. This man was married and his wife had given birth to a puny child which had died in about six weeks. The asthma still continues, but he does not expect to cure it by circumcision which he has recommended.

DR. J. FORD THOMPSON rarely stops to study up the reflexes when called to see a child with a long prepuce. It is his invariable custom to recommend circumcision when he finds a long or adherent prepuce. It is, however, remarkable how some men escape all trouble with this affection. The other day he operated upon a man of 80 who had never seen his glans penis. The man had been married forty years and had a large family of children. He never had had the slightest trouble with his penis and only came to consult a doctor because of a slight inflammation around the meatus, which bothered him on micturition. He has also had two similar cases in men over 70. In one of these cases cocaine was used; the patient suffered no pain whatever and continued telling a story which he had begun before the operation. He has been called upon to operate for incontinence less frequently than for other conditions, but he can recollect but one case of incontinence that was not relieved by the operation Many circumcisions, are however, done so early that one cannot say what might have happened without the operation. It is the rule to look at the penis in every case of chronic disease, and he is often astonished to see the number of children that require the operation. He has circumcised in apparent cases of bone and hip disease with relief to the child, and he has recently found several cases of club-foot and hare-lip which have needed the operation. Some time ago he operated for Dr. Busey, on a child with epilepsy, who had been treated unsuccessfully by some of the best doctors in another city. The result was a perfect cure. Dilating the prepuce or simply breaking down the adhesions is of little or no value. The only satisfactory way to do is to slit the prepuce back to the sulcus, and to cut off enough to keep the glans uncovered. He has operated on adults who have been virtually impotent on account of a long tight foreskin. A man of 35 once told him that though he had been with women a great deal, he had never completed the act of copulation, because when he got an erection of the penis the irritation of the tight prepuce forced the organism before he reached the woman. Dr. Thompson found an adherent prepuce and a swollen glans, and expressed the conviction that circumcision would make him a new man. The operation was done, and in six months the patient came back again, saying that he could now enjoy himself as other men, and bringing tangible evidence that he had at all events made the effort.

He saw a child with the late Dr. Newman that had been treated for hip disease. A careful examination of the hip showed that there was no disease in that region, but upon examining the penis a long and adherent prepuce was found. Dr. T. concluded that therein lay the trouble, but this opinion was not coincided in by Dr. Newman. Circumcision was, however, performed and in six months the child was well. Of course, a tight prepuce is not the cause of hip-disease, but the symptoms produced by it sometimes simulate hip or spinal trouble. His opinion is, that it is the duty of every doctor to examine the penis of every new-born male child, and where there is a long adherent prepuce to operate even before the nervous symptoms begin. Even retained smegma may cause all the symptoms of a tight foreskin, but this cannot occur if the prepuce is removed.

DR. T. E. MACARDLE agrees with Dr. Adams when he reccommends circumcision without wasting

time in attempting a cure with drugs. He also agrees with Dr. Magruder that medicinal treatment is more efficacious on females with incontinence than on males. Belladonna he has found the most useful drug in these cases. In the female ascarides or filth may be the cause of the enuresis, and the removal of the cause will often effect a cure without medication.

Dr. S. C. Busey remarked that what has been said with regard to the effects of a long prepuce, is true in many cases; he coincides to a great extent with the opinions expressed. There are, however, many cases cured without resorting to circumcision. Vesical irritation, for instance, is a not infrequent cause of incontinence, but may be cured by drugs. One remedy will not cure all cases, but the one which he has found most useful has been belladonna. In his practice the proportion has not been so high as ten boys to one girl, troubled with incontinence. While circumcision is an operation always necessary when it causes retention of urine, it does not always cure incontinence. He would like to know whether Jewish children are much troubled with incontinence of urine. If circumcision has such a good effect, the custom among the Jews of circumcision on the eighth day must make enuresis a rare disease with that race. The boy referred to had been a masturbator and an epileptic, but since the operation, ten months ago, he has had no return of the convulsions. He has also seen children with epileptiform convulsions occurring every three or four weeks, cured by circumcision, while Dr. Sayre has well demonstrated that some very peculiar nervous symptoms have been improved or cured by the operation. Idiocy has not, however, been completely cured by circumcision. There must be other causes besides a tight prepuce for the trouble occurs so frequently in females, even where there is no local irritation. As has been said, medicine acts better upon this sex than males. The medication need not be addressed directly to the local trouble, but to any constitutional cachexia that may be present, and for this purpose nothing is better than the syrup of the iodide of iron. The cause must always be sought out and whether local or not, hygiene, food and dress must be considered in the treatment.

In conclusion, he would say, that whilst he considered circumcision a valuable operation from a hygienic point of view, and would advise it in all cases of long prepuce, yet he believes that many cases of incontinence can be cured without resorting to it at all.

Dr. G. L. Magruder agrees with Dr. Thompson as to the advisability of examining the genitals of male children. In reply to Dr. T.'s remark that he had never seen a statement that a tight prepuce was the cause of hip-disease, would call attention to the observation of Dr. Barwell, who investigated this subject, and in 100 cases of hip-trouble examined, only six had a normal foreskin. Barwell has divided this condition of the penis into five degrees. The first degree, in which there is only a pin-hole opening in the prepuce, and so on down to the fifth degree, in which the organ is normal.

He also requested a friend to find the number of hip joint cases in a hospital frequented by Jews, and the friend replied, "that there were no Jewish patients with hip-disease." It seems, therefore, that there is some connection between a tight prepuce and hip-joint trouble. There is a nerve which leads from the sacral plexus into the hip joint. Barwell thinks that the influence of irritation at the glans penis can readily modify the trophic changes that take place in the hip at this time of life. On the other hand, Sayre asserts that the hip trouble is from falling down, an accident that children with tight foreskins are especially liable to owing to the weakening of the muscles produced by the condition of the genitals. Since his connection with the Central Dispensary he has seen many cases of club foot, but only two of them have been in girls. A few weeks ago he saw a child of three months who had never had a comfortable night's rest since its birth, and who had grown peevish and emaciated. The trouble was constant priapism. Two homœopaths had been pouring cocaine into the urethra in hopes that that would bring relief, but without effect. Upon examination, he found the prepuce attached over the whole of the glans, and a quantity of smegma collected behind it. He broke down the adhesions, and finding further a short frenum it was cut. The child was almost instantly relieved and has been progressing favorably ever since.

Dr. Samuel S. Adams, in closing said, that he had limited his paper to circumcision where there was an elongated prepuce, and he consequently had not encroached upon Dr. Magruder's paper, which took in a broader field. He is glad to see that Dr. Thompson has come to believe in circumcision for general symptoms. Dr. Adams, continuing, said that he had always advocated circumcision in elongated prepuce, and that this paper was a reiteration of his belief expressed when Dr. Magruder read the paper which had been alluded to.

AMERICAN SURGICAL ASSOCIATION.

Eighth Annual Session held in the Army Medical Museum, Washington, D. C., May 11, 12, 13 and 14, 1887.

Tuesday, May 12—Second Day.

Afternoon Session.

(*Concluded from page 609.*)

Dr. R. A. Kinloch, of Charleston, S. C., read a paper on

PISTOL-SHOT WOUND OF THE ABDOMEN TREATED BY LAPAROTOMY AND SUTURING THE INTESTINES.

J. B., colored, aged 27, was admitted into the City Hospital, January 21. He had been shot two hours before in the abdomen with a pistol ball. The ball entered 1½ inches to the left of the umbilicus. There was slight shock. At 10 P.M. ½ grain of morphia was given hypodermically, and shortly afterwards anæsthesia was induced. Penetration of the peritoneum was first determined, and the abdomen was

then opened by median incision. The intestines were examined piece by piece and wrapped in towels wrung out of a 1–10,000 bichloride of mercury solution. The jejunum presented four wounds. The ileum had two wounds. The mesentery was perforated in two places, and was also badly torn. There was free bleeding from a mesenteric branch, which was controlled by silk ligature. All the wounds were closed with the Lembert suture, using a fine round needle and antiseptic silk. The wounds of the mesentery were brought together as far as was possible, but there was an infiltration of blood which could not be removed. The abdominal cavity was washed out with a weak solution of hydrarg. bichloride, the abdominal wound was closed with silver sutures, and a large rubber drainage tube introduced. Antiseptic precautions were observed throughout the operation. The next morning vomiting occurred, and an examination of the wound showed that a suture had given way and a knuckle of intestine protruded. This was returned and the opening closed. At 5 P.M. the temperature was 102°. Vomiting again occurred, and shortly after midnight the patient expired suddenly.

Autopsy.—No adhesion of the parietal peritoneum had occurred. Half a pint of dark sero-sanguinolent fluid was found in the cavity. All the intestinal sutures had held and there was no fæcal extravasation. A circumscribed abscess was discovered in the meso-colon out of the line of the bullet. The ball was found behind the body of the fourth lumbar vertebræ on the left side.

This was the third case in which the author had performed laparotomy for bullet wounds of the abdomen without visceral protrusion. In two cases of such injury the patients recovered without operation. The first operation was performed May 27, 1883. This patient recovered. This was the first time that laparotomy was done for gunshot wound without protrusion.

DR. W. W. KEEN, of Philadelphia, reported a case of

PISTOL-SHOT WOUND OF THE ABDOMEN, INVOLVING THE LIVER, STOMACH, SUPERIOR MESENTERIC VEIN, INTESTINE AND KIDNEY; LAPAROTOMY; NEPHRECTOMY; DEATH ON THE FIFTEENTH DAY.

A girl of nearly 18 shot herself with a pistol, calibre No. 32, at 6:30 A.M., April 1, 1887. The ball had entered over the liver, and was found lying under the skin of the left flank. I saw her at 2 P.M. The wound of entrance was over the ninth rib, which was fractured, 4½ inches above the level of the navel, and 3¾ inches to the right of the median line. Skin not burned. The ball was located 8 inches to the left of the median line and 1½ inches above the level of the navel. There was moderate tenderness over the entire belly, hepatic dulness not changed, stomach resonant from fifth interspace, no cough, no râles, vocal fremitus normal. Renal dulness began at tenth rib on left side and was the same on the two sides. There was severe pain in the left shoulder. She had vomited 1½ drachm of clear bright blood, she told me, immediately after the accident. About a pint of urine, the first since the accident, was drawn by the catheter. It was not bloody. Pulse 104; respiration 30; no material rise of temperature. As after consultation it was deemed almost certain that the belly was invaded by the ball, exploratory laparotomy was advised, consented to, and begun at 3 P.M., and lasted nearly three hours, with every antiseptic precaution. The ball was easily removed just under the skin. Neither wound could be traced positively into the belly. On opening the belly neither blood nor serum escaped, nor was any extravasated food or fæces noticed. There was no peritonitis. Two fingers were passed in, and an effort made to discover the wound of entrance or exit, without any being revealed by touch. The wound was then enlarged and the stomach drawn out. A small round wound near the pylorus was found and was closed by four sutures (Lembert) of the finest iron dyed silk, a round ordinary sewing needle being used. This wound was practically closed by the pouting mucous membrane. As the ball had entered the stomach, search was made for the necessary wound of exit. None was to be found, but the manipulation showed that a small amount of bloody serum existed in the belly, and a large area of extravasation was seen in the mesentery. But little blood had escaped into the peritoneal cavity. The mesentery was carefully torn through and a small artery tied. The chief bleeding came from a hole nearly ⅛ inch in diameter in a large vein, so large and lax that at first I thought it the vena cava, but its position just below the head of the pancreas convinced me that it was a large superior mesenteric vein just before it forms the portal vein. After much difficulty I seized it with hæmostatic forceps, and placed a lateral ligature of chromicized catgut on it.

The anterior border of the liver had been scalloped by the ball, but as there was no bleeding, it was let alone. In addition, a large wound in a coil of small intestine in the left flank had been found. Ten Lembert sutures were used in closing it. Returning now to the stomach, a very careful search was again made for the wound of exit. It was found obscured by a slight coating of blood. This was closed by three black silk Lembert sutures. A systematic investigation of the entire bowel from the stomach to the sigmoid flexure showed no other wounds. The left kidney was badly lacerated, and was immediately removed by peeling it out of its capsule and tying the pedicle with a stout silk ligature. A rubber drainage-tube was inserted through the wound of exit into the abdominal cavity. The wound of entrance was cleansed and closed by three stitches, and the wound of exit by two. Sublimate gauze, rubber dam, and a wide flannel bandage completed the dressing.

On the 8th she had a chill lasting twelve minutes, and the temperature rose to 104°, but as the most careful examination revealed no spot of special tenderness, no dulness, no fluctuation, and she was almost, it seemed, *in articulo mortis*, it was not deemed prudent to reopen the belly.

On the 10th she improved somewhat. On the 13th she had another chill with a temperature of 105.4°,

had vomited several times, and also had some involuntary evacuations. But as her condition was fair, pulse 136, temp. 101.4°, the belly was reopened and explored. The intestines were bright and glistening and no peritonitis existed. Surgical bimanual examination revealed no pus or special tenderness at the site of the removed kidney, or, so far as it could be located, at the intestinal wound. No shock followed. The next day (fourteenth) she had two bloody motions and gradually failed, dying on the fifteenth day.

The autopsy revealed general peritonitis, but no free pus was found anywhere. Only one wound was found in the stomach, near the pylorus, and this was healed, the four stitches being seen in place. The blood in the mesentery was disintegrating and suppurating, though no abscess existed, nor was there any free pus in the peritoneal cavity. The suppuration was chiefly marked along the mesenteric attachment of the intestine. On the other side of the mesentery, corresponding in position to this wound, was a spot in the bowel wall as large as a five-cent coin, which was gangrenous, and in its centre were two perforations of the bowel. No wound was found except that discovered at the operation. No trouble was found at the site of the removed kidney. Although it was nearly ten hours from the accident to the time when the intestines and stomach were sutured, no intestinal or gastric juice or fluid escaped, though the intestinal wound was so large and vomiting occurred three times.

The kidney, I believe, has never before been removed at a laparotomy for gunshot wound, but it was clearly the right thing to do. The day following the operation the remaining kidney worked badly, only 3½ ounces of albuminous urine being secreted. But the next two days dispelled all anxiety on this score, the urine rising to 24 and 40 ounces respectively, and the albumen soon disappeared. The early and marked compensatory enlargement of the right kidney is also of great interest and importance, though, of course, now well known to follow nephrectomy.

Dr. P. S. Conner, of Cincinnati, remarked that the most important point to determine is, when should the abdominal cavity be opened? If there is extravasation of bile, fæces or urine through the wound, the nature of the injury is clear, but in the absence of these signs there is much doubt. There is no single symptom or collection of symptoms to be relied upon. He had been disposed to attach some value to the presence of profound depression of temperature. If the temperature remains subnormal four, five or six hours, penetration and perforation may be considered almost certain. Diagnostial laparotomy is admirable in certain cases. In private practice we have to be largely governed by the opinions of the patient and his friends. Most of these cases necessarily involve legal investigation, and it is a very simple matter to show that death resulted not from the original injury but from the surgeon's knife. While he considered it wise to lay down the general rule that penetrating wounds of the abdomen, and still more perforating wounds of the viscera, should be submitted to laparotomy, at the same time he held that we are not justified in laying this down as a hard and fast rule.

Dr. Moses Gunn, of Chicago: When Dr. Sims proposed this operation a few years ago the profession were not ready to accept it. All are now prepared to say that it is a proper measure to pursue, but the only question is how to make the diagnosis? We have, as has been said, no positive signs of visceral injury. He thought that we are fully warranted in saying that we may resort to laparotomy for purposes of diagnosis when we are in doubt.

Dr. T. G. Richardson, of New Orleans, stated that the statistics of the Charity Hospital of New Orleans showed that in the last five years there had been thirty-one cases of penetrating knife wounds of the abdomen, of which twenty-four recovered and seven died. There were thirty-three cases of gunshot wounds of the abdomen, with thirteen recoveries and twenty deaths. These cases were treated on the expectant plan.

Dr. D. Hayes Agnew, of Philadelphia, had very strong convictions in regard to laparotomy. He believed that where there is a reasonable degree of evidence that there is a penetrating wound of the abdominal wall, especially if a shot wound, it is the surgeon's duty to make an exploratory incision. We are not to be deterred by the possibility of some legal technicality if the case should come into court. We are to do our duty without reference to the consequences.

Drs. David Prince, Joseph Ransohoff and N. P. Dandridge also reported cases bearing upon this discussion.

Dr. J. Edwin Michael, of Baltimore, read a report of a case of

VENTRAL HERNIA SUCCESSFULLY TREATED BY OPERATION, WITH A SUGGESTION AS TO THE METHOD OF OPERATING.

Mrs. F., stout woman, 45 years of age, had a ventral hernia resulting from a fall several years previously. Great annoyance was experienced in the use of pads and bandages. The patient insisted on operation, and March 15, 1886, the operation was performed. Antiseptic precautions were adopted. Free incision was made in the median line. The sac was carefully separated from surrounding tissues. It was then emptied of its contents and opened. The sac was cut off close to the margin of the ring. Strong silver wire sutures were passed a little less than one half an inch apart, having a hold of one-half to three-fourths inch. The sutures included the peritoneal, muscular and tendinous structures only. These were twisted and perforated shot employed. The wire was then cut off close. The wound united rapidly. In October, examination of the wound showed it to be firmly united. The sutures could be felt, but gave no inconvenience. In his remarks the speaker stated that his object in using the wire sutures in this manner was the expectation that they would be surrounded by a mass of cicatricial tissue, making a permanent closure of the ring. As far as he was aware, he had used the wire for this purpose without precedent.

A paper on *Prognosis in Sarcomata of the Breast*, by S. W. Gross, of Philadelphia, was read by title.

DR. D. HAYES AGNEW, of Philadelphia, read a paper on

THE MEDICO-LEGAL ASPECT OF CRANIAL AND THORACIC WOUNDS (SUICIDAL).

The study of this subject had been suggested to him by a recent case occurring in Newport, Rhode Island. The question was as to the possibility of a cranial wound and a wound of the heart being self-inflicted. A colored man was found one morning lying dead under the breakfast-table. He had food in his mouth, and had a wound of the head and of the heart. The coroner's jury returned a verdict of suicide and the body was buried. Subsequently it was disinterred and the verdict reconsidered, and the conclusion reached that the man had been murdered. Suspicion then fell upon the son-in-law of the man, who had up to this time borne a good reputation. At the trial five medical experts were called for the prosecution, and their general testimony was that these wounds were incompatible with the idea of suicide. Subsequently the prisoner confessed that he had committed the murder. As this was an important question, the author had investigated it. Injury to the brain is not necessarily followed by loss of consciousness or by paralysis. Many cases were cited to show the truth of this statement. Numerous instances of heart injury were given in which, after the reception of the accident, the individual was able to perform many acts. Cases were also given in which persons, in attempting suicide, had produced injuries of the head and of the heart. As the result of his study the speaker concluded that it is possible for a ball to enter the brain without destroying consciousness, although for a moment it may cause mental confusion, and that a suicide may shoot himself in the head and after a moment shoot himself in the heart.

In the discussion which followed numerous cases were related in which the heart or brain had been injured and the individual had lived for some time, and had not been unconscious. Cases were also given in which both a wound of the heart and of the brain had undoubtedly been produced by the individual himself.

FRIDAY, MAY 13.—THIRD DAY.

MORNING SESSION.

The following were elected

OFFICERS FOR THE ENSUING YEAR.

President—Dr. D. Hayes Agnew, of Philadelphia.

Vice-Presidents—Dr. N. Senn, of Milwaukee, and Dr. F. S. Dennis, of New York.

Secretary—Dr. Jacob R. Weist, of Richmond, Ind.

Treasurer—Dr. Phineas S. Conner, of Cincinnati.

Recorder—Dr. J. Ewing Mears, of Philadelphia.

Council—Drs. J. S. Billings, L. McLane Tiffany, Moses Gunn, and R. A. Kinloch.

Chairman of Committee of Arrangements—Dr. John S. Billings, of Washington.

The following were elected

NEW MEMBERS.

Charles B. Porter, M.D., of Boston; William M. Mastin, M.D., Mobile, Ala.; and Morris H. Richardson, M.D., Boston, Mass.

The next meeting to be held at the call of the President.

DR. L. MCLANE TIFFANY, of Baltimore, read a paper on

SURGICAL DISEASES OF THE WHITE AND COLORED RACES COMPARED.

The paper was based on the record of 4930 cases, studied during a period of thirty-four months in a general hospital. The percentages of the affections were given in detail. The paper was simply intended as a preliminary communication, and as a result of a study of the figures obtained the following suggestions were made:

1. Surgical affections follow different courses in the white and colored races, under identical hygienic surroundings.

2. Surgical injuries and operations are better borne by negroes than by whites.

3. Surgical diseases involving the lymphatic system, especially tubercular, are more fatal and more rapidly fatal in negroes than in whites.

4. Congenital deformities are rarer in negroes than in whites.

5. The surgical differences observed in whites and negroes are due to racial peculiarities.

DR. CHRISTOPHER JOHNSTON, of Baltimore, said that his experience indicates that there are individual as well as racial peculiarities. These are most striking in proportion to the pureness of the blood. He regarded the negro as a good subject for surgical operation. He had never seen carbuncle in negro. He does not recall a cleft palate or hare lip in the darker individuals. Epithelioma is infrequent. Fibromas are quite frequent. He had found that in the negro the skin and white tissues are more frequently the seat of certain diseases than the same tissues in the white.

DR. T. H. RICHARDSON, of New Orleans, presented a detailed report of the statistics of the Charity Hospital, bearing upon this point. He had found congenital deformities rarely in the negro.

DR. E. H. GREGORY, of St. Louis, had seen keloid much more frequently in negro than in white, and had never seen multiple keloid in the white race. The ability of negroes to stand operation may be due to his indifference, and he does not comprehend the magnitude of the operation.

DR. W. T. BRIGGS, of Nashville, said that his experience confirmed the suggestions of Dr. Tiffany. Negroes are very prone to suppuration. It is extremely difficult to prevent suppuration even under strict antiseptic precaution. Negroes bear operations better than whites, but they do not get well so rapidly. While malformations are less frequent, still they do occur. The rarity of hydrocele in the hospital records may be explained by the fact that negroes do not usually seek advice until the tumor has become so large as to give rise to much inconvenience. Ovarian tumor is rare, although he had had one case.

DR. D. W. YANDELL, of Louisville, Ky., had seen

many cases of keloid in the negro, but had not seen a case in the white subject. He had seen but two cases of hydrocele in the negro, and never saw hare lip in the negro. He had seen but two ovarian tumors in the negroes, and never saw epithelioma of the face of a negro. Epilepsy is exceedingly rare in the negro. Tetanus is exceedingly common, especially in the blacker race. Stricture of urethra is exceedingly common among negroes.

Dr. R. A. Kinloch thought that in the pure negro suppuration is less likely to occur than in the white race. As a rule the pure negro is not strumous. Mulattos are, as a rule, strumous. The pure negro bears operation well and recovers promptly.

Dr. A. Vanderveer, during the past twenty years, had seen a great many negroes, United States prisoners, sent to the Albany penitentiary. The vast majority of these die of tuberculosis of some form. Many of them have soft chancre with suppurative buboes. Where there is true Hunterian chancre there has been the characteristic bullet bubo seen in the white race. There are a greater number of perineal abscesses and sinuses than in the white. If operation is done there is less probability of urethral fever.

Dr. B. A. Watson, of Jersey City, read

AN EXPERIMENTAL STUDY OF THE EFFECTS OF PUNCTURE OF THE HEART IN CASES OF CHLOROFORM NARCOSIS.

The results of sixty experiments on dogs were given in detail. The experiment consisted briefly in producing death by chlororform inhalation, and then within from one to three or four minutes an aspirating needle was introduced into the heart through the chest walls, the attempt being to reach the right ventricle. In the first fifty cases the chloroform was administered rapidly and air was excluded as far as was possible. In the last ten the chloroform was administered slowly, and with a large proportion of air. The first forty animals had already suffered some severe traumatic injury, while the last twenty were perfectly healthy animals. The punctures made in these 60 experiments were as follows: Right ventricle 38; left ventricle, 6; right auricle, 6; superior vena cava, 3; inferior vena cava, 2; apex of the heart, 2; and not stated, 1. The resuscitations were as follows: after puncture of the right ventricle, 9; right auricle, 1. The first forty experiments gave only four recoveries, while the last twenty gave six. In only one of the sixty cases did the heart fail to respond to puncture, and in this instance the use of the needle was postponed for four minutes after the cessation of the heart's action, and one minute after breathing had stopped.

Should the puncture be carried into one of the the cavities of the heart in order that blood may be abstracted? In chloroform narcosis the heart is found in diastole and the veins in the lungs are greatly distended with blood. It may therefore theoretically be assumed that blood may be advantageously drawn from the right side of the heart. The author was assured that this procedure was practical and advantageous.

The only deaths during these experiments which could be attributed directly to the puncture, were those in which the needle penetrated the vena cava. In these cases there was profuse hæmorrhage into the thoracic cavity. Punctures made into the auricle are sometimes followed by a flow of blood into the pericardium. Punctures into the ventricle are not attended with any hæmorrhage from the interior of the organ, but there may be a few drops of blood from a wounded cardiac vein.

The following conclusions were reached:

First, Puncture of the heart, especially of the right ventricle, stimulates muscular contractions, and may be advantageously applied in the treatment of chloroform narcosis.

Secondly, The best results are obtained when abstraction of blood from the cavity of the ventricle is combined with the stimulating effects produced by the entrance of the aspiratory needle.

Thirdly, The puncture of the right ventricle is a safer and more efficient operative procedure than the puncture of the right ventricle.

Dr. N. P. Dandridge, of Cincinnati, said: The conditions under which the experiments were made were different from those under which accidents usually occur in human beings. In the latter case, the accident usually occurs after only a small quantity has been taken and often early in its administration. The effect is probably due to a reflex effect upon the inhibitory action of the heart. In the experiments reported puncture was resorted to within one or two minutes after the cessation of the heart's action. In the accidents with chloroform, it is not uncommon to have recovery after apparent cessation of the heart's action for a comparatively longer period. A large number of experiments are required to test the relative value of this procedure as compared with artificial respiration. The use of nitrite of amyl, and particularly with the subcutaneous injection of atropia. This latter can always be done quickly, and has a stimulating effect upon the cardiac and respiratory centres.

Dr. John B. Roberts, of Philadelphia, said that the speaker, while he had shown the comparative inocuousness of the heart with a small needle, had also shown the danger of using chloroform as an anæsthetic in any cases, possibly cases of parturition excepted. His experiments have shown that it is more dangerous to puncture the auricle than the ventricle, which would naturally be suggested by the fact that the auricle has a much thinner wall.

Dr. T. J. Dunott, of Harrisburg, referred to a case in which the heart was twice punctured with an aspiratory needle, and blood drawn from the cavity of the heart. It was a case of dilatation of the heart with general dropsy, etc. The operation was performed by a homeopathic practitioner, under the idea that he was dealing with a case of dropsy of the pericardium. A large quantity of blood was removed, and for a time there was improvement. The symptoms again returned and the operation was repeated with a fatal result.

The committee to which was referred the *Suggestion's contained in the President's Address*, reported

that in view of the satisfactory manner in which the work of the present meeting had been prepared, it saw no reason for a change and did not recommend the appointment of a business committee. It recommended the adoption of the second suggestion with reference to the abrogation of Article 9 of the Constitution. The committee was in accord with the President, but as the article had been introduced at the express desire of the first President of the Association, it was then recommended that it be allowed to remain. The committee recommended the adoption of the suggestion that applications for membership lay over for one year.

AFTERNOON SESSION.

DR. T. J. DUNOTT, of Harrisburg, read a paper on

HYPERTROPHY OF THE TONGUE, OTHERWISE KNOWN AS LINGUA VITULI, LINGUA PROPENDULÆ AND MACROGLOSSIA.

This affection of the tongue, though rare, is mentioned by nearly all surgeons of large experience. The case described by the speaker was that of a girl, 12 years of age, admitted to the Harrisburg Hospital January 6, 1886. The tongue protruded from the mouth a distance of three and five-eighths inches. The lips were greatly distended, and the angles of the mouth not far removed from the external opening of the auditory canal. The greatest width of the tongue was four and three-fourths inches, and the greatest circumference nine and three-fourths inches. The prolapse of the tongue was only of two months' duration, and had begun without apparent cause. The measurements taken one week after admission showed a decided increase in the size of the tongue. The tongue was removed on February 19. After providing against hæmorrhage the organ was removed with scalpel and scissors, the section being so made as to secure a conical stump. All the dense fibro mass was taken away, the weight of the removed portion being over ten ounces. By January 31, the stump was entirely healed. There was no difficulty in keeping the mouth closed. When heard from March 23, she could eat and drink without difficulty and was gaining flesh rapidly. The paper was concluded with an account of the various operations which had been practiced for the removal of the tongue.

DR. L. MCLANE TIFFANY gave the history of a case. A negro girl, 5 years of age, had suffered with hypertrophy of the tongue dating from birth. Ever since the first few months of life, the child had been unable to cover the tongue with its lips. The tongue was removed with the Paquelin cautery. Within a week the patient was eating potatoes and meat, and left the hospital ten days after operation. At this time there was a healthy granulating surface.

DR. J. FORD THOMPSON, of Washington, reported

TWO CASES OF VAGINAL HYSTERECTOMY.

Case 1.—Mrs. A. E., aged 45 years, white, was seen in April, 1885, suffering with malignant disease of the uterus. There was great destruction of the cervix, the ulceration extending above the internal os. On consultation, it was decided to avoid hysterectomy if possible, but to limit the operation to amputation of the cervix with scraping, etc. During the operation the peritoneal cavity was opened. It was then decided to extirpate the uterus. The womb was separated from the bladder in front. A ligature was then placed around each broad ligament and tied. The uterus was then split in two. Each half was then brought down, the broad ligaments tied above the temporary ligatures, and the uterus removed. After thorough cleansing the vagina was tightly packed with iodoform gauze. At the end of the operation the patient was very weak, and notwithstanding all efforts died in the course of twenty-four hours.

Case 2.—Mrs. H. white, aged 55 years, came under observation with cancer of the cervix, in January, 1887. The posterior lip of the cervix was almost entirely destroyed, and the disease had encroached upon the posterior cul-de-sac. The cervical canal was involved at least as high as the internal os. The operation was performed February, 21, 1887, antiseptic precautions being adopted throughout. The dissection was begun at the posterior part, and carried around the cervix. A silk ligature was passed with a long curved needle through the lateral vaginal vault of either side and tied. The inclosed portion was then cut from the uterus. These ligatures presumably enclosed the uterine arteries and the lower part of the broad ligament. The uterus was then separated from the bladder in front, and a loop of silk was attached to the peritoneum. The posterior cul de-sac was treated in the same way. The uterus was then tilted through the opening, and the broad ligaments transfixed and tied. There was no loss of blood. The peritoneal flaps were then brought together with two catgut sutures and a drainage tube introduced into each angle of the wound. The vagina was packed with iodoform gauze. The patient recovered without any unpleasant symptoms.

DR. T. F. PREWITT, of St. Louis, agreed with the author that extirpation of the uterus is a justifiable operation. He was almost prepared to go further, and say that on the earliest appearance of epithelioma of the cervix the whole organ should be extirpated. He believed that ultimately this will be the course adopted.

DR. E. H. GREGORY said that it was one of the rules of old surgery to save every part possible, and he would no more think of removing the whole lip for limited epithelioma of that part.

DR. R. A. KINLOCH said that in the uterus we have an organ suspended in the pelvis and easily isolated. Now if statistics show that by cutting far and wide without jeopardizing life too much, we can cut short the disease, we are carrying out the rules of old surgery when we do so.

DR. T. G. RICHARDSON reported a case of

ANEURISM OF THE LEFT SUBCLAVIAN ARTERY FOR THE CURE OF WHICH THREE METHODS OF TREATMENT WERE EMPLOYED—DEATH.

The patient, a healthy muscular Irish laborer,

came under observation October 19, 1885. Aneurism of the left subclavian artery was diagnosed. The patient had suffered with syphilis and constitutional measures were first tried. Iodide of potassium in fifteen or twenty grain doses, was given three times a day. At the end of a week no perceptible effect being observed it was discontinued. Direct pressure was next tried, an elastic band with a compress over the vessel was secured to a belt around the waist This was continued a month, and although it slightly retarded the growth of the swelling, it had had no decided result. The third method, the introduction of surgical pins was next resorted to, nineteen of these measuring an inch and a half in length, were passed through the anterior wall of the tumor at different places. The aneurism was still growing rapidly, and all the pins that could be reached were withdrawn. Some of them had disappeared on account of the swelling which had taken place. An attempt was then made to ligate the axillary artery, but in spite of the utmost care the lower portion of the aneurism was ruptured in the progress of the operation. The wound was at once packed with lint dipped in Monsel's solution. The hæmorrhage having been stopped, half a drachm of a 5 per cent. solution of bichloride of iron was injected into the centre of the tumor. At the end of twenty-four hours no coagulation having taken place, a second injection of twice the strength was employed. The next morning there was a exhausting hæmorrhage, ending fatally in a few hours.

Dr. Richardson also reported a case of

FEMORAL ANEURISM CURED BY ELEVATION AND FLEXION OF THE LIMB.

The patient, an Italian, aged 55 years, was admitted to the hospital Dec. 11, 1886, with a large aneurism of the femoral artery four inches below the femoral arch. While the case was being studied the limb was flexed at a right angle at the hip and knee and suspended on a Smith's anterior splint. The next day the pulsation was greatly reduced and the patient was quite comfortable. The treatment was continued and at the end of the third day the tumor was solid. The limb was kept in this position for ten days or two weeks. The patient was discharged cured one week later. The speaker called attention to the fact that there was no direct pressure upon the tumor and that the result was due entirely to flexion and suspension of the limb.

Dr. James McCann, of Pittsburg, reported a case of

SPLENECTOMY.

The paper was a case in which removal of the spleen had been practiced with recovery of the patient.

A paper entitled *The Study of the Methods of Operation Practiced and the Results Obtained in the treatment of Cleft of the hard and soft Palates, illustrated by the record of Fifty Cases*, by Dr. Ewing Mears, of Philadelphia, was read by title.

A vote of thanks was then extended to the Surgeon-General for the use of the room; to the Cosmos Club for courtesies extended, and to the officers of the Association for the efficient manner in which the proceedings had been conducted.

The association then adjourned to meet at the call of the President.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, April 7, 1887.

The President, Thomas M. Drysdale, M.D., in the Chair.

D. B. C. Hirst read a paper on

THE ETIOLOGY AND TREATMENT OF CASES OF SO-CALLED LATE INFECTION IN THE PUERPERAL STATE.

The title of this paper is, I fear, too pretentious: Its object is merely the brief relation of four cases of so called late infection in the puerperal state, all, I believe, due to the same cause, all yielding to the same treatment and conveying therefore a lesson of some little interest and value.

The first case was young primapara delivered without difficulty after a moderately long labor. She left her bed on the eleventh day, having had no fever and having manifested no unusual symptom: Two days afterward her cervix was exposed to view by means of a bivalve speculum and a slight laceration was discovered, healing by granulation. The following morning, the fourteenth day after delivery, the patient was unwell, her temperature was 102°, large doses of quinine were given, but the temperature rose to 103° where it remained with slight morning remission for two days: A more careful examination being made, it was discovered that the uterus was unusually large, that the os was patulous, that there was a foul smelling discharge and considerable abdominal tenderness. The history of the case with these symptoms pointed to the retention of membranes, possibly a portion of the placenta and their subsequent decomposition originated by the admission of air to the vagina and uterus by the use of the speculum. Acting on this diagnosis, the uterine cavity was lightly scraped out with a dull curette and a large quantity of decomposing decidua removed This was followed by an intra-uterine injection of bi-chloride of mercury through a Bozeman's double catheter. The woman's temperature at the time was 103°. The following morning it had sunk to 99°, and within 24 hours was normal, and so remained.

The second case was also a primapara: The labor was terminated by the forceps. Upon the eleventh day the woman, although perfectly well until that time, had a morning temperature of 101° rising in the evening to 102°. The uterus was found larger than it should have been. The os was patulous and there was a fetid discharge. Profiting by the experience gained in the first case the uterus was curetted and a considerable amount of decidua removed, and a intra-uterine douche given. In this case the womb almost at once contracted and the discharge ceased; but the patient had, unfortunately, an exacerbation of a tubercular trouble in one lung which kept the temperature high for some days.

In the third case, also a primapara, after an instrumental labor and an apparently normal lying-in, the temperature rose on the twelfth day to 99.8° and on the following to 100°, at the same time a fetid mucopurulent discharge made its appearance. In this case a very large quantity of decidual membrane was removed and the scraping was repeated on the following day, whereupon the temperature fell to normal and the discharge ceased.

The fourth case was a primapara, who on the sixth day, after an easy labor, had a temperature of 100° although previously there had been no fever; the uterus here was very large, the os quite patulous, but in this case there was not much discharge. The same treatment was employed that had proved successful in the other cases, with the result of reducing the temperature within twenty-four hours to normal, where it remained.

Now this experience is entirely too limited to enable one to come to a definite conclusion as to the cause of late infection in the puerperal state, but these cases suggested to my mind the possibility at least that the retentive and subsequent decomposition of shreds of membrane or fragments of placenta will be found to be the most frequent cause of fever late in the puerperal state, and that if not interfered with this condition may lead to septicæmia and pyæmia. Other causes of fever late in the puerperal state are of course well known. Partially healed wounds of the cervix, vagina and perineum may be torn apart and the fresh wounds thus produced may give entrance to the germs of septicæmia. Exposure to an atmosphere impregnated with emanations from sewers or water-closets from bad sanitation may give rise to febrile diseases at any time during the puerperium as proved in the cases related by Dr. Playfair in a recent English journal. There is a possibility that the pyogenic micro-organisms which may carry on their work in the uterine cavity without very serious consequences to the patient, may in the tubes manufacture their product, pus, in such quantities that it cannot be drained off, thus producing an abscess that may possibly open into the peritoneal cavity. There is a still more remote possibility that a pyo-salpinx may be developed late in the puerperium by other pathogenic micro organisms, by those of gonorrhœa, of tuberculosis, or even those of actinomycosis. Finally any of the febrile diseases that may attack a woman at any time may fasten themselves upon her during the lying in period, but, as I have already said, it seems to me that the most common cause of late infection in the puerperal state is the decomposition of retained membrane or fragments of placenta, and that therefore the curette and the intra-uterine douche might be employed as a routine treatment in all cases where there occurs late in the puerperium, fever associated with a large uterus, a patulous os and a foul smelling discharge. This treatment can do no harm but may effect much good. My own experience in this direction is, however, limited, and upon this point I would like to have the opinion of the Society, whose experience collectively and individually must be greater than my own.

(To be continued.)

FOREIGN CORRESPONDENCE

LETTER FROM LONDON.[1]

Charing Cross Hospital—King's College Hospital—Sir Joseph Lister—The Spray—Sir James Paget—St. Bartholomew's Hospital—Ovariotomy—Antisepsis—Tarsotomy as it should not be done—Museum of the College of Surgeons—Professor Stewart.

Dear Dr. Fenger:—My hospital visits in London began with Charing Cross Hospital. This institution is centrally located and was built in 1837. It contains nearly 200 beds, and affords a fair opportunity for studying accidental surgery, as the majority of cases treated here are recent injuries. Bloxam, Bellamy and Barwell are the surgeons in attendance. Although the spray is still in use and antiseptic dressings are applied, I found many of the wounds suppurating; the best possible proof that the essential and pedantic details of modern treatment of wounds are not fully carried out in practice. Carbolic acid is used as an antiseptic. Frequent changes of dressing undoubtedly are responsible, in many instances, for the numerous failures in securing primary union of wounds. As in most English hospitals, the mechanical treatment of injuries and after resections consists in the use of complicated and ingenious splints which, in the hands of their inventors, answer an admirable purpose in securing rest for the parts and comfort to the patient. Almost every hospital surgeon has immortalized himself by the invention of some kind of a splint, and never tires in pointing out its advantages and the indications for its use. Every London hospital has its own medical school. The building for the school of this hospital is quite small, smaller than any of the college buildings in Chicago, and the material used for illustrating the lectures is entirely inadequate. The class which expects to become proficient in the healing art in this temple of Æsculapius numbers about 200. For a foreigner to visit such a school in the proud city of London it must become evident that science indeed travels westward, when he compares its lecture-rooms with those of the medical colleges in Chicago.

With such reflections I left this hospital and turned my way towards King's College Hospital, where I was to meet the father of antiseptic surgery. I was full of anticipations of what I should see and learn at the feet of the man whose teachings had revolutionized the practice of surgery throughout the entire civilized world. How great my disappointment! A walk through the wards of Sir Joseph Lister soon convinced me that prosperity and honors, even if well deserved, only too often exert an injurious effect upon the scientific career of distinguished professional men. Sir Joseph Lister of to-day is only the shadow of Mr. Joseph Lister of 1876. The dressings which I was shown only corroborate this statement. The only thing that was new to me in the way of dressing wounds was the colored gauze, which is used to distinguish it from gauze not rendered aseptic. Great importance is placed upon the disappear-

[1] By permission of Drs. Fenger and Senn.

ance of color on the surface of the gauze, as an indication that the secretions from the wound have reached the surface, an occurrence which is looked upon as a necessity for a change of dressing. A number of lumbar abscesses were shown which had been simply incised and drained, and where the whole dressing was composed of a very thin and small compress of gauze and a layer of absorbent cotton still smaller than the gauze compress. The tension suture, which has been in general use for more than ten years, was shown and explained as though the hearers had never seen or heard of such a thing.

The German command, *Fort mit dem Spray!* has been obeyed here. The antiseptic solution in use is a combination of corrosive sublimate and muriate of ammonia, which is preferred to the simple solution of sublimate. I am firmly convinced of the fact that had Mr. Lister remained as such in Edinburgh, the scene of his former active life, his scientific existence would not have terminated so abruptly, and many additional discoveries and improvements would have been inscribed upon his tablet of fame. Although his scientific career ended with his change of residence to London, Sir Joseph Lister must be considered as the greatest of living surgeons. The seed that he has sown has brought fruit which has been the means of saving thousands of lives. The principles of antiseptic surgery as taught by him have found the most fertile soil in Germany, where the treatment of wounds has been simplified and improved to such a degree of perfection that primary union is the rule, and the dreaded complications, septicæmia and pyæmia, are almost unknown. Indeed, it must be a great source of satisfaction for Sir Joseph Lister to know that the method of practice he promulgated so strenuously for nearly a decade has been perfected by the most prominent surgeons on the Continent, and that through it the principles and practice of surgery have undergone a complete revolution. It is not my intention to abstract from the greatness of Lister, but I cannot but deplore that for nearly ten years he has been but little else than a spectator in the arena of the surgical world.

Among the most pleasant and profitable hours spent in London I must include a visit to Sir James Paget. Around the breakfast-table we discussed for nearly two hours matters pertaining to surgical interests on both Continents. Any one who has had the pleasure of a personal acquaintance with this gentleman will not wonder any longer why he has by universal consent been the leader among medical men, not only in his own country, but almost the entire world, for nearly half a century. It would be difficult to find a man possessed of so many admirable qualities in the same degree which fit him for such position. A ripe scholar, a clear writer, a model teacher, a successful surgeon, an eloquent speaker, a perfect gentleman, are happy combinations but seldom found in the same person.

He resigned his hospital positions twelve years ago, and is now devoting his whole time to consultation practice and scientific studies. He is inclined to the belief that antiseptic surgery will eventually mean surgical cleanliness. Although advanced in years, his interest in the welfare of his profession reuains unabated and his habits of industry unchanged. He not only reads the literature pertaining to surgery from every possible source, but is likewise perfectly familiar with the recent advancements in the collateral sciences. Through his kindness I found ready entrance into the museums, hospitals and educational institutions of London.

At St. Bartholomew's Hospital I witnessed an ovariotomy by Mr. Langton. This hospital contains about 600 beds, and is connected with a medical school attended by about 350 students. The operation was performed in Martha ward, on the fourth floor, where a small amphitheatre, with room for about twenty spectators, has been built. The room is heated by an open grate fire, and the temperature was not over 70° F. The spray is used during the operation. The patient was 70 years of age and the tumor had been growing for three years. Examination revealed a large cyst in the abdomen, and a number of hard nodules in connection with the cyst could be felt in the pelvis. About fifteen students were present. The usual antiseptic precautions were observed during the operation. The abdomen was opened by an incision through the linea alba about four inches in length, and the cyst tapped with the large trocar of Spencer Wells. The puncture was followed by a free escape of fluid along the sides of the trocar, and some of it entered the abdominal cavity, and the wound was freely irrigated with the cyst contents. Sponges were used to remove the extravasated fluid, and as the cyst collapsed it was drawn out of the wound, an act which was readily accomplished, as no adhesions were found.

It has always seemed to me that the use of a large trocar with a truncated cutting edge in tapping a tense cyst is attended invariably by extravasation of fluid, and consequently increases the risk of peritonitis. When the cyst contents are fluid, the patient should either be placed upon her side during the tapping, and proper precautions adopted to prevent entrance of fluid into the abdominal cavity, or the cyst should be emptied sufficiently to bring it into the wound by the use of a small trocar or by aspiration. In case the contents are colloid they will escape through no tube, and incision of the cyst with the patient upon her side. and traction upon the cyst wall so as to keep it in uninterrupted accurate contact with the abdominal wall, are the only measures which will accomplish the desired object with safety. The pedicle was transfixed with a long-handled needle armed with a double ligature, tied on both sides, cut short and dropped. The peritoneal cavity was sponged out and the abdominal wound closed in the customary manner. The external wound was dusted with iodoform and a typical Lister dressing applied. The dressing proper was fastened upon the abdomen with broad strips of adhesive plaster; over this a cotton compress was applied, retained with a broad flannel bandage. The lower extremities of the patient were covered with a flannel blanket, but no external heat applied. Hæmorrhage, wherever it was discovered, was carefully arrested with hæmostatic forceps and

catgut ligatures. In this hospital all cases of ovariotomy are turned over to Mr. Langton for operation.

In Mr. Savory's wards in this hospital, I was informed by the house surgeon, Mr. Burd, no pretension is made to practise antiseptic surgery, and the resident staff allude with pride to the fact that during the last eleven months only one case of pyæmia occurred, and that the majority of wounds heal without suppuration. Thorough cleanliness in the ordinary sense of the word is enforced, and the wounds are protected with an oiled strip of cloth or covered with a moist compress.

In the operating theatre I found one of the attending surgeons, whose name I do not care to mention, ready to perform tarsotomy in a case of aggravated clubfoot. An incision was made in each side of the tarsus, and after many difficulties and perplexities, a tunnel was made underneath the tendons from one incision to the other, and a chain saw passed through with a probe. Now the difficult task commenced of sawing in the right direction. Two assistants attempted to obey the directions of the operator, but the chain failed to take the proper direction. Disgusted with the performance, the operator took his turn, but utterly failed to correct the insane inclinations of that beastly but determined chain to deviate from the erroneous path. After sawing in multiple directions, the bystanders were assured that one of the incisions of the V had been made, and the chain was slipped towards the ankle-joint and was again set in motion, and after the exertion of a good deal of muscular force, which brought the sweat upon the brows of all immediately concerned in the transaction, it was concluded that the V was made. By this time the operator had become very nervous, and with the forceps made a plunge for the superfluous piece of bone; and after numerous attempts he succeeded in removing a number of fragments.

When an attempt was made to straighten the foot, the disgusted operator convinced himself that more bone must be removed. Instead of using a fine straight saw, or the more modern chisel, he persisted in the use of that rebellious instrument that had already caused so much trouble and anxiety—the chain saw. After another free use of this abominable instrument a few more fragments were removed, and forcible attempt made to bring the foot in proper position. As this could not be accomplished, it was decided that the tendo Achilles was at fault, and this offending structure was handed over to the liberal use of the tenotome. Another forcible attempt to straighten the foot converted the subcutaneous tract into an open wound, and as all the resources had been exhausted by this time, a typical Lister dressing was applied. When Esmarch's constrictor was removed the dressings soon became saturated with crimson blood, which called for more antiseptic material and firmer compression. The surgeon, at this stage of proceedings, was covered with perspiration, and only revived after the patient was carried into the ward and out of sight. I am unable to say what became of the case, but if foot and life were preserved, it is safe to predict that another operation will be required in the future, or London's army of paupers will receive an additional increase.

Nearly a whole day I spent in the Museum of the College of Surgeons, under the kind guidance of Professor Stewart, a distinguished scholar and scientist. By stipulation a number of lectures must be delivered in this institution annually. The present course is given by Prof. Stewart, "On the Comparative Anatomy of the Internal Ear." I had an opportunity to examine the specimens used for illustrating these lectures, and it is safe to claim that no second collection of this kind could be found. A large and valuable library is accessible to all of the members of the college. The Museum contains John Hunter's collection. With this enormous collection as a nucleus, and the liberal donations which have been made by the Fellows and members since its foundation, this museum outranks anything of its kind in the amount of material it contains and the way in which it is classified. The specimens are so arranged that any subject in anatomy, physiology and pathology can be looked up and studied in a remarkably short time with the aid of a complete index, which can be found in its proper place in each section. Almost every subject is illustrated by botanical specimens and specimens of animals, from the lowest to the highest form. Under the head of monstrosities I examined a specimen of a fœtus in fœtu. The fœtus was found in the pelvis of a boy 15 years of age, who died of accidental causes. The fœtus is perfect in every respect, and is surrounded by a thick and dense cyst. The indefatigable energy and great genius of the illustrious founder of this wonderful collection become apparent by the many labels which are marked with his name. N. SENN.

DOMESTIC CORRESPONDENCE

ALBUMINURIA WITHOUT ALBUMIN.

Dear Sir :—I desire to present the following case to the readers of THE JOURNAL, making no attempt to explain their apparently wondrous features. The tests and observations, as well as the records, were made with all possible care and particularity.

Mrs. M., aged 51, American, mother of one child 20 years of age. She presents no special diathesis, but for several years has had a debilitated, and somewhat emaciated appearance resulting chiefly from overwork and a disturbed climacteric. In May, 1886, and during my absence from the city, Mrs. M., from exposure to cold and damp, was attacked with chills and some febrile action, for which my friend, Dr. D. was called to prescribe. Upon my return, about two weeks subsequent to her attack, I found her able to sit up, but presenting the typical pallor of countenance, with puffiness below the eyes characteristic of albuminuria. Dizziness was also complained of, and loss of appetite, with emaciation. The pulse was small, feeble and rapid. The feet, ankles, and legs, nearly to the knees, were tensely œdematous, pitting upon pressure, with the usual glistening of the distended

surface. Inquiry failed to prove any special variation in the color or quantity of the urine at any time since her attack. A specimen was obtained at my first visit, which upon standing threw down a turbid, milky deposit of considerable quantity; color (above sediment) light straw, sp. gr. 1020, heat with and without nitric acid, and nitric acid alone, failed upon repeated trial, to show the presence in any quantity, of albumin.

The microscope more than compensated for this negative chemical testimony by producing sufficient evidence in support of the diagnosis of nephritis. The specimen was marked by the absence of crystals, the field crowded with fat globules and tube casts. The casts were mostly large and roughly fractured; and some contained red blood. Subsequently, up to this date, no less than fifteen careful tests for albumin have been made, and at intervals varying from one week to a month, in some of which I have been assisted by Dr. S. G. Wilson, of this city, the result being uniform in the failure to find albumin. As this report refers only to one, but the most important, characteristic of this condition, the details of treatment are omitted.

The remarkable fact, that we may have albuminuria without albuminous urine receives support in the experience of my friend Dr. Wilson, who has a patient with much anasarca, indeed, water-logged, and whose urine, while loaded with tube casts, resists all attempts to display a trace of albumin, a fact seriously misleading, and actually defeating efforts to arrive at a satisfactory diagnosis or treatment until the tube casts disclosed the situation.

Very truly yours,

H. C. MARKHAM, M.D.

Independence, Iowa, May, 1887.

MISSTATEMENTS OF THE MEDICAL RECORD.

Dear Sir:—One might be led to believe, after reading the following item in the *New York Medical Record*, of May 14, that the editor of that journal is the advisory angel of the American Medical Association:

"The coming meeting of the American Medical Association at Chicago will not, we trust, be 'hippodromed' in the extraordinary and undignified way which characterized its session a year ago. It is not a question of codes, a climate or locality, but of self-respect, the dignity and conservatism which ought to characterize a great representative body of physicians."

It would be well if the editor of the *Record* would attend the meetings of the Association, and learn from personal observation how that body conducts itself, instead of issuing his annual diatribe a thousand miles away, and thus making himself ridiculous by his gross misrepresentations of the conduct of the meetings of the Association and of the large number of physicians who make up that body.

Very truly yours,

J. F. JENKINS, M.D.

Tecumseh, Mich., May 25, 1887.

BOOK REVIEWS.

THE PRINCIPLES AND PRACTICE OF OPERATIVE SURGERY. By STEPHEN SMITH, A.M., M.D., Professor of Clinical Surgery in the University of the City of New York, etc. New and thoroughly revised edition. Illustrated with 1005 woodcuts, 8vo., pp. xxxii—877. Philadelphia: Lea Brothers & Co. 1887. Chicago: A. C. McClurg & Co.

Since the publication of the germ of this work in 1879, there have been eight issues; but this book as it now appears is really the second, and only revised, edition. And one can form but little idea of the change made in the work without directly comparing the first issue with this last edition; the difference lies in the fact that the first edition was the exponent of the operative principles of the "old surgery," while this embodies the principles of the "new surgery."

The first chapter, on the "Civil Obligations of the Surgeon," may seem to be "matter out of place" in a work on operative surgery; but a moment's reflection will show that such is not the case, and it should be carefully read by every medical man. And certainly all must agree with him that "antisepsis imposes new obligations" upon the surgeon; in surgical cases he must apply antiseptic principles with reasonable care and diligence, or he may be justly held responsible for unfavorable results from conditions preventible by antisepsis.

It would be impossible to give an analysis of the book in the short space at our disposal; and, indeed, those familiar with surgical literature will not wish it. Dr. Smith's work does not need our commendation, and, except in a few particulars, it is beyond criticism. The treatment of stricture of the urethra is not mentioned, nor is the operation for shortening bones in extensive injuries to the soft parts.

INTERNATIONAL CONGRESS.

SECTION IN PSYCHOLOGICAL MEDICINE AND NERVOUS DISEASES.

It is proposed to give one of the Sessions of the Section in Psychological Medicine and Nervous Diseases, during the meeting of the Medical Congress, to a discussion on Syphilis and its relations to Insanity.

The discussion will be opened by Dr. George H. Savage, Senior Physician Bethlem Royal Hospital, London, England, and will embrace the following divisions:

1. Iodicy, imbecility, moral perversions due to inherited Syphilis.

2. Insanity associated with acute Syphilis, (*A*) Physical, (*B*) Moral.

3. Syphilis producing Epilepsy, with or without Insanity.

4. Syphilis producing Mental Weakness, (*A*) with, (*B*) without Paralysis.

5. Syphilis as associated with general paralysis of the insane.

6. Pathology, as represented by coarse changes like gummata, or slighter ones as seen in Arterial disease.

Several of our English confrères have already arranged to take part in the above.

Those who intend to engage in the discussion of one or more of the above "questions," should send notice to the Secretary. The time allowed for each paper in the discussion, is ten minutes. Tabular and bibliographical material can appear in the printed paper, but it is respectfully suggested that the matter prepared for reading be as illustrative and pointed as possible.

Clinical observations, post-mortem appearances and conclusions will be specially applicable.

Papers relating to Syphilis and Nervous Diseases will also be read during the same session.

E. D. FERGUSON, *Sec'y.*

Troy, New York.

ASSOCIATION ITEMS.

RAILWAY AND HOTEL RATES.

These rates have been fully published in THE JOURNAL for the past three weeks. The railways have agreed to return physicians attending the meeting, on presentation of a combined certificate and receipt, or simply a receipt from the railroad agent at starting-point, stating that *full* rate has been paid *going* to Chicago. Those who intend coming to the meeting should again read the letter of Dr. Montgomery in THE JOURNAL of May 21, page 586 before setting out.

Dr. Montgomery's instructions in brief are: He will furnish persons starting from points in Trunk Line territory—which is East of Niagara Falls, Buffalo, Salamanca, Pittsburg, Bellaire and Wheeling, with blank forms, known as the "Trunk Line Certificate," upon application to him for same. Persons from the places just named and points West thereof, will be required to use the certificates of the Central Traffic Association, which will be furnished by the ticket agent at starting point when ticket is bought. One or the other of these forms of certificate should be obtained when the ticket is bought for Chicago, as persons living East and South must have their certificates endorsed by the Chairman of the Transportation Committee.

Southern Visitors.—Dr. Montgomery will supply delegates and members of their families, with the "Southern Passenger Association" blank certificate; and such delegates (Southern), will use this certificate upon any of the 42 lines of railway South of the Ohio and Potomac rivers. As regards those living along Trunk Lines or in the Southern Passenger Association territory, Dr. Montgomery's certificates will be honored within territory West of termini of the various trunk lines of roads, as the places named above indicate, as well as to North of the Ohio river—known as the "Central Traffic Association territory."

Tickets for return journey are to be sold in Chicago at one-third the *Lowest Regular Limited Fare*, to those coming from the East or South upon presentation of certificates properly endorsed at the meeting.

In all, there are some ten or twelve members, we believe, that constitute the Committee on Transportation here, whose earnest endeavor it will be, to permit no delay in assisting our professional brethren in the matter of their acquiring full and complete information upon the above topics, at time of arrival, during the stay with us, or before the hour of departure for the return journey. Therefore, we venture a safe prediction in saying, that all who come will be cordially welcomed by this Committee, as well as by the entire profession of this Garden City.

Telegrams for blank certificates will be immediately answered.

MISCELLANEOUS.

MILK AS A MEDIUM OF INFECTION.—The spread of disease through the medium of milk has often been demonstrated, but seldom more strikingly than by an investigation lately pursued by the Massachusetts State Board of Health, for the purpose of discovering the cause of an outbreak of typhoid fever that occurred last autumn in a certain district in Cambridge. It was found that all the milk supplied to the district came from one farm in New Hampshire; that on the farm there was a well into which a privy vault drained, the water of the well being used to wash the milk cans; and, finally, that last summer a person lay sick with typhoid fever on the farm. The conclusion was unavoidable that the fever-germs were carried in the milk, and thus the disease disseminated among the people of Cambridge.—*New York Medical Journal*, March 10, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 21, 1887, TO MAY 27, 1887.

Major V. B. Hubbard, Surgeon, granted leave of absence for one month, to take effect on or about June 1, 1887. S. O. 119, A. G. O., May 24, 1887.

Capt. F. W. Elbrey, Asst. Surgeon, found incapacitated for active service by an Army Retiring Board; sick leave still further extended until further orders, on account of disability. S. O. 116, A. G. O., May 20, 1887.

Capt. H. G. Burton, Asst. Surgeon, granted two months' leave of absence, on surgeon's certificate of disability. S. O. 107, Div. Atlantic, May 25, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING MAY 28, 1887.

Deane, C. W., P. A. Surgeon, detached from "Dale," and to hospital, Mare Island.

Harvey, H. P., Surgeon, orders to "Iroquois," revoked, and wait orders.

Dickson, S. H., P. A. Surgeon, detached from Navy Yard, Washington, D. C., and to the "Dale."

Waggener, J. R., Surgeon, detached from the "Iroquois," and wait orders.

White, S. Stuart, Asst. Surgeon, ordered to receiving ship "St. Louis," Navy Yard, League Island.

Field, James G., M.D., of Gordonsville, Va., commissioned Asst. Surgeon in the Navy, May 23, 1887.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE WEEK ENDED MAY 21, 1887.

Goldsborough. C. B., Surgeon, leave of absence extended to June 1, on account of sickness. May 18, 1887.

Guitéras, John, P. A. Surgeon, granted leave of absence for four days. May 21, 1887.

Armstrong, S. T., P. A. Surgeon, to remain in charge of Service at Memphis, Tenn., until further orders. May 21, 1887.

Bevan, S. C., P. A. Surgeon, leave of absence extended thirty days. May 19, 1887.

Carrington, P. M., Asst. Surgeon, ordered to U. S. Revenue Str. "Rush." May 18, 1887.

Norman, Seaton, Asst. Surgeon, to proceed to Marine Hospital, Baltimore, Md., for temporary duty. May 20, 1887.

Heath, F. C., Asst. Surgeon, granted leave of absence for thirty days. May 18, 1887.

Woodward, R. M., Asst. Surgeon, appointed an Asst. Surgeon May 20, 1887. Assigned to temporary duty at the Marine Hospital, Balttmore, Md. May 21, 1887.

THE PRESIDENT'S ADDRESS.

CELL ANTAGONISM.

Delivered before the Thirty-Eighth Annual Meeting of the American Medical Association, June 7, 1887.

BY ELISHA H. GREGORY, M.D.,

OF ST. LOUIS, MO.

Obviously, force and matter "make up" the universe. Force implies antagonism, antagonism perpetuates motion. The living cell is the embodiment of nature. Cell antagonism is life. Multicellular organisms represent a community of vital unities. A model organism in equilibrium is health. Cell struggle is the gist of modern pathology. Every organ and every element are vulnerable. The strength of resistance in elements and organs, reinforced by the harmony and precision of coördination, and the vigor of counter-agencies, are the momentous questions.

In seeking for a comprehensive title for my address, I fell upon the two simple words "cell antagonism," which form the foundation of symptomatology and pathology, conjoined with cell changes, the basis of pathological anatomy, embracing at once the universe of life and all the possibilities of life; disease being but one of multitudinous phases of life.

Huxley has likened the body to an army. "Of this army, each cell is a soldier; an organ, a brigade; the central nervous system, headquarters and field telegraph; the alimentary and circulatory system, the comissariat. Losses are made good by recruits born in the camp, and the life of the individual is a campaign, conducted successfully for a number of years, but with certain defeat in the long run." A model organism assumes that every soldier is a stalwart; every organ, a body of stalwarts with corresponding machinery of coördination and precision, all alike concerted and vigorous to meet the myriads of counter forces, many of which are too cunning for our ken, but ever ready to take advantage of the least failure of our strength, to penetrate our vitals. This force of vital resistance forms the basis of therapeutics, this "vis mediatrix naturæ" will be always the indispensable auxiliary of the physician, without which ally abandonment of the art would be inevitable.

The morphologist distinguishes two classes of elements within the organism. One class represents the fixed cells, cells which occupy the fortifications within the inter-cellular substance; the other class provides for the formation of new tissue, and represents the standing army, sometimes called embryonal substance. Before Cohnheim, our knowledge of the mobile elements—the mobilized army—of the body, was nothing; now most of the literature relating to neoplasm is or has become obsolete. Now coagulable lymph is impossible without the white corpuscles. Organizable fluids have vanished. Through the ingenuity and industry of the great German pathologist a revolution has been worked in medical thought. The study of the mobile elements of the body—the relatively independent elements—promises much. We can almost see daybreak in pathology, a dawn before the coming light which is to illuminate some of the dark places of this most intricate subject. Already leucocytes substitute fibrin. The latter is the product of the former. Wherever there is localized impairment of nutrition referable to irritation, or defective maintenance of nutrition, the result of inherent weakness, there the leucocytes concentrate, feast on the devitalized structures, and thereby develop into a tissue replacing that which they have consumed. When the surgeon wishes to dispose of an adventitious structure—a cyst, for example, in the connective tissue, he lowers the vitality by over-stimulation—irritation, when he confidently expects the leucocytes to congregate and destroy the cyst, substituting a granulation tissue, which in time becomes scar tissue. Now an organizable fluid as the essential product of inflammation, cells playing a passive part, is a thing of the past. Now cell potency, cell subtlety, and cell antagonism constitute the pith and marrow of medical science. There was a period in the history of pathology when all the neoplasia sprang from the tissue cells; now the place and destiny of the cell tissue is fixed. When the tissue elements yet contain some undifferentiated protoplasm, proliferation is possible, otherwise not probable. The mobile cells constitute the mobilized army; the great coördinating centres assemble them at any moment, ready to antagonize hurtful agencies. Irritation always provokes a concentration of the white cells. Irritation means injury. It may be simple or specific. Either way it is a signal for moving the army in solid phalanx to confront noxious agencies, and the combat is hotly contested till victory or discomfiture.

Inflammation, the keystone of medical science, the standard process by which all other pathological conditions are measured, is only to be explained on the theory of cell antagonism; it is practically a struggle between irritant bodies and white blood-corpuscles.

Foreign bodies are invariably invaded by leucocytes, their swarming having for its object to repel or render inert the offending cause. Observations directed to the white cell have been followed by an inspiring increase in our knowledge of the vital properties of cells in general. The quality of spontaneous motion once accepted, the idea that the cell played a passive part quickly disappeared, and in its stead came the conception of autonomy, the fact that the cell nourished itself, is not nourished, that the cell specialized food for its own purposes, actually breaking up compounds and adapting the products to its own growth and development; strikingly illustrated by an independent form of government, for example, the government of the United States. A great statesman has said ours was a "government of the people, by the people and for the people." Cells live of themselves, by themselves and for the whole body. The cells make the central government. The coördinating machinery is formed by the cells, and the cells are in their turn centralized and harmonized by this power. The tissue elements are in direct continuity with the centre, but it is otherwise with the floating, wandering cells; yet their behavior gives evidence of their concern for the well being of the entire organism. Again, the free cells take into their substance the most refractory substances, digesting solid bodies; sponges and green plants yielding to their digestive and assimilative processes. Observations the most patient and trustworthy on the lower vegetables have demonstrated the fact that bacteria have been seen in the substance of amœboid cells; others have been seen pursuing bacteria, ultimately capturing and destroying them. Throughout the whole animal kingdom mesoderm cells use their ingestive power for destroying micro-organisms. Further, this property seems to be utilized for the removal of larval organs. Colorless corpuscles present the same appearances and have similar properties and the same mode of origin in the entire range of living beings. When the irritant or harmful agency is particularly obdurate, white cells exhibit a very strange habit of throwing out processes which unite with similar processes from neighboring cells, until a considerable mass of protoplasm is formed by their confluence, constituting a giant cell. Thus an army of giants may be improvised on occasions of extreme emergency; for example, when the tail and gills of the tadpole are to be swept off, this powerful division is ready for the Herculean task.

Apply these facts to the inflammatory process in mammals. Suppose a foreign body lodged, that moment leucocytes leave the blood-vessels and congregate for the purpose of opposing the intruder. In such diseases as tubercle, leprosy, etc., the giant cells appear, and in their centre—their substance—the specific bacillus is found. Koch found the bacillus anthracis and the bacillus of septicæmia in the mouse, enclosed by white blood cells. We say, with these observations before us, inflammation exhibits a new aspect; cells conquering cells as a process of normal physiology; simply the free cells, the white cells resisting injury, there being a provision not only for concentration, but for increasing their number and augmenting their strength, corresponding to the emergency. A recent authority, Mr. Sutton says: "If we summarize the story of inflammation as we read it zoologically, it should be likened to a battle. The leucocytes are the defending army; their roads and lines of communication, the blood-vessels. Every composite organism maintains a certain proportion of leucocytes as representing its standing army. When the body is invaded by bacilli, bacteria, micrococci, chemical or other irritants, information of the aggression is telegraphed by means of the vaso-motor nerves, and the leucocytes rush to the attack, reinforcements and recruits are quickly found to increase the standing army, sometimes twenty, thirty or forty times the normal standard. In the conflict cells die and often are eaten by their companions; frequently the slaughter is so great the tissues become burdened by the dead bodies of the soldiers in the form of pus, the activity of the cells being testified by the fact, that the protoplasm often contains bacilli, etc., in various stages of destruction. The dead cells, like the corpses of soldiers that fall in battle, later become hurtful to the organism they in their lifetime were anxious to protect from harm, for they are fertile sources of septicæmia and pyæmia, the pestilence and scourge so much dreaded by operative surgeons. The analogy may seem to some a little romantic, but it appears to be warranted by the facts."

Just here the question obtrudes, are the action which follows mechanical, chemical and thermal injuries, and the action caused by vital injuries alike inflammatory processes? In the one, that resulting from physical causes, the nutrient processes are not disturbed, simply increased. In the other, that resulting from vital causes, the cell processes are disturbed, thwarted and vitiated. It seems unfortunate that the action which succeeds to traumatism should be confounded with that which succeeds to specific germs. The nutrient changes come into vigorous play after an ordinary injury, altered in one particular only, viz: the presence of a palpable neoplasm, which substitutes the structures doomed by the injury. The addition of new material is invisible in ordinary nutrition, growth and maintenance for example, the substitution being atomic. When a structure is destroyed bodily, as in traumatism, the substitution is corpuscular, therefore palpable. It is certainly perplexing to assume, as does Sir James Paget, that a visible neoplasm is produced by inflammation, but its development is impossible till after the withdrawal of the inflammation. To get rid of confusion, though we do not emerge from error, is to make a step towards truth. The full effect of traumatism is immediate and complete; it cannot increase itself, therefore its effects are always limited and within the possibility of estimation, for the reason that cause and effect are in precise correspondence; besides antiseptics do not influence the changes in any particular. On the other hand, the most extensive and severe injuries of vascular parts, involving bone, joints, the great cavities, etc., are possible without producing inflammation, provided antiseptic precautions be taken. When such com-

plication ensues, it is a wound accident, not a wound incident, and the result of infection. There is no disturbing factor in the process incident to repair; no waste products. If pus is found, it is the result of the intrusion of some noxious agency, some contagion, some pestilence; in short, a specific cause.

If it be agreed to call the action inseparable from ordinary injury, physiological repair, the term inflammation is limited to the series of events referable to a vital agency, which until very recently has eluded detection. A specific agency determines a class of diseases as distinctive and definite as the living creatures studied in natural history. Cell antagonism after physical injury is simply a substitution, through the development of mobile cells, of the tissue which has been spoiled. The fixed elements multiply and develop in the expansion and perfection of the several structures of which they are components, but take no active part in the process of repair after injury. After the perfection of the body, the factors favoring proliferation and those which inhabit it must be in a state of balance. In functional hypertrophy, the balance is towards the side of proliferation. On the other hand, in non-functional hypertrophy, the problem is not so simple; the balance is disturbed towards proliferation by some mysterious agency. How strikingly different when the cell antagonism is with a vital injury; here cell mysteries clash. The bacteria enter into conflict with the mobile and fixed cells, but it is not possible to know how the conflict is carried on. Certainly a series of disturbances ensue in the normal metabolism of the elements. The functional, formative and nutritive activities, which are the expressions of cell life, must be altered; their vigor, perhaps, lessened; and their susceptibilities modified. Exceptionally their life is enfeebled or extinguished. The issue of a bacterial affection is either the death of the patient, or the destruction and elimination of the bacteria. It follows that this disturbance of cellular activities, is always at the bottom of morbid symptomatology; and observations have shown that disease of this kind, successfully withstood, leaves the elements in a peculiar insusceptible condition, insuring an immunity, almost or quite complete, against a fresh invasion of the same or kindred bacteria. This modified susceptibility was practically understood by Jenner. Pasteur, resuming and systematizing the great Englishman's work, successfully modified cell forces, rendering them harmless by cultivation, and sending them on the important mission of destroying the natural proneness to the deadly assaults of the uncultured cells. Whilst we may despair of ever understanding the essential nature of vitality, the study of the causes which regulate life, and their subordination to conditions which may be determined, has lead the way to the grandest achievements of recent times. Pasteur and Lister are the great apostles of modern practical thought.

Huxley has suggested that it may be possible to introduce into the economy a molecular mechanism which, like a cunningly contrived torpedo, shall find its way to some particular group of cells and cause an explosion among them, leaving the rest untouched. Pasteur's cell mechanisms exceed the conception of the great scientist, for they cunningly change the vital qualities of the elements without destroying them. May we not look forward for some great advance in therapeutics in the direction to which Pasteur's genius points, by the study of cell antagonism. Certainly vital subtilties may best cope with vital subtilties. Study of the conditions in which infective agents arise, by ascertaining the circumstances which limit or facilitate their diffusion, has already raised surgery to a proud preëminence. With therapeutics it is otherwise, as it is doubtful whether the new facts have yielded the slightest increase of power against the diseases of mankind. Let us not despair. Knowledge must come first, then wisdom brings its practical application. The study of cell possibilities, their readiness and energy in rendering inert noxious agencies, whether introduced from without or arising from within, exhibiting an antagonism at once potent and direct, rather tends to dampen one's therapeutic enthusiasm. The thoughtful student sees nothing abnormal in disease. To be sure there is a physiological emergency, but there is no disorder in the cell processes; rather the perfection of order. If a physical or chemical cause intensifies the cell changes, in other words, determines the physiological emergency, every cell movement is direct, purposive and efficient, ending only when the intruder is ejected, encysted or accommodated. On the other hand, if the offense be a vital one, a living cell, a microphite, the spectacle is that of one living creature preying upon another, a declaration of the first law of nature, not an enemy, but an intruder struggling for self preservation, simply a physiological fight for life. Can we hope an ideal tonic for cell antagonism, such as would innervate the cells on one side and enervate them on the other, the "Old Chestnut" "prevention is better than cure" is not yet worm-eaten.

Cell antagonism implies a struggle. The duration of the struggle is determined by the quality of the irritant and the strength and resources of the antagonists. Acute inflammation is a sharp and decisive action; chronic inflammation is slow and indefinite. There are two strikingly important chronic conditions, viz: the interstitial inflammation and the infective granulomata, interesting alike to the physician and the surgeon; both are alike disastrous, the one, interstitial inflammation, destroying by cicatrical contraction; the other, infective granulomata, by stopping at the fibro-blast stage, retrogression replacing development. The quality of infection and the failure to develop beyond the stage of granulative tissue is the exact condition as illustrated by tuberculosis, syphilis, lupus, etc., in contrast with which is fibrosis of the liver, cirrhosis, fibrosis of the kidney, Bright's disease, fibrosis of the brain, sclerosis, interstitial inflammation, destroying the tissue elements by strangulation, and infective granulomata by contamination.

Again, the two varieties of inflammation referred to declare that the quality of the irritant determines the effect of the inflammation, the interstitial variety being caused by physical agency, and the infective

by a vital one. Cells antagonize physical causes without losing any of their vital qualities. Not so when cells antagonize vital causes. When cells are pitted against cells they may be despoiled of their highest quality, as in the infection granulomata they have parted with formative activity. In short, the knowledge that pertains to the presence of a vital irritant, epitomizes all that has been taught of infective disorders. The symptomatology and pathology of this class of diseases is but the life history, the play of cell activities, metabolisms and catalysis of antagonizing organisms, as likewise the knowledge pertaining to the presence of a foreign body or physical irritant, is the knowledge in brief of fibrinoses in general of that entire class of disorders known as interstitial inflammations. A persistent irritant—injury—with its attendant concentration of leucocytes, their inevitable development and ultimate transformation, the history of the capsulation of a foreign body, whether it be animate or inanimate, is the history of cirrhosis of the liver, fibrosis of the lung, morbus Brightii, atrophy of the heart, atrophy of voluntary muscles in general, sclerosis of the brain and bones; in short, diffuse capsulation. Some disseminated irritant, say alcohol, determines a sclerosis of the liver, and how? Every particle of alcohol being a foreign particle, having its capsule, it follows that capsulation is as uniformly distributed as the cause. An artisan inhales fine particles of steel or other foreign material and fibrinosis of the lung is the consequence. The irritants of gout and rheumatism are lodged in the kidney, the interstitial tissue of the organ increases, and in the end strangulates the tubules and malpighian bodies, resulting in shrinking and total disorganization of the organ, constituting Bright's disease. Like changes occur in the heart; co-incident with the development of the interstitial fibrous tissue is atrophy of the muscular substance, substituting a fibrous induration for its normal structure. A similar change in the voluntary muscles occurs in the curious disease known as pseudo-hypertrophic paralysis, chiefly afflicting children. The connective tissue between the muscular fibres increases so much, that the muscles affected may exceed their normal size three times. Later, however, the new tissue shrinks, and the contractile material of the muscles is spoiled. The condition of sclerosis in bones corresponds to cirrhosis of the liver, and Bright's disease of the kidney. In the nerve centres the interstitial tissue—neuroglia—takes on the same chronic over-growth, strangling the nerve strands and cells, giving rise to the most singular and complicated nervous phenomena. The changes thus induced are recognized by the general term sclerosis. If it involves the fascicules of Burdack and the column of Goll, locomotor ataxia results; if the medulla, bulbar paralysis, etc.

We have purposely avoided reference to diathesis, as also to the precise neurological relationship of cells, not because we deny their influence, but because too little is definitely known. On the contrary, the behavior of cells relatively to irritants, is well understood. The presence of a foreign body is at once and directly resisted by the leucocytes; a zone of inflammation, its destruction, transportation or capsulation, even parasites which resist the death-dealing assaults of the leucocytes, are at last imprisoned in cases of fibrous tissue.

There yet remains for our consideration a mysterious possibility relating to cell life, of great practical moment, viz: that of entering upon a life of independence, separating from the central nervous system "headquarters," disregarding the "field telegraph," oblivious to the morning "drum-beat," and wholly ignoring the restraining and directing influence of environing structures. We have learned that however much irritation may affect the vital qualities of cells, their fidelity is always preserved, there being no sign of disaffection, the army ever intact, the fealty of the soldiers supreme. Physical causes—traumatism—may crush or impair the tissues, but the cells come to the rescue with all vigor and directness. The prolonged presence of bacteria may impair the forces of the cells, enfeeble and extinguish them, but as long as life lasts their efforts are in harmony with the purposes of the organism. Thus it appears that alienation is not possible through the agency of irritation, however intensified, modified or prolonged.

The question constantly obtrudes: is alienation possible to a mature element, to an element that has assimilated itself physiologically as well as anatomically, with the surrounding tissues; taking part in its functions; concurring and co operating in all the processes of the economy? This question seems to have confronted Cohnheim, when his ingenuity suggested the embryonal hypothesis, viz: that the tumor germ was congenital; that there were in the mature body embryonal elements and tissues not utilized in the elaboration of the normal structures—latent, embryonal rudiments; small embryonal cells so diminutive as to elude observation, inactive perhaps, till some exciting cause awakens activity. Is not an embryonic element in a mature organism an alien? Is it not already an independent element? Are not patches in the skin, pigmented moles, islands of cartilage in mature bone, congenital angioma, etc., independent structures, already tumor germs, congenital rudiments of tumors? Accept the hypothesis of the great German pathologist, and the problem of tumor etiology is almost solved; it remains only to find the exciting cause; the predisposition is inherited; irritation, simple or otherwise, may be nearly allied to the awakening impulse. The difficulty is to reconcile cell antagonism with the proposition, this doctrine includes: the idea that all discordant bodies are treated as intruders, either ingested, transported, or covered up. We can conceive the possibility of the existence of an inoffensive tissue or element, one that simply draws its nourishment from adjacent tissue, without any serious disturbance of their normal metabolism. We would gladly adopt the theory of Cohnheim, which ascribes the origin of tumor neoplasms to persistent germinal rudiment. Certainly it has much to recommend it. Countless latent embryonal structures, relatively independent, are tolerated by the organism, remaining inactive till

favored by some concurrent event, the nature of which is incomprehensible, when they may grow according to their bent. Is it not quite as possible there may be similar, relatively independent elements, ready when stimulated to multiply independently? Congenital angiomata often grow without definite limit; pigmented moles, black, slightly raised patches in the skin, with which all are familiar, are composed of tissue exactly resembling sarcoma; always suspicious because of their disposition to proliferate independently. It is most difficult to believe in the infidelity of covenant cells, of sundering the compact which unifies the organism. Emancipation seems almost out of the question. We must not only believe that dependent benignant elements become independent, but indifferent, vicious, infective. In short, the elements of the host, become the elements of a parasite—a parasite so vigorous, corrupt and wicked as to destroy its source.

The painful part of the retrospect of a year is that which recalls those who have been taken from us. The past year has had a very special grief for our association in the death of one of our ex Presidents, Dr. William Owen Baldwin, who died at his residence, and the place of his birth, Montgomery, Alabama, May 30, 1886. He was among the early members of the American Medical Association, and its President in 1869, presiding at New Orleans. His address on that occasion will be remembered as abounding in Christian and patriotic sentiments, eminently befitting the good and great physician. The Committee charged with the organization of the Ninth International Medical Congress, which meets at Washington City this year, had named him as one of its Vice-Presidents. Dr. Baldwin was remarkable for his culture, the eloquence of his speech and the beauty of his diction, and will be remembered as an imposing figure in the history of this great Association.

I need scarcely remind you, gentlemen, that we shall have with us, after a few weeks, the medical men of all nations. Soon we shall extend the hand of friendship to those with whom we have heretofore been united in interest and sympathy in the cause of science. We know that everything is being made ready and that success is assured. Again, you will join me, I know, in the declaration, that a hearty American welcome awaits their advent, and that the Ninth Meeting of the Great Congress will be memorable in the history of its organization.

ORIGINAL ARTICLES.

CONTRIBUTIONS TO THE CLINICAL HISTORY OF SYPHILIS.

BY H. GRADLE, M.D.,
OF CHICAGO.

This paper is based upon the clinical records of a number of syphilitic affections. They all present one or more unusual or exceptional features, which, in the author's opinion, make them worth reporting. The interest which such a record of cases can claim is that of contributing to the certainty of diagnosis and prognosis.

CASE I.—*Syphilitic Iritis—Amaurosis of both eyes of central origin—Recovery under specific treatment—Fatal progress of the brain disease.*

Mr. G., a farmer, 50 years of age, was brought to my office practically blind. About two months ago the sight of the left eye began to fail gradually, while since six weeks the right eye had become sore and weak. He has been in nearly total darkness for a week. He is a person of low intelligence and hence difficult to examine. His wife claims that for the past week or so his mind has been less clear than formerly, and that at times he talks irrationally. Until recently he was in good health. Questioned closely he states that 18 years ago, before marriage, he contracted a chancre followed by an eruption. But his history does not seem reliable. He is more positive, however, that a year and a half ago he acquired a venereal sore. This was followed by an eruption during several months.

Present condition, Dec. 29, 1885.—The patient is somewhat emaciated and feeble. He has no motor or sensory paralysis or other nervous disturbance, all reflexes are normal. He is, however, of slow understanding and his memory seems unreliable. But while in the office he presented no unmistakable evidence of mental derangement. The post-cervical glands are enlarged. There is a mixed pustular and squamous syphilide on the face and on the trunk. He has no headache and never had any. He sleeps well.

The *left* eye is pale, the pupil of medium width and immobile. Light thrown into the eye with a mirror is not recognized with any certainty. Opthalmoscopically the media are found clear and the optic disc and retinal vessels normal. There is a narrow circular comus around the disc with ill-defined outline, but the refraction is practically emmetropic. The *right* eye shows a moderate ciliary injection. The iris is discolored and the pupil narrow and closed by iritic adhesions. There is no pain only a feeling of soreness, in other words simple specific iritis. The movements of the hand can be dimly followed at one foot distance, which degree of sight is less than would correspond to the optic conditions. Moreover the field of vision as tested by throwing light into the eye with a mirror is considerably and uniformly restricted.

The patient received an eye-water of atropin (1 per cent.) and cocaine (2 per cent.) for the right eye. Mercurial ointment was to be rubbed into different parts of the skin twice daily, and one gram of iodide of potassium to be taken four times a day. The proper hygienic directions were of course given in regard to rest, diet and cleanliness of the mouth.

Two days later he returned improved. The right eye was less sore and the pupil a trifle larger. Light was more vividly perceived, and could even be recognized by the left eye

Jan. 4, 1886, the patient walked in without guidance. Left eye had a vision of $\frac{20}{60}$. Its field was

normal in extent. Of colors, red and green were recognized at once—blue with some hesitation, but yellow and orange were mistaken for blue. The pupillary reflex was normal. Ophthalmoscopically no change. The iritis of the right eye had ceased, though the pupil had not yielded any further to the mydriatic. He could follow the hand at eight feet distance, but the right visual field was still restricted. The color perception was not as certain as with the left eye, red being almost deficient. The patient had still the former dull mental condition, being somewhat dazed on trying to recollect, and his answers were not strictly to the point. But this may have been his normal state of intelligence. His wife states that he has talked more rationally at home.

Jan. 7.—There was some further improvement. On account of slight fœtor of the breath, the mercurial ointment was now dropped, but the other treatment continued. He did not return until Jan. 21st when the left eye appeared normal in all its functions with V. $\frac{20}{30}$, while the sight of the right eye corresponded sufficiently to the optic condition of the partially closed pupil, the hand being seen about 12 to 15 feet off. The right visual field was nearly normal in extent, being limited somewhat by the narrow pupil. Colors were correctly named if seen in strong light. The patient did not return after this date, and it was subsequently learned that his eyes had remained well until his death in June, 1886. His physician, Dr. Doepp, attributed the death to brain disease on account of the progressive mental impairment, but no autopsy was made.

The peculiarity of this case consists in the double-sided amaurosis. There is no special interest either in the occurrence of the iritis or in the history of his syphilis otherwise. Whether this was a re-infection, after acquiring the disease some seventeen years previously, I could not decide definitely on account of the patient's low grade of intelligence. The blindness which had increased steadily since six to eight weeks until it had become absolute in the left eye and nearly so in the right eye, yielded so rapidly to specific treatment that no doubt seemed to me proper as to its syphilitic origin. The disease must have been intra cranial since the ophthalmoscope showed no intra-ocular lesion in the left eye. There were no symptoms like paralysis of any of the cerebral nerves which could aid in locating the syphilitic process. It must have been either very diffuse or have involved the optic chiasm, since both eyes had suffered to a nearly equal extent, and recovered at about the same rate. But had the syphilitic inflammation existed in the membranes next to the optic chiasm ordinary clinical experience would lead us to expect a descending optic neuritis, which within six weeks generally reaches the intra-ocular end of the nerve. Since the left pupil did not respond to light during the height of the disease, the optic nerve fibres must have been affected somewhere peripherally from the reflex centers—the corpora quadrigemina. At any rate the process was not of a kind causing increased intra-cranial pressure, like a gummatous tumor; for neither headache nor choked disc existed. It was more like a gummatous meningitis. For although but 18 months had elapsed since the infection syphilitic disease of the membranes of the brain has been known to occur at such an early period.[1] Whether the patient died through a relapse of this lesion cannot be decided from want of data.

CASE. 2.—*Gummatous iritis; Recovery under specific treatment. Neuro-retinitis of the other eye, presumably of intra cranial origin, occurring immediately after nearly two months of specific treatment. Ultimate recovery.*

Mr. St., 38 years of age, was seen March 26, 1886, for a sore eye troubling him since ten days, which had been shamefully neglected by a general practitioner. Misguided by the Doctor's statements the patient did not understand the gravity of his disease, especially as the pain was but moderate. He had been in good health for many years with the exception of a short spell of malaria the previous year. Eighteen years ago he had had a chancre and was treated anti-syphilitically. He did not remember ever having had any secondary symptoms. He is married and has two healthy children.

Present Condition.—The right eye is normal in every respect with V. $\frac{20}{40}$. The left eye which has become more painful in the past two days shows slight ciliary injection and is somewhat tender to the pressure. The iris is slightly discolored, the pupil narrow and irregular, and its rim partially adherent to the capsule. In the substance of the iris on the nasal side of the pupil and close to the pupillary rim there is a greyish red prominent nodule of irregular surface, about two millimetres in diameter. The ophthalmoscopic reflex is very faint on illuminating the pupil. Fingers are counted at eight feet and the visual field is normal.

He was ordered to take salicylate of sodium one gram every three to four hours, iodide of potassium one gram four times per day, two daily inunctions with mercurial ointment, and to drop into the eye a solution of atropine and cocaine every two hours.

Under this treatment a progressive improvement began at once. The pain having ceased within a few days, the salicylate of sodium was soon dropped. Within ten days the nodule in the iris had disappeared. The pupil enlarged moderately, especially on the temporal side, while on the nasal side, next to the former site of the nodule, the pupillary rim had become fastened to the capsule of the lens by a broad synechia. The ciliary injection and irritation diminished steadily. But it was not until the 12th of May that the eye could be said to be entirely free from inflammatory action. During the month of May three minute spots of deposit were formed on the rear of surface of the cornea, although the inflammation was steadily subsiding. Vision had by this time reached $\frac{20}{20}$. The fundus, now visible with the ophthalmoscope, appeared normal, with the exception of slight indistinctness of the edges of the papilla, and veiling of the vessels as they pass from the papilla on the retina. It seemed to me probable that some optic neuritis had accompanied the disease in the iris, especially as the deposits on the pos-

[1] Comp. Heubner, Syphilis of the Brain in Ziemsen's Cyclopædia.

terior surface of the cornea generally indicate some involvement of the entire uvea in the inflammatory process.

The specific treatment had been continued all this time until the end of May, the use of mercury having been suspended whenever the mouth appeared suspicious, while acne pustules and iodine catarrh had repeatedly forced the patient to leave off the iodide for several days. Altogether about sixty inunctions of two to three grams of mercurial ointment had been made. Under the use of pilocarpin once a day or once in two days in a dose of 2 to 25 centigrams, the sight cleared towards the end of May up to $\frac{20}{30}$, at which level it has since remained stationary.

Mr. St. returned June 8th, complaining of severe headache since about a week, coming on in short spells. It was limited to the front part of the head, and generally one-sided, especially on the left side, but sometimes changing to the right. The eyes had not suffered in any way. As the patient attributed the headache to his constipation, he was ordered to take aloes and podophyllin, and to report at once unless relieved. Pressed by business, he stayed away until June 23d. The headache had only diminished gradually in spite of the proper action of his bowels. There was still a feeling of pressure in the head, which any excitement would intensify into a severe one-sided headache. He felt at times dizzy, and most of the time dazed. Since the previous day the sight of the right eye had failed to an alarming extent, while both eyes felt heavy.

The left eye showed no objective or functional change. The right eye, however, had but a visual acuity of $\frac{2}{30}$. The visual field and color sense were normal, but the perception of brightness reduced. There was no anomaly visible about the eye except with the ophthalmoscope. The media were clear, but the edge of the papilla was no longer recognizable, there being an opaque infiltration extending from the disc into the retina in all directions through a distance about equal to the papillary diameter. Within this zone the vessels were veiled, the arteries of normal size, the veins somewhat distended as compared with the other eye. On the temporal side of the disc there were a few minute spots of hæmorrhage. The papilla was not œdematous. Towards the periphery the retina and its vessels were sharply defined. Active treatment was at once begun, consisting in the use of salicylate of sodium, iodide of potassium and mercurial ointment. Nevertheless, vision had sunk to the recognition of fingers at three feet distance two days later. But the patient mentioned that the periphery of the visual field appeared clearer, and that the blur seemed to him more a shadow over the objects he looked at. In other words, there existed a positive central scotoma. No ophthalmoscopic change had occurred.

In view of the fact that the patient had previously had malaria, and the possibility of some malarial poison persisting, quinine, 0.3 three times per day, was now substituted for the salicylic acid. From this time on an improvement both subjective and objective began. But this could scarcely be attributed to the quinine, for the drug was only continued through three days at that time. Subsequently quinine was again prescribed several times whenever the condition remained stationary for a few days, but without exerting any further influence on the rate of recovery. It was not until July 20 that the disease could be said to have terminated.

The final result was a perfect visual field without central scotoma, and vision $\frac{20}{30}$, while ophthalmoscopically the retina and vessels were clear except at the edge of the papilla, where some opacity remained. The specific treatment had been pursued steadily with the exception of some respites on account of mercurial or iodine annoyance. During the early part of July an iodoform ointment, made up with lanolin, was rubbed into the forehead for a few days, without any noticeable influence. Pilocarpin did also not accelerate the rate of progress, but steam baths seemed to hasten the clearing of the sight. The patient has remained well up to date, and is able to use his eyes satisfactorily.

This case illustrates the long period of latency of constitutional syphilis. Eighteen years had elapsed since the occurrence of the chancre, and secondary symptoms were not remembered, in fact denied definitely. Perhaps this latency was the result of a vigorous anti syphilitic treatment, which had been kept up for some months at the time. Gumma of the iris is not of very frequent occurrence. When the patient was first seen the diagnosis rested between tuberculosis of the iris and gumma. The disappearance of the nodule under ten days of anti syphilitic treatment decided this question definitely. The use of salicylate of sodium in this case was based on my own experience with the drug. Inflammation of the iris or ciliary body, whatever be its cause, reacts to salicylic acid in one of three ways. In less than half of the cases I have seen there was no action at all. In about half of my patients with iritis and cyclitis, the pain and intensity of the irritation was controlled to a greater or less extent by the salicylate without the disease being shortened in course. This is quite often true of iritis of syphilitic origin. A small number of cases of iritis, and especially of cyclitis, are unmistakably and rapidly cured by this agent.

But with the absorption of the gumma the inflammatory symptoms did not cease. For nearly five weeks the eye was still reddened and sensitive to the light, and the optic media not perfectly clear. The deposits which appeared towards the end on the internal face of the cornea, indicated nutritive disturbance throughout the middle tunic of the eye, for in simple plastic iritis such deposits are not formed. There may have been during this time a slight optic neuritis, since the edge of the papilla has never presented the sharply cut appearance which it has in the normal eye. It is well known that a mild neuritis does not necessarily reduce sight very much.

The neuro-retinitis of the other eye might have been an independent non-specific disease. But the prodromic symptoms preceding it during three weeks, viz: headache, dulness in the head, and dizziness, suggest a descending neuritis, starting from the cranial cavity, with perhaps some involvement of the

membranes at the base of the brain. Whether this was of the nature of a gummatous inflammation is an open question. The cerebral symptoms certainly diminished in intensity *before* constitutional treatment was resumed, which fact speaks against specific origin. On the other hand, it is contrary to usual experience to find a syphilitic inflammation originating at this late period of the disease immediately after some six weeks or more of thorough specific treatment. The neuro-retinitis improved steadily after the specific treatment was resumed, but not as promptly as I would have expected of a purely syphilitic inflammation.

The conclusion seems to me not unreasonable, that the optic neuritis was a sympathetic affection starting from the inflammation in the left eye, and the primary disease would in that light appear to me as a complication of a gummatous deposit in the iris with secondary irido-choriditis of non-specific nature.

(*To be concluded.*)

LACERATION OF THE CERVIX UTERI.

BY J. HENRY CARSTENS, M.D.,

PROFESSOR OF OBSTETRICS AND CLINICAL GYNECOLOGY, DETROIT COLLEGE OF MEDICINE.

When the granite monument which may be erected over the future grave of T. A. Emmet, or the marble urn which may hold his ashes, if his body should be cremated, have long yielded to the slow but certain action of the atmosphere and disappeared from view, then the name of Emmet will still be known, and reverently mentioned in connection with laceration of the cervix. Until the last man and woman have disappeared there will be children born, and as long as children are born, tears of the external os will occur, as neither the art and science of the obstetrician nor the *vis medicatrix naturæ* can prevent them in all cases. Laceration occurs in cases left entirely to nature, as well as in the hands of the most careful and experienced accoucheur. We must start with this idea clear in our minds, that the occurrence of laceration is no proof of poor midwifery or meddlesome interference, although manual efforts to hasten dilation, or the use of the forceps before complete opening of the external os, are a fruitful cause of tears. It is claimed that abortions are also etiological factors. It seems to be the opinion of the majority of the profession that immediate repair is of little avail, as union seldom takes place, and is only indicated to stop the hæmorrhage when large vessels have been torn.

The symptoms of laceration of the cervix are usually those of some uterine disease: backache, headache, leucorrhœal discharge, bearing-down pains, etc. The symptoms vary to some degree, whether the laceration has cicatrized or not; in the latter more or less purulent discharge takes place; in the former this is not the case, and often misleads the patient and physicians in thinking there is no uterine disease.

The raw granulating surface has been called an ulcer, erosion, etc., until Emmet showed that it was a tear, and how it could be repaired. Lacerations are a frequent cause of subinvolution and displacement of the womb, the latter not subsiding until the proper treatment of the former.

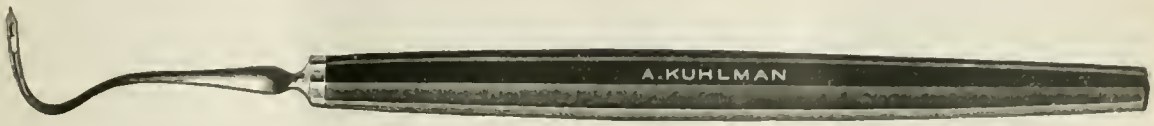
The most troublesome cases are those in which no granulating surface exists, but cicatrization has taken place. Very many of these cases do not require any treatment, as no symptoms are produced. Such cases give the easy-going physician a chance to say that cervical lacerations are of frequent occurrence and do not amount to much, as every woman has a tear if she has given birth to a child. Of course this is partly true; some women have lacerations which have cicatrized and produce no symptoms, but who wants to meddle with such cases? No one ever thinks of treating or operating on cases of that kind. But when we find cases of flexions, versions, descent and enlargements, due to a subinvolution caused by a tear, no pessaries or support, no injection or application will cure the case; only an operation can.

The reflex symptoms produced by cervical laceration are many: such as headaches, spinal irritations, palpitation, neuralgia, disturbances of the stomach, liver and kidneys. These do not come on shortly after the tears occur, but some years later. I believe the cicatrix gradually contracts and compresses some nerve filaments. The cicatrix is often not sensitive to the touch. During the menstrual period the symptoms are generally more marked, varying according to the complications which exist. The sympathetic symptoms and reflex disturbances produced by cervical laceration are almost innumerable, and for that reason the real cause of a woman's illness is often overlooked, and she is treated for almost every disease from acholia to zona.

We must also remember that nearly all observers have called attention to the fact that uterine cancer generally commences at a point of laceration of the cervix, and that we have a right to assume that a long-continued ulcerating tear in the cervix may develop into a malignant growth. Therefore, all cases of cervical laceration which have not healed should be repaired, and those cases which have cicatrized, and produce secondary effects and reflex symptoms, should also be operated on. In my experience, many cases of repeated miscarriages are caused by tears, especially if the latter are deep. Many women anxious to have children can be made happy by an operation for laceration of the cervix. We often meet cases in which women have had a severe labor during the first confinement. The child was born dead, laceration occurred, and no other child was carried to full term, labor always occurring at the third to sixth month. This variety of sterility can be cured.

The operation consists in simply paring the edges, and sewing the raw surfaces carefully together. Considerable discussion has lately taken place on the necessity of removing all cicatricial tissue. Some have even performed a second operation when the cicatricial plug has not been thoroughly removed the first time. For the purpose of making a clean cut and getting away the cicatrix at the angle there is no better instrument than Skene's hawkbill scissors, although a knife and scissors can also be used, espe-

cially the latter. The sewing can be done with various kinds of needles which have been devised for that purpose, and with silver wire, silk, catgut, or silkworm gut. As the uterine tissue is very firm and it is difficult to get a needle to pass through, I have had Mr. Kuhlman, of Detroit, make a needle with a corkscrew curve on a short handle. This enables



one to put the sutures just where he likes, and fit the raw surfaces most accurately. I have tried the various sutures. Silk prepared as proposed by Skene is very good, but requires removal after union has taken place. Silver wire is good, but difficult to remove unless the patient is again put under an anæsthetic. When silver wire is used, I find it the best plan to put four or five perforated shot on the wire, and compress the last one only. This enables one to remove the wire readily by simply cutting it be-

tween the last two shot, pulling all the shot off the wire and grasping the long ends of the latter, simply pulling them out. Catgut is very good, and need not be removed; which is a great advantage. Still, catgut is often unreliable, and is very difficult to tie so that it will hold. I have therefore lately tried silkworm gut, and find it most excellent, if a large size be used and kept thoroughly aseptic. It need not be removed, although it takes a long time to become absorbed. If the circular artery be cut, it may be necessary in some cases to ligate it, but generally the sutures will stop the hæmorrhage.

The operation for laceration of the cervix is therefore very simple: Cut out a wedge-shaped piece, and remove all cicatricial tissue; carefully adjust the raw surfaces with silkworm gut sutures. I believe in chloroform as an anæsthetic.

After the operation the patient is kept in bed for a week. Use carbolized douches twice a day; but this is not necessary, as I have often paid no attention to the patients except to see that no inflammation developed, and then examined them in five or six days, and if union was perfect, allow them to sit up; in a few days they would follow their ordinary vocation.

The operation is not dangerous unless chronic or subacute peritonitis or cellulitis exist, when no operation should be attempted until after all symptoms have disappeared; and even then great care is needed, as the uterus must be very carefully handled, and not much traction made. In these cases, also, the after-treatment must be more strict; the patient must be kept quiet and on a light diet; in ordinary cases I allow a full diet.

My conclusions are:

1. All lacerations which have not cicatrized should be repaired, even if no severe symptoms are produced, as they might be the starting-point of cancer.

2. All cases which have cicatrized and cause sequelæ, such as subinvolution, displacements, with the various reflex symptoms, should also be operated on, great care being taken in these cases to remove all cicatricial tissues.

3. The wedge-shaped piece can be removed with a knife or scissors, the latter to be preferred.

4. Silkworm gut or catgut is to be preferred, although silk or silver wire may be used.

21 Macomb St., Detroit, May 11, 1887.

MEDICAL PROGRESS.

Strophanthus in Heart-Disease. — Dr. J. Hutchinson, Physician to Anderson's College Dispensary, Glasgow, says: I have administered the drug in twelve cases of heart disease; nine were functional and three organic, and I have much reason to be pleased with the success of the treatment, and with the amount of relief I gave my patients.

On looking over my notes I find two cases of mitral disease, in one of which there was a loud murmur, both obstructive and regurgitant. The patient was a woman, aged 45, in whom the prominent symptoms were harsh, hacking cough occurring in paroxysms, dyspnœa, and even at times orthopnœa, palpitation, and œdema of feet and legs. The pulse was intermittent, with a regular irregularity, and beating 90 to the minute. Strophanthus was given in half-drop doses at first, and was gradually increased until she was taking 2 minims three times a day. Almost from the first dose taken an alteration in the sufferings of the patient was observed. The heart-sounds were firmer and steadier; the pulse-beats, though still irregular, were not so fast; cough was much less troublesome, and the palpitation was neither so frequent nor so violent. Along with this there was a copious increase in the renal secretion, which soon relieved both the visceral engorgement and the œdema in the feet and legs. In fourteen days she felt so well as to be able to return to her household duties. In the other case of mitral disease the symptoms were much the same, but not nearly so severe. The same dose was given, and the effect was as satisfactory and rapid.

Another case of aortic stenosis in an old lady, aged 60, who had for years been a martyr to chronic cough, palpitation, and the other symptoms attendant upon stenosis of the aortic orifice, received great relief from a one-minim dose of the drug. In this case palpitation was very violent, the pulse was rapid, and there was extensive passive congestion of both lungs. Œdema of the feet and legs was also present in a marked degree. Under the influence

of strophanthus the pulse became slower and firmer, the congestion in the lungs lessened day by day, and a copious diuresis soon made an alteration in the œdema. The palpitation was trifling compared to what she previously suffered, and her cough was much relieved.

In the other nine cases in which I administered the drug I could find no trace of a murmur, and the purpose for which the medicine was administered was to allay in some measure the turbulent palpitation of which these people complained. In seven of these cases the palpitation seemed to be dependent upon dyspepsia; remedies were given for that condition. Strophanthus was also used in the hope of its exerting a calming and steadying influence upon the heart, which in all of them it succeeded in doing.

The remaining two were cases of disordered innervation. The pulse was very rapid and irregular, the heart's action turbulent—so much so that at times the sounds could not be differentiated, but seemed all merged in a confused rumble. Both of these patients were much benefited, and though the symptoms of which they complained the loudest—namely, palpitation—is not banished, they find that it can be kept within reasonable bounds by a timely dose of strophanthus. All the patients expressed the opinion that the drug had a stimulating effect, which, however, soon wore off. Some of them professed to feel beneficial effects ten minutes after taking their appointed dose. The effect of the medicine was rapid, but did not remain long, and at the end of three or four hours required to be renewed. The system I found quickly became used to the drug, and to get the amount of benefit the dose required to be gradually increased. In prescribing it I combined it with some bitter infusion, and I never failed to get the physiological action, though Dr. Higham Hill remarks that it is important not to dilute it except at the time of using. I have never seen sickness or gastric irritation produced, such as we meet with sometimes after digitalis. The preparation I used was tincture of the strength of 1 in 8 prepared by Messrs. Thos. Christie & Co., London.—*British Medical Journal*, May 7, 1887.

METHYLAL.—Methylal, which was last year investigated from a physiological and therapeutical point of view by Personali, has since been experimented upon by Nicot, and more recently by two Russian physicians—Professor V. K. Anrep and Dr. M. Motrokhin. The results obtained by the latter of these observers are described in a "preliminary communication" in the *Vrach*. In frogs hypodermic injections of from 0.2 per cent. to 0.3 per cent. of the animal's weight produced more or less profound anæsthesia, which, however, quickly passed away. The lethal dose for frogs was found to be 0.8 gramme. Reflexes were weakened, and with large doses temporarily abolished. Thus, after giving a frog 0.3 gramme of methylal, irritation of the central end of the sciatic nerve during the period of complete narcosis produced no effect, but when the animal was aroused some reflex activity returned. Irritation of the peripheral extremity of the nerve showed that the drug had produced no effect upon its reflex action. Warm-blooded animals are more susceptible to the effects of methylal than frogs, a quantity equal to 0.25 per cent. of a rabbit's weight throwing it into a deep sleep lasting from one to two hours; with larger doses, loss of coördination in the movements was first observed, then the animal fell on its side, and remained in a state of narcosis for from three to four hours, after which it quickly recovered. The lethal dose was 0.45 or 0.5 per cent. of the animal's weight the irritability of the cortex of the cerebral hemispheres was lowered both by hypodermic injections and by the inhalation of the vapor. Convulsions due to strychnine and picrotoxine in animals subjected to the action of a moderate dose of methylal were diminished in violence, but when the strychnine or picrotoxine was given in lethal doses death was actually accelerated by methylal. Methylal can be employed in the form of vapor for inhalation, or as a liquid for internal administration. When given hypodermically in an aqueous solution of the strength of 1 in 3, it is very painful, and the skin is very apt to slough near the puncture. Dr. Motrokhin does not think methylal is likely to be of use in poisoning by strychnine and picrotoxine, except when only small quantities of these poisons have been introduced into the system. Regarding inhalations, 2 ounces may be inhaled, and only produce in addition to anæsthesia slight headache and dizziness. No experiments seem to have been made with a view to ascertaining the value of methylal as a surgical anæsthetic, but it does not seem to affect the heart's action perceptibly. Professor Anrep noticed especially that the anæsthesia was more marked on the upper part of the body.—*Lancet*, May 7, 1887.

THE PULSE IN MORPHINOMANIA.—At a recent meeting of the Académie des Sciences, MM. B. BALL and O. JENNINGS described certain characteristics of the pulse in morphinomaniacs. The pulse is normal during the period of satisfaction, while the patient is still under the influence of a recent puncture. When he begins to feel renewed craving, the pulse presents a flat elevated surface; this indicates the diminution of cardiac impulse, and explains the sensation of weakness experienced by the patient. The presence of this flat surface is useful in the diagnosis of morphinomania. Treatment should be directed to the stimulation of the heart.—*British Medical Journal*, May 7, 1887.

COMMON SALT IN MIGRAINE.—DR. RABOW, of Berlin, finds that half a teaspoonful or more of common salt, taken as soon as the premonitory symptoms of an attack of migraine begin to show themselves, will frequently cut it short in about half an hour; similar treatment has also proved of service in epilepsy, as was remarked some years ago by Nothnagel: the explanation being probably in both cases that a violent reflex action is set up, [though the reason and nature of this reflex action is not explained].

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address
JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS.

SATURDAY, JUNE 11, 1887.

THE MEETING IN CHICAGO.

At one time it was thought that in view of the early meeting of the International Medical Congress there would be a comparatively small attendance at this thirty-eighth annual meeting. These fears, however, are now shown, as we go to press, to be groundless. As early as Monday evening about two hundred delegates and members were registered, and it is now probable that the attendance will not fall short of fifteen hundred. The programme of the Sections shows that the number of papers and addresses is greater than ever before, being almost double the number last year. So far as can be seen at present all portions of the country are well represented except the extreme West. It will be seen that the President's Address, on "Cell Antagonism," is out of the usual line of such addresses. As a paper on the subject of which it treats it may be said to be complete, and no one can read it without instruction. The Association is to be congratulated that its Sectional work has been still further divided by the creation of a Section on Dermatology and Syphilography.

FOREIGN BODY TREATMENT OF SCANTY MENSTRUATION AND AMENORRHŒA.

With the exception of cases of absent menstruation due to constitutional causes and from some ovarian affections, there are many cases of amenorrhœa, or very scanty menstruation, in which the chief fault seems to be with the uterus. Practitioners know that many of these cases are attended with very distressing symptoms, and that relief is urgently required. The administration of emmenagogues and other drugs in such cases is usually attended by but little success; and that the means at our disposal for treating such cases are very inefficient is shown by the number of drugs and measures recommended.

Many years ago DR. JAMES BRAITHWAITE, of Leeds, after reflecting upon the hæmorrhage caused by uterine polypi, introduced small foreign bodies into the uterine cavity, and left them, when he wished to bring on menstruation or increase its amount. Hot baths, iron, aloetic aperients, and alteration in the diet and habit of the patients, were used at the same time. The most convenient foreign body he found to be a small piece of hempen ligature, doubled several times, knotted, and impregnated with pitch. These were carried up to the fundus and left there. Some success was obtained, but they were generally expelled by the uterus before they had done their work. They were therefore abandoned for a Greenhalgh's rubber stem. This he has found very efficient in a considerable number of cases. The stem is carefully washed in carbolized water, introduced into the uterus a week before menstruation is due, or supposed to be due, and left in position. A hæmorrhage will usually result in a few days; but whether it comes on or not the stem should be left in position. While Dr. Braithwaite has had many successes with this method, he has also met with failures. But the method, in his opinion, is the best and most certain means of bringing on absent menstruation, or for increasing a scanty flow. Wynn Williams' stem may also be used, and it has the advantage that it is not easily expelled from the uterus. Dr. Braithwaite has also made what he calls an artificial polypus, to remain *in utero*.

Dr. Braithwaite reports two interesting successful cases treated by the stem, the record of which may be found in the *British Medical Journal*, of April 30. This method is briefly referred to by a few writers, but it is probably unknown to the majority of the profession.

THE MEDICINE OF THE TALMUD.

Some time ago we published an announcement of DR. C. H. VON KLEIN, of Dayton, Ohio, that he would translate and publish the medicine of the Talmud, provided one thousand copies are subscribed for. We take pleasure in announcing that Dr. von Klein has received subscriptions for about five hundred copies. We make this announcement

with more pleasure since this translation is in a large measure a labor of love. It does not seem to be generally known that the compilation of the Talmud began about twenty-five hundred years ago. The works of Hippocrates, which are generally thought to be the beginning of medical history, were written only three hundred years before Christ. This book will, therefore, add three hundred years to the annals of medical science, if nothing more. While it is true there are within it many "childish and irreverent things" relating to medicine, nevertheless to those who carry not creed prejudice it will give more than history. The hygienic portion will be of benefit to sanitary science. The laws regulating separation of women during their menstrual period will be a revelation to the greater part of the profession, and the medical jurisprudence will add much to modern medicine. Besides the medicine and its collateral branches contained in the *Jerusalem* and *Babylonian Talmuds* with all their *Tosephtos* and *Siphri Medrashim*, much will be embodied from the *Rambam* (Maimonidis) *Yorah-Deah*, *Shulchan Aruch*, *Aien-Jacob*, *Eben Ha-Ezeir*, and from many other works of equal antiquity. Probably not less than three years of severe labor will be required to make the researches and translation; and we therefore appeal to literary men of the profession to subscribe, in order that the work may not be unnecessarily delayed.

SOCIETY PROCEEDINGS.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Ninth Annual Meeting, held in the Hall of the Academy of Medicine, New York, May 26, 27 and 28, 1887.

THURSDAY, MAY 26—FIRST DAY.

MORNING SESSION.

THE PRESIDENT, E. FLETCHER INGALS, M.D., of Chicago, called the Association to order, and read

THE PRESIDENT'S ADDRESS.

In referring to *Intubation of the Larynx*, the history of the operation and a description of the instruments used in the operation were given. The method of operation was then referred to. In 1858 an attempt was made in Paris to treat stenosis by intubation. Seven cases were operated on, and of these five died, and two cases recovered after subsequent tracheotomy. In 1880 O'Dwyer introduced intubation, and gave to the profession one of the most useful operations of modern times. In the after-treatment, while the tube is in position, no liquids should be allowed. Sometimes small quantities of liquid can be taken, but the danger of exciting bronchitis or pneumonia is so great that fluid should be entirely prohibited. The largest tube that can be introduced is the one most likely to be retained. The danger of the tube being forced into the trachea was referred to. In four or six days, in favorable cases, the swelling and false membrane will have so much diminished that the tube will be coughed up finally and need not be withdrawn.

The speaker had performed intubation in twelve cases of diphtheritic laryngitis. In three cases recovery followed. By a coincidence, the cases of recovery were the only ones in which the author had charge of the after-treatment. One case lived eight days and then died suddenly an hour after the tube had been removed. Another lived eight days and then died of pneumonia. Details of the cases treated were given. As a result of his experience, he concludes that the treatment after intubation should be: 1. Prohibition of fluids except by enemata. 2. Some preparation of mercury should be given in large and frequent doses. 3. In case of development of bronchitis or pneumonia, respiratory and cardiac stimulants should be given freely but cautiously.

By correspondence and study of the literature he had collected 514 cases with 134 recoveries. The percentage of recoveries will be greater when more care is exercised in the use of fluids. When medicines fail, no time should be lost in providing for the free entrance of air, either by intubation or tracheotomy. Intubation can be done more quickly, more safely, with less shock to the patient and less objection on the part of the parents. The operator should be prepared to open the trachea if loosened membrane should be forced down into the trachea. When the tube fails to relieve the dyspnœa tracheotomy should be performed, unless there is reason to believe that the latter operation will fail. When membrane is loose in the trachea, no time should be lost in the use of the forceps, which rarely succeed, but tracheotomy should be resorted to. The results obtained by intubation are about as good as tracheotomy at all ages, but apparently better in young children.

DR. CHARLES E. SAJOUS, of Philadelphia, read a

STUDY OF SOME OF THE OBJECTIONABLE FEATURES OF INTUBATION.

The principal objections to intubation, according to the degree of danger, are: 1. The tendency to the obstruction of the tube by fragments of membrane. 2. Crowding down of loose membrane during introduction of the tube. 3. Passage of food into the trachea. 4. Momentary arrest of respiration during introduction of tube. 5. Liability of the tube to be coughed out; and 6, slipping of tube into the trachea. The tendency to obstruction was attributed to the limited diameter of the tube; the crowding down of membrane to the length of the tube; the passage of fluid to the weight of the tube; the liability to be coughed out, to the limited diameter of the tube; and the slipping of the tube to the weight of the instrument and the formation of the head.

The author exhibited instruments on the principle

of the bivalve speculum which were intended to embody the suggestions made above. This tube obstructs the larynx very little, leaving the breathing space almost as great as normal. He also exhibited an instrument intended to remove loose membrane from the larynx. The instrument consisted of forceps which could be protruded into the larynx, by an arrangement in the handle, the required distance, and the membrane grasped.

Dr. F. H. Hooper, of Boston, said that while he had no personal experience with the operation, he had watched certain cases in the Boston City Hospital. Since last October, ten cases of intubation had been operated on, with two recoveries. In one case, the attempt to introduce the tube caused spasm, and tracheotomy was performed. In every case there was immediate relief of dyspnœa. In three cases the tube was coughed up and swallowed.

Dr. D. Bryson Delavan, of New York, suggested that feeding with a tube introduced into the œsophagus would overcome the difficulty. This plan can also be used in cases of tracheotomy.

Dr. Morris J. Asch, of New York, remarked that there are a few objections which should be brought to the notice of the profession. One of these is that membrane may be crowded down which is very difficult to remove, even by tracheotomy. Another objection is the difficulty experienced by the ordinary practitioner in the removal of the tube.

Dr. B. F. Westbrook, of Brooklyn, did not think that the weight of the tube is what causes the trouble in deglutition, for the muscles which elevate the larynx are quite strong. It seemed more likely that the difficulty was due to the rigid tube, which holds the larynx open. In normal deglutition the entrance of the larynx is closed.

Dr. D. H. Chapman, of New Haven, said that the most distressing symptom after the introduction of the tube seems to be thirst. It would be interesting to study the cause of this. Could it not be relieved by the use of enemata and by baths. It may be occasioned by the use of the mercury, which might be introduced in some other way than by the mouth. The use of pilocarpin, which, even in small doses, causes salivation, might be of service.

The President said that it is so rare that the tube becomes clogged that it is not necessary to have a skilled attendant. When the tube becomes clogged it is usually coughed up, and, as a rule, it is not necessary to replace it for two or three hours. The attempt to feed these patients through a tube introduced into the œsophagus has been tried in Chicago, but he had not heard any stress laid on this measure.

Dr. J. Solis Cohen, of Philadelphia, gave a description of a

MODIFIED LARYNGECTOMY.

The operation is applicable to those cases in which the disease is not too extensive, and it has the advantage over complete laryngectomy of leaving the greater portion of the thyroid cartilages undisturbed while the respiratory portion of the larynx is removed. On the cadaver the operation can be performed in two minutes. In disease limited to the interior of the respiratory tube, especially carcinomatous disease, it fulfils every indication that prompted complete laryngectomy. The advantages claimed for the operation were: 1. Rapidity, ease, and comparative safety for the patient. 2. The small size of the wound. 3. The preservation of the attachment of various important muscles and ligaments. 4. The retention of important structures in their normal relation; and 5, a firm natural support is left for the application of any artificial apparatus.

This operation should be performed for complete laryngectomy when not precluded by the extent of the disease.

PRESENTATION OF INSTRUMENTS.

Dr. T. A. DeBlois, of Boston, exhibited a portable apparatus for compressing air.

Dr. E. C. Morgan, of Washington, presented a universal powder blower, which could be used in abscesses of the nose, throat, vagina or rectum.

Dr. Allen, of New York, exhibited an improved form of snare which could be used with one hand.

The following were appointed as the Nominating Committee: Drs. Beverly Robinson, of New York, W. C. Glasgow, of St. Louis, and S. H. Chapman, of New Haven.

Afternoon Session.

Dr. John B. Mackenzie, of Baltimore, read a paper entitled

THE PATHOLOGICAL NASAL REFLEX—AN HISTORICAL STUDY.

The fact is established beyond doubt that a causal relation exists between diseases of the nasal mucous membrane and other portions of the respiratory tract and many conditions of distant parts of the body. Hay fever can be traced to the time of Galen. The fact that tickling of the nose would arrest hiccough is referred to by Plato. The irritating effects of the odor of flowers were recognized in very early times. Reference was made to the observations of various individuals in regard to reflex conditions due to nasal disease. During the eighteenth century much was written upon this subject.

Dr. John O. Roe, of Rochester, read a paper on

HAY FEVER. ANALYSIS OF CASES, WITH RESULT OF TREATMENT.

Up to the last hay fever season, the author had treated forty-two cases. A study of these cases tended to confirm the opinions expressed in February, 1883. Some of these views have been modified. Of the forty-two cases, twenty-six were males and sixteen females. The attacks came on between May 1 and August 1. In all, the active symptoms subsided soon after the appearance of frost. In some cases the hay fever dated from a severe attack of cold. In every instance there was disease of the nasal passages. The location of the sensitive areas is not constant, but they are usually most marked over the areas of greatest hypertrophy. The areas have not been confined to the posterior portion of the turbinated bone, nor especially to the anterior portion of

the turbinated bones. In the majority of cases the septum was as sensitive as the turbinated bones. Thirty-one patients suffered with asthma. But twelve patients had a distinctly nervous temperament, while nine were distinctly phlegmatic.

The plan of treatment adopted is to restore the nasal passages to as near as possible a normal condition, and destroy the sensitive areas. These areas are to be destroyed by cauterization. Deep cauterization has been most effective, while superficial cauterization had no marked effect. The condition of the larynx, pharynx and bronchi must not be overlooked. Not infrequently enlarged tonsils will keep up irritation in the turbinated bones. A neglect to cure a bronchitis may account for a return of the disease.

Thirty-five of these cases have practically been cured. Seventeen have remained exempt for periods varying from one to nine years. Four were not relieved, owing to imperfect treatment, and four have been lost sight of. The following conclusions were presented:

1. All cases of hay fever have the initiatory lesion in a diseased condition of the nasal fossa.

2. All diseases of these tissues induce in the ganglionic centres connected with them an abnormal activity, which is reflected to other organs.

3. The sensitive areas in the nose are not found in any particular portion of the cavity. Nor are there any zones which, when irritated, produce always the same manifestations.

4. The direction in which the irritation is reflected is always in the line of least resistance. Irritation in the same region may be reflected in one direction at one time and in another direction at another time.

5. The disease in the nose may produce disease in other portions of the respiratory tract, which may become independent centres of irritation.

6. The affection recognized as hay fever is due to local irritatives brought in contact with the sensitive areas in the nose.

7. The affection is not *per se* neurotic, nor is the so-called neurotic condition of the person necessary to render a person susceptible to local irritation applied to the air passages. It is not necessarily associated with the nervous temperament.

8. The neurotic condition which is often regarded as the cause of the hay fever, is often the result of the local irritation.

9. By careful and thorough treatment of the disease of the nasal tissue, combined with that of other portions of the respiratory passages below, which have become secondary sources of irritation, we need not fail to cure hay fever.

DR. C. E. SAJOUS stated that at the last meeting he had reported some cases in which the use of the cautery had been only of temporary benefit. He now believed that the failure was due to the fact that the cauterization was only superficial. Since he had employed deep cauterization he had cured the disease.

DR. J. N. MACKENZIE regarded hay fever as a neurosis. That it is a disease of the nose producing reflex symptoms he held was not the fact. Where, in hay fever, disease of the nose is found, the question arises whether this is primary or secondary, or whether it is only an accidental condition. There is, I think, always some more central cause than the affection of the nose. Where the disease is recent, it may possibly be arrested by local treatment, but where the affection is of long standing, he did not believe that simple local treatment of the nose would overcome the difficulty. Last summer, in treating hay fever, he made no application to the nose, and his results were better than ever before. He gave in large doses zinc, nux vomica, quinine and arsenic.

DR. F. I. KNIGHT, of Boston, asked if any of the members have had any experience with diversion of nervous influence in any of these cases? In one case coming under his notice the attack was arrested by the patient breaking his leg. Another patient had the attack arrested after consulting a disciple of mind cure.

DR. W. C. GLASGOW, of St. Louis, thought that the evidence shows that hay fever is not a local affection, but that it is a general nervous disturbance. It is difficult to judge of the influence of treatment, for in the same individual the severity of the attack varies from year to year. He believed that constitutional treatment is an important element in the case.

DR. F. H. HOOPER had regarded hay fever as a neurosis and had treated it in the manner spoken of by Dr. Mackenzie. This accomplishes great good, especially in young children.

DR. J. SOLIS-COHEN thought that the views of Dr. Mackenzie are very nearly correct. Many cases occur in those who are overworked and have resorted to stimulants. These patients are often benefited by rest in the mountains or at the seashore. He had obtained benefit by tonic treatment, modifying the diet, and restricting the use of meat. The more we look upon this as a constitutional affection and the less as a local condition the sooner will we get at the truth. A large number of these sufferers have obstruction in the nasal cavities, but many have no such obstruction.

DR. J. O. ROE considered hay fever as the reflection of some irritation from the nasal chambers, which irritation is produced by some foreign substance coming in contact with the mucous membrane of the nose. Irritation reflected from other situations to the nasal chambers is not hay fever. He thought that Dr. Mackenzie includes some such cases. He had never seen any evidence to show that this was a neurosis.

DR. D. BRYSON DELAVAN read a paper on

THE TREATMENT OF ATROPHIC RHINITIS BY APPLICATIONS OF THE GALVANIC CURRENT.

Some years ago Dr. E. L. Shurley, of Detroit, recommended the use of the galvanic current in the treatment of dry catarrh of the pharynx, and related cases in which benefit had followed its use. He also advocated the same treatment in atrophic rhinitis. There is no disease which is more discouraging to the physician and patient than this of atrophic rhinitis. The author had tried this method of treatment in certain cases. The positive pole of a constant current battery was applied to the nape of the neck,

while the negative pole was applied directly to the mucous membrane by an electrode consisting of a copper wire around which absorbent cotton is wrapped. The strength of current employed varied from 4 to 7 milliampères. In more recent cases of the affection the effect is marked, but even in the older cases the method is not without benefit. The author has found this measure useful in these cases, and reported illustrations. The objection to the method is the amount of time which it requires.

Dr. T. A. DeBlois, of Boston, had applied this treatment in two cases, one of atrophic and the other of hypertrophic rhinitis. In the first cases there was almost complete loss of smell and taste. The applications were made three times a week for six months. Both cases were improved.

Dr. Knight asked what experience the members had with plugging of the cavity of the nose? He had used this measure, and produced relief of the most distressing symptoms. One side of the nose is thoroughly stopped with a piece of absorbent cotton, which is allowed to remain three hours during the morning. It is then removed and the other side is stopped in the same way for three hours in the afternoon.

Dr. Roe had used the plugs of cotton, but with no other effect than to set up irritation. He had used with marked benefit the application of a weak solution of nitrate of silver, 5 or 10 grains to the ounce, the parts having previously been cleaned. This, applied every other day, almost entirely relieved the symptoms.

Dr. Sajous had used in two cases, with absolute relief of the symptoms, the application of chromic acid in a solution made by simply allowing the acid to absorb moisture from the air.

Dr. S. H. Chapman, of New Haven, read a paper on

MYALGIA OF THE PHARYNX AND LARYNX.

He called attention to certain peculiar conditions of the muscles of the upper air passages which occur oftentimes in malarial disorders, and which, on account of their severity, are brought to the notice of the specialist. The muscles most likely to be affected are the pectoral, the muscles of deglutition, and those of the voice.

Dr. F. I. Knight, of Boston, read a paper on

SENSORY AFFECTIONS OF THE THROAT.

The principal experience of the author had been with hyperæsthesia and paræsthesia. In hyperæsthesia the general condition of the patient is, as a rule, not sufficiently considered. The worst cases are alcoholic subjects and those with digestive disorders. These will often yield to withdrawal of the alcohol or regulation of the diet. Astringents are frequently of service. In the cases of paræsthesia which he had seen there had been a feeling of fulness, pressure, burning, globus hystericus, or the sensation of a foreign body in the throat. In these cases there is impairment of the general nervous system. The exciting cause may be some disease of the throat. Fatigue usually exaggerates these sensations. He had never met with paræsthesia of the larynx as the earliest symptom of phthisis, as had been claimed by some observers. The prognosis in most cases of paræsthesia is good if a careful treatment be carried out. The treatment of the neurosis of sensation must be aimed to cure the constitutional vice.

Dr. W. C. Jarvis, of New York, recently saw a man complaining of pain on either side of the tongue which had existed for the past two years. He was suffering from the effects of syphilis, and with the neuralgia of the tongue there was frontal neuralgia and pains in other parts of the body.

Dr. Sajous had seen two or three such cases. In one there was follicular pharyngitis, and although the pathological condition was cured, the pain remained. The pain seemed worse in damp weather, and the gentleman had the habit of bathing every morning in cold water. The history of the case seemed to indicate a rheumatic trouble, and such may have been its nature.

Dr. W. C. Glasgow: Many of these cases he thought were due to malaria, and some to the gouty diathesis. Sometimes the trouble is kept up by a single hyperæsthetic follicle. A reduction of the inflammation will be followed by a subsidence of the neuralgia. Sometimes the source of irritation is found with difficulty. In the rheumatic cases there is usually exacerbation at night. These affections in some cases appear to have a tendency to the induction of melancholia.

(*To be concluded.*)

SUFFOLK DISTRICT MEDICAL SOCIETY.

Section for Clinical Medicine, Pathology and Hygiene.

Stated Meeting, April 31, 1887.

Dr. F. L. Knight, Chairman.

Albert N. Blodgett, M.D., Secretary.

Dr. F. C. Shattuck reported *four cases occurring in hospital practice:*

TUBERCULAR PERITONITIS; SLOUGHING OF THE UMBILICUS AND FISTULA.

P., æt. 24, entered the hospital June 21. A sister died of phthisis. About a year before entrance the patient began to suffer from attacks of abdominal pain, distension and tenderness, lasting five to ten hours, and relieved by bilious vomiting. These attacks recurred at intervals of about a month. The last was four weeks before entrance; he did not rally from it but felt poorly, lost flesh and strength, and had moderate diarrhœa much of the time. He had no cough or other pulmonary symptoms. Pulse 100. Physical examination showed slight consolidation at the right apex without softening. In the umbilical region a rounded cake-like tumor with irregular surface, four inches in diameter, and apparently covered over by intestine, was felt. On the right side of the tumor and in the right iliac fossa, tender-

ness was marked. Diagnosis; tubercular peritonitis.

July 3. The patient was evidently weaker. Moderate fever was constant with evening exacerbations. The abdomen was more distended, peritoneal crepitus could be felt; night sweats, occasional vomiting, and abdominal pain were noted. The scanty sputum was examined for bacilli with a negative result.

July 14. Several days before this date it was noticed that the skin about the navel was getting red and œdematous. On this date a small perforation took place through which with each inspiration was emitted offensive gas, on deep inspiration offensive greenish fluid; during the act of vomiting this fluid was ejected with force.

July 18. The fistula gradually enlarged, and the patient was transferred to the surgical side.

July 19, and again on the 22d, dejections of normal consistency passed the rectum, the only discharges of any kind through that outlet between the appearance of the perforation and death, which took place July 28, from exhaustion.

Autopsy.—The right pleural cavity was obliterated by old adhesions, a few of which were also found on the left side. The apex of the right lung was thickened, shriveled and dense; on section, numerous small gray tubercles, and some pigmented fibrous tissue were seen. Throughout both lungs there was occasional cheesy patches, a half inch or more in diameter, some of them partially softened, surrounded by deeply injected borders containing miliary tubercles. A fistulous opening through the umbilicus contained a drainage-tube entering the peritoneal cavity partially obliterated by old adhesions. This encysted cavity extended upwards beneath the right lobe of the liver, and downward on the right to the pelvis, containing masses of necrotic fat tissue (omentum), and several ounces of offensive fluid; it communicated with the rectum above the internal sphincter by an opening in the anterior wall one-half inch in diameter. The intestine contained tubercular nodules and ulcerations, chiefly in Peyer's patches. The pathological diagnosis was then as follows: Chronic pulmonary tuberculosis, acute bronchitis, tubercular peri-bronchitis, chronic tubercular peritonitis and enteritis, umbilical fistula, perforating ulcer of rectum. The special reason for reporting the case is the comparative rarity of spontaneous porforation of the abdominal wall in tubercular peritonitis. The seat of the perforation was also somewhat remarkable, the strong fibrous structures of the umbilicus being completely destroyed.

CIRRHOSIS OF THE LIVER; ASCITES ABSENT UNTIL A FEW DAYS BEFORE DEATH.

A widow, æt. 49, entered my service October 9, 1886; she was the mother of nine children, the youngest 13 years old. She had never had any special illness, but had overworked herself from time to time, and been obliged to go to bed several days to rest. The past two or three years these periods of overstrain had been more frequent. About three months before entrance she had an attack of "dysentery" with pain, bloody discharges, and tenesmus. The blood in the stools was quite abundant and persisted for three weeks; during the first week of her illness she vomited blood several times in considerable quantities; she was six weeks in bed. Since she got up there had been no recurrence of hæmorrhage; but the blood loss was not made up and she steadily lost in flesh and strength, and was entirely unfit for any work; nausea and vomiting after taking even small quantities of food, unattended by any pain, had been prominent symptoms. The two days before entrance vomiting was still more frequent, and she again passed blood from the bowels, but this time without pain and the blood in clots. The patient was very anæmic, very slightly jaundiced, and the skin over the neck, arms, and body contained capillary dilatations. The hepatic dulness was increased in width both upwards and downwards, and the edge of the liver was distinctly felt an inch and a half below the ribs; its surface was lacking in smoothness. The abdomen was distended with gas, but no ascites could be positively made out. The spleen was not enlarged. The urine contained a small trace of albumen and a few casts. A very loud systolic souffle was heard over the heart, loudest in the pulmonic area; over the apex a thrill could be felt, but there seemed to be no enlargement of the organ. Diagnosis: cirrhosis.

October 10. Passed a large blood clot and about ℥iii of fluid blood with fæces.

October 11. There was now unmistakable ascites, the liver could no longer be felt, the diaphragm was pushed up, and there was slight œdema of the abdominal wall and feet. The vomiting continued from time to time, but there was no recurrence of hæmorrhages of any kind.

October 14. The ascites had increased rapidly, and caused so much distress that she was tapped. After the withdrawal of the fluid the roughness of the liver surface was distinct, and the contour of the lower edge of the organ could be well made out. Considerable relief followed the tapping, but the patient gradually failed in strength, and October 16, six days after entrance, she died.

A full autopsy could not be secured, but my efficient house-officer, Mr. L. T. Stevens, succeeded in extracting the liver, in two portions, and some of the other organs through the rectum. The heart was normal and showed no anatomical explanation for the very loud murmur heard during life. The lower portion of the ileum and upper part of the colon were full of black, tarry material. The liver was not materially altered in size and was eminently cirrhotic. The spleen was increased in density, though not in size. The kidneys showed moderate chronic interstitial changes. It is a matter for regret that it was impossible to make the autopsy in the usual way. To remove the liver through the rectum it was necessary to cut it in half, and the precise condition of the portal vein and its main branches was thus impossible to make out. The extreme rapidity with which ascites appeared and progressed suggests the possibility of its dependence on thrombosis of the portal vein. The severe intestinal hæmorrhages showed that great portal congestion had existed for some months, and it also seems pos-

sible that in the occurrence of free bleeding is to be found an explanation of the late advent of ascites, the hæmorrhage relieving the stasis.

HÆMOPHILIA.

H., a clergyman, æt. 52, entered the hospital, July 12, 1886, for tonsillar abscess, of which he had had several previous attacks. The first was treated by incision, which was followed by hæmorrhage that did not finally cease until six weeks had elapsed. In a day or two after entrance the abscess broke, and the day after this he began to pass bloody and smoky urine, the source of which the microscope showed to be the kidneys. He reported that hæmaturia had followed each previous attack of parenchymatous tonsillitis, and was also brought on by unusual mental excitement or exertion. In all, he thought he had had as many as 150 attacks. If he kept quiet, and drank large quantities of water, the bleeding generally ceased in five or six days, but if he worked it lasted from twenty to thirty. When a child, slight knocks produced large, black-and-blue, painful swellings, which were slow to subside. When 21 years of age he had an epistaxis which threatened life, but bleeding from this source has never recurred. The tendency to bleed has, he thinks, diminished as he has grown older, but slight cuts are still followed by free and persistent hæmorrhage. No history of hæmophilia in either parent or grandparent could be obtained; all were long-lived. Of his seven brothers and sisters, one brother shows this tendency, and a sister's son exhibited the hæmorrhagic diathesis to a marked degree, finally dying of persistent hæmaturia.

Hæmophilia, like color-blindness and pseudo-hypertrophic paralysis, is transmitted through the females of a family, the females themselves generally escaping. The tendency can thus oftentimes be followed through many generations. My patient is an unusually intelligent man, and the fact that he can not trace the diathesis behind his own generation is one reason for reporting the case.

A CASE OF TETANY(?).

A stable-boy, 19 years of age, of good family and previous personal history, entered the hospital September 30, 1886. He was muscular, well built, and ruddy. He said that for the past year there had been slight, but constant, stiffness of the jaw, which had not hindered speech or mastication, but had been sufficient to give him a constant desire of moving the jaw from side to side, and this had now become a habit. The day before entrance, without any assignable cause or any warning, the stiffness of the jaw increased very much, the hands and forearms became numb and rigid; also the legs, to a less degree. This was soon followed by general tremor. The whole attack lasted some ten minutes. During the attack he had a dull feeling in the back of his head, whence the numbness and stiffness seemed to start. There was no loss of consciousness or disturbance of vision. He had three such attacks yesterday, and two to-day. In the intervals between the attacks he felt perfectly well. On entrance, the patient was in the midst of an attack, and was reported as having a chill. The temperature was 99.4°. By the time the house officer reached him the attack had nearly passed, and his condition was as follows: He was much excited, free from pain, but complained of a disagreeable, indescribable sensation over the whole body. The pulse was rapid and strong, the breathing quickened. The expression of the face was peculiar, suggesting the *risus sardonicus*. The masseter muscles were hard to the touch; speech was difficult; there was marked stiffness of the arms and hands, the fingers being semiflexed. Efforts to strengthen the fingers encountered resistance, and caused slight pain. The legs were also somewhat rigid.

October 1. I saw him for the first time. During the night he had had an abortive attack. Examination of the internal organs gave entirely negative results. As I finished testing the reflexes, which were not remarkable, an attack came on, preceded, for a few moments, by discomfort slight mental excitement, and forced respiration. Stiffness then came on in the hands, arms, and fingers, which were all semiflexed: the thumbs were held firmly between the first two fingers. The spasm was tonic, with slight tremor at times, and forcible attempts to counteract it caused pain. The mind was perfectly clear, and the patient was positive that he had no real pain, though decided discomfort was caused by the rigidity of the muscles. After fifteen or twenty minutes the stiffness disappeared entirely. Whether this result was furthered in any way by the inhalation of a little ether, I cannot say. He was put on a full dose of bromide and chloral, every three hours, for several days. Slept nearly all the time, and had no more attacks, either spontaneously, on testing the reflexes and the electrical reactions, or during pressure on the brachial artery and nerve. There was no increased electrical reaction of the muscles, the current being passed through the nerve.

October 9. The patient was discharged, apparently well in every respect, except that slight stiffness in the jaw persisted. The diagnosis seemed to involve the consideration of only three affections: tetanus, hysteria, and tetany.

The feature of the case, which is chiefly suggestive of tetanus is the stiffness of the jaw, but this had been present for a year; this fact, with the absence of rigidity of the neck and back muscles, and the transitory character of the attacks, with entire freedom from symptoms in the interval, warrant us in excluding tetanus. Hysteria is not so easily, and I do not feel that it can be positively excluded, especially as Dr. Weir Mitchell to whom I very briefly stated the case, thought it probably of that nature. But, apart from the attacks, there was nothing whatever about the boy to suggest hysteria. He dreaded the attack, as indeed, do hysterical women oftentimes, for that matter. During the attacks he was perfectly reasonable, and he was glad to be discharged from the hospital. In the diagnosis of hysteria, the impression which the individual makes upon the observer counts for something, and this impression was, in the case before us, opposed to such a diagnosis. Moreover, the diagnosis tetany, in a mild form, explains very well the symptoms.

Tetany is a disease which is so rare with us—I can find no mention of it in Pepper's "System of Medicine"—that I may be pardoned for the following brief description of it: First described by Dr. Dance, who called it "intermittent tetanus," the term "tetany" was first applied to it by Corvisart, and later adopted by Trousseau, who also called attention to its comparative frequency in nursing women. It is classed as a neurosis, affects young adults by preference, and is characterized by intermittent, tonic contractions, rarely of the trunk and face, most frequently of the upper extremities, and chiefly of the flexor muscles, the intellect always remaining clear. It is bilateral. The attacks are generally preceded by somewhat ill defined prodromata, and recur at variable intervals during periods of a few days to months. In the intervals between attacks, patients appear well. Trousseau first showed that attacks may be brought on at will by pressure on the nervous and arterial trunks, the spasm ceasing as soon as the pressure is relieved. Erb has shown that the muscles are stimulated with undue ease by means of electrical currents through the peripheral nerves. As long as these two phenomena are present, there is a liability to the recurrence of the attacks. Attempts to elicit the phenomena in my case failed, but the patient was already under the influence of chloral and bromide when the attempts were made—a fact which may or may not be of importance. The affection nearly always passes off without leaving any trace behind it. After carefully considering all the facts in my case, I repeat that I am inclined to consider it as one of tetany of a fairly mild form, and very short course—three days. At the same time, I am far from wishing to suppress the points opposed to this diagnosis, namely, the trismus of a year's duration, and the failure to bring out the signs of Trousseau and Erb, on which the books lay considerable stress.

DR. MINOT said that Dr. Shattuck's case corresponds closely with the description of the disease in a paper read by Dr. Lyman, of Chicago, at the annual meeting of the Association of American Physicians, in June last, and printed in the Transactions of the Association. Other cases were reported at the same time by Dr. Carpenter, of Pottsville, Penn. I should say that the disease is not extremely rare in children under four or five years of age. We see the thumbs bent toward the palm of the hand, the other fingers partially flexed, and the toes strongly flexed. There is usually some swelling of the hands and feet. These children are always feeble, insufficiently nourished, and often bottle fed, perhaps undergoing the process of dentition. In one case, that of a child, three months old, under my care, which was artificially fed, immediate improvement took place when a wet-nurse was procured for the patient, who is now fifteen years old, and in good health. I have never seen a case in an adult which I recognized at the time, but possibly that of a physician who consulted me, and also Dr. J. J. Putnam, might come under this category. The movements were very striking, and corresponded to those in one of Dr. Lyman's cases, which were communicated to him by another physician.

With regard to the subject of hæmophilia, I think it remarkable that the now well-known spontaneous hæmorrhage of new-born children (umbilical hæmorrhage), which is to all intents and purposes the same disease, although fatal in eighty-four per cent. of the cases, yet in the few cases which recover does not recur, the hæmorrhagic tendency being as it were, extinguished, as I have seen in several instances.

DR. PUTNAM: I will merely speak of the case mentioned by Dr. Minot. I have never seen any of these attacks, and cannot recall the case very accurately, but it certainly did not suggest itself to me at that time as a case of tetany. The only case that I have seen occurred in an under-fed child of not more than a year old. In adults I have never seen it. I have seen a large number of nervous diseases at the hospital, probably five hundred a year for a number of years, and I have never seen a single case of this kind.

DR. WEBBER: I remember two cases of tetany; I was asked to see a patient several years ago, the muscles of the legs and trunks were affected, the arms less so. When the attack came on the patient suffered very severely from a strong muscular contraction which could not be overcome by manual force. Ether had been used to some extent for relief. The drug which gave the most relief was fluid extract of conium, after some doses had been taken at intervals of two hours, the attacks ceased; the man got well. He had had the affection for a number of days before I saw him. The other was a case in which the arms were chiefly affected, the trunk was not affected. The spasms had continued for several weeks, several attacks each day, but nothing I could do gave him any relief. I tried conium, electricity, etc. The attacks were quite painful. The man came to see me several times but obtaining no relief, became discouraged and I saw no more of him. The attacks were very similar to those described by Dr. Shattuck.

DR. KNAPP: Tetany is so rare an affection that I may be justified in citing a case which resembles some of those spoken of to-night. The patient was a neurotic, poorly-nourished boy of fourteen, who had been at some charitable school, where his food and hygienic surroundings were not of the best, and where, according to his story, he was not very well treated. A week before he came to the City Hospital, he held his breath for some time in order to avoid a disagreeable smell, and after this he began to have cramps, numb spells, and "pins and needles" sensation in his hands and feet. The cramps affected the whole body, and the pain was so severe as to make him cry out. These came on quite frequently. During the cramps he found it difficult to speak or move. They lasted from half a minute to a minute. He had occasional sick headaches and was rather costive. He was not strong, and was rather deficient mentally, and, as I said, was poorly-nourished, and rather emaciated. While in the out-patient room he had an attack which I was able to observe. He seemed nervous and agitated as it came on. He said that the attack began in his feet and went up, the muscles of his abdomen being most affected. He stood up, his limbs were rigid, his arms were by his side with the fingers much extended and

somewhat abducted, his face was drawn with an expression of pain—whether from spasm or voluntarily from pain, I could not say,—he made no movement, except a slight general tremor, and he made no answer to my questions, because he could not move his lips and tongue he told me afterwards. He understood perfectly what was said during the spasm. Motion relieved the spasm. After recovery from the spasm I examined him, finding nothing abnormal in the chest. Pressure was made over the median nerve and brachial artery, and soon after a second spasm came on. Further pressure, after this, did not excite another spasm, so I am disposed to regard this as merely a coincidence. I then examined him with electricity. The muscles and nerves of the arms responded to a very mild faradic current. With the galvanic current KaSZ=AnSZ with $\frac{2}{10}$ to $\frac{3}{10}$ Ma. in the various muscles of the arm. The median nerve responded to $\frac{2}{10}$ Ma. The boy was sent into the hospital, but I am unable to give any further account of him except that a diagnosis of pavor Mocturnus was made, which was only a part of his trouble. I am still unwilling to call this case tetany. The spasm involved the muscles of the trunk, which is rare except in the severest forms of tetany; the fingers were extended and abducted, instead of being flexed and abducted as in the hand when it is about to be introduced into the vagina; there was no undue excitability of muscle or nerve to electricity, and the attacks were not provoked by pressure on the nerve or artery. Such a combination of symptoms, therefore, is not like the symptom complex of tetany, as given in the books, yet the condition was certainly curious.

Dr. Weeks: I have met one family of bleeders, who did not seem to feel the law of transition laid down by the authorities. Some five or six years ago I was called to a little child about two years of age, who was teething, and had a slight abrasion of the gum from which a persistent hæmorrhage had been going on for some time. I applied styptics, and after a time the bleeding ceased and has never recurred. I learned that the elder boy, some ten or twelve years of age, was troubled in the same way when he was an infant, and had since outgrown the diathesis. The family were of German extraction on the mother's side, the father was an American I believe. The mother seemed quite an intelligent woman, and said that her father was a physician, and that the case of the elder boy troubled him somewhat; he said he knew of no cases of the kind in his family or his father's family. This same boy I was called to treat, some two years afterward. I went to Melrose where the family had moved, and got there perhaps an hour after being notified, as I was out when called, and when I got there he had died of epistaxis.

Dr. Baker asked whether a tendency to umbilical hæmophilia was ever transferred to the offspring? Whether their children showed it?

Dr. Weeks had never seen a case of direct transmission. The case he mentioned was that of a young lady now married; he went to attend a relative of this patient, either a sister of hers; the sister of the first one who died, was a victim of this disease. His impression was that she was married and left a son about eight or ten years old. He has never had any disposition to bleed. These cases are almost always hereditary. The remarkable point was that when the patient recovered, she recovered completely and permanently and never had another attack.

Dr. Blodgett had had an opportunity of learning the history of one case similar to that reported by Dr. Shattuck, of a certain family of which I have considerable knowledge. This patient, a male, was one of several children of the same father and same mother. He is the only one who showed a disposition to bleed. On several occasions he bled alarmingly from the nose, the surface was blanched, he became unconscious, and was evidently in the last extremity. He has not had other forms of hæmorrhage, and the nose-bleed was the only accident he dreaded and from which he expected to lose his life. He is now fifty or sixty years old. Certainly the greater part of his life has been passed in imminent peril from loss of blood, and he has been at death's door from this cause a number of times. I do not know that I am warranted in calling this a case of hæmophilia, though the hæmorrhage was very severe in its character.

Dr. Henry Jackson read a paper on

MYOSITIS UNIVERSALIS ACUTA INFECTIOSA, WITH A CASE.

I saw last spring in Strassburg the following rare case. The above diagnosis, made by elimination during life, by Professor Kussmaul, was sustained by the result of the autopsy performed by Professor von Recklinghausen. The case entered the hospital May 18, and was demonstrated in the clinic May 22:

Woman, aged 36; family history good; she has two healthy children; lives in a district apparently healthy; no one else sick in the house. Was never sick before so far as she knows. Six weeks ago first felt sick (unwohl). Malaise, inability to work; had a red, papular eruption on the face, pain in the neck, pain in swallowing. She was treated for a sore throat. The eruption disappeared in a week's time and treatment. After the disappearance of the eruption, first noticed swelling, accompanied by pain in the shoulders, legs and sacral region; the swelling in legs soon passed off, appearing in the arms. Last two weeks pain in the neck, swelling less marked. The pain, which was first sharp, has become dull (dumpf). Pain has always been in the muscles and not in the joints. Throughout the sickness appetite fair, thirst marked, sweating, moderate fever, constipation, no vomiting, urine scanty and high-colored.

On entrance, May 10, slight fever, mind clear, slight œdema of face and extremities, muscles of extremities flexed and rigid; extension caused pain. Paresis of soft palate, electrical reaction in general diminished, reflexes absent (aufgehoben). Examination of chest and abdomen negative. During last few days high fever, rapid respiration, pulse 140. Several small patches of pneumonia (Schluck pneumonie).

Professor Kussmaul considered the diminished electrical reaction as due, in part, at least, to the

œdema, the abolition of the reflexes as of peripheral, not central origin; he considered the pneumonia as very probably due to particles of food which get into the lung on account of the difficulty in swallowing. Mind clear to the last; no symptoms pointing to disease of the abdominal organs. Death on May 24; ultimate cause, broncho-pneumonia.

Trichinosis was first thought of; eliminated by the history (her husband did not allow her to eat raw sausages), by the absence of the gastro-intestinal symptoms as prodromata in this disease, by the fever in present case. Professor Kussmaul said the case reminded him clinically of one in which thousands of miliary aneurisms were found all over the body. The fever, the widespread muscular pain and œdema pointed to a diffused myositis without any discoverable local cause, hence the diagnosis was as stated.

Autopsy, May 25. Brain and spinal cord presented nothing abnormal. Veins of abdominal cavity very full of blood. Spleen soft, enlarged. Stomach and intestines presented nothing abnormal. Stricture at the entrance of the pelvis of right kidney into the ureter, which had caused hydronephrosis of right kidney with almost total disappearance of the substance of the right kidney. Left kidney much enlarged, otherwise not abnormal. Heart pale. In both lungs several small patches of pneumonia. The muscles throughout the body, especially in the extremities, the trunk and the face (orbicularis), pale in color and moist; many small hæmorrhages in sheaths of the muscles; rupture of left rectus abdominis, with hæmorrhage.

Under the microscope the muscles showed waxy and granular edges; fibres broken; small-cell infiltration in the interstitial tissue, in no place amounting to the formation of abscesses visible to the naked eye. Nuclei of the muscles increased markedly, showing a real proliferation of muscular tissue, as well as a degeneration. I heard no report of a bacteriological examination, but reasoning by analogy with diseases which have been studied, we may say that bacteria were most probably associated with the inflammation.

Professor von Recklinghausen told me that when he was an assistant to Virchow he had seen two similar cases, but I have been unable to find a report of them. We have here some acute disease of a febrile nature, rapidly ending in death. At the autopsy a widespread myositis is found, otherwise no pathological lesions which can be considered as a primary cause of the severe symptoms existing during life.

Dr. Blodgett kindly called my attention to a similar case published lately in the *British Medical Transactions* (December 18, 1886, p. 1215): Acute myositis (Mr. Treves). After exposure to severe cold, the following symptoms were manifested; chill, malaise, fever, loss of power in arms, cramp like pain. Similar pains in legs. Gradual recovery in six weeks. Mr. Treves divides myositis into; (1) Simple, due to injury. (2) Myositis from cold. (3) Infectious boil or osteo-myelitis. (4) Attending various infectious diseases. (5) Trichinosis. This is the only case I find in the recent medical journals, German or English. In the fourth volume of "Virchow's Archives," (1852), is an article by Virchow on myositis. Anatomically, he divides myositis into: (*a*) Interstitial. (*b*) Parenchymatous. (*c*) A combination of (*a*) and (*b*). Etiologically divided into: (*a*) Traumatic. (*b*) So-called muscular rheumatism. (*c*) Syphilitic. (*d*) Septic. Then goes on to say: (*e*) "One sees finally abscesses occur in muscles under conditions as yet not made out, under conditions spoken of by the Vienna school as 'spontaneous pyæmia.' General symptoms are chill, high fever, disturbance of heart, severe widespread pains; death in a few days. Such processes may be of spontaneous origin, more commonly due to other septic diseases, especially typhoid."

A similar allusion I find in Förster. In Lobstein a case of death where the only lesion was a myositis (general?) and local patches of pneumonia. In none of the more recent works on pathology do I find any mention of a myositis, widespread in area and independent of some preëxisting centre of infection.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, April 7, 1887.

THE PRESIDENT, THOMAS M. DRYSDALE, M.D., IN THE CHAIR.

(*Continued from page 640.*)

THE ANTISEPTIC PAD.

DR. HIRST exhibited the antiseptic pad used by Richardson, of Boston, and Garrigues, of New York, to prevent the entrance of pathogenic germs to the vagina after labor.

DR. PARVIN was not impressed with the necessity for the antiseptic pad, believing that as good results could be had from antiseptic napkins. The oiled silk or muslin used in making it, it seemed to him, might hinder the ready escape of the lochia. After labor the vagina is practically a closed canal, open only for the egress of uterine discharge, and disease germs cannot enter unless that canal be opened by some manipulation of the nurse or the physician, as in giving a vaginal injection, or in making an examination. It seems to me needless to completely close the vulva, and it also seems possible that such closure hinders the escape of the lochia. But be this as it may; if the vulva is carefully washed twice a day with an antiseptic solution, and if napkins, that have been wrung out of a 1 to 2000 corrosive sublimate solution, are applied over it, changing them more or less frequently according to the amount of the flow, he thinks as good results can be had as by using the antiseptic pad. Moreover, it seemed to him doubtful whether antiseptic pads, though they have proved very useful in maternities, will be readily accepted in private practice, especially in the country. In regard to the results in hospital practice from the use of antiseptics, he has no doubt of their value, and should insist upon their employment. So, too, in private practice he has used them, and

has for some years, but it is only comparatively recently that he has learned how they should be used.

Dr. Parvin objects to the glass tubes for intra-uterine injections. Take for example Chamberlain's, and especially that of the late Albert H. Smith, and they will be found too large for use in some cases where injections are required. Then, too, the liability of glass to break is to him a conclusive argument against the introduction of an instrument made of this material into the uterus or into the vagina. The best instrument, he believes, is Bozeman's catheter. Formerly it was his custom to wait, in cases of septic infection, until the flow was offensive, and then at first to endeavor to correct the condition by vaginal, before resorting to uterine injections. He now knows that is wrong, for the patient may perish or have a protracted illness and then make but partial recovery without the lochia at any time having an offensive odor. Within a year he has seen in hospital practice and in consultation eight cases of septic infection where the happiest results were promptly had from antiseptic solutions injected into the uterus. Most, if not all, of these patients would probably have recovered without these injections, but their recovery, judging from similar cases, previously observed by him, would have been slow, possibly imperfect, and after a more or less prolonged period of suffering upon their part, and of anxiety on the part of the practitioner. We have in antiseptic uterine injections the essential, and the almost invariably successful, treatment of puerperal septicæmia, if this treatment be begun soon enough and properly carried out.

Dr. Barton inquired if the antiseptic pad was applied dry or moist.

Dr. T. M. Drysdale, while conceding the importance of antiseptic precautions in hospital, thought the advantage of these methods in private practice more difficult to prove. Until he relinquished obstetric practice, in 1874, he had met with but five cases of puerperal fever in over two thousand deliveries, and in none of these women were any antiseptic precautions used, other than cleanliness, as they were not then known.

Dr. Longaker believes, with Dr. Hirst, in the great utility of intra uterine post partum medication. Dr. Hirst has neglected to notice an agent in which he, Dr. Longaker, has the greatest confidence: iodoform, as used by Ehrendorfer, of Vienna, in the form of 100-grain pencils. One of these is introduced into the cavity of the womb after irrigation; it dissolves very slowly and continues to medicate the entire utero-vaginal canal for forty-eight or seventy two hours. In removing shreds of membrane, after labor at term or after an incomplete abortion, he uses the finger and prefers it to any form of curette he has used. Theoretically he would prefer a glass tube for intra uterine irrigation, chiefly for the reason that it is more easily cleansed and kept clean. Hitherto he has always used the Bozeman canula, the only objection to which is the difficulty of cleansing, and hence a possible danger of carrying sepsis from one case to another.

Dr. Baer emphatically endorses what has been said in favor of Bozeman's tube for intra-utering irrigation, and against the glass tube. The return current is sure, and the small size of the instrument, as compared with the glass tube, renders the introduction easy and safe.

Regarding the pad exhibited by Dr. Hirst, if he believed the theory that the atmosphere is constantly impregnated with germs which poison whenever they come in contact with open vessels, I would certainly advocate the use of an impervious covering for the vaginal orifice. For the theory teaches that where there is no contact with the air there can be no sepsis. But he does not believe this fully. Therefore he thinks it safer to place the napkin under, and not over, the vulva, so as to permit as perfect drainage as possible, thereby giving free exit to the lochia by making of the vagina a drainage tube, its natural function after parturition.

Dr. Hirst remarked that the pads were used dry by Dr. Richardson, and moist by Garrigues.

LABOR COMPLICATED BY LARGE HARD HEADS.

Dr. M. Price was called to this patient three weeks before her delivery. She informed him that she was in labor and that her time had expired. Examination showed the cervix but little dilated, the os not being larger than a silver quarter. There was quite a discharge from the vagina. The pains were at short intervals and were unquestionably labor pains. The woman was in good condition and he had no doubt that labor would go on. He left, giving instructions to send for him if the pains increased, and if not sent for he would call next day. He had attended this woman in two previous pregnancies, both children being large and the labors tedious, so he anticipated that this one would be a slow labor. The next day the pains were less than on the previous day, and there was no change in the cervix. He did not hear again from her for three weeks, when the husband called and stated that his wife had been in labor all night and all day. He now found the cervix wide open, but the presenting part so high up that he was not able to say what part was presenting. Passing the entire hand into the vagina, he found a vertex 2nd, but the head would not engage. After waiting two hours he found the head had been pushed to the side of the pelvic inlet, with the occiput resting on one side and the neck and shoulders on the other, and determined to ascertain the difficulty. He pushed his hand up into the womb, and had no difficulty in bringing the head back to its first position, but found that it was completely ossified. There was no pulsation in the cord that he could detect, and he at once decided to deliver by turning, as he thought he could deliver the child in that way sooner than in any other. He at once secured the feet and soon had the body and arms delivered. The forceps were applied to the after-coming head, and it was delivered after quite a pull at the superior strait, but with ease through the soft parts without the instruments. There was no injury to the mother and she made a rapid recovery. The child was still-born. Its head measured sixteen inches in occipito frontal circumference.

There can be no doubt that the mother's pelvis is much above the average size, as a head perfectly ossified could not have passed through a pelvis of less than sixteen and one-half inches, as the soft parts would take up at least one-half inch. Standard authorities give the circumference of the female pelvis at the inlet at from thirteen to thirteen and one-half inches.

DR. JOSEPH PRICE read a paper on

ABDOMINAL SECTIONS.

In reporting a mixed group of cases treated by those methods of which Mr. Tait has been the first and chief advocate, I desire to make brief reference to Dr. T. Gaillard Thomas's article on "Laparatomy as a Diagnostic Resource," published in the *Medical News*, Dec. 11, 1886. Therein Dr. Thomas expresses in full Mr. Tait's views. They are simply without the mention of Mr. Tait's name, an embodiment of the views given vent to by Mr. Tait while on a visit to America in the autumn of 1884. Dr. Thomas would select the text of Mr. Tait's law, his own axiom, as a motto for the walls of a hospital devoted to abdominal surgery. "When a doubt, as to the diagnosis of an abdominal neoplasm of a serious character, or of certain obscure pathological conditions of the abdominal cavity which threaten life, exists, give the patient the benefit of explorative incision." Mr. Tait, in like clean and terse English, expressed the same view in a clinical lecture at the Hospital of the Jefferson Medical College, Sept. 15, 1884, when he said "My experience teaches me that it is a surgical crime to allow a patient to go to her grave without operation where it offers a possibility of relief." Dr. Thomas, with great frankness, reports five cases as examples of the class in which he had to regret non interference on his part: cases in which "we" or "I" decided againt operation—the patients died. Further he says: "I regret to say that I could more than double the cases illustrating this part of my paper. Few such cases occur to me now for the very reason that I am a strong advocate for explora tive incision as a diagnostic resource." As to another class of cases in which Dr. Thomas meets with happy results, he reports as follows: "There is a class of cases in which, in my hands, explorative incision has yielded such brilliant results that I shall devote full consideration to it; I allude to cases of ascites in the female." Mr. Tait, in the address I have referred to, gave as as example in point a case operated upon four years previous. "The patient, a young lady, had an enormously enlarged abdomen due to ascites, a fact I had recognized. I opened it by incision for exploration and drainage: by this means the fluid is evacuated just as well as with the trocar, but you cannot feel anything with a trocar; but with a clean cut of two or three inches you can introduce one or two fingers and find out the actual condition of the pelvic organs as you can in no other way." The pioneer work done by Mr. Tait, his influence in exploratory work and treatment of diseased conditions of the tubes, is referred to by Mr. Greig Smith in a very fair and generous spirit. "Tait's name is mainly connected with inflammatory diseases of the tubes, and his influence has been strongly felt in the substitution of operation for actual disease as against vague nerve symptoms." I am strongly of the opinion that an incision which admits only two fingers and not the whole hand is a sufficient incision. Dependence upon fingers skilled in manipulation will serve best, and effectively guard against danger in any pelvic operations. Herein I differ from Dr. Thomas, who urges: "Make an incision which will admit the whole hand; one which will admit two fingers only is hardly warrantable." There is great danger in multitude of fingers of irritating the bowels with the hand and further running great risk by exposure.

Many fatal results attend men beginning the study and practice of surgery of the abdomen. This is illustrated by the statement of an abdominal surgeon: "I do not count my first thirteen cases, because I was learning how to do it." In this there was considerable Rip Van Winkle arithmetic: "We won't count this one." The present good results in the hands of young surgeons must not be attributed to the taking advantage of all the so called "latest antiseptic improvements." In this relation I will make brief allusion to an experience with well trained young surgeons, six in number, doing nine pelvic operations due to inflammatory trouble, suppurating, adherent, and matted together pelvic viscera. The operations were all completed, with but one death, notwithstanding they were all bad cases.

In illustration I present a specimen of *Pyosalpinx* removed by Dr. Thomas G. Morton. This patient had an enormously enlarged abdomen. She had been seen by a prominent gynecologist who had plainly stated that there was no ovarian trouble and recommended tapping, which was done. It is my impression that by the first tapping the large cyst was ruptured, the dropsical accumulation followed. Dr. Morton found upon examination, after repeating the tapping, (the patient refusing any other operation) a small tumor or collapsed cyst. He refused to repeat the tapping and urged section. He kindly asked me to see the patient. Upon examination I was fully satisfied of the correctness of Dr. Morton's diagnosis and agreed with him in urging section. It was immediately done. Extensive adhesions had developed from the tappings, free hæmorrhage followed. He removed a large collapsed cyst, and by irrigation large quantities of old clot. An interesting feature of the case was the existence of two pedicles, the pelvic, and a fan-shaped one over the diaphragm and stomach. The case presented very interesting and instructive features.—Result: cure.

PYOSALPINX.

Ella DeLacy, white, æt. 18 years, on October 31, 1883, presented herself at the Philadelphia Dispensary complaining of attacks of free bleeding and of pain in the left groin and left sub-mammary region, intensified by locomotion. On examination the uterus was found low down and retroverted, the left ovary was tender. On June 16, 1885, vulvo vaginal gland enlarged and tender: abscess incised and packed. On July 1, 1885, she complained of pain in

the back, left shoulder and left inguinal region. She was put on general treatment. Menstruation was normal Nov. 9, 1885. Examination showed the uterus retroverted and the ovaries tender, vulvo-vaginal glands enlarged; abscess incised and packed. Nov. 25, 1885. The uterus had been treated for its displacement and at this time was found in good position. Both ovaries were enlarged and tender. Feb. 24, 1886. Complained of pain on coition. January 25, 1887. Pain in right inguinal region. On examination there were found tortuous, cystic, boggy masses, filling up the whole right side of the pelvis. January 26, 1887. Dr. Price opened the abdomen in the median line, the incision being enlarged to three and a half inches on account of deep adhesions to all of the pelvic viscera. The right tube charged with pus and the right ovary with a parovarian cyst as large as a cricket-ball, were removed, the pedicle ligated with silk and dropped. Free irrigation was employed; the wound was closed with silk.

PYOSALPINX.

Reported for T. S. K. Morton, M.D.

Mrs. S., white, æt. 36, complains of pain in right illiac region and extending down the right thigh increased by locomotion. General condition bad. Dissipated. *Examination.* Uterus in good position; to the right of cervix is a firm pedunculated tumor filling up the pelvic cavity on that side, firm, nodular and adherent. *Operation*, Jan. 25, 1887. A two inch incision was made two inches above the pubis, two fingers were introduced and everything found practically normal except the right ovary and fallopian tube. The ovary was as large as a pigeon's egg and firmly bound down in every direction and apparently more cystic than normal. The tube was likewise bound down, extremely thickened and contained fluid. After carefully examining all around the adherent mass, a point more friable than the other adhesions was found and torn up. This done the enucleation became a matter of patience and application of judicious force until the whole mass had been shelled from its inflammatory bed. When thus freed, the ovary and tube were brought out of the wound and the pedicle doubly ligated as near the uterine cornu as possible and divided with scissors. Previous to dropping back the pedicle the remainder of the fallopian canal in it was thoroughly swabbed out with strong bichloride solution, 18 grs. to ℥j. Scarcely any oozing took place and after thoroughly irrigating with water that had been boiled, and carefully sponging the peritoneal cavity was found to be perfectly dry. The incision was closed without a drain. Time, 55 minutes. *Progress.* Occasional slight nausea was the only untoward symptom following the operation; evening temperature, 99 4°; next morning, 100°. After that it did not rise until the evening of the fourth day, when it mounted to 102° and she complained of considerable abdominal pain with much vomiting. This set-back had come on as a result of getting up and walking about the room some hours before during the absence of her nurse. The fifth day found her with marked symptoms of peritonitis, vomiting, and towards evening shock and evidently dying. Death occurred during the night.

Autopsy.—Parietal wound in good condition; about half-a-pint of cloudy serous fluid in the peritoneal cavity: abdominal contents matted everywhere with very recent lymph; no blood or clots; kidneys somewhat granular, but not nearly so much so as might have been expected from her dissipated manner of living; other organs practically normal.

OVARIAN CYST SIMULATING ECTOPIC GESTATION.

Reported for Dr. F. A. Packard.

Kate Taggaronni, white, æt. 29, married the second time about two years ago. Had five children, all by the first husband; no miscarriages, labors all easy and natural, made good recoveries and nursed all her children. Menstruation regular in time and quantity until November, 1886, when they were absent in November and December.

For the past month she had been bleeding freely, the hæmorrhages appearing in clots mixed with what seemed to be shreds of decidua. The breasts tingle but are not apparently enlarged; face blotchy; no abdominal enlargement noticed. She has had nothing like labor pains. The discharge is of bad odor. She has had no fever or chills. *Examination* showed a cystic tumor, in the pelvis to right of the uterus, about the size of gravid uterus of second month. *Operation.* On January 10, the patient being etherized, an incision three inches in length was made in the median line of the abdomen just above the pubis. Hæmorrhage from the abdominal wound was slight. A small cyst of the right ovary was found consisting of two chambers, one being filled with clear serous, the other with darker blood-stained fluid. There was no adhesions. The cyst was removed unruptured; the pedicle ligated with silk and returned. The cyst was about the size of a small orange and sprang from the right ovary. The patient's condition after the operation was excellent. She had no rise of temperature or pulse, and no pain. Four stitches were removed on the fifth day and the remainder on the seventh day. There has been no return of the bleeding.

ABDOMINAL SECTION FOR INTESTINAL PERFORATION.

Reported for Dr. Francis L. Haynes.

Mrs. M., æt. 20, nullipara, had suffered for nearly a year from diarrhœa, cough with purulent expectoration, and symptoms produced by uterine disease and general weakness. March 9, 1887, she was suddenly seized with severe abdominal pain, which shortly became intense in a spot two inches to the right of the median line and three inches above Poupart's ligament. The temperature varied from 100° to 104°; pulse from 120 to 140. Vomiting and purging and slight balooning were other symptoms. The attending physicians, R. and F. L. Haynes, diagnosticated perionitis from intestinal perforation. As the patient gradually became worse, Dr. Jas. Price made abdominal section on March 14. The intestines were found matted together. They were washed and wiped with sponges. Two pieces of fecal matter, each about the size of a pea, together with some serum were removed from the cavity. The abdom-

inal pain and swelling now diminished and by the third day after the section had entirely disappeared. The temperature gradually sank to normal. On the seventh day the patient became delirous, collapsed and died on the morning of the eighth day after the section. No autopsy was allowed. It was thought that general tuberculosis was the cause of death.

(*To be concluded.*)

FOREIGN CORRESPONDENCE

SURGEONS AND SURGERY IN LONDON.[1]

St. Thomas's Hospital—Strangulated Hernia—Mr. Malcolm Morris—Mr. Pearce Gould—Mr. Timothy Holmes—Suppurative Inflammation of Shoulder Joint—Destructive Inflammation of Foot in Diabetes; amputation—Sir William MacCormac—Guy's Hospital; Its Museum—Congenital Hydrocele of the Cord—Mr. Thomas Bryant—Epithelioma of the Hands.

Dear Dr. Fenger:—A visit to St. Thomas's Hospital afforded me an opportunity to witness an operation for strangulated inguinal hernia by Mr. Sidney Jones, Senior Surgeon of the Hospital and Professor of Surgery in the school in affiliation with this institution. Full antiseptic precautions were observed, including the now almost obsolete spray. The patient, a man about 40 years of age, claimed that he was never aware that he had a hernia until the evening before, when a swelling formed rapidly in the right groin, followed by symptoms indicative of a strangulated hernia. When admitted into the hospital the lesion was readily recognized as a strangulated hernia and several gentle attempts were made to reduce it by taxis, but without success. The tumor was nearly as large as a fist and very tense. A long incision was made down to the sac and all hæmorrhage carefully arrested before the peritoneal covering was laid open. On opening the sac a large mass of omentum came into view, underneath which a loop of intestine intensely congested was found. The omentum was divided into four parts just below external ring, tied with catgut, and the portion below the ligatures cut off and the stump returned. The internal ring was divided in the usual manner, the loop of intestine drawn forward, examined and returned. At this stage of the operation it was evident that internal hæmorrhage was taking place as arterial blood escaped from the empty canal. A search for the omentum through the opening proved fruitless and it became necessary to lay open the entire inguinal canal, but even this extensive enlargement of the wound did not afford access to the retracted omentum, and the abdominal wall was incised for at least three inches more, when the omental stump was found and brought into the wound. One of the ligatures had slipped and caused free arterial hæmorrhage. The hæmorrhage was arrested by the application of another catgut ligature and the stump again reduced. The neck of the sac was tied and stitched into the wound. The extensive wound was closed with deep sutures including the peritoneum, drained and a dressing of iodoform gauze and cotton applied. This hospital is one of the best in London, contains 600 beds, which furnish the material for clinical instruction for the students attending the school connected with this institution.

A visit to the residence of Mr. Morris afforded me an opportunity to examine an excellent collection of renal calculi removed by nephro-lithotomy. Mr. Morris is a young surgeon of great promise, who has had an unusually large number of cases of renal surgery. He is one of the surgeons to the Middlesex hospital and enjoys a good reputation at home and abroad.

A call upon Mr. Pearce Gould, who lives in the same part of the city, was remunerated by a profitable conversation touching upon recent topics in surgery. Mr. Gould is a thorough scholar and an able surgeon, and has done excellent work in the Middlesex hospital.

At St. George's hospital, I made the acquaintance of Mr. Timothy Holmes, the author of a voluminous, and I might say the best, English text-book on surgery. Although advanced in years he still retains his youthful energies and continues his work of giving regular clinical instruction. A female, 20 years of age, suffering from a suppurative inflammation of the shoulder joint, furnished the subject of his clinical lecture on this occasion. A contracted, fistulous tract commencing at the lower margin of the pectoralis major communicated with the shoulder joint. The joint was laid open by a straight anterior incision, and after severing numerous adhesions the upper extremity of the humerus was brought into the wound and the bone divided with an amputation saw just below the tuberosities. Parts of the capsule were removed with curved scissors and a drain introduced through the fistulous tract which had been previously scraped out and dilated. The dressing consisted of a thick compress of antiseptic guaze. He said nothing about the pathology of the case but made the assertion that in such instances it is superfluous to make the operation subperitoneal as such a procedure would be of doubtful advantage, but in case it became necessary to divide the bone at a lower level the periosteum should be preserved. The best functional results he has seen after excision of the shoulder-joint were patients who could raise the arm to a horizontal position.

When Mr. Holmes finished his remarks Mr. Hayward took his place and presented a diabetic patient who had recently become the subject of a destructive inflammation of one of his feet, which had terminated in extensive sloughing which had opened the ankle joint. Amputation was performed at the junction of the middle with the upper third of the leg, by making a long anterior and short posterior flap. The periosteal flap was made, and the flaps were sutured in the ordinary manner and a transverse drain introduced. A gauze dressing was applied. In this connection I will give you the result of a conversation with Professor Koenig a few days ago, concerning the propriety of resorting to amputation in diabetic patients suffering from gangrenous inflammation of an extremity. He stated that while

[1] By permission of Drs. Fenger and Senn.

it had been customary heretofore to resort to preparatory treatment prior to amputation, with a view of diminishing the sugar in the urine, he had during the last year operated upon several cases where the patients had high temperature and the urine contained large quantities of sugar, with the result that almost immediately after the operation the temperature became normal and the specific gravity of the urine less. The result of these observations has convinced him of the fact that it is dangerous to delay the operation whenever the local symptoms indicate the necessity for such a procedure in diabetic patients. In corroboration of this statement it may be said that quite recently a French chemist has shown that the introduction of septic material into the blood produces an artificial diabetes which disappears as soon as the septic condition subsides.

A third operation was performed by Mr. Dent. The case had been diagnosticated as lipoma, but during the dissection the cyst ruptured and the escape of other omatous material showed the fallacy of the diagnosis and proved that the swelling was not a tumor but a retention cyst. I have every reason to believe that in many of these large metropolitan hospitals the diagnostic resources are not always exhausted prior to the operations, and that often the true nature of the case is only revealed during the course of the operation. Many of the most prominent surgeons are not exempt from this fault. The greatness of a surgeon should never be measured by the brilliancy of his operations but by the knowledge and care he exercises in rendering a correct diagnosis upon an anatomico-pathological basis.

The pleasure of my visit in London reached its maximum at a dinner with Sir William MacCormac, at the Reform Club. On this occasion I met the house surgeons of St. Thomas's hospital, and Mr. Trimmer, Secretary of the College of Surgeons. I shall always cherish the recollections of that evening as a bright and verdant oasis of a laborious professional life. The last day of the week I spent in London I devoted to a visit to Guy's hospital. One of the great attractions of this institution is the anatomical and pathological specimens, modeled in wax by the skillful hands of Mr. Thomas Town, who spent nearly half a century of his useful life in their preparation. Hundreds of specimens, as natural as life itself, can be found here illustrating normal anatomy and pathological specimens. I know of no better anatomical school than the museum of Guy's Hospital, where, upon long tables under glass covers, the most beautiful models, taken from actual dissection, illustrate every organ and every region. The students appear to take advantage of this opportunity to master their anatomy, as quite a number were seated in front of the specimens with Gray's Anatomy in their hands. The models illustrating pathological specimens show the tissue changes much better than the original specimens. In the afternoon Mr. Davies-Colley operated upon a case of congenital hydrocele of the cord in a boy 8 years of age. The testicle could be distinctly isolated from the swelling, and there was reason to believe that the communication with the peritoneal cavity was a small opening. During the delicate dissection made with a view of extirpating the sac, it was found very difficult to isolate the cord, and the tunica vaginalis was opened at a small point corresponding to the upper surface of the testicle. The neck of the sac was ligated, and subsequent examination of the specimen proved the correctness of the diagnosis. The operation was performed under a spray and a Lister dressing was applied.

On a previous occasion I had made the acquaintance of Mr. Thomas Bryant, the author of the familiar text-book on surgery, and at this time I had an opportunity to hear him lecture and see him use the knife. From a practical point of view his clinic was unimportant, but exceedingly interesting from a pathological standpoint. The patient was an old gentlemen who had been suffering from a papilloma upon the dorsum of one of his hands for twenty years. For the last two years the tumor increased quite rapidly in size and the surface ulcerated, features which led Mr. Bryant to the belief that the benign papilloma had undergone transformation into a sarcoma. To me it appeared that the transformation had taken place in the epithelial covering, and that the tumor was not a sarcoma, but a squamous epithelioma; an opinion in which I was confirmed in my own mind by a macroscopical examination of a section of the tumor, where the cylindrical cords from the surface of the tumor towards its centre could be distinctly recognized. Mr. Bryant's favorite antiseptic solution is a weak watery solution of iodine, which he prefers to any other antiseptic, and with which he has had most excellent results. In my next letter I hope to give an account of my observations gathered from the two most noted European laparotomists, Tait and Péan.

N. Senn.

DOMESTIC CORRESPONDENCE

GALVANIC MEASUREMENT.

Dear Sir:—In a few of your recent numbers, not only have I been the subject of criticism for my advocacy of strong currents of electricity in the treatment of fibroid tumors of the uterus, but the technical correctness of some of my statements has been questioned. In regard to the first I think I will be able to justify myself, while the latter simply requires an explanation.

In order for one uninitiated to understand how it is possible to employ, without disastrous results, a current of electricity of as great intensity as that recommended by Dr. Apostoli, or as recommended in my article in The Journal of April 4, it is necessary that he be made familiar with the following points: 1. The toleration of the particular tissues traversed by the current; 2, the end sought by the operation; 3, the principles of the electrodes; 4, kind of current and method of appliance; 5, the electro-motor force of the current.

The maximum strength of current recommended in ordinary cases (from 200 milliampères upwards),

is only employed in the needle operation and for the purpose of checking alarming hæmorrhage from the cavity of the uterus. As the latter constitutes one of the most alarming, and very often the only grave symptom of this distressing malady, we are frequently consulted for that difficulty alone. The end sought in the treatment of such a case is to seal up the blood-vessels that are discharging their contents into the uterine cavity. This effect is accomplished not only as may sometimes be temporarily done by an actual or galvano-cautery, or strong acid, or caustic alkali, or the curette, but also because it produces a similar though less destructive effect upon the deeper tissues as the current passes through them. The internal electrode that is employed in a case in which this result is sought is of platinum, and has an active surface in contact with the tissues to be affected of from 4 to 8 square centimetres. From this small surface the current radiates, as from the centre of a sphere, to a large portion of its circumference, which is represented by a large, concave, abdominal electrode, which is arranged to conduct equally from its entire surface. This external electrode may have a conducting surface varying from 400 to 800 square cm. The portion of the patient, then, that the electricity traverses might be represented by an inverted cone, the apex of which is at the internal electrode, with a surface of from 4 to 8 sq. cm., the base corresponding to the external electrode, with a surface of 400 to 800 sq. cm. If we should remove this cone of tissue and analyze it in many cases of fibroid tumors of a hæmorrhagic nature operated upon, we would find about one fourth of the cone from its apex toward its base composed of hard, unsensitive muscular tissue of the uterus, two thirds of the remainder of unimpressionable myoma, while the base would be composed of the most sensitive tissues of the mass—the abdominal wall and its integument.

The enormous current of electricity that this cone of tissue will tolerate, without injury to innocent parts, is what I have been criticised for advocating. The effect which is necessary for us to accomplish in this cone of tissue in order to effectually check hæmorrhage from its apex, or the internal surface of the uterus, is as follows: At the apex, where the powerful current is concentrated on a surface of from 4 to 8 sq. cm., we seek mild cauterization; as the current reaches the tissues immediately beneath the surface, and is not quite so concentrated, we want strong coagulation without positive destruction; as the current still further radiates we get milder coagulation, then strong electrolytic action, then milder electrolytic action; and when the more sensitive tissues of the surface are reached, the current is so thoroughly diffused that nothing more than a smart burning sensation is produced, and a temporary reddening of the skin. The strength of current in milliampères that will accomplish this effect is directly proportionate to the conducting surface of the internal electrode. For instance, if the conducting surface of the internal electrode is 1 sq. cm., and a definite effect is obtained, with a 100-milliampère current it will require just double that strength of current to produce the same effect if that surface is increased to 2 sq. cm.

While the density of the current is dependent upon the size and character of the electrodes, the pain produced in conducting a current through a tissue is also dependent, to a great extent, upon their character and position. With a small active electrode, internally applied, where the tissues are not sensitive, and a dense and high-tensioned current is not only tolerated, but necessary, the external abdominal or surface electrode must be of such a character that it will accomplish the greatest possible diffusibility, and possess the maximum conductivity consistent with little pain. The electrodes by which I make this possible were described in an article in THE JOURNAL of April 23, 1887.

It is not a difficult matter to understand that a painful and disastrous result would ensue if, instead of the large surface electrode externally applied, a small, highly conducting electrode should be substituted. In such a case, of course, the same effect would be produced upon the sensitive external tissue that we expect internally (cauterization and coagulation), because of the condensation of a strong current, that was just tolerated when diffused over a surface of from 400 to 800 sq. cm., to a surface of very much smaller dimensions.

Again, while it is necessary to have proper electrodes to prevent destructive and painful effects, it is also necessary to have a steady and uninterrupted current. If it is even and continuous, a much stronger current will be tolerated than when it is uneven and interrupted. The mechanical effect of an interrupted current of 25 milliampères strength through the abdominal walls could not be tolerated for a moment without the most excruciating pain, while a smooth and uninterrupted current of 300-milliampère strength, properly applied through the same tissues, is often received without a complaint.

For the same reason, the greatest precaution must be exercised in turning on the current, to see that it is done gradually. A much stronger current will be tolerated without discomfort if it is increased in strength a cell at a time than if the full force of the battery is switched on at once.

In estimating, then, the effect of a strong current of electricity upon a body, it is of the greatest importance to take into consideration: 1, the toleration of the particular tissues traversed by the current; 2, the end sought by the operation; 3, the density of the current and the principles of the electrode; 4, kind of current and method of appliance; 5, the electro-motive force of the current. The bearing the electro-motive force has in the case will be referred to shortly.

If the above points are thoroughly borne in mind, it seems to me even the most uninitiated can appreciate how utterly void of value the example cited by Dr. Engelmann in his last letter, in support of his opinion in regard to the point at issue between us, is. "Ten ampères," he says, "is the current used in the large electric lamps upon our streets. . . . . If an unfortunate fireman comes in contact with such a current for a moment he is struck dead! The fatal shock is caused by about one-tenth of an ampère, 100 milliampères, through the high resistance of the

human body." If this is a conclusive argument, or any argument at all, why 10 ampères cannot be used in the method I have described, why is it not as conclusive an argument against the use of 280 milliampères, which Dr. Engelmann maintained in his letter of April 11 that he himself had used? The argument is still further confused by the following statement: "The current used for the Brush Electric Light is about 10 amperès; if this is sent through the human body (the part of the body is not mentioned) which, with the dry skin, represents a resistance of 30,000 ohms, roughly estimated, one-tenth of an ampère (100 milliampères), strange as it may seem, would be the actual current passing through and causing the fatal stroke!" If we analyze the above statement we will not only see that it is without value as an argument against strong currents properly used, because it is in no way a parallel case; but we will also find that the conclusions are not necessarily correct.

It is not a parallel case because, first, the part of the body through which the current passes, in the case of the "unfortunate fireman," cannot possibly have the toleration that is possessed by the cone of tissue I have described. Presumably, in the case of the fireman, the current traverses the body from hand to hand. Here, instead of a solid section of tissue, two thirds of which is made up of pathological tissue and involuntary muscular fibres, the combined resistance of which may be as low as 50 ohms, we have the sensitive voluntary muscles of the arms and shoulders, with their sensory nerves, the lower cervical and upper dorsal spinal cord, the accompanying vaso motor ganglia of the region, the vagus and other important nerves, and the enormous resistance of 30,000 ohms.

2. In the operation I have described, by the use of the peculiar electrodes I have adopted, it is possible to use a much more powerful current, because it is widely diffused where it comes in contact with the more sensitive tissues, while, in the case of "the unfortunate fireman," the current enters the body in the most concentrated form, from the small section of a highly conducting metal wire.

3. I have endeavored to point out how necessary it is for us to have a steady and uninterrupted current, the necessity of increasing its strength very gradually, so as to produce no shock. In the case of "the unfortunate fireman," as he severs the wire, the whole force of an electric light system with an electro motor force of from 1,000 to 40,000 volts, is instantly flashed through the most sensitive part of his body.

4. The volt-force necessary to get a current of 100 milliampères through the tissues of the abdomen and fibroid tumor by the method I have described, if we allow that the resistance of the tissue between the electrodes is 60 ohms, the resistance of electrodes, conducting wires, galvanometer and battery at 200 ohms, will be not more than 26 volts; while the electro-motive force of the current that passes through "the unfortunate fireman," at the lowest estimate, if it overcomes 30,000 ohms, is 10,000 volts. Surely, can a current of 10,000 volt force be used with fairness to demonstrate that 100 milliampères is unsafe, where the resistance is so small that only 26 volts are necessary to give the same current?

5. Then, after all, if Dr. Engelmann's illustration should be considered of any value—and I think that I have demonstrated why it should not—his conclusion that death necessarily follows such a shock is not well grounded. While, occasionally, a death is reported from severing electric light wire, a number of well authenticated cases can be cited to each one of these, where the shock from the same cause produced but temporary inconvenience.

Dr. Massey, of Philadelphia, in his letter of May 14 on this line, after figuring the power of my battery to a maximum current of 40 or 50 milliampères, says: "But even 40 or 50 milliampères really used by Dr. Martin are strong doses, when applied to the delicate lining membrane of the uterus, or concentrated at a single point within the tissue." That is just where we are misjudged. If Dr. Massey had read my paper carefully he would have noticed that we *seek* to coagulate or liquefy (as the indications demand) the tissues with which the active pole comes in contact. If he realizes this, he must appreciate that this cannot be accomplished, in the majority of cases, by a 40 or 50-milliampère current.

Finally, in answering the criticisms of Dr. Massey made in his letter of May 14, and the criticism, in the same line, of Mr. H. L. Bailey in his letter of May 28, I wish first to make an explanation: The battery with which I do most of my office work consists of 115 gravity cells. Under ordinary circumstances, this accomplishes all that I require. However, connected with the same switch board I have 36 cells, manufactured by McIntosh & Co., of this city, called "improved gravity cells." Each one of these cells has an electro-motive force of 1.5 volt; these cells added make the combined electro motive force of my office battery 174 volts. Besides this power, which I find ample for all except extraordinary purposes, I have been indebted to Dr. McIntosh for additional apparatus whenever I have, for experimental purposes, found it necessary. I made this explanation, as I have no desire to mislead my readers, or to pose as a violator of Ohm's Law. However, from my 115 gravity cells I am able to get, and do get, a current of from 300 to 600 milliampères. The internal resistance of the battery is 230 ohms, instead of 1,150, as figured by Dr. Massey; the resistance of the tissues and electrodes is not more than 150 ohms. The electro-motive force of the battery is about 130 volts. By Ohm's Law we get $\frac{E}{R} = \frac{130}{380} = C = .342 +$, or 342 milliampères. If the resistance is less, as is often the case, the current will be correspondingly higher. By switching in my additional cells, representing 54 volts, I increase the current to 400 or 800 milliampères.

I wish to correct any impression, however, that I am using a current, at any time, that cannot be readily borne by a patient unanæsthetized. The current is turned on a cell at a time, with great care, until the required strength is reached. If the electrodes become painful before the required current is obtained, it must be carefully turned off and the elec-

trodes changed or rearranged, so that the required current may be obtained without pain. The greatest care must always be observed in the selection of electrodes and the proper manipulation of the current. Yours truly,

FRANKLIN H. MARTIN, M.D.

163 State St., Chicago, May 30, 1887.

BOOK REVIEWS.

MEDICAL ELECTRICITY. A Practical Treatise on the Applications of Electricity to Medicine and Surgery. By ROBERTS BARTHOLOW, A.M., M.D., LL.D., etc. Third Edition, Enlarged and Improved. With Illustrations. 8vo, pp. 304. Philadelphia: Lea Brothers & Co. Chicago: A. C. McClurg & Co.

This book, in its preceding editions, has been before the public long enough to be well known. All the works written by Professor Bartholow are deservedly popular, for they are clearly and well written. The present volume covers the usual ground gone over by treatises on this subject. Electricity, its nature and modes of manifestation, are first considered; then the means of generating it; later electro physiology, or its physiological action; and finally its use as a diagnostic and therapeutic agent. The additions to this edition have been chiefly to the sections on therapeutics. The portions devoted to electric illumination and galvano-cautery have been enlarged. Galvano-faradization and electric baths are also described. Without doubt this edition will maintain the popularity of the work.

MISCELLANEOUS.

NEW HAMPSHIRE STATE MEDICAL SOCIETY.—The ninety-seventh annual meeting of this Society will convene in the Opera House, North Main Street, Concord, N. H., Tuesday, June 21, 1887, at 11 o'clock A.M. The Councillors will meet in the office of Dr. Conn at 8:30 P.M. of the previous evening, June 20. Prof. Carlton P. Frost, Hanover, President; Dr. G. P. Conn, Secretary.

STATISTICS OF TYPHOID FEVER.—In an Amsterdam graduation thesis, by DR. M. NIEMEIJER, on the Statistics of Typhoid Fever, out of fifty cases in which complete observations were recorded, prodromata occurred in twenty five, rigors in sixteen, "cold shivering in one, pain in the left side in seven, diarrhœa in forty two, splenic enlargement in forty-eight, rash in forty seven, ileo cæcal gurgling in nineteen, and pain in the same region in twenty, bronchial catarrh in forty-three, albuminuria in twelve, in three of which cystitis followed. In sixty-three cases, relapses occurred six times. With regard to complications, out of seventy-three cases, intestinal hæmorrhage occurred in five; peritonitis in three, perforation occurring in two of these. Other complications were: pharyngitis, one; acute follicular sore-throat, one; parotitis, one; epistaxis, three; laryngeal perichondritis, one; pulmonary infiltration, thirteen; pleurisy with effusion, three; thrombus of the crural vein, one; acute nephritis, one, in a somewhat doubtful case; nephrolithiasis, two; herpes labialis, three; cutaneous hæmorrhage, three; periostitis of the tibia, one; joint-affections, three; meningitis, one; neuralgia of the sole, one; profuse perspiration, two; polyuria, one; mental disturbance, four; deafness, five; bleeding from the ear one. The total number of patients on whom observations were made was 194. Of these, twenty, or 10.3 per cent., died, the male mortality being decidedly higher than that occurring amongst female patients—12.5 per cent., as compared with 6 per cent.—*British Medical Journal*, May 7, 1887.

GASEOUS TREATMENT OF CONSUMPTION.—Dr. Henry Leffmann, Editor of *The Polyclinic*, (P. O. Box 791, Philadelphia), desires to obtain results of the new treatment of Pulmonary Consumption and Phthisis by gaseous enemata, *for publication in The Polyclinic*. The correct therapeutic value of this method can only be arrived at by the collection of statistics, and he therefore requests any one who has administered the gas to communicate the result to him, the formula used, and any special information that may be useful.

ABDOMINAL SECTIONS.—Professor Joseph Eastman, of Indianapolis, Ind., recently reported the results of twenty four cases of abdominal section with twenty recoveries. Four were operated on in the City Hospital, ten in his private hospital, and ten in private residences. In twenty-two of the cases the operations consisted in removal of one or both ovaries, and in fifteen of these, the tubes were included. The operation was exploratory only in one case, revealing encephaloid disease of the left ovarium and adjacent parts; and in the remaining case a fibroid tumor of the uterus was removed, weighing six pounds.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 28, 1887, TO JUNE 3, 1887

Capt. H. O. Perley, Asst. Surgeon, relieved from duty at Ft. Maginnis, M. T., and ordered for temporary duty at Ft. Snelling, Minn. S. O. 49, Dept. Dakota, May 23, 1887.

First Lieut. Wm. N. Suter, Asst. Surgeon (recently appointed), ordered for temporary duty at Washington Bks., D. C. S. O. 122, A. G. O., May 27, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING JUNE 4, 1887.

Bransford, John F., Surgeon, ordered to the Smithsonian Institution, at Washington, D. C.

Tryon, Rufus J., Surgeon, detached from the U. S. Str. "Quinnebaug," and ordered home.

Siegfried, Chas. A., Surgeon, ordered to the U. S. Str. "Quinnebaug."

Martin, Wm., Asst. Surgeon, detached from the U. S. Str. "Pinta," and ordered home.

Fitts, Henry B., P. A. Surgeon, detached from the receiving ship "Vermont," and ordered to the U. S. Str. "Pinta."

Field, James G., Asst. Surgeon, ordered to the receiving ship "Vermont."

ADDRESS IN MEDICINE.

Delivered before the Section of Practice of Medicine, Materia Medica, and Physiology, at the Thirty-Eighth Annual Meeting of the American Medical Association, at Chicago, June 8, 1887.

BY JOHN S. LYNCH, M. D.,

OF BALTIMORE, MD.

In searching the records of this Association to find how my predecessors have discharged the duties of the position which the partiality of my fellows in the Section on Practice of Medicine, Materia Medica and Physiology has assigned to me, in order that I might profit by their illustrious examples, I find that with rare exceptions, these addresses have not been (what the Association originally intended they should be) a review of the advances and discoveries made during the past year in the branches of medicine in this section; but have consisted of discussions of a single topic which has recently most prominently occupied the attention of the profession. If I should follow the example thus set me I would be greatly puzzled in making the selection of such a topic; for there are really so many subjects of transcendent importance crowding upon our notice, of either one of which so much could be said, that I should finally neither satisfy myself nor the audience I address by the selection I should make. Moreover, as most of these topics would necessarily have to be discussed in a manner more or less speculati e, it occurs to me that few would take any interest in *my* speculations upon any of them. I shall, therefore, as briefly as I can, glance at some of the discoveries, or pretended discoveries, advances, or hoped for advances, in our departments of medical science, not of this year alone, but during the past few years. For while the time of the announcement of a discovery or advance, may constitute an important epoch long enough to be remembered afterwards, it is only after long trial during which the real value of the discovery is to be tested, that we can accept it as of proven and established value.

ANTIPYRETICS.

Unquestionably the means of safely reducing and keeping down morbidly high temperatures constitute the most powerful weapons we possess in combatting a large majority of the diseases to which mankind is heir to. As I grow older and my experience enlarges I become more and more convinced that fever is the lethal agent which destroys life in almost every disease in which that functional derangement is present. Whether in specific diseases or common inflammations it is most frequently the morbid high temperature by its wasting destruction of tissue, the arrest of nutrition and the associated derangements of function that determine the fatal result. Of course in the so called specific fevers it is the sole destructive agency. In consumption (which in temperate climates destroys nearly one-sixth of the population) it is the accompanying fever and its grade which determines the duration of the disease. Ninety cases in a hundred of pulmonary consumption die from asthenia long before the destructive processes going on in the lungs have deprived the patient of a sufficient amount of his respiratory apparatus to destroy his life. He dies not of apnœa but of asthenia. Even in ordinary inflammations it is usually the fever that kills and not the destruction of the organ inflamed; while the fever, although perhaps at first directly caused by the inflammation, reacts upon it, continues and intensifies it. . . .

Until a very few years ago we had but a single agent that could be used sucessfully as an antipyretic, and this was so uncertain and so irritating to the gastric mucous membrane that it often failed us, and still more frequently could not be tolerated in doses sufficiently large to do its work. Indirect antipyretics of great activity we possessed in veratrum viride, aconite and digitalis, but these were too energetically poisonous to be safely used on all occasions. Apyretics—that is medicines which increased heat loss—we had in abundance; but these could not be continued long, for although the nervous system may be protected from the directly injurious effects of heat, by them, they did not arrest the too active combustion going on and the patient died of exhaustion almost as soon as if left alone. We may heap ice on our steam boiler and thus prevent the formation of steam, or perhaps cause its recondensation as soon as formed, but we do not stop the consumption of coal in the furnace underneath. And so, too, we may by bathing, sponging or sweating keep down the temperature of the body externally, but the combustion is still going on internally, not quite so rapidly perhaps, but still at a sufficient rate in protracted fevers to produce final exhaustion and death. What we wanted then was something more certain and effective than quinine, less disagreeable to the stomach, and less injurious to the nervous system, and free from any poisonous effect, that would put out the fire by stopping combustion—an antipyretic.

This most desirable agent has been found in a substance discovered by Knorr, of Erlangen, Germany, which he named antipyrin. Early in November, 1884, I began its use in all diseases attended with fever, and my own estimate of its value may be inferred when I say that since that date I have not seen a single person die of enteric fever, scarlatina or measles, only one of croupous pneumonia (seen too late), and that the duration of cases of phthisis seems to be very nearly doubled. In acute inflammatory rheumatism it seems to be scarcely less efficient than sodium salicylate. The dose should be about one gramme, repeated at first every hour until three doses have been taken, and afterwards every three or four hours. It is very soluble in water, has a slightly pungent and bitterish taste and rarely excites nausea. If it should do so it may be given in lime water or combined with other alkalies.

Another substance belonging to this class of remedies has recently been brought to our attention under the name of acetanilid, and has been sold in some of the shops as antifebrin. From a few observations it has been found to be even more powerful in antipyretic action than antipyrin. It has the advantage of being very much cheaper than the latter, which is unfortunately a patented article; but it has the disadvantage of being entirely insoluble in water and alkaline solutions; and for children, therefore, who cannot swallow pills or capsules it is much more difficult of administration.

CARDIAC STIMULANTS.

During the past year two new cardiac stimulants have been brought to our attention, for one of which the valuable claim was made, that it energized the heart without increasing arterial tension. I have used the substance, which has been called strophantin, but have not been able to realize the valuable properties claimed for it. Spartein sulphate I have used in a single case only, but it produced in my patient such an intense, agonizing headache that I have not ventured to prescribe it a second time. It is hardly possible that we shall ever find a better remedy for all cardiac lesions than digitalis, which combines the two valuable powers of energizing the heart and stimulating the action of the kidneys at the same time.

PHTHISIS.

The etiology, prevention and cure of pulmonary phthisis must always be to us as well as to the people at large a subject of paramount interest. As already stated it is the cause of death throughout the temperate zones of our planet of nearly one-sixth of the population. It destroys more people probably than war, pestilence and famine combined. All the so called zymotic diseases together, including cholera, yellow fever, malarial fever, small pox, diphtheria, scarlatina and measles, do not destroy so many of our race as this deadly foe to human life. If an epidemic of cholera or small pox should break out in your city and produce an annual mortality one half of that produced by consumption alone, public indignation would be aroused against the inefficiency of your health boards, and millions of dollars would be expended in stamping out the pestilence. Yet this terrible pest is silently doing its deadly work but excites no public attention—no public protest against its ravages.

It was sincerely hoped that when Koch announced his discovery of a peculiar microbe in the lungs and sputa of tuberculous patients, and by experiment on some of the lower animals had, as he supposed, established an etiological relation between this microbe and tuberculosis, that one step had been made in advance towards preventing at least, if not curing, this dreadful disease. His discovery was hailed with delight, and his conclusions were accepted without question (and I might add, almost without reason) by a large majority of the ablest and oldest members of the profession. For a long time we heard of scarcely anything but the bacillus tuberculosus and the contagiousness of phthisis. In order to make facts conform to theories, even the able and rational views of Virchow and Niemeyer in regard to the nature of tubercle were discarded, and the older and cruder doctrines of Laennec were revived, that everything is tubercle that has or can undergo the caseous transformation or degeneration. The idea that the bacillus tuberculosis might be the special agent which attacks and destroys dead cellular masses that have undergone the caseous degeneration, whatever may have been their origin; just as the vibrio and its congeners attack pus; the yeast plant saccharine solutions, which in turn, when fermentation ends, is attacked by the bacterium of active fermentation; the oïdium albirans particles of putrefying milk in the mouth of an infant; and the micrococcus the plastic exudations of croup and diphtheria, was scouted by the followers of Koch as absolutely absurd. And yet, more recent and careful experiments seem to show that this is probably the truth, and that the bacillus tuberculosus is only pathogenic when previous pathological changes have produced the conditions favorable for the growth of the microbe, or the animal is placed under such conditions as to invite and cause those pathological changes.

The recent experiments of Dr. Truesdale, of New York, related in a paper read before the Climatological Society at its last meeting in Baltimore, show this, we think, with tolerable clearness. This gentleman took fifteen rabbits, which he divided in three equal groups. Five were inoculated with Koch's bacilli and placed in a damp, dark cellar and insufficiently fed on unwholesome food. They all became sick and died with tubercles. Five others were placed in a damp pit and badly fed, but were not inoculated with tubercle. One of these died and all became sickly. When killed no tubercle bacilli were found, and, as far as he could see, no tubercles. The last five were inoculated with tubercle bacilli and turned out on a rich pasture, with plenty of air and abundant, wholesome food. They remained perfectly healthy, and when killed showed no tubercles or bacilli. Sternberg's experiment several years ago showed virtually the same thing.

Now, what is the rational deduction to be drawn from these facts? That tuberculosis is a contagious

and infectious disease solely, and that the agent of this infection is the bacillus tuberculosis? Surely not, because even rabbits, who are more prone to tuberculosis than any other animal, except, perhaps, their congener, the guinea pig, cannot be infected by inoculation when placed in good hygienic conditions, and sufficiently supplied with wholesome food. But it may be said that other animals not reckoned among those liable to tuberculosis, as the dog and cat, have been infected with inoculations of bacilli. This is true, but in order to accomplish this the microbes must be introduced into a serous membrane, where they excite pain, fever and inflammations, usually attended with cellular exudations, which in turn undergo caseation; so that here, too, they find the conditions favorable to their growth. If tuberculosis is a contagious and infectious disease, it must differ from all other diseases of this class. Every one will take variola, or measles, or scarlatina, when sufficiently exposed, unless protected by vaccination in the one case or previous attacks in the others. Yet comparatively few take the tubercular disease, even in those regions where it is most abounding; and an occasional case occurs in regions where it does not abound, and where infection would seem to be physically impossible. And yet, man is preëminently a tuberculous animal, and far more human creatures die of the disease than of any other animals when left in their natural conditions.

But while denying, as I do, that the bacillus tuberculosis is the sole, or even a frequent etiological factor in initiating tuberculosis, I do not assert that it has no pathogenic significance. I have already expressed my belief that this microbe is the agent which destroys and breaks down matter that has undergone caseation, converting it into a semi-purulent, putrid mass, whose contact with the living tissues around it is sure to set up inflammatory and ulcerative processes, and whose absorption into the blood, with or without the bacillus, will lead to that general degradation and depravation of the circulatory fluid which is sure eventually to lead to certain quasi-inflammatory processes elsewhere of which miliary tuberculosis is a most frequent result, and cellular exudation an invariable one. To a person, therefore, who has had the misfortune to contract a catarrho pneumonia which has left behind it a cellular exudation into the alveoli of the lungs which has undergone the caseous degeneration; or even a so-called scrofulous gland which has undergone the same process, the introduction of the bacillus of Koch will be fraught with the most terrible consequences. That one may carry a caseous mass in his lungs for years, and yet enjoy fairly good health, is well known to all practitioners of long experience. I recall two such cases: In February, 1862, a soldier in the Confederate Army contracted a catarrho pneumonia from which he recovered with a permanent consolidation of the upper lobe of his left lung. Two years ago I had an opportunity to examine this man, and found the induration still there, but his health was fairly good. I have no doubt in the world that the introduction of the bacillus tuberculosis in this man's blood would at once set up pulmonary phthisis. The other was a ship carpenter in Baltimore, who for nineteen years had a complete induration of the lower lobe of his left lung, but still remained in sufficiently good health to follow that laborious occupation. At last, however, the mass began suddenly to break down, and he died in about four months from pulmonary phthisis. The case of this man was particularly interesting and instructive, as showing that the danger from bad hygienic surroundings, and especially from bad air, is even greater than the danger of direct contagion. He married a young woman who was then in good health and remained so for six years. At the end of that time she was attacked with uterine hæmorrhages which made serious inroads upon her health, and finally culminated in an attack of true miliary tuberculosis of the lungs which destroyed her life in about four months. Notwithstanding he occupied the same room and bed with his wife during her illness, he remained in his ordinary health for two and a half years afterwards, when, his business becoming dull, he obtained an appointment in the Maryland oyster navy as common seaman. Two months of sleeping in the fetid atmosphere of the dark, damp forecastle of his vessel brought on the rapid consumption which ended his life. While, then, it cannot be denied that infection may, and probably does set up consumption in those who have suffered either of the accidents I have mentioned (viz.: catarrho-pneumonia and scrofulosis), we must remember, after all, that it is bad hygienic surroundings which cause the pathological lesions which constitute the basis of fully 90 per cent. of all the cases of consumption we meet with, and invites the injurious action of the pathogenic microbe which brings to a fatal termination lesions which might otherwise remain quiescent for many years, and even be not inconsistent with a fair degree of longevity.

Here, then, is a field in which we can work for the good of our common humanity. Let us try to teach our people, in building our cities and towns, to avoid the construction of narrow alleys into which the sunlight never comes; that living in damp cellars and basements, where not only is ventilation impossible, but into which will infallibly gravitate the deadly carbonic dioxides exhaled by men and animals in the neighboring streets, which not only directly poison the nerve centres and produce deficient functional activity of all the glandular organs, but diminish the amount of oxygen inhaled, impairing the aeration of the blood, and thus causing pulmonary stasis which must end in some form of the pneumonic process.

BERGEON'S TREATMENT.

Acting upon the theory of Koch and his followers, that consumption is caused by a microbe in the alveoli of the lungs, numerous plans of treatment which have for their object the destruction of these microbes have been devised. All of these promise some success in the beginning, because it gives the unfortunate a new hope to cling to, and places them in a state of pleased expectancy which for a time buoys them up, and even reacts upon their morbid physiological processes. For no sick person is so hopeful as a consumptive. It is not surprising, therefore, that

these several plans of treatment should be precipitately heralded to the world as most pronounced successes.

The latest of these plans is that proposed by Dr. Bergeon, of France, who, in the latter part of 1886, announced that he was curing consumption by injecting into the lower bowel a mixed gas consisting of sulphuretted hydrogen and carbon dioxide. The theory upon which this treatment is based is that this gas is absorbed through the intestinal mucous membrane and exhaled through the pulmonary surfaces, and, coming in contact with the pathogenic microbes there, destroys them. Dr. Bergeon must have forgotten that these microbes are not found in the alveoli free from disease, and where, if at all, the gas must be exhaled, but in the solid tubercular masses occupying these air sacs, into which the gas can hardly penetrate, and from which no exhalations take place. Even then, admitting that his mixed gases can destroy the microbes, which seems highly improbable, in view of the fact that they are continually exposed to an atmosphere so highly charged with carbonic dioxide that its retention in the lungs for five minutes will produce unconsciousness, it is not clear how they are to reach the objects intended to be destroyed. Accordingly, we find that in other hands the plan has proved to be a wretched failure. As physician to Bayview Asylum (the Baltimore city almshouse) I have given the plan a fair trial in several cases, and I can report nothing in favor of the treatment. One case was, I thought, injuriously affected by it, and died apparently a little sooner than if he had been left alone. While the antiseptic, or rather the aseptic, treatment may have a certain value in surgery and obstetrics, in medicine it must always remain an impossibility. For, admitting all that is claimed as to the agency of microbes in setting up and keeping up disease processes, it must be remembered that they are biologically as high in the plane of life, and if all experiments can be believed, have a higher resisting power than the cells which compose the living elements of our tissues. Any germicide, therefore, which can destroy the one, must inevitably also destroy the other.

In conclusion, I desire to call attention to what I consider to be a vicious custom that has grown up among the chairmen of our Sections. When elected to this position last year at St. Louis, I was surprised to be told that I and the Secretary of the Section were expected to write letters to prominent members of the profession throughout the country requesting and urging them to write papers to be read before the Section; and that it is a common practice pursued by all the chairmen. It occurred to me that by this course I might secure a large number of papers, possibly, but from gentlemen who, wishing to please, would write something under stress, and not because they had anything which they really wished to communicate to the profession. Years ago, when the membership of our Association was small, this practice of inviting contributions may have been necessary; but now, when our membership runs high up in the thousands, these solicitations ought to be unnecessary. There must always be, among the four thousand odd members, a sufficient number who have, or think they have, something which they wish to tell and which is worth hearing. I have therefore ignored the old custom, and have not written a single letter soliciting contributions. The result has been that we have more papers than the Section can possibly read and discuss, and which have the advantage of being entirely spontaneous, and inspired only by the enthusiasm and energy of their authors.

ORIGINAL ARTICLES.

CONTRIBUTIONS TO THE CLINICAL HISTORY OF SYPHILIS.

BY H. GRADLE, M.D.,
OF CHICAGO.

(*Concluded from page 652.*)

The following case has but an incomplete record, but the past history and the array of symptoms presented by the patient give it some clinical interest. The diagnosis of syphilis was disputed by the patient, but seemed to be inevitable.

Case 3.—Persistent headache for months, with nocturnal exacerbations. Repeated transient attacks of hemi-paresis. Sudden blindness receding spontaneously. Paralysis of branches of the oculo-motor, and some other cerebral nerves.

History.—A. W., a laborer. æt. 32, had always been in good health, with the exception of malaria in 1878 and a short relapse in 1879. He denies syphilitic infection strenuously, but admits of having run the chances of it during his youth. He has two healthy children. He has never smoked or drank to excess. Eight months ago he was attacked by severe frontal headache lasting almost steadily, and always worse at night. About five weeks ago this became more limited to the left side, and has since diminished gradually. He has suffered from sleeplessness, but is better now. Four months ago he felt a sudden weakness of the left side of the body, which passed off soon, but recurred four times the same day. Since that time he has had some dizziness occasionally. Two months ago, while at work, his sight failed him almost completely. He had to grope his way, but did manage to get home without guidance. The left eye recovered in three or four days. The sight of the right eye improved likewise, but is even yet not quite normal. As his sight returned, objects appeared to him double, for which annoyance, principally, he consulted me. At first the right eye could not be opened fully on account of weakness of the lid. This trouble has now passed from the right to the left side.

Present Condition.—October 19, 1886. The eyes appear normal externally and the pupils respond to light. The left eye has a V. $\frac{20}{35}$, normal field, color and light sense. Ophthalmoscopically, the only peculiarity is tortuosity of the retinal arteries. Otherwise the disc, retina and vessels are normal, which is also true of the right side. The retinal arteries, however, appear a trifle narrower in the right eye

than in the left. The refraction in both eyes is that of very slight hypermetropic astigmatism. Field and light-sense are normal in the right eye, but colors appear dimmer than with the left eye; they are, however, correctly seen. V. is $\frac{2}{5}\frac{0}{0}$, undoubtedly on account of a faint corneal opacity dating back to childhood. Yet the visual power is not normal in either eye, for the patient cannot read more than a few lines with either eye, the other being covered, before everything becomes misty, even with convex glasses. Especially is this true of the right eye. On the left side there is incomplete ptosis and paralysis of the superior rectus muscle; the right superior rectus is merely paretic, but still obeys some. But the right external rectus is entirely paralyzed. Although the right eye can turn towards the left side on looking to the left, it does not move at all during efforts at convergence.

The patient is a muscular man who has, however, lost in strength and in weight to the extent of some twenty-five lbs. since the disease began. Besides the paralysis of the ocular nerves he presents slight paresis of the labial and nasal branches of the right facial nerve. The tongue deviates to the left side. The palate is normal in its movements. Apart from the general weakness there exists no other muscular disturbance. The knee-jerk is, if anything, exaggerated on both sides. His sexual power and desire have gradually failed, and are now gone entirely. There is no sensory anomaly.

The heart and, as far as could be learned, all other visceral organs, are normal. He is somewhat constipated, but seems to feel no direct effects from it. His urine, of a sp. gravity of 1023, is chemically normal, but has an abundant but very delicate precipitate, which consists microscopically of fragments of structureless pliable membrane, to which the stained amorphous urates cling. The significance of this deposit I have not been able to learn.

The patient was put upon iodide of potassium, 1.3 four times a day, and one dose of calomel was given for the bowels. Two days later there was no change, beyond slight increase of the ptosis of the left lid. Mercurial inunctions were now begun twice daily, and quinine ordered three times per day, in the dose of 0.3 grams. To keep the bowels regular, sulphate of sodium was to be taken in hot water on rising. Four days later he showed a decided improvement in his malaise, headache, sleeplessness and general condition, but objectively there was no change. For the quinine, strychnia was now substituted to the extent of 3 milligrams twice a day. He was seen the last time on November 4, *i. e.*, after 16 days of treatment, when he felt better in every way subjectively, but was anxious to have his diplopia cured. He was told that this could not be promised with certainty, as the lesion might possibly be irreparable on account of the duration of the disease, but that he could go to work if he felt strong enough. He was ordered to continue the iodide of potassium and strychnia, and to suspend the mercury. But he did not return after that day.

Although the patient did not remember any syphilitic infection or symptoms, and no characteristic lesions could be found externally, I believe that the continuous headache, worse at night, the apoplectiform attacks without loss of consciousness at the age of 32 years, the exaggerated knee jerk, and the multiplicity and changeability of the pareses of the ocular nerves, admit of no other diagnosis but gummatous meningitis, probably with extensive syphilitic disease of the cerebral arteries. He was markedly benefited, as far as comfort and subjective feeling were concerned, by the antisyphilitic treatment, though no objective change occurred. But, whatever way the various nerve-paralyses of the ocular and facial nerves were produced, they had probably led to partial degeneration by the time I saw the patient. The recovery, if at all possible, could hence not be expected within any short period of time. According to the patient's statement he had probably had some iodide of potassium from another physician before I saw him. But of this I am not certain. The data do not seem to me sufficient to determine accurately which particular lesion caused the sudden transient blindness. There was nothing visible in the eye to indicate its character. The tortuosity of the retinal arteries may have preëxisted. The veins were certainly normal. Of special interest is the dissociation of the two nerve paths controlling the internal rectus muscle of the right eye. Although the patient could turn the right eye freely towards the left, he was not able to perform the same movement on attempting to converge the two eyes for an object approaching in the median line. The symptom suggests an encroachment of the disease upon the nuclei of the ocular nerves beneath the third ventricle, for it is there only where the nerve tracks of convergence and of independent action of the internal rectus are separated from each other.

The following two cases would not present any features of special interest had the syphilis followed its ordinary clinical course. They illustrate, however, the occurrence of very late tertiary symptoms after unusual mildness or absence of earlier symptoms. Hence their diagnostic value.

Case 4.—Gumma at the Root of the Tongue. Mr. S., æt. 32, had noticed for some two months some irritation of the lower part of the throat, lately amounting to pain on swallowing, with radiation of pain towards the ears. He had always enjoyed good health. On December 12, 1885, I found his ears normal. There was slight hypertrophic catarrh of the pharynx, but on looking down with the laryngoscope there was seen a flat nodule, about the size of an almond, at the root of the tongue just in front of the epiglottis. It had about the color of the mucous membrane in that region, but its centre was ulcerated, with steep edges. It felt hard to the finger. No enlarged glands could be detected under the jaw. Was it epithelioma, gumma, or, less likely, tubercular infiltration? The patient, perfectly honest and thoroughly frightened, knew nothing of previous syphilis, and he seemed to be sufficiently self-observing to entitle his judgment to credit. He had had a gonorrhœa during his youth, but never anything else. Moreover, his wife and child were healthy.

Dr. Fenger was asked in consultation, but he, too,

was unable to decide the diagnosis absolutely. He advised, however, antisyphilitic treatment, until he could examine microscopically a bit of the nodule which he snipped off at the time. Mercurial inunction and the use of iodide of potassium to the extent of 1.5 four times per day were at once begun. Within three days the diagnosis was assured by the subjective improvement of the patient, the report of Dr. Fenger of finding the tumor to be a granuloma and the recollection of Mr. S. that some years ago he had had persistent pains in the bone of the leg. However no nodes could be found on the tibia. The steady improvement now continued until the gumma entirely disappeared in the course of three weeks.

Case 5.—Gummatous Infiltration of the Soft Palate. Mr. B. has complained for several months of obstruction of the nose, loss of smell, discomfort in the palate and throat, sometimes slight pain and lately obstruction of the right ear and dimmished hearing. He is 32 years old, has never been sick since childhood and has a healthy wife and child.

Present Condition.—Nov. 1, 1886. The ears, especially the right one, show the effect of closure of the Eustachian tube. The use of the catheter relieves subjectively and improves the hearing, and I may as well add at once that daily catheterization rendered the ears perfect in a fortnight. The nasal mucous membrane was reddened, the passage narrowed by enlargement of the cavernous tissue. The rear part of the inferior meati was filled with crusts, not however presenting the smell of ozæna. The rear of the nose could not be examined very fully on account of the narrow configuration. There was some hypertrophic catarrh of the pharynx. The soft palate was swollen in its central part and congested, but the livid color indicated venous stasis rather than arterial hyperæmia. There was no tenderness indicative of an abscess. At the juncture of the front and rear pillars of the palate on the right side there was a small ulcer. The patient was so sensitive and inclined to vomit, that the rhinoscopic mirror could not be used then and even later on it was so disagreeable to him that I did not make any further attempts.

I could but diagnosticate an infiltration of the soft palate, probably of syphilitic nature, with consecutive irritation of pharynx and nose. But the patient had absolutely no syphilitic history. Both from personal acquaintance, and his evident anxiety, I feel confident of the correctness of his statements. Moreover, there were no other objective evidences of the disease. I concluded to wait a few days, using in the meantime the Eustachian catheter, the post-nasal syringe, an insufflation of nitrate of silver followed by iodoform, and directing him to wear absorbent cotton in the nostrils to prevent the formation of crusts. He improved in comfort but during the next week the infiltration of the soft palate increased, the ulcer over the right tonsil deepened into a fistula about 1.5 centimeter deep and two other small ulcers appeared on the oral surface of the palate. I now ordered inunctions of mercury and four grammes of iodide of potassium per day. The patient delayed this order a couple of days, during which time the ulceration and infiltration of increased. On Nov. 11, he began the specific treatment and within three days its influence was noticeable. About one month later the parts were practically normal. The local treatment had been continued two to three times per week and had no doubt caused the nasal and pharyngeal catarrh to disappear at the same rate as the gumma, since its omission during several days was always noticeable to the patient.

When did these two patients acquire syphilis? For I fully believe their ignorance of the disease. There was not the least indication of congenital disease on the skin, teeth or eye, and nothing suggesting this view in their own or their family histories. Perhaps infection occurred accidentally during childhood, followed by a very benign syphilis as it is often observed in children. Possibly they may have had chancres too insignificant to be noticed, and not followed by secondary symptoms. I have seen two cases of typical hard chancres not followed by secondary consequences. Believing fully in the dual nature of venereal sores, I would not speak of these as hard chancres had they not presented all the characteristic appearance, viz., indurated base, indolent ulceration not progressive in extent, and a long period of incubation after suspicious intercourse. These cases can be briefly detailed.

Case 6.—Gonorrhœa one week after intercourse. Typical hard chancre in the uretha one inch behind the orifice occurring during the second week of the gonorrhœa and lasting about two weeks under iodoform insufflation. Painless induration of the inguinal glands. No Syphilis. This happened to a young man in 1881. I have since seen him socially and professionally very often, and can vouch for his present health. He married one and a half years later and his wife and two children are healthy.

Case 7.—Typical hard chancre behind the glans about twelve days after intercourse. Slight induration of the inguinal glands. No Syphilis. The patient had been circumcised and there was no chance for a clean excision of the chancre. It lasted about twenty-five days. As he is a married man I explained to him the great responsibility. This happened in Feb., 1885, and I have since watched him in vain for syphilis. He has remained free to date.

Will these two patients ever present tertiary symptoms?

Although I see but rarely any patients with syphilis except it involves the eye or ear, it may be of interest to detail my limited experience in the abortion of syphilis by excision of the initial lesion. I have done this five times. One case was a failure. Four were followed by unqualified success. The operation is simple enough when anatomically feasible. I have operated of course antiseptically and used sutures where the edges of the small wound gaped.

Excision of Chancres.—Case 1.—Dispensary patient of whom no full record was kept. Man 23 years of age. Typical hard chancre on the rather short prepuce near the frenulum which was excisd in September, 1877. No (?) buboes. Union by first intention. Seen of and on during the next three months during which time no secondary symptoms appeared.

Case 2.—Mr. B., circumcised, contracted a hard chancre on the scrotum two weeks after exposure. Excised on the fourth day (July 3, 1880). The wound reopened in spite of stitches and changed into a characteristic chancre, which required five weeks to heal. Three days after excision a bubo appeared in the left groin. Six weeks after the operation roseola and sore throat indicated constitutional syphilis.

Case 3.—Mr. S., a married man of 48 years of age, observed a pimple on the prepuce three weeks after an illegitimate intercourse. On the sixth day of the disease I found a flat nodule of the size of half a pea with funnel shaped ulcerated centre and well marked induration. No buboes. Excision. (July 19, 1880.) Wound became ulcerated and assumed appearance of a large hard chancre which healed slowly by the middle of August under the use of iodoform, but not until it had been cauterized with nitric acid. A soft chancre was excluded by the hardness of the base and the absence of any progressive ulceration. No buboes formed. The patient observed himself closely and came often for examination during the next three months. I have seen him a number of times since and have never found any evidence of syphilis.

Case. 4.—Mr. M. had had a gonorrhœa since six weeks. He was about well when he exposed himself again two weeks ago. This rekindled the urethal discharge and produced an inflamed and tender bubo on the *right* side. Since six days (about eight or nine days of incubation) he detected a pimple on the *left* side of the frenulum on the foreskin (which had been circumcised at birth). At the time I saw him (Feb. 8, 1884,) this pimple had developed into a typical hard chancre. In the left groin four or five very small but hard glands could be felt which he thought had always been there. Excision. The wound did not close entirely by first intention, but remained healthy and aseptic under iodoform. Within a week it was healed. But the bubo on the right side began to trouble him so that he went to a hospital, where it was opened. This suppurating gland being on the other side of the median line, could not have been started by the hard chancre, but must be attributed to the gonorrhœa. I saw the patient various times while in the hospital, where he stayed five weeks, and again in October the same year, without finding any evidence of syphilis.

Case 5.—Mr. T. complained of discomfort and an oozing from the penis two weeks after intercourse, and called on me about three days later. The prepuce was long and tight and could be stripped back only with difficulty. On its inner surface near the edge there was an ulcer with hard base and all appearances of a hard chancre. After washing with corrosive sublimate solution ($\frac{1}{10}$ per cent.) I returned the foreskin over the glans, applied pellets of cotton moistened with cocaine solution to the mucous surface, and without much pain to the patient removed the chancre by performing ordinary circumcision, closing the wound with a few stitches. There were no buboes at the time (Jan. 13, 1885). The wound did not heal entirely by first intention, but did not become hardened or unhealthy in appearance. It was closed by Jan. 30. The patient fully warned as to the significance of syphilis should any symptoms occur, did not return to my office until April, 1887, for some other complaint. He had not had any indications of constitutional syphilis.

Typical hard chancres not followed by constitutional syphilis, as in cases 6 and 7, occur too rarely to explain the success of this small series of excisions.

TREPHINING IN A CASE OF INTER-MENINGEAL HÆMATOMA, WITH HEMIPLEGIA. RECOVERY.

Read in the Section on Surgery and Anatomy, at the Thirty-Eighth Annual Meeting of the American Medical Association.

BY S. T. ARMSTRONG, M.D., PH.D.,

PASSED ASSISTANT SURGEON U. S. MARINE HOSPITAL SERVICE.

In presenting to this Section the history of a single case, it is hoped that the interest attached to the subject of cerebral localization from a surgical standpoint, as well as the comparative rarity of recorded operations for the conditions herein reported, will prove to be sufficient excuse for soliciting your indulgence.

Case.—George Jones, negro, aged 53 years, a native of Virginia, shoemaker by occupation, on February 27, 1887, was struck on the left forehead by a brick, the edge of the missile producing an irregular, lacerated wound, about one-half an inch above the external edge of the eyebrow. He was unconscious for a short time; cold water dressings were applied to staunch the hæmorrhage from the wound, and he was put to bed.

I was called to see the patient on the morning of February 28, and found his general condition good, but the wound unpromising on account of being filled with dirt particles acquired from the brick. Probing detected no denudation of, or other injury to, the skull. The wound was cleansed as much as possible, and dressed antiseptically. There was no subsequent malaise, though slight annoyance from roaring in the left side of the head; he walked half a mile to my office, when subsequent dressings were required; and the wound having healed by granulation, he was discharged, recovered, on March 14.

He consulted me again on April 24, stating that the roaring in the head had continued, and that on April 18, while walking, he suddenly noticed a tendency of the right foot to drag slightly. On the 19th, while eating breakfast, his head fell forward on the table, and his right arm and leg seemed paralyzed; that morning he had a slight chill followed by fever. Since the 19th, the right foot dragged a little more, and he would notice an occasional loss of control of the muscles of the right leg and arm.

At this examination the presence of *arcus senilis* was noticed; the pupils were small, but responded well to light. The right ear heard the watch at six inches; the left at three. The tongue was protruded straight, and the facial muscles were not involved. The heart's action was regular; pulse 90, tense, and

arteries rigid. Muscular power of hands (tested by my own, no dynamometer at hand) the same. Either from dulness of the patient, or the existence of slight anæsthesia, no satisfactory results were obtained from the æsthesiometer. In walking he drags the right foot slightly. On April 26, the paralysis of the lower extremity was more marked, and on the 28th the right arm was found to be less powerful than the left. The symptoms, as presented, had evidenced a cortical cerebral lesion, affecting the middle frontal convolution (which lay beneath the site of the original injury) and extending upward and backward gradually involving the ascending frontal convolution. The lesion seemed thus circumscribed because if it involved the inferior frontal convolution there would have been aphasic symptoms present.

In view of the chilly sensations every morning, the septic character of the wound, and the slow but late development of the hemiplegia, it seemed probable that septic matter had been absorbed, and an internal purulent inflammation developed. The condition was carefully explained to him, and an operation advised as a *dernier ressort*. On April 29, Dr. Nalle, of Memphis, was called in consultation, and he agreed in the necessity for an operation. Dr. J. L. Minor made an ophthalmoscopic examination, and found: "the right eye, optic nerve red, border indistinct, vein large and slightly tortuous—diagnosis, low grade of optic neuritis; left eye, optic nerve red, border indistinct, prominent from œdematous infiltration, veins large and tortuous—diagnosis, optic neuritis."

On May 1, assisted by Drs. J. L. Minor and R. M. Pate, of Memphis, the patient having been bathed, bowels vacuated, scalp shaved, etc., chloroform anæsthesia was produced, and a curved incision made, the convexity towards the eyebrow, and the incision extending upwards on the scalp so that, if necessary, it could be continued to a point over the upper portion of the ascending frontal convolution; if the operation demonstrated no lesion over the middle frontal convolution, and trephining would have to be repeated higher up. Some time was spent in controlling the free hæmorrhage resulting from the incision; the periosteum was eventually reflected, Galt's trephine applied, and the button of bone removed. A small branch of the meningeal artery presented on the dura-mater, and hæmorrhage from it was controlled by applications of hot water.

No intra-cranial fracture of the bone was found. The dura-mater was dark colored, and had no communicated pulsation from the brain. The long needle of a large sized hypodermic syringe, was passed through the dura-mater, and on withdrawing the piston the chamber of the syringe was filled with dark brown blood. Removing the needle similarly colored blood was ejected from the puncture in the dura mater, and with a bistoury the hole was slightly enlarged, permitting the pulsations of the brain to throw out the fluid in larger quantities, until it was almost evacuated. Four strands of disinfected horsehair were passed through the dural incision in order to secure drainage, boracic acid applied to the wound, the flaps replaced, a layer of absorbent cotton loosely covered it, and bandage applied. The operation had lasted an hour, and several times hypodermatic injections of brandy were given. The patient seemed to be quite weak at the completion, and he was ordered brandy every half hour. At 7:30 o'clock in the evening he was visited: the dressings were stained with dark blood discharged from the meningeal space. He was feeling perfectly comfortable, his pulse was 72, temperature 98.6° F., and his muscular control of the right arm and leg *had returned*. Morph. sulph. gr. ⅓ at bed time.

May 2. He reported having rested well during the night. No pain in the wound. Pulse 78, temperature 98.4°. Had eaten a light breakfast. He was kept quiet—in bed—for a week; the wound was dressed every third day; and on May 8, he sat up, and was able to walk about the house with undiminished muscular control. No untoward symptom subsequently presented, the man being now as well as ever, A microscopical examination of the blood withdrawn by the syringe showed it to consist of a brown colored serum and colorless red blood corpuscles. It seemed devoid of fibrin ferment, as it did not coagulate.

In regard to finding blood, instead of pus, this corroborated the dictum of Nancrede (International Cyclopædia of Surgery, Vol. V, p. 50): "A differential diagnosis can, under the most favorable circumstances, be only probable, and in most instances impossible."

Pathologically the case is still obscure, and the comprehensive term of inter-meningeal hæmatoma was adopted as most closely covering the condition as evidenced. Agnew (Surgery, Vol. I, p. 287) explains the condition as "a vascular paralysis so modifying the vital properties of the walls of the blood-vessels of the brain, as to favor the free escape of their liquid contents." Considering the non-coagulability of the blood—and had the hæmorrhage been from a ruptured vein or artery, clot would have been present—this explanation is worthy of consideration. Pachymeningitis would have presented somewhat identical symptoms, as in the case of Professor Grainger Stewart referred to below.

The literature of this subject is scanty, though the surgical popularity of trephining from most ancient times is well-known, and it is scarcely improbable that similar cases have presented earlier symptoms of compression and have been successfully operated upon. Indeed, Kurt Sprengel, in the elaborate history of the operation, refers[1] to Meekren (circ. 1519), Binninger (circ. 1673), Jean Murat (1711), Jean Jacques Wepfer (1717), Jean Maurice Hoffman (1719), and Laurant Heister (1758), having trephined for the relief of effusion in cases of injury to the head without fracture of the skull. Nancrede (op. cit.) refers to successful operations by Morand (Opusculi de Chir., Paris, 1768. T. 1. p. 171), Ogle (Brodie, *Med-chir. Trans.*, Vol. XIV, p. 391), and Bruns (Handbuch der prehtisch. Chir. Ab. I, S. 931). Dr. Physick, in the latter part of the last century, in a case of contusion of the head without

[1] Histoire de la Médecine, Traduite par Jourdan. Paris, 1815. T VII, p. 25, et. seq.

evident fracture, trephined for the relief of cerebral symptoms, extracted a blood clot, and the patient recovered.

In contemporary literature Jones, (*Lancet*, 1881, II, p. 40), in a male, aged 19, in whom insensibility, convulsions, and paralysis of the right side, followed a fall on the head, trephined over the middle meningeal artery. Death followed. Necropsy showed tear of longitudinal sinus.

N. Weljaminow (*St. Petersburg med. Wochen.*, 1881, VI, p. 455–7) reports a successful case of trephining for intra-cranial hæmorrhage. And Weir (Gross' Surgery, Vol. II, p. 44), trephined for relief of coma and slight hemiplegia, removed a clot between the brain and dura. Death in a few days.

Sylvestrini (*Bull. de l' Acad. de Méd., Paris*, 1883, p. 439), reported a case of kick from a horse over the right temporo-frontal region of a boy aged 15. Two months after the injury, temporary right hemiplegia. Five months later, paralysis of right arm and leg and lower part of right side of the face, complete aphasia, incontinence of urine and fæces, right hemi-epilepsy. He trephined over the centres for the upper and lower extremities, extracted piecemeal a hard organized clot. Patient died on fourth day from purulent meningitis and brain abscess.

Hulke (*Lancet*, 1883, Vol. II, p. 814), in a case of blow over the right temple followed by right hemiplegia and coma, and later spastic rigidity of the left arm, trephined and evacuated inflammatory fluid by dural incision. The cerebral symptoms disappeared and the patient recovered.

Surgeon Major J. Ewart (*Ind. Ann. Med. Sci.*, Calcutta, 1873–4, XVI, p. 165), trephined to relieve symptoms of extravasation of blood in a case of injury to brain caused by a fall from a horse. Partial relief of symptoms; death of patient.

Bryant (*Lancet*, 1884, Vol. II, p. 823), in a case of scalp wound followed by brain symptoms, trephined on the thirteenth day affording temporary relief, but the patient died on the twenty-fourth day after the accident, from meningitis and bronchopneumonia.

Grainger Stewart (*British Med. Jour.*, Vol. 1, 1887, p. 877), in the case of a man who fell, striking the head, slightly wounding the scalp, but suffering no inconvenience for two weeks, when severe headache commenced, and later feebleness of legs and staggering walk succeeded by right hemiplegia, trephined two months after injury over posterior part of third left frontal convolution. Incising the dura-mater a hæmorrhagic effusion was evacuated. Motor power returned after operation. The patient died on the sixth day of leptomeningitis.

This list is possibly incomplete, including only reports of such cases as were accessible. However, they demonstrate that in cases of injury to the head, without injury to the skull, in which late symptoms of cortical brain complications appear, the locality of the trouble may be ascertained by the rules of cerebral localization, and operative interference will offer hope of improvement if not of complete recovery.

MEDICAL PROGRESS.

Antipyrin and Antifebrin in Headache and Epilepsy.—In a paper on this subject Dr. Allen McLane Hamilton says: In January last Ungar related his experience with antipyrin in the treatment of hemicrania, and in March Dr. C. B. Lyman, who had been induced to try the remedy after the publication of Ungar's success, administered it in several cases of neuralgia of the cervical, facial, and supra-orbital or mixed varieties, with more or less benefit. The first of these observers experimented with it as a successor to the salicylates, which have proved to be of great value in his hands in several varieties of headache, and he witnessed no evil results from doses of even 23 grains. Lyman used an initial dose of 15 grains, repeated two or three times if necessary, and relieved the paroxysms, but did not prevent their recurrence. In March last I began a trial of this drug, and afterward its successor, antifebrin, in a variety of headaches, in insomnia, and in epilepsy. Some of these cases had been treated with more or less success with the salicylate of sodium, and the usual remedies, and the cases of epilepsy were under modified bromide or other treatment. The cases of headache selected were those of migraine of angeio spastic and angeioparetic varieties, as well as ordinary facial or suboccipital neuralgias; and the cases of epilepsy which were chosen were those of the symptomatic form complicated with objective and subjective indication of cerebral disease, as well as the simpler forms which seemed to be dependent upon continued states of cerebral ischæmia, cerebral instability, etc.

In angeio spastic migraine with evidences of cutaneous anæmia, dilated pupils, and coldness, the headache commencing in the morning, I found both antipyrin and antifebrin would quickly abort the paroxysms after the first dose.

In four cases of epilepsy in which either antipyrin or antifebrin was used there was some improvement in three of the cases, in each of which there was post epileptic headache; and aggravation of the disease in the fourth, the patient's paroxysms being symptomatic of coarse cerebral disease. In one case of pure hystero-epilepsy the beneficial action of the remedies were absent.

I have also used both drugs in cases of habitual insomnia in doses varying from 3 to 8 grains of the antifebrir, and 10 to 20 of the antipyrin, without appreciable result, though in a case of maniacal excitement, due to nervous exhaustion and connected with moderate rise of temperature (102° F.), 15 grains of antipyrin repeated twice produced refreshing sleep and a subsidence of excitement. There can be no doubt, however, that in wakefulness due to general disease, especially with high temperature (and I have seen such), the value of both of these drugs as hypnotics is very great.

It would seem as if both remedies were of value in headaches or cerebral states attended by anæmia, or in the excitement due to cell mal-nutrition and exhaustion; and, though antipyrin seems to be the

more serviceable remedy, it possesses drawbacks which do not belong to antifebrine. It would appear as if the remedies were valueless or even harmful in cases of organic or symptomatic epilepsy, but worthy of a trial in the light cases attended by rather general cerebral vascular spasm and not much muscular movement. In several cases of *petit mal* the good effect of continued doses of antipyrin and antifebrine is manifest, for the losses of consciousness are far less frequent than when the patients were under other treatment. So far as tolerance goes, I have given to one patient 45 grains of antipyrin in two hours without ill effects.—*N. Y. Medical Journal*, May 28, 1887.

CARBOLIC ACID INHALATIONS IN WHOOPING COUGH.—In the *Deutsche Med. Wochenschrift*, No. 21, 1886, DR. R. PICK, of Koblentz, published several cases which seem to show that the inhalation of concentrated carbolic acid solutions has a powerful curative action in whooping-cough. Dr. Kniaziolucki, of St. Zofia's Hospital in Lvov, in Galicia, (*Wiadomosis Lekarskie*,) No. 3, 1886, p. 82), accordingly tried the same method in a severe case of his own occurring in a weak, emaciated, febrile girl, aged 9. The affection had lasted for about four weeks, and the paroxysms occurred about twenty-eight times a day. The inhalations of carbolic acid, either pure or diluted with an equal amount of distilled water, were repeated hourly, the administration being continued for ten minutes on each occasion. The number of paroxysms during the subsequent days fell to 20, 19, 12, 12, 6 respectively, and from the sixth day of the treatment the patient had not a single attack. The temperature became normal on the third day. After ten days' stay in the hospital the girl was discharged quite well. No poisonous symptoms were observed either in this case or in those related by Dr. Pick. Equally satisfactory results were obtained by Dr. W. Jakobski, of Odessa (*Wiadomosis Lekarskie*, No. 9, 1887, p. 280), who used a 50 per cent. solution of the acid, the inhalations being carried out for ten minutes every two hours. In one of his cases the daily number of paroxysms fell rapidly from thirty-two to six. Dr. Jakobski differs from Pick and Kniaziolucki only as regard the details of the method. They principally employ a mask resembling that used for giving chloroform; this is placed over the patient's nose and mouth. Dr. Jakobski, on the other hand, finding that this apparatus frightened children and led them to resist the application, devised an instrument like a toy, consisting of a pastboard tube with gold paper gummed over it, and fitted with a handle. Within the tube are two thread nets, and between them a layer of Bruns' cotton-wool, which is moistened with the carbolic solution. Jakobski found that with this there was no difficulty in getting the little patients to take the inhalations.—*British Medical Journal*, April 30, 1887.

IODOL IN LARYNGEAL TUBERCULOSIS.—In the *Journal of Laryngology* for February, 1887, LUBLINSKI's conclusions are given as follows: Iodol is scarcely soluble in water, but is dissolved by alcohol and ether. Schmidt proposed a mixture of iodol, 1 part; alcohol, 16 parts; glycerine, 34 parts. This is, however, too weak. Lublinski has used the powder pure for laryngeal insufflation. It causes no pain or cough, and it remains a long time in contact with the surface. He has used it in the treatment of fifteen cases of tuberculosis. He administered one insufflation daily, or, in some cases, two or three times a week. Under its influence ulceration quickly heals, the base becoming clean and granulating, dysphagia disappears, and the patient's health improves. Tannin, boric acid, lactic acid, and other applications will produce this effect, but not so rapidly as iodol, the action of which is striking. He gives details of two cases of tuberculosis in particular, in which iodol produced rapid curative effects. In both there was extensive ulceration. The author also regards iodol as useful in ozæna and scrofulous rhinitis, with ulcers on the septum.

JÁMBÚL SEEDS IN DIABETES.—In 1883 Mr Banatrala called attention to jámbúl as a remedy in chronic diabetes. DR. GEORGE C. KINGSBURY thinks the drug has not received as much attention from the profession as it deserves. The seeds are the product of *Eugenia jambolana*, and must not be confounded with "jumble heads" or jequirity seeds, an infusion of which was introduced a few years ago as an application for granular lids.

He lately tried powdered jámbúl seeds in a case of diabetes in which the patient had been ill for over six months, was greatly emaciated, and quite prostrate. He was suffering from great thirst and ravenous appetite; there was also great restlessness. The urine had a specific gravity of 1040 to 1042, and from seven to seven and one half quarts were passed in the twenty four hours. Five grains were given six times in the twenty-four hours for a fortnight. At the end of that period, the patient was able to get up, and walk out for an hour at a time, was neither thirsty nor abnormally hungry, and was passing four to five quarts of urine of a specific gravity of 1020; he could sleep well, and felt strong. During the time he was taking the jámbúl his diet was not restricted in any way.—*British Medical Journal*, March 19, 1887.

IODIDE OF SODIUM.—Iodide of sodium is considered by DR. RICHARDSON as a valuable substitute for, or adjunct to, iodide of potassium. In chronic eczema and painful rheumatic affections it often answers well when iodide of potassium does not agree with the digestion. Combined with arsenic it is useful in lepra and psoriasis. Externally applied, in cases of indolent ulcer, chronic syphilitic sores, and offensive discharges from the nostrils, it acts as a good antiseptic. The following is a useful formula for the purpose: Sodium iodide, ℥ss; tincture of myrrh, ℥i; rectified spirit, ℥ii; distilled water, ℥vi; to make a solution of eight ounces. Used in the form of fine spray from Seigle's steam spray-inhaler, Dr. R. found it of the greatest service in a case of syphilitic ulceration of the fauces.—*Provincial Med. Jour.*, Mar. 1, 1887.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

The Editor of this Journal would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

Subscription Price, Including Postage.

Per Annum, in Advance.....$5.00
Single Copies.....10 cents.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in registered letters.

Chicago, Illinois.

SATURDAY, JUNE 18, 1887.

AMERICAN MEDICAL ASSOCIATION.

The thirty-eighth annual session of the American Medical Association, held in Chicago, June 7 to 10 inclusive, proved to be one of the largest, most pleasant, and most profitable that has been held during the history of the Association. The large auditorium of Central Music Hall was full to overflowing during the general meetings, and the several Section rooms were better attended and supplied with more interesting papers than usual. The aggregate number in attendance was not only unusually large, but it embraced members from almost every State and Territory in the Union. Instead of being substantially a Western gathering, there were present a fair number of representatives from every State east and southeast from Maine to Florida, except Delaware, and from all other States except Oregon in the extreme Northwest. The quantity and quality of the scientific and practical work accomplished will compare favorably with that of any preceding meeting; and the evening receptions, both general and private, were well arranged and appeared to give entire satisfaction to those for whom they had been prepared. The following officers were elected for the ensuing year: President, A. Y. P. Garnett, of Washington, D. C. Vice Presidents—Duncan Eve, of Nashville, Tenn.; David Collville, New York; Charles O'Hagan, North Carolina; and A. Stedman, of Colorado. Permanent Secretary—W. B. Atkinson, Philadelphia. Assistant Secretary—Jos. Ransohoff. Cincinnati. Treasurer, Richard J. Dunglison, Philadelphia. Librarian—C. H. A. Kleinschmidt, Washington, D. C.

Cincinnati, O., was selected as the place for the next annual meeting, and Dr. W. W. Dawson, of that city, was appointed Chairman of the Committee of Arrangements. The full official record of proceedings will be published in the next number of The Journal.

THE BERGEON METHOD AGAIN.

It was with some surprise that many members of the Association heard the Chairman of the Section on Practical Medicine, in his address last week, utterly condemn the Bergeon method, after making the indefinite statement that he had given it a "fair trial." The *rationale* of the gaseous treatment of phthisis has been given so fully in former issues of The Journal that it is quite needless to go over the ground again. But it seems that certain facts in regard to the method need repetition.

Whatever may be the reasons assigned for the use of any method or drug, the value of it must depend on the results obtained in actual practice. If a theory seem to be correct and success be not obtained by a practical application of the theory, we may be certain that: 1. The theory is wrong; or 2. That the test was incorrectly applied. On the other hand, while a method may be theoretically wrong, what seems to be a practical application of it may be productive of good results. And if such be the case, what does it matter, practically, if the theory is wrong? If we can do the same amount of work, and good work, by putting the cart before the horse, let us travel in that way until some one shows us how we can do better work by a reversal of the process. Why, then, should Bergeon's method be dismissed with the assertions: "The theory upon which this treatment is based is that this gas is absorbed through the intestinal mucous membrane, and exhaled through the pulmonary surfaces, and coming in contact with the pathogenic microbes there destroys them. Dr. Bergeon must have forgotten that these microbes are not found in the alveoli free from disease, and where, if at all, the gas must be exhaled, but in the solid tubercular masses occupying these air sacks, into which the gas can hardly penetrate, and from which no exhalations can take place. Even then, admitting that his mixed gases can destroy the microbes, which seems highly improbable in view of the fact that they are continually exposed to an atmosphere so highly charged with carbonic dioxide that its retention in the lungs for five minutes will produce unconsciousness, it does not seem very clear how they are to reach the objects intended to be destroyed. Accordingly we find that in other hands the plan has proved to be a wretched failure." These statements need

no other criticism than to say that in the hands of a number of men, other than Bergeon, this method has given good, if not satisfactory, results.

As we have already said in a former editorial, it is too early to draw definite and exact conclusions as to the value of Bergeon's method. But however wrong Bergeon's theory may be, if it be wrong (and so high an authority as Cornil has not found objections to it) the fact remains that good results have been obtained by the practical application of the method. More than this, the scientific world is not satisfied with such assertions as that one or two men have given a method a "fair trial." The details of the trial should be given, after which it is no difficult matter to see whether or not mistakes were made in the experiment. Mankind is too prone to error to accept unsupported assertions. Too fresh in our memory, in connection with this subject, is the statement made four years ago by an eminent pathologist that he had caused tuberculosis in rabbits by the inoculation of inert substances—and the subsequent proof that his methods were faulty and his statements incorrect.

Is antiseptic, or aseptic, medicine an impossibility? Is it true that anything which will destroy microbes must necessarily also destroy the cells of living body-tissue? Do we not know already that different microbes are differently affected by so-called germicides, and by different agents? And do we not constantly see such things in relations to creatures of a higher plane? Why should we assert positively that whatever will kill germs must destroy living body-cells, when we know that parasites of a higher order can be destroyed and expelled from the body without injury to the patient. There are men living to-day who would have asserted twenty-five years ago—fifteen years ago—that aseptic surgery was impossible; and there are still those who endeavor, despite the light set before them, that antiseptic surgery and obstretrics is a myth—a delusion. There are very, very few things of which we can assert impossibility. And, certainly, the labors of Selmi, Gautier, Tanret, Brieger, Brouardel, Martini, Dujardin-Beaumetz and Goetze may be said to be a sufficient answer to those who assert that antiseptic medicine is impossible.

There is, as we said a few weeks since, a tendency among American physicians to run after novelties. But while avoiding a headlong rush after new things let us avoid the opposite extreme, and by all means let us not decry honest work. Whatever is bad must be shown, proved, to be bad by actual experiment and trial; what is good we must remain in ignorance of until it is shown to be good. But the day is past when assertions can prove or disprove anything to scientific men.

To conclude this matter, as to Bergeon's method and antiseptic medicine, we may quote the conclusions of Dr. E. L. Trudeau, of Saranac Lake, N. Y., in a paper entitled "A case of Phthisis treated for eight weeks by Rectal Injections of Gas. With Notes and Experiments," which may be found in the *Medical News*, April 23, 1887: *The gas as it enters the body appears to have no germicidal value whatever.* A satisfactory conclusion as to the real therapeutic merit of this method, cannot necessarily be reached for many months to come, but so far as the evidence procured by its application to one case for so short a time may be of value, it would seem that rectal injections of gas by Bergeon's method have a beneficial influence on the suppurative processes of phthisis. The method seems deserving of a most thorough and extended investigation, and *though the treatment may prove in the future to be a useful therapeutic measure, a consideration of the facts here presented does not in the least warrant the assumption that a specific for tuberculosis has been discovered.*

FOOD ADULTERATION.

A recent issue of the New York *World* contained a list of adulterants found in articles of food and drink, which is instructive reading to the public generally, and to sanitarians particularly. It is of interest to every dweller in a civilized community, and of quite as much importance to this country as its commerce, the improvements of its rivers and harbors, or any questions of coast defense. On reading the list one is amazed at the ingenuity and dishonesty of civilized, Christian man. The majority of our foods and condiments, of our articles of drink, are so adulterated that it may now well be said: he is a wise man who knows what he is eating. It has not been very long since we commented on this subject—but so long as the evil exists it is of importance that repeated attention be called to it. Below we give the list as printed in the *World*:

Coffee (ground).—Chicory, peas, beans, date-stones, biscuits, figs, roasted hominy, burnt sugar, acorns, mangel-wurzel, dandelion, turnips, parsnips, carrots, and rye and potato flours.

Tea.—Exhausted tea leaves (faced or colored and fixed up with plumbago, gum, indigo, Prussian blue, turmeric, China clay, mica, soapstone or French chalk, sulphate of lime, rose pink, Venetian red, carbonate of copper, arsenite of copper, chromate and bi-chromate of potash, and carbonate of lime and magnesia), leaves of the elder, willow, sloe, and other plants and trees, lie tea, paddy husk, sweepings of the tea-house floors, sand, quartz, starch, and magnetic oxide of iron.

Sugar (cane).—Grape or starch glucose, wheat and potato flours, tapioca starch, blood, pipeclay, marble dust, gypsum, bone dust, lead, iron, lime, sand.

Cocoa and chocolate.—Arrowroot, sago, starch, chicory,

ferruginous earths, chalk, oxide of iron, sulphate of lime, wheat and Indian flours, tapioca, cocoa husks, old sea biscuit, potatoes, molasses, and animal fats, such as tallow and lard.

Wheat flour.—Adulterated with inferior or old flour, potato flour, ground beans, peas, rye, barley and rice, alum, chalk, gypsum, soapstone and carbonate of magnesia.

Buckwheat.—Wheat and other flours.

Honey.—Cane sugar, chalk, sulphate of lime, pipeclay, gypsum and glucose.

Lard.—Oleomargarine, cotton-seed oil, potato flour, water, mutton suet, alum (for color), carbonate of soda (for taste), caustic soda (for taste or smell).

Cream tartar.—Gypsum, starch, acid-phosphate of calcium, tartaric acid.

Saleratus.—Most of what is now sold as saleratus is bi-carbonate of soda.

Bi-carbonate of soda, or baking soda.—Gypsum, sulphate of soda, carbonate of lime.

Sugar confectionery.—Glucose, terra alba, chalk, arrowroot, sand, wheat, and potato flour, hydrated sulphate of lime, with—for coloring—cochineal, lake, indigo, and Prussian blue, carbonate of copper, carbonate of lead or white lead, vermilion, gamboge, chromates of lead, sap green, arsenite of copper, Indian red, umber, sienna, Vandyke brown, cobalt, smalt, litmus, Naples yellow, bi sulphuret of mercury, sulphuret of arsenic, bronze powders or alloys of copper and zinc.

Mustard.—Flour, turmeric, cayenne pepper, ginger, plaster of paris, linseed meal, radish seeds, chromate of lead, gypsum, sand.

Oatmeal.—Barley meal, rice and corn flour, ground husks of the cereals.

Wheat bread.—Barley, oat and pea flours, bone dust, carbonates of lime, magnesia and soda, sulphate of copper and lead chromate (for color), alum (for taste).

Cheese.—Oleomargarine, lard, cotton-seed oil, borax, saltpetre, potatoes, beans, soapstone, soda, potash, urine, sulphate of zinc, blue vitriol, arsenic (in foreign cheese).

Butter.—Oleomargarine, cheaper fats, cotton-seed oil, alum, borax, barium, chalk, flour, gypsum, lead carbonate, yellow lead chromate, potato flour, salt, soapstone, starch and sodium silicate or soluble glass.

Arrowroot.—Sago, potato and tapioca starches, and ground rice.

Cinnamon.—Cassia and most of the other spices, flour, meal, and arrowroot.

Pepper.—Ground rice and beans, mustard husk, salt, oil-cake and clay, and for colors red lead, vermilion or bi-sulphuret of mercury, Venetian red, turmeric and charcoal.

Ginger.—Wheat, sago and potato flour, ground rice, mustard-husks, turmeric.

Maple sugar.—Cane sugar, glucose, and flour.

Chicory.—Roasted wheat and rye flour, burnt beans and acorns carrots, mangel-wurzel, roasted biscuit, sawdust, and oak-bark tan.

Sago.—Potato flour.

Vinegar.—Water, with burned sugar for color, sulphuric acid, acetic, hydrochloric, nitric and tartaric acids, cayenne pepper, salt, and mustard seed.

Pickles.—For coloring, acetate of copper.

Sauces.—Chalk and plaster of Paris, and for coloring red earths.

Marmalade.—Pulp of apple or turnip.

Olive oil.—Cotton-seed oil and the cheaper oils of the poppy, peanut, grape seed and beachnut, and coaloil, with lead to correct rancidity and copper for a greenish color.

Brandy.—Water, corn spirits, molasses, burnt sugar (for color). Artificial brandy made from other spirits and flavoring extracts is common.

Gin.—Water, cayenne, flavoring extracts, slum, and salt of tartar (for fining), sulphuric acid, coriander seed, oil of almonds, calamus root, orris root, orange peel, acetate of lead, oil of turpentine, and gray and white salts for taste or smell.

Rum.—Water, cayenne, burnt sugar, and cocculus indicus for taste or smell.

Whiskey.—Principally water, cayenne pepper, bitter almonds, tonka bean, burnt dried peaches, beet root, and a variety of flavoring extracts, sulphuric acid, creasote, and sweet spirits of nitre.

Wines.—Mixtures of inferior wines, cider, and the juices of rhubarb, gooseberries, and pears, with—for coloring—logwood, elderberry juice, Brazilwood, bilberries, burnt sugar, black cherries, and cochineal, and for taste and smell, sulphate of potash, bitartrate of potash, lead, oak sawdust, catechu, cherry-laurel water, carbonate of soda, and artificial flavorings.

Ale, beer and porter.—Water, with, for taste and smell, cocculus indicus, opium, cayenne, ginger, quassia, colocynth, caraway and coriander seeds, orange powder, honey, licorice, sulphate of iron, sulphuric acid, cream of tartar, camomile, alum, carbonate of potash, nitric acid, horehound, blessed thistle, sweet flag, gentian, aloes, molasses, juniper berries, burnt flour, isinglass, albumen, ivory, black gypsum, salt, glycerine, salicylic acid, decoction of calves' feet, glue, copperas, henbane, belladonna leaves, nux vomica, hartshorn, strychnine, tobacco, shavings and oyster shells.

Milk.—Water principally, flour or starch, boiled white carrots, milk of almonds, sheeps' brains, gum tragacanth, carbonate of soda, chrome yellow for coloring.

As medical men we are concerned with the detection and punishment of dishonesty only when its results are injurious to health. It requires no great amount of argument, however, to show that food adulteration is prejudicial to health. From causes which we need not stop to mention the American public has come to be too lenient with the dishonesty which shields itself under the name of "business." Such laws as we have for the protection of health and life are, as a rule, improperly enforced. As self-constituted conservators of public health should we not bring this matter before our legislative bodies—not once, but repeatedly—until this disgrace is wiped out from the country?

Can there be any wonder after reading the above list, that we are a nation of dyspeptics? While it may be said that many of the adulterants of our foods are innocuous, it must be admitted that others, taken repeatedly, even if in small quantities, are injurious—and are certainly not foods in the common acceptation of the term. For example, an enormous quantity of tea is consumed in this country, and a reference to the list will show that tea is more largely and more perniciously adulterated than any other article in such common use, except, perhaps, malt liquors. The consumption of sugar confectionery by children is very large—and the adulterants of this article are by no means harmless. And when it is remembered that milk is the principal food of a very large proportion of the population—young children—who can take no other food, the possible and almost certain injury may well cause us to endeavor, by every possible means, to throttle an evil which is worse than the plague.

NINTH INTERNATIONAL MEDICAL CONGRESS.

The Executive Committee of the Ninth International Medical Congress held a full and harmonious meeting in the Palmer House, Chicago, on the 6th and 7th inst. Full reports were made by sub-com-

mittees and the chief officers of the Sections, which showed a most satisfactory degree of progress in all the necessary arrangements for a large and successful Congress. The several Sections are well organized, and for the most part with arrangements for an abundance of scientific and practical work of importance, furnished in fair proportion by parties of reputation in other countries. The local arrangements at Washington are also rapidly maturing, and include not only the best possible accommodations for the regular work, but a series of appropriate entertainments and probably an excursion for the foreign guests to Niagara Falls and return to New York, after the close of the Congress. An outline of the whole programme will soon be given to the public.

PERTUSSIS IN A CAT.—MR. O. BOWEN, of Liverpool, reports this rare case of infection of one of the lower animals from a human being. The cat was infected by a little boy, and for about two weeks had five or six distinct fits of coughing daily, similar in every respect to those exhibited by the boy, with expectoration of frothy mucus afterwards. Between the attacks the cat was bright and active, though not so much so as before, and lost flesh during its illness.

SOCIETY PROCEEDINGS.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Fourth Annual Meeting, held in the Johns Hopkins University, Baltimore, Md., May 31 and June 1, 1887.

TUESDAY, MAY 31—FIRST DAY.

AFTERNOON SESSION.

The Society was called to order by THE PRESIDENT, FRANK DONALDSON, SR., M.D., of Baltimore, who delivered the *President's Address.*

PROPHYLACTIC TREATMENT OF THOSE WHO INHERIT A PREDISPOSITION TO PHTHISIS.

Thirty per cent. of the cases of phthisis have an inherited predisposition to the disease. The hereditary form, when developed, offers the least prospect of recovery. Reference was made to the pathology of the disease. Five years have elapsed since the contagion of tuberculosis was alleged to have been discovered, and nearly all observers have now confirmed the views of Koch. There is abundant evidence that human subjects readily yield to the bacillus poison when previously they have been in good health. The bacillus is always present in phthisis, and we must accept it as the full explanation of the manifestations of tuberculosis. The disease may be propagated by the inhalation of the dried bacillus from the expectoration of diseased persons, by persons predisposed to tuberculosis. The various theories which had been advanced to explain heredity were discussed. The prophylactic treatment embraces two elements: 1, the improvement of the general health of the subject; and 2, the protection from contagion. The tuberculous mother should not nurse her child, but if possible it should be given to a healthy wet-nurse. The hygiene of the nursery should be looked after carefully. The room should be well ventilated and kept at a comparatively low temperature. The subject should live much out of doors, especially between the ages of 15 and 20 years. The beneficial influence of sunlight should be borne in mind. All causes of glandular irritation should be avoided. Scrofulous glands should be dispersed or removed. The physical form of the chest should be enlarged by gymnastic movements. If possible, life should be passed in a high altitude. Oleaginous fluids are useful if they can be digested. The milk and flesh of tuberculous animals must be avoided, for cooking rarely destroys the bacilli of beef. If the prophylactic treatment is thoroughly carried out, the hereditary proclivity may remain latent and the individual never contract the disease.

DR. B. F. WESTBROOK, of Brooklyn, said that the anatomical and physiological conditions which predispose to this trouble are, according to the results of certain observations, a disproportion between the size of the heart and the lungs, the heart being smaller in proportion to the size of the lung than in the ordinary individual, and a disproportionately small digestive apparatus. The former condition interferes with the circulation at the apices of the lung, while the latter condition causes a lack of nutrition.

DR. JAMES R. LEAMING, of New York, read a paper on

THE PHILOSOPHY OF CLIMATIC TREATMENT OF DISEASES OF THE CHEST.

The author stated that it had been observed that the greatest improvement takes place during the first three weeks of the patient's stay at a new place. The suggestion was made that a line of resorts be established along the Atlantic seacoast. The patient could begin in the summer at the most northern and gradually pass southward, making a stay of a few weeks at each place. Having completed the series, the patient may return, taking the stopping-places in a reverse order. This same plan might be applied to the Pacific coast and to the mountains. The speaker also suggested the propriety of State and municipal authorities furnishing sanitariums for the benefit of those unable to avail themselves of the advantages of existing institutions.

DR. R. G. CURTIN, of Philadelphia, read a paper on

THE INFLUENCE OF SEA AIR ON SYPHILITIC PHTHISIS.

He gave in detail the histories of five cases of what appeared to be syphilitic phthisis in which improvement followed prolonged sea voyages, and in each case the symptoms returned when the patient again took up his residence on land. He was led to

consider the cases observed as cases of syphilitic phthisis, for the reasons that there were no symptoms of chronic pneumonia preceding the attack, that the lung trouble followed syphilitic infection with constitutional symptoms, that the disease was influenced to some extent by constitutional treatment, and that there was no tendency to tuberculosis in these cases. He referred to the observations of Dr. Wm. Porter, who relies upon the following points in reaching a diagnosis of syphilitic phthisis: 1, abundant expectoration without signs of softening; 2, a debilitated condition, without marked emaciation and a rational history of phthisis; 3, pronounced dyspnœa without evidence of cardiac or pulmonic obstruction to the circulation; 4, pain along the sternum and the tibial crests; and 5, the satisfactory response to treatment. Dr. Porter had examined the sputa in 100 cases without finding the bacillus. The speaker was not prepared to say why it was that the sea air proved beneficial in these cases, while in most of the ordinary cases of phthisis residence on the sea-coast was not desirable.

Diseased Conditions for which Sea Air is of Doubtful Benefit, by Dr. Boardman Read, of Atlantic City, was read by title.

Dr. E. T. Bruen, of Philadelphia, thought that it was probable that in syphilitic phthisis the benefit of the sea air is due to its influence on the catarrhal processes. In catarrhal affections of the mucous membranes in general, it has seemed to him that residence at the sea-shore was useful. On the other hand, in tuberculous phthisis it has seemed that the influence of sea air was disastrous. He was led to make these remarks because he found so many patients with phthisis recommended to reside at the sea-shore or to take ocean voyages. He had found that the cases benefited by prolonged sea voyages are those in which there is no inherited tendency to tuberculosis.

Dr. V. Y. Bowditch, of Boston, would make a great distinction in speaking of the sea-coast air and the pure sea air. Cases which could not stand the harsh, cold and changeable air of the sea-coast may be benefited by a sea voyage or residence on an island some distance from the shore, where the conditions are similar to those which obtain in a sea voyage.

Dr. James C. Wilson, of Philadelphia, said with reference to residence at the sea-coast in the treatment of phthisis, that in his experience there are three classes of patients with consumption who cannot go to our Atlantic sea-coast without risk. These are, first, those in which there is active febrile disturbance; secondly, those of a highly excitable and nervous organization; and thirdly, those who suffer from repeated attacks of spitting of blood. Such patients cannot safely reside for any length of time on the Atlantic sea-coast.

Dr. Frederick C. Shattuck, of Boston, said that the author had referred to syphilitic phthisis; that is to say, a destructive process in the lung not due to tubercle, but to the syphilitic virus. It seemed to him to be a difficult matter to determine whether or not there is such an affection. Tubercular phthisis varies so much in its symptoms that the points mentioned could not be relied on. The criterion would be the presence or absence of the tubercle bacillus. The author had referred to Dr. Porter as having examined the sputa from 100 cases of supposed syphilitic phthisis without finding the bacillus. That number is so large for the short time that this test has been available, that it would make us a little doubtful of the methods employed. The fact that the bacillus is not found is no proof that it is not present. The German Committee on the Collective Investigation of Disease studied this matter last year, and came to the conclusion that so-called syphilitic phthisis had no real existence. Both syphilis and tuberculosis are common diseases, and the one offers no immunity from the other, so that we should expect to frequently find them combined in the same individual.

Dr. J. H. Musser, of Philadelphia, had never seen a case of phthisis which he considered of syphilitic origin. He had seen only one case in which the lesions bore any resemblance to what we should expect to find in syphilitic phthisis. This was the case of a young man with syphilis and cirrhosis of the liver due to syphilitic interstitial hepatitis. There were also syphilitic gummata in the brain, and the patient died of syphilitic meningitis. There were scattered through both lungs innumerable miliary granules not at all resembling miliary tubercles. He was unable to find the bacillus of phthisis; but, as has already been stated, the failure to find it is no proof of its absence. He would not call this a case of syphilitic phthisis, but rather a case of syphilis of the lungs.

Dr. E. Fletcher Ingals, of Chicago, had been much interested in the remarks of the gentleman from Boston, but thought that most of the members had seen cases in which the syphilitic nature of the disease admitted of no question. Even if the bacilli are found, it would be no proof that the case nad not originated as a syphilitic trouble and that it had subsequently become tubercular. He related a case in which the syphilitic manifestations were very prominent. There was consolidation of the lungs, particularly of the middle portion of one lung. There was a history of syphilis and distinct cutaneous lesion. The patient had been in Colorado and returned much worse. On his return to a lower altitude, he was put on the use of iodide of potassium, and ultimately apparently recovered.

Dr. J. H. Musser read a paper on

THE TREATMENT OF THE FINAL STAGE OF PHTHISIS.

The paper consisted of a detailed account of the symptoms met with in the last stages of phthisis, and referred to the various measures which he had found useful in these cases. To relieve the high temperature he had resorted to antifebrin with advantage. Quinine was found to act unsatisfactorily.

The President announced as the Nominating Committee, Drs. F. C. Shattuck, E. T. Bruen, Willis E. Ford, B. F. Westbrook, and W. H. Geddings.

(*To be concluded.*)

ST. LOUIS MEDICAL SOCIETY.

Stated Meeting, April 2, 1887.

The President, S. Pollak, M.D., in the Chair.

F. D. Mooney, M.D., Secretary.

Dr. Charles Barck presented a specimen of

ABSCESS OF THE BRAIN CONSEQUENT TO OTORRHŒA.

The patient was a girl, æt. 15; she had had otorrhœa about eight years. It was sometimes worse, sometimes ceased altogether. For the last month she complained of headache on the left side. About three weeks ago the otorrhœa was stopped suddenly at a dispensary, after which she did not go for five days; on the sixth day she had nausea, photophobia, higher fever; the seventh day she became delirious and comatose. Dr. Kay was called in. Temperature was 104° or 105°. He made a diagnosis of meningitis basilaris. The next day the ear ran some and I was called in consultation. I found pus in the external auditory canal, but the walls were so thickened that it was not possible to get a view of the membrane. The mastoid region was swollen and tender. I advised opening of the mastoid process. This was done on March 17. As soon as I had scraped off the periosteum we saw yellow fetid pus escaping from the mastoid process, where there was a big cavity. The next day water thrown into the mastoid came out of the canal. The fever came down, the coma reduced and she began to answer short questions. The discharge of fetid pus was profuse. The next week the patient grew worse and died two days ago. We found that the bottom of the interior of the skull was filled with very fetid pus. The brain did not show any symptoms of inflammation; it was only adherent around the opening of the abscess, which was about the size of an ostrich's egg. In the bone itself you will see here an artificial opening from the outside into the mastoid antrum, showing the carious condition. The pus found its way from the tympanum into the brain.

Dr. J. B. Shapleigh said he was struck with the beneficial effect the operation seemed to have on the disease. Unfortunately he saw the patient too late to get the full benefit of that most important and useful operation. If he had seen the case sooner, he had no doubt that it would have been saved. Even when the temporal bone is already carious, if by the operation free drainage can be had, a cure often results. Its good effect was seen in the amelioration of the symptoms.

Dr. L. Bremer said that it was an old story that the doctor has been called too late. He believed that the doctor might have been called in a half a year ago, and he would have been too late. He does not believe that at any time this condition was accessible to any operation. The abscess was a very old one, probably years old, because it has what is erroneosly called a pyogenous membrane. There is one important point that attaches to the lesion, which has not entered into the consideration of those that observed it. The seat of the abscess is the left temporal lobe; that is to say, that portion of the brain where the impressions of the ear are interpreted; its psychical auditory centre, so-called. A lesion there produces deafness on the opposite side. The clinical history does not say anything about this, and certainly if the child had heard with the opposite ear there is nothing in cerebral localization. There are a few cases on record where after congenital deafness, these parts were found to be in a state of atrophy, just as there are a few cases where after congenital blindness the angular gyrus was found to be atrophied. However, these questions have not been settled.

Dr. Barck had seen the girl only in the comatose state. There is no doubt that she didn't hear very well in the left ear; it was in a diseased condition for the past year. He did not know anything about the right ear. In his opinion, and that of Dr. Bremer, the abscess was an old one, existing probably six years. The opening into the abscess was about as large as a penholder, and was situated opposite a hole just as large in the periosteum. On the posterior wall, and between the two holes was a big piece of cheesy matter, and just around this place were more or less adhesions between the brain and periosteum. His opinion was that there was inflammation of the tegmen at first, and in consequence caries of the bone, and from that abscess of the brain formed, and was during the last few weeks closed around by the adhesions, and then gave rise to meningitis. It did not give rise to any brain symptoms during life other than the headache from time to time.

Dr. Robert Barclay said, concerning the operation of trephining the mastoid, that the danger does not lie in the mastoid, but in the middle ear, and if proper drainage could be had there, there would be no inflammation of the mastoid. The most dangerous form is that which has its seat in the attic, where lies the head of the malleus, and the main portion of the body of the incus. Water splashed up into the mouth of the Eustachian tube frequently causes inflammation of the flaccid portion of the membrane, and the hearing is often good, even where there is intense pain and inflammation. In this the hearing remained to a certain extent in the left ear, which is an important point in such a case. The drumhead was not visible; it is possible that the pus burrowed out between the auditory plate and the flaccid portion and broke through there. The main difficulty is in draining the attic, and it requires skill to do this; it is only $\frac{1}{16}$ of an inch between the middle ear, the brain, the carotid canal, the internal jugular vein, and the internal auditory canal, and the brain lies nearer than the others. It is often difficult to differentiate between acute neuralgia and neuralgia of acute meningitis. This operation of trephining, a magnificent one for aurists, is, I think, often unnecessary, if we will get drainage from the external auditory canal.

Dr. D. V. Dean had had five cases in which he had trephined the mastoid, three of which recovered. They had gone on to mental trouble; the friends of one, a girl of 12 to 14 years, thought she was becoming insane. In one of the two cases that died he

had the opportunity of making a post-mortem examination. He thought trephining was frequently performed when unnecessary, but thought it was quite as frequently neglected. The profession is in part to blame for this fact. The physicians were often, until recently, in the habit of telling the families that the child would outgrow its ear trouble, and it thus came to be the belief of many parents. It is well recognized by pathological anatomists that the *tegmen tympani* and the roof of the mastoid antrum are peculiarly susceptible to certain pathological changes. In this case the necrosis is evidently on the anterior or outer side of the petrous portion, and the roof of the attic is nearly or quite open.

A very interesting case "came too late" literally under his care, which showed beautifully that it is not always the attic or the tympanum at all that is at fault, or from which treatment must be carried out. The soft tissues about and behind the right ear were infiltrated with pus, and the muscles also of that side of the neck. He opened above the external ear into an abscess within the skull containing much pus—the opening through the squamous portion, 1.5 cc. in diameter. The patient died, and he found post-mortem that the whole base of the petrous portion had necrosed and disappeared, except a bridge 1 to 3 mm. wide and 1 mm. thick, supporting the superior petroyal sinus. The opening, therefore, tunneled under the lateral sinus. The cavity also communicated with the external meatus in the upper posterior outer part by an opening 1 cm. in diameter. Below it opened 1 cm. in diameter through the occipito-mastoid suture a little behind the stylo-mastoid, and necrosis and pus encroached upon the jugular fossa. Pus had burrowed and the bone was partly necrosed under the temporal and mastoid muscles down the sterno cleido muscle and the rectus, around the condyle and left side of foramen magnum and the occipito-atloid ligament. There were in the lateral sinus phlebitis and thrombus; a meningitis extended over quite a large area, and yet the whole middle ear was apparently entirely free from destructive disease; and to this day the hammer, anvil and stopes are in place except the long process of the anvil which has been recently broken off.

Dr. Borck believed that in this specimen it could not be clearly made out by which way the inflammation spread into the brain. It may have been through the *tegmen tympani* or along the auditory nerve.

Dr. S. Pollak had had very little opportunity to make such examinations; only once had he trephined the mastoid process, when pus escaped very freely from the opening which we made, and the person recovered very rapidly afterwards. Diseases of the mastoid cells and of the middle ear are much more common than we imagine. In the case he had a few weeks ago there was destruction of the whole mastoid process and the communication between the mastoid cells and the meatus, and yet the patient feels comfortable, although a frightful pathological process constantly goes on.

Dr. W. S. Ford thought Dr. Barclay quite correct in assuming that free drainage is very important in these cases. A patient of Dr. Spencer's had otitis media purulenta chronica. The drum membrane had come away. He had been treating the case for four or five months and regarded it as getting along very well. She had lost her hearing on that side. He was called in to attend to a little disturbance in the neighborhood of the pain. It increased in violence until it was atrocious. There was confusion of thought, anxiety and pain in the mastoid region. Suddenly she was affected with Bell's palsy, which has not passed off entirely yet. Local sedatives had no effect, and he bled her nearly a quart, with the result of immediate cessation of the pain. Dr. Gamble and he had agreed to perforate the mastoid cells, but it got well without it. From the loss of the bones and drum, free drainage was possible, and to this he attributes the failure of the inflammation to extend further.

Dr. F. R. Fry wished to question the statement made by Dr. Bremer, that it could be proven in this case that there were no disturbances of hearing in the opposite ear it would be a severe blow to cerebral localization. Ferrier, in his experiments on animals, proved that when there was disturbance in the temporal lobe on one side, there would be disturbance of hearing on the opposite only temporarily, and there were permanent disturbances only after this region on both sides of the brain had been injured, seeming to indicate the fact that the functions of this region might be vicariously taken up by the opposite side of the brain. At any rate, as Dr. Bremer has said, experimentation, as well as pathological evidence in regard to this region of the brain is unsatisfactory, and the evidence regarding cerebral localization from disturbances in this region is not near as convincing as that from experimentation of the brain.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Ninth Annual Meeting, held in the Hall of the Academy of Medicine, New York, May 26, 27 and 28, 1887.

(*Concluded from page 659.*)

Friday, May 27—Second Day.

MORNING SESSION.

Frank Donaldson, Jr., of Baltimore read

FURTHER RESEARCHES ON THE FUNCTION OF THE RECURRENT LARYNGEAL NERVE: A SERIES OF EXPERIMENTS FROM THE BIOLOGICAL LABORATORY OF THE JOHNS HOPKINS UNIVERSITY.

At a previous meeting he had read a paper criticizing certain conclusions advanced by Dr. F. H. Hooper, of Boston. The conclusions which Dr. Donaldson reached were: That the constrictors do not cease to act under deep narcosis or suspension of consciousness from any cause; that we do not always obtain abduction or irritation when consciousness is suspended; that the abduction was

not reflex and was not dependent on unconsciousness; that it is with weak stimuli that abduction takes place, and the movement passes into adduction as the stimulus was increased; these results invariably followed whether the animal was slightly or deeply narcotized, or when the medulla was destroyed or when local death had taken place. That after stronger continued stimuli the abductor muscles become worn out and did not respond to stimuli.

These conclusions had been strongly criticized and the present series of experiments were performed to test the correctness of the above views. He had shown, that abduction of the vocal bands can be obtained without ether and that it is a physiological fact that opening or closing the larynx depends upon the strength of the stimulus. With weak stimuli abduction was produced, while with strong stimuli adduction was caused.

DR. FRANKLIN H. HOOPER, of Boston, read a paper on

THE ANATOMY AND PHYSIOLOGY OF THE RECURRENT LARYNGEAL NERVE: FROM THE PHYSIOLOGICAL LABORATORY OF THE HARVARD MEDICAL SCHOOL.

The anatomy of this nerve is now complete and exact, but up to a very recent date much confusion existed on this subject. The larynx possesses three functions controlled by three distinct sets of muscles all innerrated by the recurrent nerves. These functions are: 1. Respiration; 2. Sphincter action, which closes the larynx and prevents the entrance of foreign bodies, and plays an important part in expulsive acts; 3. Phonatory action. Stimuli applied to recurrent nerves produces adduction in certain animals (dogs) and abduction in other animals (cats). Only a few experiments have been made in man but as far as they go they seem to show that stimulation closes the glottis. Under ether or profound morphia narcosis, stimulation of the recurrent nerves produces opening of the glottis in dogs. Three hundred and twelve experiments were reported, some of the animals were under the influence of chloral, chloroform, morphia or ether. Under ether, dilatation was produced with weak currents, while contraction could not be produced with even the strongest current. As the dog begins to come out of the ether dilatation can not be induced with any current, while contraction is brought about by currents decreasing in intensity as the effect of ether passed off. A similar effect was observed in one case after use of a large dose of morphia. After small doses of ether stimulation produces two effects: first, vibration, second, closure. Under large doses of ether, four effects were observed, according to the intensity of the irritation: vibration, complete dilatation, mixed movement and closure. After small doses of morphia, chloral and chloroform, stimulation produces the same effects as after small doses of ether.

DR. F. I. KNIGHT, of Boston, saw some of the experiments of Dr. Hooper. In one case he saw a failure to get the ether effect, which was attributed to the size of the dog.

DR. S. W. LANGMAID, of Boston, stated that in one of Dr. Hooper's experiments recently made, the skull was trephined and insensibility produced by pressing a plug against the cortex. In this case dilatation was very marked under stimulation of the recurrent nerve. That is the only case in which he had seen dilatation similar to that which he thought Dr. Donaldson describes.

DR. HOOPER said that he had been trying to get the effect with feeble stimuli which Dr. Donaldson describes but had been unable to do so. The only point on which they disagreed was with reference to the effect of weak stimuli in unnarcotised animals. He had done a number of experiments following the method of Dr. Donaldson, but had not gotten his results.

AFTERNOON SESSION.

DR. WILLIAM C. GLASGOW, of St. Louis, read a paper on

CERTAIN MEASURES FOR THE RELIEF OF CONGESTIVE HEADACHES.

The most severe symptoms in this condition are the pain and sense of constriction of the forehead. If the pain is analyzed it will be found that it is of two kinds. In the one there is a fullness of the vessels, and in the other, disordered nerve action. Both varieties are often due to the same pathological condition of the nasal chambers. During congestive headache if we examine the nose we find the cavernous bodies are full and tense. The degree of tenseness corresponds to a certain extent to the degree of headache. The method of treatment which he had adopted during the past four years had been the local abstraction of blood. A knife is not required, a simple prick is sufficient. In many cases the relief is immediate. The operation may have to be repeated in a month or two. He had seen few cases in which permanent relief had not followed a repetition of the operation from two to six times. The amount of blood drawn rarely exceeds an ounce. A number of illustrative cases were cited.

DR. J. N. MACKENZIE, of Baltimore, said that some years ago he had advised that in acute coryza an incision be made in the turbinated tissues with a sharp pointed bistoury.

DR. C. C. RICE, of New York, said that his experience was somewhat different from that of the author. So far as chronic hypertrophic catarrh is concerned, he had come to look in these cases of headache for hypertrophy over the middle turbinated bone, pressing against the septum. There has not been much congestion but simply contact. In these cases he had used the galvanic cautery, and had not tried to draw blood.

DR. HARRISON ALLEN, of Philadelphia, was more in accord with the last speaker than with the author. The trouble may come from turbinated bones, but he had attributed it to pressure effects. The proper treatment is to separate the parts. He did not hesitate to etherize the patient, and introduce the finger, and push the septum into place. In one case, a lady came to Philadelphia with a complication of disorders.

She had reflex headaches which were so severe as to lead to a fear of mental aberration. On examining the nose the condition referred to above was found and the speaker insisted that the headache was due to the trouble in the nose. He etherized the patient and separated the parts with the finger. The headaches entirely disappeared.

Dr. F. H. Bosworth, of New York, said that it is a fact that in many cases where we find contact between the middle turbinated bone and the septum there are no symptoms that can be referred to this condition. Judging from analogy, we have in no other portion of the body neuralgia caused by the contact of mucous surfaces. In the vagina and in the urethra, we have mucous surfaces in contact. We may, however, safely say that it is a proper course to pursue to put the nasal cavity into a condition as near normal as possible.

Dr. Glasgow, in closing the discussion, remarked that the paper said nothing at all about hypertrophy. No one recommends bleeding for hypertrophies, for these do not bleed. The fullness of the cavernous sinuses is simply the sign of the fullness of the frontal sinuses. It is not the cause of the trouble. He takes blood from this part simply because this is the most convenient place to do it.

A Case of Leucoplakia; Recovery: by Dr. W. C. Glasgow, of St. Louis, was read by title.

Dr. J. Solis-Cohen, of Philadelphia, opened the discussion on

THE TREATMENT OF LARYNGITIS IN PROFESSIONALS WHO ARE UNABLE TO REST.

Sometimes a professional had consulted him with hoarseness, the result of laryngitis, and want to use his voice in a few hours. The best method to accomplish this that he had found, has been the administration of a sharp emetic and then let the patient rest until the time of the performance, sucking pieces of ice and keeping a cold compress to the neck. In chronic laryngitis he had found nothing of the same service as the use of a weak solution of sulphate of zinc, two grains to the ounce, used in a spray apparatus. In the intervals of the play the patient may inhale a little compound tincture of benzoin if he finds that he is hoarse. Another remedy of considerable service is the use of a respiratory with turpentine, terebene, or eucalyptol, or something of that kind. I am, however, not aware of any special method which is adapted to this class of individuals.

Dr. T. A. DeBlois, of Boston, had endeavored to keep up the systematic use of sulphate of zinc, but had found that the hoarseness continues unless the voice is rested. He had occasionally had to treat vocalists who could spare a few hours, and have found excellent results from the use of nitrate of silver, and the most disastrous results from the use of cocaine. There seems to be a certain amount of relaxation following the use of muriate of cocaine. It may be said that in these cases that unless there is rest there is no cure.

Dr. Beverly Robinson, of New York, stated that his experience with the class of cases under discussion would lead him to believe that so far as the acute cases are concerned there are milder measures than the use of an emetic. He had found under these circumstances that the use of tablet triturates of chloride of ammonium repeated as often as once every fifteen minutes is one of the most efficient methods of overcoming the difficulty. For local application he did not think there is anything better than carbolized spray. In the chronic form of laryngitis in vocalists he believed that we could not obtain much information from the appearance of the mucous membrane. In these cases the membranes may be red and this may continue after the trouble with the voice has disappeared. He believed that there the trouble is chiefly in the nervo-muscular apparatus and had found the internal use of good wine of coca, with application of a faradic current to the neck, very useful. The faradism should be repeated once or twice a day.

Dr. F. H. Bosworth held that there is no such disease as larnygitis as that term is used to mean an inflammatory process. The seat of the disease is not in the larnyx but in the nasal passages. If you apply cocaine to the nasal mucous membrane, causing contraction of the blood vessels, and follow this by the use of chromic acid, thus eliminating the cold in the head, it will usually be found that the laryngitis has disappeared. Relaxation has been spoken of as following the application of cocaine. Although he had used the drug in many cases he had seen this result in only two, and they were cases of hay fever. His method of using cocaine is to suspend it in fluid cosmoline and direct the patient to spray the nose and inhale it.

Dr. C. E. Sajous, of Philadelphia, had treated many cases of this trouble. The action of cocaine in laryngitis is pernicious. In cold in the head cocaine is useful but it should not be used within four hours of the time when it is desired to use the voice. In the majority of cases of chronic laryngitis the condition is due largely to fatigue. He had found that the use of quinine and nux vomica internally with the external use of a weak faradaic current are the best measures to employ.

Dr. Morris J. Asch, of New York, considered the employment of muriate of ammonia is useful. He gives it in solution in compound liquorice mixture which contains a little tartar emetic. The chronic cases are more difficult to treat because the patients can not quit work. He had found nothing equal the application of astringents. He had used the spray in some cases, but more good is done by the use of the brush. The solution which he most frequently used was one of perchloride of iron, thirty to sixty grains to the ounce. Where a person has to use the voice in a few hours, a single application will put them in good condition temporarily.

Dr. F. H. Hooper, remarked that in these professionals there is sometimes an alteration in the quality of the voice the result of over-exertion. Here there seems to be want of tension in one vocal cord. To relieve this he had used electricity outside, with the internal use of aromatic spirits of ammonia, thirty to forty drops in half a glass of soda water.

Dr. J. N. Mackenzie thought that Dr. Bosworth

is to a great extent right with reference to the dependence of laryngeal disease on nasal trouble, and that the vast majority of cases of laryngitis are associated with disease of the nasal passages and upon the recognition of this fact depends the successful treatment of many cases of chronic laryngitis. I should never use cocaine just before a person was going to use the throat. The sensation which it produces in the larynx is only next to that of hanging. In the nose the effect is very pleasant provided some of the solution does not trickle into the nose or larynx.

DR. C. C. RICE, of New York, read a paper entitled *Glandular and Connective Tissue Hypertropies in the Lateral Walls of the Pharynx.*

DR. CHARLES H. KNIGHT, of New York, read a paper on

THE GALVANO-CAUTERY IN THE TREATMENT OF HYPERTROPHIED TONSILS.

The speaker first referred to the objections to the cutting operation. The principal of these is the danger from hæmorrhage. At times the tonsil is so deeply situated that it is not possible to get the tonsilotome over it. In other cases the patients positively object to the cutting operation. There are two methods of using the galvano-cautery, one is by puncture and the other by the snare. The former is much the slower. Not more than three punctures should be made at each sitting. The number of sittings required vary from five to ten. The latter method with the snare is much the quicker. The current should be used intermittingly and traction should only be made during the passage of the current. He did not recommend this as an universal operation. In the majority of cases the cutting operation is easier and better. It should be used where there was danger of hæmorrhage, and he was almost disposed to say that the galvano-cautery should be used in all cases of adults.

DR. A. W. MACCOY, of Philadelphia, said that in the treatment of these cases he made a distinction in the methods employed. In the glandular enlargements he had used puncture, while in the interstitial hypertrophies he had not used it, for in these cases you are apt to get cicatrices which give considerable trouble. He was not satisfied that the puncture is any better than chromic acid fused on a probe and passed into a crypt.

DR. BEVERLY ROBINSON had long held that we know of no simple operation in surgery. There is nothing so unpleasant as to have to remove large tonsils from a small child. Although, as a rule, the hæmorrhage is readily controlled, yet he always undertakes the operation with a good deal of reluctance. He was disposed to think that galvano cautery is one of the best methods. We can thus remove many tonsils that give us a good deal of apprehension.

DR. RICE said that very little can be accomplished with the cautery in the large white hypertrophies in children. The cutting operation is what must be done in these cases. In adults, however, galvano-cautery is the most useful measure.

THE PRESIDENT said that he had used the cautery, but a certain amount of soreness has always followed its use. In children, in order to avoid the pain and nervous shock attending the cutting operation, he was in the habit of etherizing the patient and removing the tonsil with the snare.

DR. HARRISON ALLEN remarked that while it may be proper to do the cutting operation in certain cases of hypertropied tonsils which have been selected with great care, yet he thought that we err in making broad statements in regard to this operation. He believed that the number of cases in which serious hæmorrhage occurs is much larger than is supposed. All the disastrous cases are not reported. He was not willing to perform the operation until he had studied the case very carefully. Other measures should be first used and the knife resorted to at the last.

DR. D. BRYSON DELAVAN, of New York, held that where the operation of tonsillotomy is done with proper care and with suitable styptics at hand, there is not much danger from hæmorrhage. At first there is a gush of blood, but in a few seconds this stops. He had found it very difficult to get authentic reports of cases in which serious hæmorrhage followed this operation.

DR. MORRIS J. ASCH, with reference to the question of hæmorrhage, stated that some time ago one of his assistants removed a small section of the tonsil. The next day there was serious bleeding, and it was found necessary to keep up pressure on the tonsil for six hours before it was controlled.

DR. J. SOLIS-COHEN thought that a great deal of the trouble in tonsillotomy is due to the adhesion of the anterior fold of the palate to the tonsil. It has been his custom to first free the tonsil from the palate. In many cases the tonsil will then go down without any treatment whatever. He thought that the hæmorrhage comes from the cutting of this fold, for, as the vessels run in a vertical direction, they are cut obliquely. He had never been able to use the cautery with the success of the reader of the paper. In his cases it has required from twenty to fifty sittings.

DR. BEVERLY ROBINSON, of New York, read a note on

A FREQUENT CAUSE OF NASAL HÆMORRHAGE.

In the experience of the author the ulcerations in atrophic rhinitis had been a most frequent cause of hæmorrhage. He had found himself unable to detach the crusts from these ulcerations either by the use of douches or sprays so well as by the employment of ointments. In the course of two or three days the patient is able to blow out the crusts. The best ointment for this purpose is the ammoniated mercurial of the Pharmacopœia, made with vaseline, one half full strength. After plugging the nostrils, especially in children, he has found flexible probes most useful. He has never found anything to arrest the hæmorrhages so well as sheet sponge, which is cut into long strips and pushed into the nares till the bleeding stops.

SATURDAY, MAY 28—THIRD DAY.

MORNING SESSION.

THE PRESIDENT called the Association to order,

and Dr. S. W. Langmaid, of Boston, read a paper on

CONSTITUTIONAL CAUSES OF THROAT AFFECTIONS.

However important and interesting the morbid changes in the upper air-passages may be locally, the important lesson should be learned that there are underlying constitutional causes which must be removed in order to effect a cure. Syphilis, alcoholism, rheumatism, and gout, etc., are ever at work, and their influence must be combated. Local treatment is in the nature of repair, while constitutional and hygienic treatment must be in the direction of the renewal of normal processes.

Dr. Glasgow, of St. Louis, regarded the paper as one of the most timely which had been presented to the Association. He thought the statement made by Dr. Daly, of Pittsburg, that the laryngeal physician should become a laryngeal surgeon, as one tending to do much harm, and it had done much to retard progress in this department of medicine.

Affections of the Crico-arytenoid Articulation, by Dr. George W. Major, of Montreal; *Cancer of the Larynx*, by Dr. Hosmer A. Johnson, of Chicago; and *A Case of Recurring Laryngitis Hæmorrhagica*, by Dr. C. E. Bean, of St. Paul, were read by title.

Dr. Morris J. Asch reported a case of

STENOSIS OF THE LARYNX

treated by divulsion and systematic dilatation. The opening of the larynx was diminished to one-third its normal size. The dilatation was accomplished by Schroeder's hard-rubber tubes. It was a case of hypertrophic laryngitis below the local cords, and the relief afforded by treatment had been permanent. He preferred this to any other method in this class of cases.

Dr. Cohen had not had the courage to attempt to dilate without preliminary tracheotomy. He believed it was better to perform tracheotomy first, and then pursue the most active measures possible for the relief of the stenosis.

Dr. Knight said that Schroeder's method had been very slowly popularized in this country. He regarded it as a sub-glottic laryngitis of some kind, as had been expressed by Mackenzie, of London, and would discard the name *corditis*, etc.

Dr. Morgan, of Washington, related a case in which he used dilators without permanent benefit, and in which he kept the disease in abeyance by constitutional measures and local applications. He recommended from time to time tracheotomy, to be followed by dilatation, but the patient declined, and finally died suddenly of laryngeal spasm.

Dr. Delavan, believed that the method of treatment by dilatation would receive important modifications by O'Dwyer's method of intubation.

Dr. Asch spoke of some theoretical objections to O'Dwyer's method for the treatment of these cases. He agreed with Dr. Knight that the term *corditis*, etc., should be abandoned. He regarded it as one of the advantages of this method that tracheotomy was avoided.

Dr. D. Bryson Delavan, of New York, then read a paper on

THE ETIOLOGY OF DEFLECTIONS OF THE NASAL SEPTUM,

in which he had gathered the scattered views on the causes, which were generally admitted to be obscure. After discussing the predisposing causes, as race and diathesis, he spoke of the exciting causes under the headings, traumatism, local malnutrition, and occlusion of the nasal passages.

Dr. Morgan, had been able to trace his case to traumatism almost invariably, when the history had been carefully studied. He had seen but few cases in the African, but whether or not this was real exemption he was unable to say.

Dr. Donaldson was also of the opinion that perhaps it was less frequent in the African than among the whites.

Dr. Solis-Cohen had noticed that high-arched palate and deflected septum go together in a majority of cases, perhaps; but he had also seen many cases in which there was deflected septum without high-arched palate, and also high-arched palate without deflected septum. A great many children under *seven* years of age have deflected septum. He thought that the question of traumatism was a difficult one to settle. So also it was difficult to get at the exact influence of racial peculiarities. Over and over he had seen marked deflection of the septum *without* difficulty of breathing.

Dr. Sajous thought that traumatism as a cause could not be clearly defined.

Dr. Mackenzie had not seen a case of deflected septum in the African that required an operation. He regarded *traumatism* as the most prolific cause. He had also been surprised at the brilliant results said to attend some operations.

Dr. DeBlois said that he had observed the nose of several pugilists and had been surprised to find that the septum was in the correct line, while the nose in general had been flattened and bruised with great severity and repeatedly. He thought that these cases could with propriety be regarded as traumatic.

Dr. Roe spoke of several peculiar varieties of deflected septum, and particularly objected to the use of the punch in the treatment.

Dr. Ingals had seen deflected septum in children two years of age, and he had also come to the conclusion that, unless the nasal bones were fractured or cartilages dislocated, deflection of the septum was not likely to follow traumatism.

Dr. Langmaid, of Boston, reported a case of

A PIN REMOVED FROM THE LARYNX,

where it had been for two years. It was sticking through the ventricular band and pointing backward.

Dr. Rufus P. Lincoln, of New York, reported a case of

RECURRENT NASO-PHARYNGEAL TUMOR,

which he had cured by electrolysis. He used a single needle, and made sixteen applications in from four to six days. The growth had not shown any tendency to return.

Dr. W. C. Jarvis, of New York, reported

TWO CASES OF CONGENITAL OCCLUSION OF THE ANTERIOR NARES.

This is a rare condition. He had been unable to find a case recorded in medical literature, and the two reported were the only cases which he had met with in several thousand patients examined at his clinics. They were treated by means of his nasal drills and electro motor. In one case the obstruction was fibrous, and in the other osseous, and the results of treatment were very satisfactory.

AFTERNOON SESSION.

DR. ALEXANDER W. MACCOY, of Philadelphia, read a paper on

A COMPARATIVE STUDY OF SOME OF THE METHODS OF TREATMENT BEST ADAPTED TO THE RELIEF OF OCCLUSION OF THE POSTERIOR NARES

due to hypertrophy of soft parts, and not bony occlusion of the posterior nares, which he had never seen. He referred to different methods, and the difficulties which had been offered in way of reaching the posterior nares, and lack of precision in making applications. Since the advent of cocaine these difficulties, to a certain extent, had been overcome, but the effect produced by the drug rendered comparatively useless certain instruments which heretofore had been used satisfactorily; for instance, Jarvis' snare, the use of which he had ceased, except for the removal of nasal polypi, etc. From the fact that cocaine caused such retraction of the tissues, he had not been able to make use of the needle recommended by Jarvis; but, at the same time, the drug had brought into greater use the galvano cautery and chromic acid. The chief point in the paper was to present the superior advantage offered by a concealed flexible instrument for applying fused chromic acid. He preferred this to all other methods for removing these posterior hypertrophies.

DR. JARVIS regarded his transfixion needle as one of the most serviceable instruments he used for the removal of hypertrophied nasal tissue. He never used cocaine as a preliminary step, but first included the hypertrophy within the loop, drew the wire home, and then applied the cocaine. He regarded chromic acid as dangerous and likely to be followed by unpleasant results. He never attempted to remove a hypertrophy by means of the galvano-cautery.

DR. RICE said that it was often difficult to remove these hypertrophies. He had given up the use of the transfixion needles. There were cases in which it was difficult to apply the loop posteriorly. He had never met with the disadvantages in the use of chromic acid spoken of by Dr. Jarvis.

DR. DONALDSON favored the use of chromic acid, as did his father, who had used it without bad results for many years. As to the needles, technical skill was required for their use, and in one case he had profuse hæmorrhage following their use.

DR. DELAVAN had used chromic acid, discarded it, used it again, and had again discarded it. As for hæmorrhage, he had not seen a case where it could not be controlled readily, and he believed that, practically, there was no danger from it.

DR. JARVIS said that an attempt to remove a posterior hypertrophy, while a deflected septum existed, was very poor surgery. First repair the deflected septum, and the hypertrophy will disappear of itself. He regarded it as trifling with the patient's nostrils to use chromic acid when the hypertrophied tissue can be removed so easily with the transfixion needles.

DR. MACCOY said that he had never been able to reach the posterior face of the middle turbinated bone before his little instrument was invented. A single application of chromic acid was, as a rule, all that was required. In comparison with it, he regarded the use of the needle as a very difficult operation. He never uses chromic acid without immediately antagonizing it.

DR. JARVIS remarked that the fault was not in the needle but in the operator, who failed to make the few simple manipulations necessary to its successful use.

Plaster-of-Paris Dressing for Fracture of the Nose, by Dr. J. W. Robertson, of Detroit, was read by title.

DR. DEBLOIS, of Boston, exhibited a plaster of-Paris splint which he had used with good result in one case of fractured nose.

DR. ROE, of Rochester, exhibited a nasal saw which was operated by means of an electro motor.

The committee on *The Congress of American Physicians and Surgeons* presented its report, which was received and adopted.

The following were elected

OFFICERS FOR THE ENSUING YEAR.

President—Dr. R. P. Lincoln, of New York.

Vice-Presidents—Drs. J. N. Mackenzie, of Baltimore, and S. W. Langmaid, of Boston.

Secretary and Treasurer—Dr. D. Bryson Delavan, of New York.

Librarian—Dr. T. R. French, of Brooklyn.

Council—Drs. Frank Donaldson, of Baltimore, J. Solis-Cohen, of Philadelphia, F. H. Hooper, of Boston, and E. C. Morgan, of Washington.

The following were elected Corresponding Fellows: Dr. A. Gougenheim, of Paris, and J. Moure, of Bordeaux.

Dr. A. Jacobi, of New York, was elected Honorary Fellow.

The Association then adjourned.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, April 7, 1887.

THE PRESIDENT, THOMAS M. DRYSDALE, M.D., IN THE CHAIR.

(*Continued from page 668.*)

DR. J. M. BALDY presented a specimen of

PYOSALPINX IN ITS RELATION TO PUERPERAL FEVER

not simply because it was one of pyosalpinx, but because of its extremely important relation to the puerperal state and, as far as he is aware, because it is the first of its kind ever operated upon, and life saved when the patient was dying from, so called, puerperal fever. The patient, Mamie P., twenty-three

years of age, was delivered of a male child after a tedious but normal labor some four years ago. She was at that time confined to her bed for eight weeks "with an inflammation in her stomach." She however made a good recovery and has not suffered from pain or ache in her abdomen since. On February 3, he was called to attend her in her second labor. Although he went with the messenger he found the labor over; a dead child, together with the placenta and all the membranes intact, lay between her thighs. Her uncovered arms, chest and legs were exposed in a room without a fire. No examination was made but she was put between warm, dry bed clothes as quickly as possible. On the second or third day she had a chill with a quick rise of pulse and temperature, a tympanitic and tender abdomen. These symptoms abated somewhat and he lost sight of her for several weeks. On the third of March, one month after her confinement, he was again summoned to her and found that she had been suffering ever since he had last seen her. She had become so emaciated that he hardly recognized her. Her temperature was 102°F. and pulse 130. She had continued chills and creeps, hectic, night-sweats, and sleepless nights; her abdomen was swollen and tympanitic and intensely painful, her bowels loose and fœtid; micturition and defecation were both painful. She was evidently fast approaching death. An examination of the soft parts showed no sign of a recent tear. The uterus was sub-involuted and on the left side there was a large boggy mass firmly adherent, tortuous and extremely tender. The right side was tender but no mass could be detected. Abdominal section was advised as the only remaining hope of saving her life, and the proposition was eagerly accepted by the patient and her friends. Dr. J. Price saw the patient and confirmed my opinion of immediate operation. He operated on March 5, the delay being necessary to have her surroundings cleansed. Drs. J. Price, McMurtrie, of Danville, Ky., and Mr. Eckman, of Scranton, Pa., were assisting. The right tube and ovary were healthy and were not removed; the left tube was almost as large as the uterus and firmly adherent in all directions, especially to the bowels from which it was separated with great difficulty An abscess of the cellular tissue was ruptured while breaking up the adhesions and pus welled up through the abdominal incision. Both tube and ovary were removed. A large cheesy mass on the bowels at the point of adhesion was trimmed down with scissors and Monsel's solution applied to the bleeding points. After a free irrigation, a drainage tube was put in and the incision, which was only one and a half inches in length, was closed. The tube was found to be distended with pus, the ovary was disintegrated and contained pus. The patient rallied quickly and had no shock. Her pulse fell to 80 and her temperature to normal within twelve hours, and remained so. The tube was removed on the seventh day. There had been little or no pain, no catheter, no laxative or drug of any kind had been employed. The day after the removal of the tube her pulse began to rise as also did her temperature. Pain developed in the left ovarian region and she began to have hectic and cold creeps. About the eleventh day there was a free gush of pus from the tube tract and she began to improve again from that moment. A rubber tube was inserted and passed deep into the pelvis and the abscess was washed out twice daily. The discharge gradually diminished and the tube was again removed. The wound is now completely healed and the patient is a well woman.

The belief that a certain proportion of our puerperal fever cases are simply cases of salpingitis septica is by no means a new one, and is probably held by most of the great operators in the world. Dr. M. Sänger says that "salpingitis septica co-existing with severe puerperal septicæmia has never as yet given the surgeon an opportunity to remove the principal focus of disease by the extirpation of the tubes. It is possible, however, that under certain circumstances such a proceedure might be indicated." Dr. Carl Schroeder holds that "septic endometritis does not extend to the tubes as a rule; occasionally, however, it does go on to a purulent salpingitis." That these cases do exist much more frequently than we have had any idea of is certain, and that oftentimes a life otherwise doomed can be saved by operative interference, is proved by the case presented to-night. Mr. Tait mentions four deaths from this cause in Queen Charlotte Hospital alone, and says "that these cases were, during life, all regarded as puerperal fever." Dr. A. Mastin, out of a total of two hundred and eighty-seven cases, found that seventy resulted from the puerperal state. Dr. Sänger mentions two cases which have come to his knowledge in which the over distended tubes burst and discharged pus into the abdominal cavity with death on the fourth day after confinement in one case, and on the twenty-first day, in the second case. He thinks that in both these cases the salpingitis existed before delivery, and mentions a case in his own practice in which this certainly was the condition. Hecker, as early as 1878, mentions two cases in which the pyo-salpinx was old and was only lit up by the puerperal state. Whether the disease arises *de novo*, or having already existed from other causes is simply lit up by the puerperal state, must be determined in each individual case. Hecker's and Sänger's cases as mentioned, had pre existing salpingitis, but in the seventy cases reported by Martin the micro-organism of puerperal septicæmia were found in the contents of the tubes and no mention is made of any other micro-organism, so it is fair to presume that these cases arose from the puerperal state pure and simple. Of course the possible contagion of gonorrhœa can never be eliminated except by a microscopic examination. In his case, although the trouble seemed very clearly to have arisen at the time of the second labor, possibly with her first also, yet the chance of gonorrhœal infection both before and after her first pregnancy are so great that he cannot pretend to say it was not present. The operation has up to this time been done at least four times in Philadelphia; one case was operated on just two weeks previous to mine by Dr. Longaker, in which a pyo-salpinx was found and removed, the patient dying on the second day. Dr. J. Price has since operated twice, and in

one case found more than a quart of pus in the abdominal cavity. The case, unfortunately, fell into his hands too late and the patient only survived two days. These cases, though few in number, certainly teach us that the work done in this direction is encouraging, and although a large percentage have died, it only warns us of the extreme importance of an early diagnosis and prompt surgical interference. It becomes our imperative duty in every case of post-puerperal trouble to make a thorough investigation of the case on the appearance of the first symptoms, and should a fullness be found on either or both sides of the uterus, accompanied by pain on touch, and with constitutional symptoms of gravity, there should be no hesitation as to the course to pursue. This being secured our present high mortality, of one woman out of every hundred delivered in large cities, as recently stated in a statistical paper on lying-in charities in the United States, must be largely diminished, and the fatal influences now surrounding our parturient women must become infinitely less.

DR. J. PRICE, remarked that the operation in this case was difficult and tedious, and was done with great care. He believes that conception can take place coincident with desquamative salpingitis. Salpingitis, even of gonorrhœal origin, may affect one tube only, and the other, being normal, may give exit to an ovule. Six months ago, he removed a large pus-tube from the right side; the woman is now four months pregnant. If he finds induration and distension of a tube, with inflammatory symptoms during the post parturient period, he does not hesitate to operate at once; the operation involving less danger to the patient than the rapid progress which the inflammatory process will take at that period. He read from a letter from Mr. Tait: "There can be no doubt as to the frequency of the occurrence of puerperal pyosalpinx, and what we want to do, is to hammer at people until we get them to open the abdomen in primary puerperal peritonitis." Dr. Price does not think septic post-partum salpingitis would be unilateral. He would also call attention to the extreme degree of degeneration that has taken place in the tissue of the tubes themselves, and most commonly unilateral only; they are quite cheesy in character. This change could not occur in so limited a space of time, a few days only.

DR. LONGAKER remarked that one of the four cases, referred to by the author of the paper, was a patient who was under his care and who died forty hours after operation. Briefly, the history of the case is as follows: A young woman, from Maryland, came to my office, being in the sixth month of her first pregnancy, for treatment for a profuse mucopurulent discharge having all the characteristics of a recent gonorrhœa. A month later premature labor set in. The child did not live. The placenta came away entire. Four days after labor she began to complain of severe pain in the left inguinal and hypogastric regions, paroxysmal and associated with great tenderness. The tongue was dry, but there was no nausea or vomiting. There was no chill, but the temperature was slightly elevated. The same symptoms continued for the next two days. On the morning of the eighth day, 7 A.M., she began to complain of intense cutting pains, temperature 96.5, pulse 96. Four hours later, under the free use of morphia, the pain was relieved, the temperature had risen to 102° and the pulse to 120. Dr. Jas. Price kindly saw the case with him and they agreed on the advisability of laporotomy. During the afternoon her temperature continued to rise, reaching 104° in the evening. On the following day she was much better, was free from nausea and vomiting and had no severe pain. Owing to this apparent improvement, Dr. Longaker allowed himself to be persuaded to put off operating. The abdomen was opened Feb. 14, 1887, the ninth day after delivery, and nearly sixty hours after the onset of acute peritonitis. General peritonitis and a large quantity of pus in the left region of the left comus uteri, exceedingly foul in odor, were found: the left tube was removed, it was an inch in diameter. The uterus was fairly involuted, it was firmly fixed in the pelvis. The wound drained freely, but incessant vomiting set in and the patient died forty hours after the operation. Is it not assuming too much to say these cases had pyosalpinx before conception? He is sure such was not the case in his patient. Though she had lived irregularly with a man for some five years, she had at no time such symptoms as would lead us to suspect this disease. It would be possible, if pyosalpinx be the consequence of a poison from without, to find entrance to the tubes during the first three and a part of the fourth month before decidua vera and reflexa became firmly united, but the result would most likely be an abortion at the time of the invasion. The morbific matter probably obtains access to the tubes after parturition is completed, and owing to the combined circumstances, acts in an explosive manner. Is not the pyosalpinx originated after labor as the result, it may be, of a gonorrhœa contracted between conception and labor, or before conception?

DR. HIRST presented a specimen from a case of

VIRULENT PUERPERAL SEPSIS,

by permission of Prof. Parvin, in whose service the case occurred. The specimens are interesting, not merely because they come from a case of puerperal fever, which unfortunately is not a rare disease, but from the rapidity with which the disease terminated fatally, and from the possible point of entrance of the septicæmic poison. The history of the case before delivery presents nothing worthy of note. Immediately after delivery the temperature was 99.5° and in spite of the most energetic antiseptic treatmeant of the vagina and uterine cavity, the temperature rose to 102°, but dropped again to 99.5°, only to rise again to 102°, where it remained till the woman's death, about seventy two hours after the birth. The post-mortem examination showed diphtheroid patches in the vagina extending into the cervical canal. The uterine cavity and walls were normal, the peritoneum, tubes and ovaries healthy, the kidneys were the seat of numerous metastatic abscesses, and there were several infarcts in the liver. The lungs were healthy. The rectum was covered

with extensive patches of diptheroid membrane, a very interesting condition, for it indicates the possibility at least, that here was the point of infection, and if this is the case, this specimen at once assumes considerable importance, for he knows of only three such cases recorded in medical literature, one by Winckel, the others by Koester and v. Recklinghausen. These specimens may well serve to call attention to the possibility of infection by the administration of enemata, and to the importance of observing the most minute precautions as to the chemical cleanliness of every instrument that may come in contact with the parturient or puerperal woman.

(*To be continued.*)

FOREIGN CORRESPONDENCE

TAIT AND PEAN.

Dear Dr. Fenger :—On Sunday evening, March 27, I called at the residence of Mr. Lawson Tait in Birmingham. As dinner-time was near at hand, I was invited to remain to meet some of his personal and professional friends. As I had been in training for some time to acquire the proficiency of eating two dinners in rapid succession, I readily consented to avail myself of this opportunity to meet the great laparotomist in the sanctum of his own home. Mrs. Tait is proud of the distinction her husband has attained, and takes a deep interest in his work. I found it quite difficult to keep Mr. Tait in the channel of thought for discussing subjects of professional interest upon which I wished to obtain information. The evening was devoted to social pleasures and the many good things spread upon the table, and I had to submit to the inevitable. During my conversation about my prospective trip to the Continent, I was made to understand that German gynecology was not appreciated in this part of England, and that it had done little or nothing towards the advancement of modern gynecology. If I had met with such an assertion under different circumstances I should not have hesitated a moment to resent most emphatically such an insinuation, and in support of my arguments I should have quoted the results of scientific investigations and conscientious work of such men as Schroeder, Winckel, Olshausen, Hegar, Kaltenbach, Sänger and others, whose names are household words wherever modern gynecology is known and appreciated; but under the existing conditions I had to control my temper and leave the remark unchallenged.

Mr. Tait takes great interest in specimens of antiquity, and his capacious house is one great curiosity shop. That the Tait family is childless became apparent to me by the kind attentions which were bestowed upon a fine specimen of a Maltese cat. In my mind the sight of that cat revived the memory of the useful purpose I had assigned to that brute in my researches in experimental surgery, but as I was aware that Mr. Tait entertains no kindly feelings towards experimenters, I made no suggestions in this direction. It is not necessary for me to give a description of Mr. Tait's personal appearance, as the photograph I sent you some time ago speaks for itself. If you add to the large head, the long and capacious chest and still more voluminous abdomen a pair of short legs, you have Mr. Tait as I saw him.

The next morning at 9 o'clock found me again at Mr. Tait's house, as the operations were to be performed in his private hospital, which constitutes a part of his house. I was shown into a room where a number of physicians had congregated. As we were all strangers to each other, silence reigned supreme until we were informed by one of the nurses that everything was ready. We filed up a flight of stairs and entered one of the rooms, where we found Mr. Tait standing by the side of the anæsthetized patient in his shirt-sleeves and a rubber apron. The temperature of the room was comfortable. A female assistant administered the anæsthetic, and a young physician stood opposite Mr. Tait ready to render assistance, but it soon became evident that his presence was more ornamental than useful, as the operator appeared to require no assistance. The few instruments that I saw were kept in clean pans. The often described bag containing the sponges was hanging from a nail upon the wall, and was taken down and a few sponges thrown in a basin of warm water. The patient's abdomen had not been shaved, and was now sponged off lightly and covered with a rubber cloth with a slit in the centre. The first patient was a lady about 50 years of age, suffering from an abdominal tumor which extended a little above the umbilicus. The abdominal incision was made quickly and was about 2½ inches in length. The omentum was found adherent to parietal peritoneum, and the adhesions were separated by tearing. As soon as the cyst was exposed it was tapped with the blunt fenestrated trocar devised by the operator. This instrument does not cut the tissues when it is pushed through the cyst wall, and consequently extravasation along the side of the tube does not take place, a source of trouble and danger attending the use of all trocars with a cutting edge. The pedicle of the cyst was twisted and appeared like an umbilical cord. The pedicle was transfixed with a long needle slightly curved at the end, and threaded with medium sized Chinese silk which, after the needle was withdrawn, was tied into a Staffordshire knot. The operator showed his unlimited confidence in this method of tying by dropping the pedicle at once in every instance, without examining the cut surface or separately ligating any of the visible vessels.

The immense experience Mr. Tait has had in this manner of securing the pedicle certainly entitles him to speak with authority, and after seeing him tie five pedicles I am convinced of the advantages of the Staffordshire knot over the ordinary methods of tying, and should recommend its general adoption. During the whole operation I observed that the abdominal wound was kept practically closed, either with the cyst, the pedicle, a sponge or the fingers of the operator. This I observed not only in this case but in all of the three cases, and to this circumstance, undoubtedly, a great share of the wonderful success

[1] By permission of Drs. Fenger and Senn.

of Mr. Tait must be ascribed. The operations are done, as it were, subcutaneously, thus reducing the danger from infection to a minimum, provided the hands of the operator, the instruments and the sponges are aseptic, and that this is the case in Mr. Tait's practice I became convinced, and his results only corroborate this statement. Mr. Tait may not be an antiseptic surgeon, but he is certainly, in principles and practice, an ideal aseptic surgeon, whether he is willing or unwilling to acknowledge such a designation. The abdominal wound was closed with four deep sutures. A small gauze compress and a thick layer of cheap cotton, with a wide flannel bandage, constituted the dressing. Time of operation and dressing, twelve minutes.

As soon as the operation was completed, the visitors were requested to retire to the same room, where I spent half an hour in meditation, trying to unravel in my own mind the mysteries which had led this wonderful man to such unparalleled success, when I was aroused from my dreaming condition to reality by another message that everything was ready. The little crowd of seekers for knowledge were led into another room, where we could hardly find time to arrange ourselves around the table when Mr. Tait was already in the abdomen with his bulky index finger, searching for the ovaries. In this case the incision was a mere button-hole. We were informed that the removal of both ovaries and tubes would be done for the purpose of preventing pregnancy in the future, as the patient had suffered greatly during and after delivery on account of a contracted pelvis, including the formation of a vesico-vaginal fistula, which, however, had been cured by operation. Both ovaries and tubes were removed. It was also stated that the patient was suffering from prolapse of the uterus, and this opportunity was utilized and the uterus was stitched to the inner surface of the abdominal wound after both tubes and ovaries had been removed. The whole operation, including the dressing, occupied only seven minutes. I forgot to mention before that the dressing is first fastened upon the abdomen with numerous strips of adhesive plaster which overlay each other, and embrace about two-thirds of the circumference of the body, over which another cotton compress is applied, and retained with a broad flannel roller.

To me the indications which had led to the removal of the ovaries and tubes in this case afforded abundant food for serious thought. There can be no question in my own mind, and in the mind of any one who has the well being and happiness of his fellow-beings at heart, that it was not desirable that this woman should again be exposed to the dangers of another pregnancy, but as a practical American it occurred to me that it would have been wiser to resort to the less hazardous procedure of unsexing her husband, which would have certainly secured the same immunity at a minimum risk to life, and morally would have been more justifiable. This poor creature had suffered untold agonies, and why submit her to such a serious operation to procure sterility, when the same object could have been reached without any danger to life by unsexing the other party?

The third operation was set for 12 o'clock. I was told the evening before that this patient was probably suffering from a pelvic abscess, and I was exceedingly anxious to see the operation devised by Mr. Tait for the radical cure of this often intractable affection. The abdomen was again opened by an incision only sufficiently large to introduce two fingers. A brief digital exploration resulted in the announcement that the swelling in the pelvis was not an abscess, but a small fibroma of the uterus. As it was claimed that this tumor must be the cause of the recurring attacks of pelvic inflammation, it was decided to again remove the uterine appendages. One of the ovaries was adherent, and required more than the usual length of time for its removal. Duration of operation and dressing, nine minutes. The explanation of the cause of the pelvic inflammation was new to me, as I had always entertained the idea that submucous and interstitial myo fibromata of the uterus, even when of large size, seldom give rise to inflammation of the adjacent or contiguous tissues, but for the sake of the patient I hope that the interpretation of the case was correct, and that the operation will be the means of preventing future attacks, as the patient who has lost one of her most important organs is certainly entitled to an equivalent of happiness in another direction.

From what I gleaned from my observations in the practice of Mr. Tait, I have come to the following conclusions: 1. He is a skilful and dexterous operator. 2. He depends on a diagnosis by digital exploration in the majority of cases. 3. He removes the ovaries and tubes in cases for indications which few gynecologists would be willing to accept as justifiable for such a serious procedure. His wonderful success may be attributed to: 1, aseptic surgery; 2, small incisions; 3, no unnecessary exposure of peritoneal cavity; 4, perfect familiarity with pelvic and abdominal surgery as far as the mechanical performance of operations is concerned; 5, rapid operating; 6, careful personal supervision in the after-treatment. There can be no question that much of his success also depends on the fact that he performs his operations almost without assistance, and in this respect all laparotomists should lose no time in imitating his example. With all his faults, Mr. Lawson Tait has done much towards the advancement of gynecology, and we may learn from him many a valuable lesson which will add to our success in practice.

I arrived in Paris via London, Dover and Calais, March 29. My principal object in visiting Paris was to see some of the abdominal work of Péan. In the evening I called at his residence, but failed to see him, as he had gone out to make his evening visit. In the absence of her husband Mrs. Péan kindly invited me to attend his operations next morning at the Hôpital, rue de Sarlé, where most of his abdominal operations are performed. The next morning at 9 o'clock I met him at the hospital, and was fortunate enough to see him perform two of the most difficult operations in surgery during the forenoon. Péan is a large man, with black hair and side whiskers, and is 58 years of age. His face shows intelligence and determination, and his whole appearance indicates a

man of superior knowledge and great courage. As soon as I entered the operating room my attention was attracted by the display of numerous instruments; the number of large and small hæmostatic forceps could not be counted, but there must have been at least more than a hundred. Usually he has four assistants. The operator wore a fur-lined vest and rubber apron. The operating-room is quite small, and was not specially heated for the operations. Chloroform is used exclusively as an anæsthetic. Only five visitors were present at this operation, which gave us a good opportunity to follow every step.

The first patient was a woman about 35 years of age, who had been suffering for many years from a myo fibroma of the uterus which at present reached above the umbilicus. Shaving and disinfection with a sublimated solution (1–1000) was done by Péan himself after the patient was under the influence of the anæsthetic. During the operation the sponges are in the hands of two sisters; one of them washes them in warm water, while the other wrings them out of a 1–1000 solution of corrosive sublimate and hands them to the operator or one of his assistants. The instruments are all immersed in a 5 per cent. solution of carbolic acid, and the hands of the operator and his assistants are thoroughly washed and disinfected before the operation. During the operation the abdomen of the patient is covered with a rubber cloth with a slit in the centre. The incision through the abdominal wall extended from above the umbilicus to the pubis. Before opening the peritoneum all hæmorrhage was carefully arrested with forceps, which were allowed to remain. On opening the peritoneal cavity to the full extent of the wound the tumor came into view, but could not be delivered through the wound by manipulation, and the operator transfixed it from side to side with a large, stout curved needle supplied with a handle, which gave him an opportunity to make traction at the same time one of the assistants made compression of the abdomen from behind in a forward direction, and the combined forces readily brought the tumor out of the wound. The broad ligament on each side of the tumor, with the enormously distended vessels, was compressed with two forceps and divided between with a pair of scissors. After reaching the base of the tumor in this manner on both sides, an elastic tube was applied and kept in place at the point of crossing with a pair of forceps. As soon as the abdomen was opened an assistant protected the omentum and bowels with a dry towel which had been rendered aseptic by boiling in a sublimated solution; this precaution is kept up during the entire operation, so that none of the abdominal contents are brought into view. These towels are used whenever it becomes necessary to protect the peritoneal cavity, and sometimes several are in use at the same time, and when they become saturated with blood they are changed.

During the whole operation the operator sits between the patient's legs, a position which certainly offers great advantages in operations upon the uterus which are necessarily prolonged. After the elastic constrictor was applied the tumor, which was composed of many portions, was removed in large slices with a large amputating knife, and whenever hæmorrhage occurred it was at once arrested by applying the large compression forceps. At times at least twenty-four forceps could be counted in the abdomen. When the base of the tumor was reached the bladder came into view in front, and injury to its walls was carefully avoided by ascertaining its exact position by means of a catheter. In tying the short pedicle, composed of the uterus itself, a large, blunt, curved needle, mounted on a handle, was passed on each side of the uterine canal, and the double ligature cut as the needle was withdrawn; this left four ligatures in two tracts. The outer portion on each side was tied with one of the ligatures which secured the large vessels on each side of the uterus, and the central portion was secured by tying two of the ligatures in front and behind. The remnants of the tumor above the ligatures were carefully dissected out, the mucous membrane of the uterine canal excised and the canal closed with deep silk sutures, all visible vessels were carefully tied with catgut, the surface cleansed, closed and dusted lightly with iodoform. The cut surfaces were brought into accurate apposition by suturing the muscular tissue with silk sutures, and finally, a row of catgut sutures for the peritoneal cavity. No hæmorrhage was observed after removing the elastic constrictor, and the operation was almost bloodless. The pedicle was dropped into the abdominal cavity, and after a careful cleansing of the wound it was closed in the usual manner. The wound was covered with a compress of sublimated gauze which was fastened with strips of adhesive plaster, over which a thick layer of absorbent cotton and flannel bandage was placed. The operation lasted two hours, and as the room was only moderately warm, it was not surprising that the patient showed some symptoms of collapse, from which, however, she recovered a few hours after the operation. Péan can well be called "master of forceps," and although he may carry the use of forceps to extremes, there can be no doubt that a full supply of such hæmostatic forceps as he uses will be of great use to the surgeon in performing bloody operations, and a source of comfort in times of greatest need, when troublesome and sometimes almost uncontrollable hæmorrhage stare him in the face. Péan shows no fear of blood, as he has full confidence in his forceps, which are often allowed to remain in the wound when ligation appears difficult or impracticable.

After this operation was completed a woman was brought in who had suffered for years from excruciating pelvic distress which had failed to yield to the usual treatment. The question presented itself whether the ovaries should be removed to bring about the anticipated climax, but, as Péan had failed in many instances to obtain the desired result by such a procedure, he has in a number of instances resorted to vaginal hysterectomy, and with better success. After the patient was under the influence of the anæsthetic the parts were disinfected, and the operation made with the patient in the exaggerated lithotomy position. The vagina was distended with two flat retractors, and the uterus drawn down with a

vulsellum forceps. The circular incision, through the mucous membrane, was made with a scalpel, and the tissues around the uterus seized step by step with compression forceps, and the dissection made with scissors, fingers and blunt instruments, almost bloodlessly. At first the Douglas cul-de sac was opened, and an attempt made to retrovert the uterus sufficiently so as to bring the fundus through this opening; this, however, failed. Next, the peritoneal cavity was opened in front of the uterus and the uterus was brought out through this opening. The round and broad ligaments were secured with forceps. After the uterus was removed, almost without the loss of a drop of blood, about twenty forceps occupied the vagina, and were allowed to remain. A few small pieces of sponge, secured with a string and dusted with iodoform, were introduced along with the forceps. The forceps are allowed to remain for twenty-four hours, when they are removed. It is said that secondary hæmorrhage never was observed after performing vaginal hysterectomy in this manner. The operation lasted an hour.

The next day I had an opportunity to see another supravaginal hysterectomy at the same place. The tumor reached to the ensiform cartilage and displaced the viscera in an upward direction. The patient was about 40 years of age, and had become quite anæmic from repeated losses of blood. The tumor was irregular in contour and presented a nodulated surface, owing to numerous small subserous myofibromata. The abdominal incision in this case extended the whole length of the linea alba, and the tumor was lifted out from the abdomen with the same instrument. Copious hæmorrhage took place from the punctures, which was promptly arrested by compression with sponges. The remaining steps of the operation were the same as in the first case, and the time occupied in its completion was two hours.

Péan is an untiring worker. Endowed with a vigorous body and an active brain, he finds no pleasure in rest. His voluminous works testify to his zeal and fertility as a writer, and the clinical material they embody shows an amount of personal experience seldom acquired by a man of his age. I was informed that frequently he performs from six to seven operations during a forenoon at the Hôpital St. Louis. Perhaps one of the best evidences of the high esteem in which he is held in the hospitals with which he is connected, is that his aged assistants submit humbly to his frequent and noisy scoldings, and that he is permitted to swear, and swear as only a Frenchman can, in the presence of the sisters, who evidently fail to appreciate that part of the performance, and who lose no time to do all they can by way of repair in silent prayer. Very sincerely your friend, N. SENN.

MISCELLANEOUS.

HEALTH IN MICHIGAN.—For the month of May, 1887, compared with the preceding month, the reports indicate that the cholera morbus increased, and that pneumonia, influenza, rheumatism, bronchitis, consumption of lungs, and tonsilitis decreased in prevalence. Compared with the preceding month, the temperature in the month of May was much higher, the absolute humidity was much more, the relative humidity was about the same, the day and the night ozone were more. Compared with the average for the month of May in the nine years, 1879–1887, intermittent fever, remittent fever, consumption of lungs, scarlet fever, diphtheria and diarrhœa were less prevalent in May, 1887. For the month of May, 1887, compared with the average of corresponding months for the nine years, 1879–1887, the temperature was higher, the absolute humidity, the relative humidity and the day ozone were more, and the night ozone were less.

Including reports by regular observers and others, diphtheria was reported present in Michigan in the month of May, 1887, at thirty places, scarlet fever at thirty-two places, typhoid fever at four places.

Reports from all sources show diphtheria reported at five places more, scarlet fever at seven places less, typhoid fever at four places less, measles at fourteen places more in the month of May, 1887, than in the preceding month.

COLORED NURSES.—The Atlanta University has established a training school for colored nurses, a much needed institution.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 4, 1887, TO JUNE 10, 1887.

Major B. E. Fryer, Surgeon, granted two months' leave on account of sickness, with permission to apply for an extension. S. O. 28, Div. Pacific, May 2, 1887.

Major B. E. Fryer, Surgeon, granted sick leave for one month. S. O. 28, current service Div. Pacific, amended by S. O. 29, Div. Pacific, June 2, 1887.

Major W. S. Tremaine, Surgeon, sick leave still further extended two months, on account of sickness. S.O. 129, A. G. O., June 6, 1887.

Capt. Paul R. Brown, Asst. Surgeon, granted leave of absence for four months. S. O. 126, A. G. O., June 2, 1887.

Capt. A. H. Appel, Asst. Surgeon, granted leave of absence on surgeon's certificate of disability for six months. S. O. 127, A. G. O., June 3. 1887.

First Lieut. Leonard Wood, Asst. Surgeon, ordered for temporary duty at Ft. Huachuca, A. T.; relieved from duty at hdqrs. Dept. Ariz. S. O. 126, A. G. O. June 2, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING JUNE 11, 1887.

Surgeon W. K. Van Reypen, ordered June 8 for examination preliminary to promotion as Medical Inspector.

Medical Inspector Somerset Robinson, ordered June 20 before a Retiring Board convened at Mare Island, Cal.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE TWO WEEKS ENDED JUNE 4, 1887.

Surgeon C. B. Goldsborough, detailed to represent the Service at the meeting of the American Medical Association at Chicago, Ill., June 6, 1887. June 1, 1887.

P. A. Surgeon C. E. Banks, when relieved to rejoin station at Boston, Mass. May 23, 1887.

Asst. Surgeon Seaton Norman, when relieved to rejoin station at Cape Charles Quarantine. May 26, 1887.

ADDRESS IN SURGERY.

TRACHEOTOMY AND INTUBATION — PERITONITIS.

BY H. H. MUDD, M.D.,

OF ST. LOUIS.

Read by Title, at the Thirty-Eighth Annual Meeting of the American Medical Association.

The increased power conferred upon the surgeon by the developments resulting from Listerism, has wonderfully enlarged the sphere of his action. In deed so widely recognized is this power and so attractive the outlook, that nearly every physician has become a special surgeon, and to day there is no specialty so neglected as that most valued and essential one of internal medicine. The science of Surgery is being so rapidly advanced, and the changes are so radical, that it would be impossible to present to you those which commend themselves to an individual judgment. It would weary and but little profit you to listen to the long list of surgical proceedures which are new, or are debatable ground. The seeming perfection of many of our operative procedures leaves apparently little to be desired. Yet so rapid are the genuine advances, that the text books of the day are old on the morrow, and need revision before the printer's ink is dry on their pages. The medical mind of to day has broken away from the trammels of the dogmas, and the traditions of the past. Sometimes it finds sorrow and trouble in its wanderings, and returns to the principles recognized by the Fathers in Medicine. At other times we find much comfort and great congratulation in our new achievements.

The physiologist and experimentalist are now as fully appreciated by the surgeon as is the anatomist. The anatomist guides the hand, while the experimental physiologist tells of new regions to be explored, and new possibilities to be attained by the surgeon. The flood of light and the maze of facts presented to us by the physiologist, the pathologist, the experimentalist, and the practitioner, is so great that an active brain and an energetic body must be ever at work winnowing, assorting, and arranging the facts and theories which guide the work of the day.

The shrewd guess and the daring operation of to-day is the science of the morrow.

The surgeon in entering hitherto unexplored regions demonstrates new physiological laws and makes possible more daring operations. He garners from every field, and tests the knowledge thus obtained in the crucible of experience. The surgeon, then, must be a scientist, and it is a great comfort to every practitioner to recognize the fact that his work is becoming more precise. Diagnosis, prognosis, and therapeutics are each day becoming more accurate. In other words the opportunities for applied science are daily increasing. There is no problem more complicated or one that requires greater mental acumen, or more physical energy and endurance than the proper adjustment of the means to the end in the practice of medicine and surgery. The man who can accomplish this is as truly scientific as he who delves among the abstruse problems of astronomy or anthropology.

The recognition of disease and its treatment is but part of our work, for its etiology is also sought in our appeal to the profession of the world through the Committee for the Collective Investigation of Disease. The Committee of the British Medical Association, through Mr. Henry Butlin, reports that, to use his own words: "I confess that when I first proposed the subject of inheritance of cancer, for collective investigation, it was with a very small belief in the reality of inheritance. I am forced to own that the mass of evidence that has been accumulated by the inquiry has led me to take a different view. Our returns show that there was a history of Cancer in the direct line of descent in 20.60 per cent. of the cases, and if only the fathers and mothers of the cancerous patients are considered, that there was a percentage then of no less than 16.84." Again, to quote from the report, "The impression of Prof. Humphrey, that large eaters, and especially large meat eaters, are particularly liable to Cancer, does not seem to be supported by the information obtained by this committee."

These and kindred subjects involve great knowledge and research, and vast as is the knowledge at command, and precise and exact as are many of our methods, it should be clearly recognized that all surgical rules have their exceptions, and the surgeon is not a carpenter, who with his square and compass at hand works upon inert material which responds always and ever the same to the saw and file. The results in surgery are not always assured, even when the procedures are well considered. What wonder, then, that we, in our vain endeavor to harmonize development and life, with disease and decay find many mooted points for discussion?

It would be strange if workers so persistently en-

gaged did not contribute to scientific facts to other departments of knowledge. Surgeons not content with applying knowledge gained from other fields, contribute through the perfection and the accuracy, and the thorough appreciation of every detail of their work, truly scientific facts to the sciences of biology, bacteriology, physiology, pathology, and even anatomy. Scientific practice stands as an entity, worthy of the devotion of the scientific mind.

Many surgical diseases which have long been with us receive routine treatment, which it is becoming evident is erroneous. So it is with some of the so-called advances of the year which must be accepted with a doubt and rejected after a trial. Individual judgment is all powerful with us yet, and practice is as varied as the surgeon and the patient.

Hence in stating my view to day of points in practice, I shall no doubt clash with some of you. Let it not then be understood that, however earnest I may be in stating my convictions, I regard or ask you to accept as final, any expression of mine on matters of practice ; and if I state too strongly any point, it is the earnestness of conviction, and not the dogmatism of intolerance that causes me to speak forcibly.

Patients and surgeons are not the same from day to day. It has been well said, "The privileges of a wise man, is to make mistakes—only fools are perfect, (perfect fools)." The dull and stupid surgeon is the only one who is satisfied, and is surely right in following rules.

It is not to the rare and brilliant procedures of surgery to which I invite your attention; but rather to the common and frequent diseases. I shall endeavor to discuss two subjects that are now undergoing the test of experience. These subjects are alike important to the physician and to the surgeon.

I ask your attention first to *Tracheotomy and Intubation for Diphtheria and Croup*, and then to the subject of *Peritonitis*.

TRACHEOTOMY AND INTUBATION.

The question of Tracheotomy or Intubation has been on trial and I think progress has been made in the treatment of the laryngeal stenosis, which so frequently accompanies diphtheria and croup. The progress of the past year or two in the solution of this very difficult problem is shown in the disposition to give prompt and early relief to the obstruction, rather than in the introduction or revival of intubation. Diphtheria and croup are always with us, and are so destructive to life that many physicians assert, the one that diphtheria, the other that croup never gets well, and that operative interference is of no avail. Yet patients recover from either or both diseases. Culpable is the man who recognizes this fact and stands at the bedside of the little sufferer and waits for nature to relieve it from the laryngeal obstruction. The history of laryngeal diphtheria, is that the obstruction is progressive, and becomes severe enough to demand relief on the fourth or sixth day; and failing to obtain this relief, soon ends life. I can well see how practitioners vary much in their estimate of the virulence of the diseases which produce laryngeal stenosis ; but I can not find any excuse for one who will permit a child to die from mechanical obstruction, no matter what disease originated it, or how fatal that disease may be in its tendency.

Some of you may think it unnecessary to dwell on this point; but I am sure there are many here who have seen children die from this obstruction, before the disease producing it terminated life. Tracheotomy is not a pleasant operation, and many shrink from it ; it is performed for a disease progressive and fatal in its tendency. The results are not brilliant, and there is nothing to induce the surgeon to urge the operation, except humanity and the positive knowledge that lives are thus saved. Statistics are not always reliable, and especially will they vary from year to year in the mortality of different epidemics of diphtheria. Nevertheless, I venture to present some statistics taken from the records of our private office, for I think they illustrate and demonstrate an important point which I wish to emphasize. It is, however, possible that the great improvement in the results of the last few years have been due to the fact that the patients have very generally been subjected to repeated doses of corrosive sublimate by the attending physician before it was necessary to operate. Some practitioners assert that the surgeon has been displaced by the use of corrosive sublimate. I believe, however, that all who consider the circumstances under which these statistics were collected will admit that the gradual improvement is due to the fact that the operation during the later years was not withheld from the patient until such changes were induced by the long continued obstruction as to lead to fatal results, without reference to the primary disease.

I was associated for many years with the late Dr. John T. Hodgen, who was one of the staunchest advocates of tracheotomy. The records of our office for the past thirty years show 170 cases of tracheotomy for diphtheria and croup, with 46 recoveries, or a percentage of 26.9. The record of the operations by Dr. J. T. Hodgen begins in 1856, and ends in March, 1882. He made 14 consecutive operations without a recovery in the early part of its trial. In the period ending March, 1877, he had made 70 operations with 9 recoveries. During the last five years of his life, ending in 1882, he made 21 operations with 6 recoveries. My record begins in 1872, and with the close of 1883, out of 42 cases there were 12 recoveries.

1884—4 cases; 1 recovery.
1885—3 cases; 2 recoveries.
1886—22 cases; 11 recoveries.
1887—3 cases; 2 recoveries.

And from January, 1884, to date, 32 cases with 16 recoveries; or a total of 28 recoveries out of 74 cases, beginning in 1872 and ending with present date.

My brother, Dr. Harvey G. Mudd, has had 6 cases with 3 recoveries. This makes a total of 171 tracheotomies with 46 recoveries.

The statistics show a progressive improvement in the results, attributable, I believe, in great part to the fact that the class of cases offered to the opera-

tor is better than in former years. The operation is not so often postponed until death is imminent, and yet these cases are such as demanded the operation because of the severity of the symptoms of obstruction. In only two of the whole number of cases was tracheotomy performed before the obstruction was sufficiently urgent to demand relief. One of these two died from the virulence of the diphtheritic process, and the other recovered after wearing the tube for twenty days. The indications demanding tracheotomy or intubation in diphtheria or croup are plain. The labored respiration is preceded by a slight or well-defined hoarseness, and is interrupted by suffocative attacks, accompanied by violent and labored muscular efforts to obtain air. If these attacks recur and are violent, it makes necessary earlier operative interference. If the stenosis rapidly increases, the demand is much more urgent with the same degree of obstruction than if slowly progressive. The steadily increasing difficulty in respiratory movements is evinced not in the rapidity of the movement, but in the muscular effort displayed. Inspiration excites the trapezius, the sterno mastoid, the laryngeal, the inter scapular muscles, the intercostals, and above all the diaphragm, to violent effort.

A labored expiratory effort in which the abdominal muscles are rigid and contracted, accompanied by depression of the supra-sternal tissues and the sharp pitting at the ensiform cartilage, is the most evident sign of laryngeal stenosis. The child keeps the body straight, and is inclined to throw the head back, producing slight orthopnœa. The face, at first flushed, soon becomes pale and dusky, with blueish lips. How very different is the appearance when respiration is insufficient from deposit in the bronchi. Here respiration is more rapid and superficial, and the pitting of the epigastrium and of the supra sternal tissues is less marked. The skin is livid, and the eyes listless and with dilated pupils. Diminished vesicular respiratory murmur is present in either case, and before effusion into the bronchi occurs. The first group of symptoms is urgent in its demands for relief; the latter does not demand operative interference, for the conditions cannot be so relieved. Yet the two conditions are sometimes combined, and it is almost impossible for the surgeon to say of a given case, "It is hopeless," for recoveries from the most desperate conditions sometimes follow operations. There are many conditions when the surgeon may stand by and watch for the progress of the case to relieve him of the need for operation; but laryngeal stenosis is not one of them, and no child should be permitted to die without the relief afforded by tracheotomy or by intubation.

Tracheotomy is, in my opinion, the better, the safer operation, and I believe time will attest its value as a therapeutic measure, and make clearer its importance to the profession and the public. The statistics here presented result from its use in many different epidemics, and where it was permitted as a last resort—yet the percentage of recoveries is more than one in four; or, to be exact, 26.9 per cent.

My experience with intubation has not been very extensive; but sufficient to lead me to believe that intubation, though more readily performed, is not less dangerous. Consent can sometimes be gained for it when for tracheotomy it would be denied. It is perhaps admissible where, in the absence of urgent symptoms, tracheotomy should not be urged or permitted. Tracheotomy prevents the development of bronchitis and bronchial pneumonia, which is consequent upon the congestion and effusion which results from the obstruction. Intubation develops a bronchitis and pneumonia of its own, as a result of the influx of fluids in the necessary effort of deglutition. A large number of those who have been subjected to this operation have died from this broncho-pneumonia before the fatality of the diphtheria could assert itself. In my limited experience, I have had one case in which the tracheal and bronchial catarrh was so profuse as to become exhausting and in itself dangerous. Another, in which the child repeatedly ejected tubes of different sizes, until its vitality, from the dyspnœa of recurring obstruction, was nearly exhausted. A third in which detached membrane obstructed the tube and suffocation was imminent. A fourth in which the tube was ejected and another physician made a tracheotomy. Two cases in which recovery followed a subsequent tracheotomy, and in which I am satisfied the patients would have died if continued reliance had been placed on intubation.

Dr. O'Dwyer has given a very fair exposition of the advantages and difficulties attending intubation; but I cannot agree with him that his "long tubes are likely to prevent plugging of the tubes by detached membrane, or that the tube is easily expelled when plugged by portions of membrane." It is my observation that when the membrane once extends into the trachea, it extends throughout its length, and the presence of a laryngeal tube will not prevent this extension.

Experience and reason tell me that the tube is much more frequently expelled by cough where there is no tracheal or bronchial obstruction than where one of these exists. The expulsive force is better applied, and the muscular power greater, than where such a process has advanced down the trachea and into the bronchi. (Vol. iv, Handbook of Medical Sciences.)

The long tube, I believe, gives an opportunity to start expulsion by bending the neck, thus loosening it from the larynx. The limited motions of the cord, the infiltration of the tissues of the larynx, and the paralysis of the muscles occasionally demand a long continued use of the tube which is incompatible with the life of the patient, since deglutition and nutrition are attended with difficulty while using it.

Tracheotomy. on the other hand, rarely interferes with the nutrition of the patient. Fluids as well as solids are taken readily when other symptoms permit, and the nutrition of the patient, the most important element in the treatment of diphtheria, is not disturbed. The trachea is exposed, and can be more readily cleansed of membrane. The lumen of the trachea tube is larger and favors the expulsion of membrane, and if, in expulsive effort, it should become blocked, any nurse, no matter how ignorant, can remove the tube, and respiration will ordinarily

be maintained through the larynx or tracheal wound until the surgeon is called. The operation is not so easily performed as intubation; but it is not more dangerous, and should be accomplished in from five to twenty minutes. I do not know of any more trying or disagreeable operation than tracheotomy when the demand for relief is urgent; but I firmly believe that it offers a better chance for curative influence than intubation. When a surgeon skilled in the operation is not at hand, no one should shrink from the operation if the obstruction is marked.

In estimating the value of tracheotomy in diphtheria, I hope all will remember that it is performed for one of the most fatal and desperate of diseases, and only for the severer forms of the disease. The greater and more marked is the triumph when success is attained. Like ovariotomy, its statistics will improve as the recognition of its necessity is earlier appreciated, though its results in diphtheria will never equal the marvellous records of ovariotomy. They are sufficient to appeal to every physician for its employment before the child reaches a moribund condition. The gradual diminution of the tidal wave, the increase of the residual air, and the consequent congestion of the mucous surface, with its attendant bronchial effusion and catarrhal pneumonia, will not then add to the gravity of the case.

The apparent results of tracheotomy would, I believe, be vastly improved if it were applied to such cases as I suspect have been utilized for intubation. Yet I wish to emphasize the fact that tracheotomy should not be made until there is a marked recession of the supra- and sub-sternal tissues during inspiration, followed by a forced expiratory effort. This muscular effort is incompatible with very rapid respiration; but it indicates a local, usually laryngeal obstruction to the respiratory movements. The rapid respiratory movements which are found in children suffering from pneumonia, from capillary bronchitis, and from the deposit of diphtheritic or croupous membrane in the bronchi, is very different, though often mistaken for that slower but more labored respiration of local obstruction. Occasionally the two conditions are combined and the differential diagnosis is impossible.

I think Dr. F. E. Waxham has improved the gag of Dr. O'Dwyer, and improvements in the instruments used in intubation may render it still more useful; but as yet it cannot compete with tracheotomy where there is need for operative interference. Tracheotomy gives fresh air to the lungs, and if care be taken to moisten and warm this air, there is practically little danger of serious bronchitis or pneumonia, and there is less danger of the extension of the membrane downward, than if the respired air first passed over the foul and diseased mouth and pharynx. This, I believe, is no small factor in favor of tracheotomy. Again, after tracheotomy it is the exception to find an extension of the membrane in the fauces; but the local condition often begins to improve after operation. Watson Cheyne, of Edinburgh, attempts to show "that tracheotomy ought to be performed in cases of diphtheria as soon as it is certain that the larynx is affected, chiefly with a view of preventing the spread of the disease downward." There may be some reason in the rule; but there are many reasons why I do not favor its recognition. Nor do I believe in our ability to control the extension of the membrane by antiseptic solutions and forcible cleansing of the surface involved, as advocated by Mr. Cheyne. Certain it is, however, that it is rare to have the membrane extend down the trachea, unless it has already invaded it at the time of the tracheotomy. In this connection it may be well to consider another suggestion made by the same author, that is, "the utility of packing the epiglottic space above the tracheal opening with an antiseptic plug." The paper referred to seems to be absolutely theoretical in every part, and I am not disposed to believe that his conclusions are practical; but experience will, I think, confirm the thought that tracheotomy helps to prevent the extension of the membrane down the trachea, and possibly an antiseptic plug may be found useful. These remarks may lead some of you to accept the following deductions as practically correct. It would far transcend the limit of time allowed me to put before you all that might be said on the subject:

Mechanical obstruction in the larynx demands relief when sufficiently great to threaten death. Tracheotomy when performed under similar conditions with intubation promises better results, because:

1. It does not interfere so much with deglutition and nutrition.

2. The opening can be maintained as long as desired.

3. The opening is larger and is not so likely to become plugged with membrane.

4. If plugged the tube can be removed by the most ignorant attendant.

5. It enables us to introduce moist, warm, pure air to the lungs.

6. It gives us a much better chance to clear and cleanse the trachea.

7. The operation is not more dangerous from hæmorrhage from injury of important parts, from death by chloroform, narcosis, or from suffocation, than is intubation, from the laceration of contiguous parts, from the escape of the tube into the stomach, or from suffocative attacks excited by manipulation, and by the detachment of membrane.

Intubation is, however, not to be condemned. It has its sphere of usefulness and it may be said in its favor:

1. It is bloodless, and consent can be obtained when other operations would be denied.

2. It is more quickly performed and is done without an anæsthetic.

It will relieve ordinarily the symptoms of dyspnœa.

I believe, however, it will find its chief benefit when applied to chronic obstruction of a cicatricial character, and that its influence will be pernicious in these acute conditions because it does not fulfil so well all the necessities of the case, and will be resorted to by the unskillful and the timid surgeon, who is willing to accept an easy way out of a difficult position.

PERITONITIS.

The subject of peritonitis with laparotomy, prophylactic or curative is just now of vast importance. The magnitude of the subject and the mass of literature already accumulated preclude the possibility of fully considering the one, or of reviewing the other. Yet, I believe it will not be unprofitable to consider briefly what seem to be, in the absence of well established rules, justifiable procedures in the treatment of peritonitis.

Laparotomy is urged for gun shot wounds, stabs, contusions, ruptures and ulcerations, where it is supposed that visceral involvement has made possible the escape of fecal matter. The most difficult matter here to be considered is diagnosis. Are the diagnostic signs of such visceral effusion as may be expected to accompany shot wounds, stab or rupture promptly manifested and clear in their character? The shock of a penetrating wound varies not only with the amount of the injury inflicted, but with the individual and may delay distinct evidence of visceral, injury until a peritonitis fatal in the shock attending its onset closes the scene. Positive signs of perforation will in many cases be absent, and we must make our operation one of exploration, or else await the development of the case. In the absence of clinical signs, positively indicating visceral lesion, must we promptly resort to exploratory laparotomy in all cases of gun shot wounds?

I take the gun-shot wound as a typical one, apt to produce visceral lesion with effusion, and because there is greatest need for improvement in the therapeutic measures in this class of injuries. The answer to this question must be guarded, for a categorical one would but poorly express the sentiment of the profession of to-day. We may first exlude such cases as are accompanied by profound shock, evidenced by lowered temperature and loss of general vital power, since the minute examination of the abdominal viscera necessary to repair such injuries is likely to intensify the shock and hasten an unfavorable result. Again, it cannot be successfully denied that cases recover after visceral laceration by bullet wounds without operative interference. These recoveries are more apt to follow where the ball is small, and the intestinal canal is comparatively empty. The proportion of these spontaneous recoveries is as yet unknown; but they are, I believe, sufficient to justify non interference in penetrating wounds inflicted with a small ball, where urgent symptoms due to the escape of visceral contents, are not present. There remain, then, for exploratory laparotomy, cases in which shock is not too great or where it is transient, and followed by pain, anxiety, tympanitis and other symptoms indicative of visceral injury. Theoretically, the exploratory operation is correct and should be applied to every case of bullet wound since perforation is expected in all; but in practice there are many obstacles, and it is questionable how great an improvement in results obtained will follow the enforcement of this therapeutic measure. The average result attending the expectant treatment is bad, yet it must be remembered that the injury is severe.

Laparotomy as a therapeutic measure is one about which surgeons are anxious, and which they guard with every precaution against untoward results, although laparotomy performed on an unintflamed peritoneum is not considered a dangerous operation, and is usually innocent of harm. In estimating the absolute need for operative interference it should be remembered that all perforating visceral wounds do not permit the escape of visceral contents into the peritoneal cavity, and that small quantities may be absorbed or encapsulated, and the consequent inflammation be limited and a cure established. On the other hand, it is known that an acupuncture may excite peritonitis, that a bullet wound is prone to ulcerate at its exposed surface, that a break or rupture in the peritoneal surface which communicates with a connective tissue space or a visceral cavity is a focus for a diffuse peritonitis, while a smooth well approximated wound in which the peritoneal surfaces are in contact, readily heals.

If the severe shock of a great injury merges into a violent peritonitis, or the milder cases where diagnostic signs have been absent develop a diffuse inflammatory process, what are we to do? The peritonitis, diffuse and violent may develop without the escape of visceral contents, and the patient recover. Peritonitis following the escape of the visceral contents is almost certainly fatal. A laparotomy performed in the presence of peritonitis is certainly injurious and without any benefit unless we can remove septic fluids, drain purulent pockets, repair leaking rents in the viscera, or cut off from the peritoneal cavity infecting pockets by approximating serous surfaces. Diagnosis is here again deficient, and we are unable to determine the necessity for operative interference, the operation is again exploratory, except where the septic serous effusion is large or the peritonitis is circumscribed and purulent pockets are perceptible. Here the demand is unequivocal and clear and is not to be ignored. The well-founded general laws of surgery give warrant for this laparotomy and no exceptions are admitted where the vitality of the patient is not exhausted and death iminent. General loss of vital power threatening death, or grave functional disturbance, or the known presence of visceral contents in the cavity are urgent demands for operative interference, notwithstanding the presence of peritonitis. The laparotomy will be curative in its influence if visceral lesions are repaired, antiseptic cleansing thoroughly established, and good drainage effected. If the peritonitis is slow in its development and the diagnosis is uncertain, there is a wide diversity of opinion as to the method to be pursued. Operative interference is pernicious, and a toilet of the peritoneum is of no avail as a therapeutic measure unless septic fluid is removed or lacerations repaired.

Surgeons of wide experience do not interfere as long as there is a possibility of a spontaneous cure; others advise the operation as soon as peritonitis is evident.

The difficulty with most surgeons will be in the fact, that it is impossible to determine that conditions are present which demand interference and

which would be benefited by so grave an operation as abdominal section. I believe it to be safer to wait in the presence of peritonitis until definite indications are present to show fæcal extravasation, septic fluid, purulent collections, or a fatal tendency in the inflammatory process before resorting to a secondary operation. There is then no rigid rule to govern us in these cases. Each case is to be well considered and the result obtained, may neither uphold nor condemn the course pursued. Recovery follows desperate injuries and desperate remedies are legitimately applied to conditions of such grave prognosis.

It would be useless to quote the authorities, old and new, on this subject, since antiseptic surgery has revolutionized the entire subject of abdominal section. It is quite impossible in the time allowed now to analyze the subject or give reasons for the position here assumed. I believe, however, that immediate exploratory laparotomy offers the better field for operative work, and that it is justifiable where there is reason to think that visceral contents or considerable amount of blood has escaped into the peritoneal cavity.

Laparotomy is not demanded in the presence of peritonitis except where septic fluid is abundant, a purulent collection is evident, a general loss of vital power threatens death, or where there is grave functional disturbance.

These deductions are not so radical as many would like but they are less conservative than many practice, and I believe they fairly represent the position of the profession on a mooted point, which only the recorded experience of years can definitely determine. They are the principles which would at present guide me in the management of such cases, and are the deductions made from a limited experience and the study of some of the recent literature bearing upon the subject.

MEDICAL PROGRESS.

THE INFLUENCE OF TEA, COFFEE, AND COCOA ON DIGESTION.—DR. JAMES W. FRASER, in the recent number of the *Journal of Anatomy and Physiology*, has recorded the results of an interesting series of experiments on the action of our common beverage on stomachic and intestinal digestion. The experiments have been most carefully arranged from a physical standpoint, and give us some valuable hints on the digestion of the chief alimentary principles, but they have no bearing, it should be mentioned, on individual variations of human digestion, or on the influence of various glands in preparing the gastric or intestinal juices. They are, however, of much value in showing how standard preparations of the peptic and pancreatic ferments are modified in action when our ordinary daily beverages are allowed their free action on the digestion of various articles of food. The digestive processes were carefully investigated, and absorption was imitated by a proper dialysing arrangement. An artificial peptic juice, and afterwards an artificial pancreatic juice, were employed, and the amount of nitrogenous matter dialysed was most carefully estimated. The food stuffs experimented on were raw and cooked serum and albumens, raw and cooked myosin, syntonin, alkali albumen, casein, gluten, starch, and oleine. The results obtained from an exhaustive series of experiments and analyses show that all the three typical infused beverages — tea, coffee and cocoa—retard the digestion and absorption of all the nitrogenized proximate principles of dietetic substances when peptic and pancreatic digestion are taken together, and that they uniformly retard peptic digestion, although tea may assist the diffusion of peptones from the stomach. Pancreatic digestion is also uniformly retarded, and diffusion thereafter is but rarely assisted, so that neither of them compare advantageously with water as a standard beverage for experimental investigarions. A summary of dietetic advice is added to Dr. Fraser's observations, which will, in the main, agree with that which is now given by our best authorities in cases of dyspepsia; and we are glad that experimental injuries afford so strong a basis of support to empirical observations:

"1. That it is better not to eat most albuminoid food stuffs at the same time as infused beverages are taken, for it has been shown that their digestion will in most cases be retarded, though there are possibly exceptions. Absorption may be rendered more rapid, but there is a loss of nutritive substance. On the other hand, the digestion of starchy food appears to be assisted by tea and coffee; and gluten, the albuminoid of flour, has been seen to be the principle least retarded in digestion by tea, and it only comes third with cocoa, while coffee has apparently a much greater retarding action on it. From this it appears that bread is the natural accompaniment of tea and cocoa when used as the beverages at a meal. Perhaps the action of coffee is the reason why, in this country, it is usually drunk alone or at breakfast, a meal which consists much of meat, and of meats (eggs and salt meats) which are not much retarded in digestion by coffee. 2. That eggs are the best form of animal food to be taken along with infused beverages, and that apparently they ase best lightly boiled if tea, hard boiled if coffee or cocoa, is the beverage. 3. That the casein of the milk and cream taken with the beverages is probably absorbed in a large degree from the stomach. That the butter used with bread undergoes digestion more slowly in presence of tea, but more quickly in the presence of coffee or cocoa; that is, if the fats of butter are influenced in a similar way to oleine. 5. That the use of coffee or cocoa as excipients for cod-liver oil, etc., appears not only to depend on their pronounced tastes, but also on their action in assisting the digestion of fats."—*Lancet*, May 7, 1887.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Thirty eighth Annual Meeting, held in Central Music Hall, Chicago, June 7–10, 1887.

TUESDAY, JUNE 7—FIRST DAY.

The Association was called to order at 11 A.M. by CHARLES GILMAN SMITH, M.D., Chairman of the Committee of Arrangements.

Prayer was offered by Rev. S. P. McPherson.

The President, Dr. E. H. Gregory, of St. Louis, Mo., Vice-Presidents, Drs. P. H. Millard, of Minnesota, Wm. H. Pancoast, of Pennsylvania, and W. C. Wile, of Connecticut, the Permanent Secretary, Dr. Wm. B. Atkinson, and the Treasurer, Dr. R. J. Dunglison, were present.

HON. JOHN A. ROCHE, Mayor of Chicago, was introduced by the Chairman of the Committee of Arrangements, Dr. Chas. Gilman Smith, and delivered an

ADDRESS OF WELCOME.

Mr. President and Gentlemen, Representatives of the Science of Health and Life:—In the name of the citizens of Chicago, I welcome you to this city, distinguished for the large number of able and eminent members of the medical profession, and for the exemplification, in all the avocations and pursuits of life, of the precept: "Whatsoever thy hand findeth to do, do it with thy might." Your mission—to preserve health and remove disease, to prolong life and make it a blessing—is a beneficent and noble one, worthy of all honor. And though you have not yet succeeded in overcoming death, you have robbed it of half its terrors.

The present generation has seen great progress in medical science, and the medical profession, I think, has kept pace with the other learned professions, if it has not even excelled them, in original investigations and practical discoveries for the benefit of mankind.

When in health, we laugh at the doctors, and sometimes enjoy a joke at their expense. But in sickness, you are our hope and refuge, and to the worn and wasted patient, just struggling back to life from the gates of death, you are like "the shadow of a great rock in a weary land."

The interchange of ideas and experience, and the discussion of theories and experiments by large bodies of educated men, gathered from different and distant sections of the country, by which the individual thought and knowledge of each becomes the property of all, is a comparatively modern outgrowth of society, and must contribute greatly to the interest and usefulness of the medical profession, being full of promise for the future. These gatherings for mutual comparison and consultation minimize differences, soften asperities cultivate the amenities, strengthen the humanities, stimulate inquiry and investigation, extend the horizon of mental and moral vision, enlarge the boundaries of human knowledge, and tend to the unification, improvement and well-being of the whole community.

Gentlemen: I came here as the official representative of a great and hospitable city whose latchstring is always out, to emphasize the welcome of Chicago to this large, intelligent and representative convocation of a profession whose chief occupation is to *save* life and not *destroy* it, and whose cardinal doctrine is, that a sound mind in a sound body is essential to the best performance of the duties of *this* life, and a great help in fitting men for the life *hereafter*.

Invitations were presented and accepted from various institutions and clubs of Chicago.

Ex-Presidents Drs. N. S. Davis, Wm. Brodie, J. M. Toner, and T. G. Richardson, by invitation, were seated on the platform.

A number of voluntary papers were announced and referred to the appropriate Sections.

Vice-President Perry H. Millard, of Minnesota, occupied the Chair while the President delivered the

ANNUAL ADDRESS.

(See THE JOURNAL, June 11.)

On motion, a vote of thanks was tendered the President for his able and interesting address, and it was referred for publication.

DR. A. NELSON BELL, of New York, offered the following

REPORT OF THE COMMITTEE ON MEMORIALIZING CONGRESS RELATIVE TO MEDICAL AND SANITARY SERVICE ON BOARD IMMIGRANT PASSENGER VESSELS.

Your Committee regrets that, notwithstanding the delay of its report (which would have been submitted last year but for the unaccountable failure of the mail delivery to the meeting at St Louis), the purpose for which it was appointed is still unattained. After conference and considerable correspondence with the House Committee on Commerce, your Committee was given to understand that the "Act to Regulate the Carriage of Passengers by Sea," of July 22, 1882, already provided against the evils of which it complained. To that reply the Chairman of your Committee addressed a letter, January 21, 1886, to the Hon. John H. Reagan, Chairman of the House Committee on Commerce (and author of the "Act to Regulate the Carriage of Passengers by Sea" as it now obtains), calling his attention to the manner in which the obligations of the law are evaded, and requesting that it be amended accordingly; comprehending such suggestions for amendment as had been agreed upon by your Committee.

The chief evasions of, and abuses under the law are, firstly, wherever the law reads "whereon emigrant passengers, or passengers other than cabin passengers," *first* cabin and *saloon* passengers are construed into exemption from the legal obligation; and secondly, in the incompetency, insufficiency and disgraceful status of the medical officers.

To meet these evasions and wanting conditions, your Committee recommended and still urges that the law be amended as follows:

1. Wherever the words "cabin passengers" occur, they should be made to read *first* cabin and *saloon* passengers.

2. That section 5, of the Act of July 22, 1882, which requires that "Every steamship or other vessel carrying or bringing emigrant passengers or passengers other than cabin passengers exceeding fifty in number, shall carry a duly qualified and competent surgeon or medical practitioner," besides the amendment of the words cabin passengers, be further amended, after the first occurrence of the word "practitioner," to read as follows:

And where the number of such passengers and crew is over six hundred, a junior or assistant surgeon or medical practitioner in addition shall be appointed. And the services of such surgeons or medical practitioners shall be promptly given without fee in every case of sickness, disease or accident originating on board and incident to the voyage, to any of the passengers or crew, or to any infant or young child of any such passenger who may require their services; and the medical officer, where there is but one, and the senior where there are two, shall also be required to perform the duties of sanitary officers; to make daily inspections of all inhabitable portions of the vesssl, and daily reports in writing thereon to the master of the steamship or passenger vessel, together with such suggestions and recommendations as in his judgment may be necessary to the preservation of health on board. He shall also exercise constant vigilance in regard to the condition of the provisions and water, and promptly report to the master anything which may appear to him to be deleterious to the health of any person on board. And for the prompt exercise of these functions and the maintenance of the respect to which such medical and sanitary officers are entitled, they shall be provided with a steward or apothecary competent to dispense medicine under their direction and for their special service; and their tenure of office, remuneration and right to quarters, subsistence, and attendance shall be upon the same basis as, and coördinate with the purser of the vessel on which they serve.

For a violation of these provisions, or either of them, or the disregard of the recommendations made in writing by the military and sanitary officers as herein provided, the company to which the steamship or other passenger vessel belongs shall be liable to a penalty not exceeding two hundred and fifty dollars in every case. Moreover, it shall be the duty of the sanitary and medical officers of every steamship or other vessel carrying or bringing passengers to the United States, to report in writing under oath, to the health officer of the port at the port of arrival, in detail, every case of illness or accident, with the nature and the result thereof, and every case of imbecility or insanity which may have fallen under his observation, and upon all the conditions herein provided for the protection and presevation of the health of all persons on board, and for the protection of the United States against the immigration of persons excluded by Section 2 of the "Act to Regulate Immigration" of August 3, 1882.

Your Committee feels constrained to urge that, notwithstanding the apparent conclusion of the House Committee on Commerce that the laws governing immigration are already sufficient, the exceptions to which your attention is invited are of such importance as to call for additional Congressional action, not only for the evils incident to an increasing immigration, overcrowding and excessive mortality from ordinary diseases on board ship, but also on account of the increased danger of introducing epidemic disease by reason of the incompetent medical service and the want of proper sanitary care.

The average duration of the time of emigrants on board ship to the time of their discharge at Castle Garden, New York, is about ten days. Common observation and some familiarity with the salutary effects of a sea voyage on such persons, justify the opinion that there should be an improvement in their health and a decrease in their ordinary rate of mortality; yet, by the most recent summary at the disposal of your Committee, of 27,157 emigrants who took passage to New York during the month of April last, 41 died on the voyage—an annual rate of over 55 per 1,000; more than twice as large as the average death rate of the populations at the ports of departure, and larger than that of any similar number of persons, in the absence of an epidemic, of which your Committee has any knowledge. The death rate of Cairo, in 1885, was 48.5; of Alexandria, 51.4. But the mortality of both those places is exceeded by the deadly artificial climate of this class of passenger vessels, and the criminal negligence of those who transport emigrants to the United States!

Your Committee has not felt itself called upon to enlarge its investigation into the extent of the failure of that portion of the law which is intended to prohibit the immigration of convicts, lunatics, idiots and other persons liable to become a public charge. It will suffice to state that all persons familiar with the statistics of institutions for the care of such persons in the United States, are abundantly conversant with the magnitude of the evil. But it has been our effort to meet it by securing such amendments to the laws as we have recommended.

With the hope that the effort of the Association may be more successful, if it be your pleasure to accept this report as final and to adopt it as its sense of the issue, your Committee offers the following resolution:

Resolved, That the Secretary of the Association be and is hereby directed to transmit copies of this report to the Hon. Secretary of the Treasury of the United States and to both the Senate and House Committees on Commerce, and in behalf of the American Medical Association we urge upon them such action, through Congress or otherwise, as will secure better protection to the health and lives of emigrants, and the United States against the immigration of dependent persons.

A. N. BELL, M.D., Chairman,
I. N. QUIMBY, M.D.,
H. H. SMITH, M.D.,
A. L. GUION, M.D., *Committee.*

On motion of Dr. D. J. Roberts, of Tennessee, it was accepted and the appended resolution adopted.

Dr. Wm. Brodie, of Michigan, moved to take up the amendment offered last year creating a Section on Dermatology and Venereal Diseases.

Dr. G. H. Rohé, of Maryland, moved to amend the title to be the Section on Dermatology and Syphilography. This was accepted by the original mover and unanimously adopted.

Dr. J. McF. Gaston, of Georgia, as Chairman of the Committee to Memorialize Congress on Yellow Fever Inoculation, asked leave to report.

On motion of Dr. J. M. Toner the matter was referred to the Section on Practice of Medicine.

After the various delegations had been requested to meet immediately upon adjournment for the purpose of selecting their members of the Nominating Committee, the Association on motion adjourned, to meet on Wednesday at 10 A.M.

WEDNESDAY, JUNE 8—SECOND DAY.

THE PRESIDENT called the Association to order at 10 A.M., and prayer was offered by Rev. F. W. Gunsaulus.

On motion of Dr. J. V. Shoemaker, of Philadelphia, the regular order of business was suspended until the business of this session should be disposed of.

The Chairman of the Committee of Arrangements presented several invitations, which were accepted.

By permission, Dr. N. S. Davis gave notice that the extensive

LIBRARY OF THE LATE DR. J. S. JEWELL

was for sale in the book-store of A. C. McClurg & Co., cor. Madison St. and Wabash Ave., Chicago.

DR. J. M. TONER, President of the Board of Trustees of THE JOURNAL, read the

REPORT OF THE TRUSTEES OF THE JOURNAL

including in it the report of the Editor, as follows:

The Board of Trustees for publishing THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION respectfully submit their annual report for the year ending March 31, 1887. At the earnest request of the Trustees, Dr. N. S. Davis consented to continue the active management of THE JOURNAL in both its editorial and publishing details. The uniform regularity of its issue has been unbroken. The practical operation of THE JOURNAL'S own printing office has been more gratifying during the past year, as will appear from the editor's report. Gradually we may expect this office to enlarge its already valuable service to the Association. It is hoped that all members of the Association who are able will visit it at 68 Wabash avenue.

The report of Dr. Davis to the Board of Trustees is so full in all details that we submit it with our report, as follows:

Annual Report of the Editor of the Journal of the American Medical Association for the Financial Year Ending March 31, 1887; Made to the Board of Trustees April 15, 1887.

To J. M. TONER, M.D., PRESIDENT OF THE BOARD:

In accordance with your rules I respectfully submit the following report concerning the progress and financial condition of THE JOURNAL of the Association during the year ending March 31, 1887, at this early period, that the members of your Board may have more time to consider its contents, and be better prepared to submit their own report at the next meeting of the Association.

Weekly Circulation.—At the date of this report, March 31, 1887, the total regular weekly circulation of THE JOURNAL was 4,387, of which 3,478 are sent to members of the Association whose names are furnished by the Treasurer, and 909 are furnished to regular subscribers and exchanges. This shows a net increase in the *membership* of 104 and in the total weekly circulation of 116, since my annual report for March 31, 1886. The number of copies of THE JOURNAL printed each week during the past year has been 4,800, an increase of 300 over the number printed each week for the preceding year. Although the excess printed has been 413 more than required for the regular weekly mail list, yet the number required to supply extra copies to contributors, to complete files for members, and sample copies when called for, is such that we have not more than about 200 complete files on hand for future use.

Receipts.—The receipts at the office of publication relate only to money received from subscribers, advertisements, reprints and extra JOURNALS; all membership dues being paid to the Treasurer of the Association and accounted for by him in his annual report. From the sources just named there has been received at this office during the year ending March 31, 1887, the sum of $7,580.63; of which $2.494.09 was from subscribers, $751.35 for reprints, and $4,335.19 for advertisements; making an increase from these sources of $2,250.17 over the receipts from the same sources the preceding year.

Expenses.—The total cost of publishing THE JOURNAL, 4,800 copies each week, and such reprints as have been ordered by contributors, for the year ending March 31, 1887, is $13,162.01, of which $751.35 was for reprints, making the cost of the publication of THE JOURNAL alone $12.410.66; an increase of $1,426.99 over the cost of publication of the preceding year. This additional cost is fully accounted for by the 300 more copies of THE JOURNAL and from eight to ten more pages of advertisements each week, than was published the preceding year; and is considerably more than balanced by the increased receipts at the office of publication as shown in the preceding paragraph. The total amount drawn from the Treasury for editorial expenses, including foreign and domestic correspondence, reports of proceedings of medical societies, clinical lectures, etc., and the salary of an Assistant Editor in the office, during the year ending March 31, 1887, is $2,758.95; making the total cost of THE JOURNAL of the Association for the year ending March 31, 1887, $15,920.96. And the total receipts from all sources, as will be shown by the annual report of the Treasurer, $21,723.22.

Property on Hand.—The cash value of the type, fixtures, etc., belonging to the Association printing office as established last year, after deducting 15 per cent. for wear, is $921.34, to which has been added new type, etc., as needed during the present year, costing $137.22, making total cash value of the printing office at date of this report $1,058.56; on

which we have a policy of insurance for $800. (The sum of $137.22 paid for new type is included in the aggregate publication expenses given in a preceding paragraph.) Some of the numbers belonging to each of the first four volumes of THE JOURNAL are exhausted, and consequently we can no longer furnish those volumes complete. Of volumes five and six we have about fifty copies on hand, and of volumes seven and eight (not yet finished) we have nearly 200 copies. When republishing the constitution, by-laws and Code of Ethics in the last number of volume vii, we had printed in neat *reprint* form an edition of 8,000 copies of the Code of Ethics, at a cost of less than two cents per copy. About 4,000 have already been sold at such prices as fairly covers the cost, leaving 4,000 on hand as the property of the Association. We have been furnishing single copies to applicants at three cents, which covers the original cost and postage; deeming it desirable to encourage as wide a distribution of the Code as possible without actual loss to the Treasury.

Explanations.—The figures given in the paragraph of this report relating to the weekly circulation of THE JOURNAL make it appear that the increase in the membership of the Association during the year had been only 104, and in the total circulation only 116. The details upon our books show that the actual addition of new members during the year was 506, and of new subscribers 18; making a total of 524 additions. On the other hand, early in the year the Treasurer ordered the names of 202 members to be stricken from our mail list for *non payment* of annual dues, and 42 from deaths, making a loss of 244 members. In my last annual report it was stated that about $2,300 was due from subscribers, some of whom had received THE JOURNAL from the beginning of its publication without payment. And during the first half of the present year it was found necessary to erase the names of 249 of these subscribers for continued non-payment; making the loss in members and subscribers 493, or only 31 less than the total of additions. Nearly all the losses were incurred during the first half of the year, and before the close, a few of those who had been discontinued paid up and were reinstated, making the net gain as stated in the paragraph under the head of "weekly circulation."

It must not be forgotten that when the publication of THE JOURNAL was commenced in 1883, the New York State Medical Society had recently repudiated the National Code of Ethics, thereby forfeiting her right to representation in the American Medical Association, and the seditious doctrine of a "*New Code*" or "*No Code*" was being actively disseminated in other States, and the Association was being misrepresented and denounced by some of the most influential medical journals in the country. The result of this Code controversy was the final withdrawal from membership of a large number of those who espoused the New York Code during the years 1883–4. Hardly had this Code revolt spent its force, when the still more bitter opposition was encountered by the Association, in attempting to effect a preliminary organization for the Ninth International Medical Congress—an opposition which did not yield until after the annual meeting of the Association in May last, and many of those engaged in it had withdrawn either by direct request or by refusal to pay their dues. The full force of this last revolt was fairly spent during the first half of the present JOURNAL year, and during the last six months there have been more applications for membership and renewals of subscriptions than at any previous time since THE JOURNAL was established. The fact that in less than four years of such unprecedented professional controversy THE JOURNAL should have been sustained while steadily, firmly, though temperately defending the Association, its National Code of Ethics, and persistently advocating the only practicable representative organization of the whole profession by local, State and National associations, and more than double its circulation and at the same time increase the income of the Association more than threefold, certainly demonstrates the wisdom of its establishment, if it does not prove the ability, efficiency and prudence of those having the responsibility of its management.

Suggestions.—The experience and results of the past year's work cause me to recommend a continuance and more permanent establishment of THE JOURNAL printing office. Both the financial resources and the number and quality of the contributions make it desirable to add four more pages of reading-matter to THE JOURNAL at the commencement of the next volume. But in doing so, the same caution must be exercised to avoid making any such increased expenditures as will place the Treasury in debt.

Dr. Wm. G. Eggleston has continued to fill the position of Assistant in the editorial work during the year, with promptness and ability—and to the rare faithfulness and business capacity of Mr. J. Harrison White do we owe much, in his capacity of both foreman of the printing office and Advertising Agent of THE JOURNAL.

Respectfully submitted.

Yours truly, N. S. DAVIS, M.D.

Editor of The Journal of the American Medical Association.

In reviewing this report we note (1) The regular issue of THE JOURNAL has been increased by three hundred copies per week. This is exactly the same increase as occurred during the previous years. This increase was in spite of the fact that several hundreds of delinquent subscribers were cut off. (2) The income of THE JOURNAL, from its subscribers, its advertisements and its reprints, was $7,580.63, or $2,250.17 more than during the previous year, from the same sources; this is exclusive of all membership dues to the Association, which are paid directly to the Treasurer at Philadelphia. (3) THE JOURNAL'S expenses for publication are increased by $1,426.69. The reasons for this are fully explained in the editor's report. But it also appears that the increased receipts are largely in excess of the increased expenditures. The total amount paid for all editorial work to March 31, 1887, was $2,758.95, making the total expense of THE JOURNAL to that date $15,920.96, or $1,822.19 more than the previous year. (4) Your Trustees were authorized to expend $6,000 for

editorial work. But they have been unanimous in the determination to incur no debt, hence they have expended only such sums as the income of the Association has warranted. This they have been compelled to limit to $2,758 95. (5) In common with others, we look forward to constant increment in the resources of the Association, and an equal increase in the labor that can be employed to advance THE JOURNAL toward the highest attainable standard. (6) The marked success that has attended the publication by the Association of its journal in its own office fully warrants the Trustees in its continuance and gradual enlargement. (7) The increased receipts of the Association also warrant substantial additions to the working editorial force and the increase of the number of pages of THE JOURNAL. (8) The Trustees are happy in being able to announce that at their solicitation Dr. Davis has consented to continue the management of the affairs of THE JOURNAL.

On motion of Dr. Wm. Brodie the report was accepted and adopted.

DR. N. S. DAVIS then read the

REPORT OF THE SPECIAL COMMITTEE ON CHANGES IN THE PLAN OF ORGANIZATION AND BY-LAWS OF THE ASSOCIATION,

appointed in accordance with the following resolution adopted by the Association at the last Annual Meeting:

Resolved, That a committee of nine members, including the President, President-elect, and the four Vice-Presidents elect, be appointed by the Chair to consider the various propositions looking to the amendment of the organic law of the Association by the *establishment of Branches*, or in any other way; said committee to report at the next annual meeting what measures of organization, if any, may be desirable.

Familiarity with the history of this Association shows that the adoption of this resolution was inspired by two leading considerations: First, the desirability of a more permanent and representative business committee to perform the duties now devolving upon the Committee on Nominations, and to consider all other questions of importance that may be referred to it by a vote of the Association, and report upon the same at such time as the vote of reference shall direct. Second, the desirability of increasing the paying permanent membership, that the annual revenue may be increased. Perhaps no other part of the practical working of the Association has occasioned so much adverse criticism as the hasty and imperfect method of selecting, after the commencement of each annual meeting, of the Committee on Nominations by such little groups of delegates from each State and Territory, as could be gathered in some corner of the room in the brief recess of fifteen minutes, and on whom devolved the paramount duty of nominating all the general officers of the Association, of seven members of the Judicial Council, three members of the Board of Trustees, and the selection of the next place of annual meeting; duties that the members are generally required to commence discharging immediately after their names are announced from the platform as having been selected for that purpose.

A committee thus hastily appointed, compelled to discharge duties of the greatest importance with equal haste, and then cease to exist, could not fail to commit some errors and to make some injudicious recommendations. Besides the absence of any permanent committee during the interim between the annual meetings to which proposed changes or amendments of the by laws or other important topics, requiring time and deliberation, could be referred, has occasioned no less embarrassment than the hasty work of the Committee on Nominations. For instance, amendments to the organic laws proposed at one meeting cannot be acted upon until the next annual meeting. Literally they lie on the table, receiving the special consideration of no one, and when the time comes to act upon them, they have neither been moulded into proper form to fit the place they were designed to occupy, and perhaps their authors even are not present, to explain their practical bearing either for good or evil.

The desirability of having more time and deliberation given to the purely business matters of the Association by a properly organized Council or standing committee on business, has long been recognized by all the more experienced members of the Association; and various plans have been suggested from time to time without leading to any definite action. For several months prior to the last annual meeting of the Association, those who were more particularly influenced by the desire to obtain a large revenue, suggested and actively discussed the practicability of so changing the plan of organization as to admit the formation of Branches whose members should be also permanent members of the Association, amenable to the payment of membership dues, and thereby entitled to THE JOURNAL. These suggestions had for their object the assimilation of our organization to that of the British Medical Association, by which it was claimed that a much larger proportion of the profession could be included in the membership nominally, while the whole business management could be confided to a *Council* of limited number. A large part of the criticisms hitherto made, have obviously emanated from parties who have but a limited knowledge of the history of voluntary medical organizations and of the practical working of the principles necessarily involved. Still less have they studied the influence of density or sparcity of populations, national habits, modes of thought, civil institutions and municipal divisions, on the success or failure of voluntary professional organizations in any given country. Yet all of these have their influence, and need to be carefully studied by all who would successfully shape the permanent social automony of any profession or class of people. For instance, the members of the medical profession of Great Britain, numbering little more than 25,000, constituting a part of an enlightened people occupying the British Islands, a territory scarcely equal to the six New England States or to the single State of Texas, and accustomed to no well-defined political divisions with each its own legislative and judicial functions, like our several States; but thoroughly accustomed to look to one central imperial government, naturally, and probably judiciously, adopted

a national organization founded on the idea of making it possible for all the legally qualified members of the profession to become members. For this purpose, such rules were adopted that the members of the profession in any part of the country could associate together to constitute a *Branch Association* or not less than a specified number, and by conforming to the general rules prescribed and paying the annual membership fee, they became members of the National organization, entitled to attend the annual meetings and receive the *British Medical Journal*. A *Council* of a limited number was formed to which was committed the entire business management of the affairs of the National Association, and to this Council each *Branch Association* was authorized to elect one member or more according to the number of its regular members. The British Medical Association, organized on the plan here briefly outlined, commenced its history fifty-five years since, or fourteen years before the organization of this body. Its progress has been such that at present its total membership, including the membership of all its Branches, numbers about 12,000, or a little less than half of the legally registered members of the profession in that country; while its governing Council numbers seventy-one members. Looking from this distance, upon its steady growth, the amount of scientific and practical work accomplished, the high reputation of many of its members, and the value of its journal, we rejoice on account of its success, and very naturally feel inclined to copy its methods. Before doing so, however, it will be wise to inquire whether the extent of our country, the sparseness or density of its population, the freedom and habits of thought of our people, and the political influences exerted by separate State governments and their diverse legislation are such as to permit the same methods to be applied with equal success here? If it has taken more than half a century for the British Medical Association to so extend its Branches over its comparatively limited but densely populated territory as to include less than half the registered practitioners of that country, how many centuries would it take an Association, on the same basis, to so extend its Branches as to include an equal ratio of the profession scattered over the vast territory from Maine to California, and from Lake Superior to the capes of Florida? And if the members of the *Council* of the British Medical Association from the Branches more distant from the central places of meeting four times a year, find attendance so burdensome that several do not attend even once during the year, and some of the Branches become so indifferent as to neglect the election of delegates to the Council to which they are entitled, as shown by reports at the last annual meeting in Brighton, how would it be if the attempt should be made to require a select *Council* of this Association to meet four times a year, composed of delegates from Branches in California, Maine, Minnesota, Texas and Florida, at some central place, as Washington, Philadelphia, or Chicago, for the satisfactory consideration of all its important interests? If the practical result of the experiment by the British Association, where all the circumstances have been most favorable, has been to put the entire control of the affairs of the Association in the hands of those members of the Council in London and in the few important cities affording most ready access thereto, and thereby to create much jealousy and dissatisfaction in some quarters and great indifference in other places, it requires but a moment of serious reflection upon the extent of our country, its division into nearly forty States, each legislating independently on all matters of education and professional regulation, with all classes of the people, not excepting the members of the medical profession, thoroughly imbued with the idea of equal rights and equal privileges, to be exercised either in person or by a chosen representative, to see that the evils actually developed in the progress of the British Association would be produced with far greater rapidity and intensity, if the same machinery and methods were adopted here. Indeed, if the exact plan of organization and methods of the British Medical Association were substituted for the present plan of organization of this Association, it requires no prophetic vision to see clearly that in less than two decades of years the members of the *Council* furnished by the *Branches* of five or six States in which are embraced as many chief cities, would have entire control of the affairs of the Association, and the Branches in the more distant States and the great mass of general practitioners in all would no longer have either voice or interest in the organization, and the already visible antagonisms and prejudices between the specialist and the general practitioners would have been intensified a hundred fold, to the great detriment of both. The three objects of paramount importance to be accomplished by medical organization are: *a*, the promotion of direct personal and social intercourse between physicians, by which mutual respect, personal friendship and unity of sentiment are greatly promoted; *b*, the more rapid increase and diffusion of medical knowledge, scientific and practical; and *c*, the developing, unifying, concentrating and giving efficient practical expression of the sentiments, wishes and policy of the profession concerning its educational, legal and sanitary welfare and the relations of the latter to the community as a whole.

As the gathering of all the members of the profession, numbering many thousands, from so widely extended a country as ours, into a single society for personal intercourse, is impracticable, the first of these leading objects can only be attained by organizing primarily into city, town, county, and limited district societies, in which the necessary personal intercourse can be enjoyed without material expense, or being placed beyond the reach of their patients. The same object is further promoted by sending a delegation from each of these circumscribed or local societies, once or twice a year, to constitute the State Society; and still further by these State Societies sending delegates to one more protracted meeting each year, which would constitute the National organization. Thus by the constant changing of the personality of the delegations, the profession of the

whole country is made to feel the genial influence of personal intercourse and mutual respect.

By the more frequent meetings of the primary local bodies and the more free or informal discussion of all professional topics, a general interest for more knowledge is fostered, and the spirit thus developed is carried by their delegates to the State Societies, where its practical fruits appear in the form of reports on recent improvements or on the special developments of disease, and in papers the consideration of which intensifies still further the spirit of inquiry, of scientific investigation, and a wider range of discussion; and these results are carried with the delegates from the State Societies to the National organization, where the mingling of the more intelligent and ambitious from all parts of our wide domain in social union and in the scientific and practical discussion of important topics belonging to every department of medical science and art, adds still further to the development and diffusion of medical knowledge, both scientific and practical. We say diffusion as well as development, because every item added to the stock of knowledge, and all the increase of mental activity, discipline, and breadth of view, gained by the successive exercises from the smallest town society to the National Association, are carried back by the delegates to the State Societies, and by them to the local societies in every populous city and county in all the States of this Republic. And not only so, but a still more rapid and wider diffusion of whatever is evolved of value is given in the pages of the medical periodical literature: and thereby the second object we enumerated is most efficiently accomplished.

For the accomplishment of the third important object to be attained by medical organization, unity and concert of action, certainly no scheme has been yet devised equal in fairness and efficiency to that which gathers the active working members of the whole profession into primary local societies, from which delegates chosen on a uniform ratio of representation are made to constitute the State Society; and from these again delegates on a similar ratio of representation are sent to constitute the responsible voting part of the National Association, thus constituting a ready professional mechanism through which the views and wishes of the profession can be gathered and efficiently expressed on all questions relating to education, medical legislation, and the sanitary interests of the people. And the same can be brought to bear with equal force upon the action of legislative bodies, either municipal, State or National.

The organization of the whole profession we have so briefly outlined, with the great leading objects it is designed to accomplish, is but the ideal representation of the actual organization of the profession in this country at the present time. The organization of this Association commenced in 1846, and completed in 1847, is, and has been from the beginning, a representative body with the State and local medical societies in all the States for its essential constituency, or "Branches," (if there is any particular merit in that name). It is true the fundamental representative principle was at first imperfectly or unequally applied, in consequence of the comparatively small number of either State or local societies then existing. But the clear recognition of the local and State societies as the National basis, and the fixing of a uniform ratio of representation for them, led to so rapid an increase in the number of regular medical societies, that in less than twenty years every State had its society sending delegates to the National Association, and almost every city and populous county or district, its society, furnishing delegates to the State and National organizations, and including an aggregate number of members of the profession greater than now constitute the British Association with its Branches.

The outline of a systematic and harmonious professional organization having thus rapidly extended over the whole country, during the last twenty years its basis in the local medical societies has been steadily increasing and becoming more efficient for good; the State Societies in the same ratio increasing in membership and more methodical and efficient in their work; while this National Association has increased with every increase in the constituent societies, steadily rendered its work more systematic and efficient, by providing for the scientific and practical work of every legitimate department or special branch in its Sections, as well as the general business interests of the whole, and at the same time removing the errors and inequalities at first made in the application of the principle of representation, until practically the regular local and State societies are as truly "Branches" of this Association as are the *Branch* Societies in Great Britain Branches of the British Medical Association, with the very important advantage of having the right to send to this body one delegate for every ten of their members, instead of one delegate from each Branch to a limited council, while by the amendment to the constitution adopted in 1884, every member of the regular local and State societies entitled to representation, may at any time become a *permanent member* of this body by furnishing a certificate of good standing in his local society and paying the annual membership fee. Thus perfected by the experience of the past forty years, a system of professional organization has been developed in strict accordance with the spirit of all our institutions and the habits of thought of all classes of our people, capable of indefinite extension, and each part harmoniously fostering every other. By making membership in a local society a necessary qualification for membership in the State and National Societies, the strongest possible inducement is presented for organizing and maintaining these primary and essential bodies by all intelligent members of the profession. By providing for delegates from the local and State societies on a uniform ratio of representation, and placing the whole business management of the Association in the hands of such delegates by restricting to them the right of voting, the most reliable check is put upon the tendency to centralization or local control, or any form of class supremacy, while the door to permanent membership is open to all who are willing to support the interests of the pro-

fession in their own districts. After a most careful study of the history and practical development of medical organizations, both at home and abroad, your Committee cannot recommend any radical changes in the existing plan of organization for this Association. On the contrary, we urge the preservation of all the essential principles involved, and their present accurate adjustment for the accomplishment of all the legitimate objects of voluntary medical organization in a country of free institutions and representative governments, while careful attention should be given to the correction of minor defects in practical application, and such changes in by-laws as will facilitate both the business and scientific interests of the whole body.

However, the changes made in the publication of the proceedings and papers, the increase in the number of Sections, and the necessity for a more permanent committee on business, have made some sections of the Constitution and By-laws inapplicable or incapable of proper execution, and therefore need readjustment, with perhaps some additions.

In the second section of the Constitution, or Plan of Organization, title, *Members*, is the following paragraph, adopted as an amendment in 1884: "*Members by Application* shall consist of such members of State or County Societies, certified to be in good standing by the President and Secretary of said Societies, as shall make application for admission. They shall simply have the right to receive THE JOURNAL on the same terms as other members." This is defective: *a*, in limiting the privilege of making application to members of State and County Societies only; *b*, in not specifying whether such State and County Societies are entitled to representation in this body or not; and *c*, in giving no adequate motive in the last paragraph for seeking that kind of membership. Any member of the profession, without regard to membership in any society, by paying the subscription price, $5 per annum, which is the same as the Annual membership fee, can receive THE JOURNAL. To afford a valuable and adequate advantage to members by *application*, and at the same time guard against their admission from such State or County Societies as are themselves not entitled to representation by delegates in the Association, we respectfully propose the following as a substitute for the paragraph previously quoted:

Members by *Application* shall consist of such members of the State, County and District Medical Societies entitled to representation in this Association, as shall make application in writing to the Treasurer, and accompany said application with a certificate of good standing signed by the President and Secretary of the society of which they are members, and the amount of the annual membership fee, $5. They shall have their names upon the roll and have all the rights and privileges accorded to *Permanent Members*, and shall retain their membership on the same terms.

This enables any one or even all of the members of recognized State and local Societies, under adequate safeguards, to become *de facto Permanent Members* of the American Medical Association without the expense of attending an annual meeting.

From the *fifth section* of the *Constitution*, relating to "*Standing Committees*," the *first* and *third paragraphs* should be stricken out, leaving intact only the second paragraph, relating to the "Committee of Arrangements." In place of the first paragraph to be erased, your Committee recommend the insertion of the following important provision, viz.:

The General Committee or Council shall be composed of *two members* from each State and Territorial Medical Society entitled to representation by delegates in the Association, and from the Medical Departments of the U. S. Army, Navy, and Marine Hospital Service. They shall be chosen by the members registered and present at each annual meeting, from each State, Territory, and from the Medical Corps of the U. S. Army, Navy, and Marine Hospital Service, acting separately, on the third day of each annual meeting; each delegation reporting the names of the members chosen to the Permanent Secretary of the Association on the same day, that they may be announced by him at the opening of the morning session of the fourth day. At the first election each delegation shall choose *two* members of the General Committee, one of whom shall serve *one* year and the other *two* years, and at each annual election thereafter one member shall be chosen to serve for two years, thus making the term of office of members of the General Committee *two* years. It shall be the duty of the General Committee, thus constituted, to organize by choosing annually a Chairman and Secretary, and such sub committees as may be found necessary to facilitate the work that may be assigned to it; to meet annually at the place and on the day preceding each annual meeting of this Association, and as often during that week as may be necessary; to nominate, on the third day of each annual meeting, all the general officers of the Association (none of whom shall be members of its own body), the members of the Committee of Arrangements, the Committee on Necrology, seven members of the Judicial Council, and three members of the Board of Trustees for Publication for election by the Association; to recommend the place and time of holding the next annual meeting; and to consider and report upon all subjects that may be referred to it by vote of the Association. The presence of one-third of the whole number of members elected to the General Committee shall constitute a quorum for the transaction of business. If, at any annual meeting of the Association, it shall be found at the close of the general meeting of the first day that a quorum of the General Committee is not present, it shall be the duty of the President and Permanent Secretary to fill the vacancies in the Committee temporarily by selections from the lists of delegates registered as present from the States to which the vacancies belong.

Should this provision be adopted by the Association, the Permanent Secretary should be authorized to substitute the name "General Committee" for "*Nominating Committee*," wherever the latter occurs in other parts of the Constitution and By-laws.

The third paragraph of section *five*, as it now exists in the Constitution, provides for the annual election

of a *Committee of Publication*, charged with the performance of certain important duties. But at the annual meeting in Cleveland, 1883, all the duties of this committee were transferred by resolution to a *Board of Trustees* for journalizing the Transactions of the Association, organized at the preceding annual meeting in St. Paul. Your Committee, therefore, recommends the adoption of the following provision and its incorporation in the Constitution, as a substitute for the paragraph relating to the "Committee of Publication," viz.:

The *Board of Trustees* shall consist of nine members, three of whom shall be elected annually on the nomination of the standing General Committee, and shall serve for three years. It shall be the duty of this Board to provide for and superintend the publication and distribution of all such proceedings, transactions, and memoirs of the Associatinn as may be ordered to be published, and in such manner as the Association may direct; and in doing this, it shall have authority to appoint an editor and such assistants, and determine their salaries, and procure and control such materials, as may be necessary for the accomplishment of the work assigned to it. To further facilitate its work, it shall be the duty of the Secretaries of the Association and of the several Sections, during each annual meeting, or as soon thereafter as practicable, to deliver to the Board, or such editor or agent as it shall appoint, all such records of proceedings, reports, addresses, papers, and other documents as may have been ordered for publication, either in the general sessions or in the Sections. All moneys received by the Board of Trustees or its agents, resulting from the discharge of the duties assigned them, must be paid to the Treasurer of the Association, and all orders on the Treasurer for disbursements of money in any way connected with the work of publication, must be endorsed by the President of the Board of Trustees. It shall be the further duty of the said Board of Trustees to hold the official bond of the Treasurer for the faithful execution of his office; to annually audit and authenticate his accounts, and present a statement of the same in its annual report to the Association; which report shall also specify the character and cost of all the publications for the Association during the year, the number of copies still on hand, and the amount of all other property belonging to the Association under its control, with such suggestions as it may deem necessary.

The foregoing proposed amendment to Section V of the Constitution is simply placing in due form, and in its proper place, the actual regulations that have been in operation for the past four years under resolutions adopted at the annual meetings of 1882 and 1883, and if it is adopted the Permanent Secretary should be directed to do the clerical work of erasing the name of "Committee of Publication," and where necessary, substituting the *Board* of *Trustees*, wherever the former occurs in other Sections of either Constitution or By-laws, in such a way as to place them in harmony with this amendment.

In addition to the foregoing proposed amendments of the Constitution, your committee recommend the following important amendments and additions to the By laws that have no necessary connection with the proposed amendments to the Constitution, viz.: To so amend the paragraph under Section II of the By-laws relating to the duties of Chairmen of Sections, that it shall read thus: "The Chairman of each Section shall prepare an address on the recent advancements in the branches belonging to his Section, including such suggestions in regard to improvements in methods of work as he may regard important, and present on the first day of its annual meeting, the same to the Section over which he presides. The reading of such address not to occupy more than forty minutes."

Hitherto, the paragraph for which this is intended as a substitute, has required the Chairmen of Sections to prepare and read addresses in the general sessions of the Association, which, on account of the increase in the number of Sections, has become impracticable. There being now eight Sections, with another proposed, and only three general sessions of the Association in which they can be read, it is obvious that one-third of these addresses must be read by title only, as has been actually done for the last two or three years, or no other business of the Association can be transacted after the first day of each annual meeting. On the other hand, if the Chairman of each Section should deliver his address at the opening of his Section, it would add much to the interest of the Section itself and afford opportunity for suggesting important improvements in methods of investigation, and tend strongly to give increased strength and greater individual attachment to each Section. It is the same method as practiced in the Sections of the British Medical Association.

Also an additional By-law, to be numbered *XIV*, as follows: "The Association shall annually elect, on the nomination of the Nominating Committee (or the standing General Committee), three members of the profession, eminent in some of its departments, to deliver addresses in the general sessions of the next ensuing annual meeting, one on some topic or topics relating to general medicine, another relating to general surgery, and the third relating to public medicine, including under that head, hygiene, sanitation, prophylaxis, education and medical legislation; each of such addresses not to exceed one hour in its delivery."

This suggestion is also in accordance with the practice of the British Medical Association, and its advantages cannot fail to commend it to the favorable consideration of all thoughtful members of this body.

In conclusion, your Committee will only add, that all the changes recommended in this report have for their object the better adjustment and more efficient practical development of the systematic general organization of the medical profession of our country, on those principles of equality and just representation in strict consonance with the habits of our people and the institutions of our country; and which afford the only basis on which the whole regular profession may be brought together in local professional intercourse, and through chosen representatives into State and National communion, where every legitimate special-

ist finds an appropriate field for work in some one of the Sections, and at the same time is enabled to mingle in the general sessions with the great body of general practitioners, to the mutual benefit of all. In union there is not only *strength* and *harmony*, but the most sure and rapid progress, while exclusive organizations and class distinctions beget prejudice, foster divisions and retard true progress. All of which is respectfully submitted.

N. S. DAVIS, J. M. TONER,
WM. BRODIE, E. H. GREGORY,
P. H. MILLARD, W. H. PANCOAST,
W. B. WELCH, W. C. WILE.
Committee.

Dr. Albert L. Gihon, U. S. N., the remaining member of the Committee was not present at the conference when the report was adopted.

Dr. R. C. Early, of Penna., moved that the report be accepted and the Committee discharged.

Dr. A. S. von Mansfelde, of Neb., moved that the report be adopted. The motion was adopted.

Some discussion having arisen relative to the matter, Dr. Eugene Grissom, of N. C., arose to a point of order, that this action was final and hence the changes proposed by the Committee did not lie over.

The Chair decided that this was correct, and that changes recommended by the Committee had been adopted.

Some further discussion having arisen, Dr. A. N. Bell, of N. Y., offered the following:

Resolved, As the sense of this Association, the question has already conformed to the Constitution, having been before it one year.

A call of the house having been demanded, a vote standing was taken, resulting in 272 in the affirmative and 232 in the negative.

A motion to reconsider the vote was, on motion of Dr. E. Grissom, laid upon the table.

The Permanent Secretary then called the roll of States and announced the following as the

COMMITTEE ON NOMINATIONS.

Ala., W. C. Cross; Ark., D. C. Ewing; Cal., J. W. Robertson; Col., P. Brumund; Conn., W. H. Whittimore; D. C., J. M. Toner; Fla., M. B. Phillips; Ga., A. G. Whitehead; Ill., E. P. Cook; Ind., T. B. Harvey; Iowa, Wm. Watson; Ks., W. L. Schenck; Ky., D. S. Reynolds; La., T. G. Richardson; Me., D. E. Marston; Md., T. B. Evans; Mass., E. W. Cushing; Mich., W. Brodie; Minn., J. A. McGauhey; Miss., T. R. Trotter; Mo., J. M. Allen; Neb., W. M. Knapp; N. C., Eugene Grissom; N. H., J. W. Parsons; N. J., Lott Southard; N. Y., Darwin Colvin; Ohio, X. C. Scott; Pa., E. A. Wood; R. I., W. J. Burge; S. C., T. Legaré; Tenn., J. B. Murfree; Tex., R. W. Park; Vt., S. H. Griswold; Va., H. M. Nash; W. Va., J. E. Reeves; Wis., J. K. Bartlett; U. S. N., D. Blood good; U. S. M. H., H. M. Goldsborough; Dak., E. L. Dals; N. M., R. Bailey.

A communication from the American Pharmaceutical Association was presented, enclosing the following:

Resolved, That this Association solicit the aid and cooperation of the A. M. A. in promoting the prescribing by physicians of officinal medicines only, or such preparations as have published formulas in preference to others.

On motion, the resolution was adopted.

DR. J. S. LYNCH, of Baltimore, Chairman of the Section on Practice of Medicine, delivered the

ADDRESS IN MEDICINE.

[See JOURNAL, June 18.]

On motion, it was referred for publication.

On motion, the Association adjourned until Thursday at 10 A.M.

THURSDAY, JUNE 9—THIRD DAY.

The President called the Association to order at 10 A.M., and prayer was offered by Rev. J. H. Barrows, D.D.

The Committee of Arrangements announced a number of invitations, etc. Two charges against members, of an ethical character, were presented, and referred to the Judicial Council.

A congratulatory telegram was read by the Permanent Secretary, from the Ontario Medical Association, then in session. On motion of Dr. William Brodie, it was received, and the President was requested to send a response. His reply was: "The President and members of the American Medical Association acknowledge the friendly greeting of the Ontario Medical Association, and desire to convey to them their feelings of sympathy and good fellowship."

Dr. Brodie, as Chairman of the Committee on Nominations, reported the following

OFFICERS FOR THE ENSUING YEAR.

President—Dr. A. Y. P. Garnett, Dist. of Col.

Vice-Presidents—Drs. Duncan Eve, Tenn.; Darwin Colvin, N. Y.; Charles J. O'Hagan, N. C.; A. Stedman, Col.

Librarian—Dr. C. H. A. Kleinschmidt, D. C.

Treasurer—Dr. R. J. Dunglison, Pa.

Assistant Secretary—Dr. Jos. Ransohoff, Ohio.

The place for next meeting is Cincinnati, on the second Tuesday in May, 1888. Chairman of Committee of Arrangements, with power to appoint members of Committee, W. W. Dawson, of Cincinnati.

Trustees of THE JOURNAL—Drs. L. Connor, Mich.; E. O. Shakespeare, Pa.; W. T. Briggs, Tenn.

Judicial Council—Drs. J. H. Murphy, Minn.; Joseph M. Toner, D. C.; J. K. Bartlett, Wis.; A. B. Sloan, Mo.; X. C. Scott, Ohio; B. McClure, Iowa; D. W. Stormont, Kas. To fill a vacancy, James F. Hibberd, Ind.

Committee on State Medicine—Ala., Jerome Cochrane; Ark., R. G. Jennings; Cal., J. W. Robertson; Col., P. Brumund; Conn., W. H. Whittimore; D. C., G. W. Cook; Fla., N. D. Phillips; Ga., T. S. Hopkins; Ill., E. P. Cook; Ind., J. M. Beard; Iowa, G. F. Jenkins; Kas., W. L. Schenck; Ky., J. A. Larrabee; La., T. G. Richardson; Me., Thos. Foster; Md., G. H. Rohé; Mass., Grace Wolcott; Mich., A. W. Alvord; Minn., C. N. Hewitt; Miss., T. R. Trotter; Mo., Lester Hall; Neb., Wm. Knapp; N.

C., Eugene Grissom; N. H., W. P. Porter; N. J., B. A. Watson; N. Y., A. N. Bell; Ohio, F. C. Bain; Pa., J. C. Dunn; R. I., W. J. Burge; So. C., T. Legare; Tenn., R. Cheatham; Texas, J. E. Sears; Vt., S. H. Griswold; Va., H. M. Nash; W. Va., J. E. Reeve; Wis., J. K. Bartlett; U. S. N., Delavan Bloodgood; U. S. M. H., C. B. Goldsborough; Dakota Ter., E. M. Dow; New Mexico, R. Bailey.

Committee on Necrology.—J. M. Toner, Washington, D. C., Chairman; T. E. Murrell, Ark.; B. B. Wyman, Ala.; J. G. Terry, Cal.; M. H. Sears, Col.; R. A. Lancaster, Fla.; E. Ingalls, Ill.; J. F. Hibbard, Ind.; J. M. Emmert, Iowa; L. M. Minney, Kas.; J. G. Brooks, Ky.; R. Matas, La.; John Morris, Md.; E. C. Bell, Mass.; G. E. Ramsey, Mich.; A. W. Strickfield, Minn.; H. B. Merrill, Mo.; A. S. von Mansfelde, Neb.; J. H. Tucker, N. C.; J. F. Ill, N. J.; J. W. Parsons, N. H.; L. D. Trowbridge, N. Y.; J. H. Tucker, N. C.; H. J. Herrick, Ohio; F. Woodbury, Pa.; W. J. Burge, R. I.; F. L. Parker, S. C.; J. M. Savage, Tenn.; R. W. Park, Tex.; M. R. Crane, Vt.; L. Ashton, Va.; J. T. Reeve, Wis.; J. N. Weir, Dakota; R. Bailey, New Mexico.

On motion of Dr. P. H. Millard, the report was accepted.

The Permanent Secretary read the officers for the Section on Dermatology and Syphilography, Chairman, L. D. Bulkley, N. Y.; Secretary, T. F. Dunlap, Kentucky.

Section on Obstetrics and Diseases of Women—Chairman, Eli Van de Warker, N. Y.; Secretary, E. W. Cushing, Mass.

Section on Anatomy and Surgery—Ch'n, Donald McLean, Mich.; Sec'y, B. A. Watson, N. J.

State Medicine—Ch'n, H. B. Baker, Mich.; Sec'y, S. T. Armstrong, Tenn.

Diseases of Children—Ch'n, F. E. Waxham, Ill.; Sec'y, W. B. Lawrence, Ark.

Oral and Dental Surgery—Ch'n, J. Taft, Ohio; Sec'y, E. S. Talbot, Ill.

Practice of Medicine, Materia Medica and Physiology—Ch'n, A. B. Palmer, Mich.; Sec'y, N. S. Davis, Jr., Ill.

On Medical Jurisprudence—Ch'n, E. M. Reid, Md.; Sec'y, C. B. Bell, Mass.

Dr. N. S. Davis, Sr., having mentioned the necessity of appointing members to prepare the three addresses, in accordance with the amendments which had been adopted, after some discussion Dr. D. J. Roberts, of Tenn., moved that action on this point be deferred until 1888. Dr. Davis moved as an amendment that the action as to the By-Laws be permitted to remain, inasmuch as there were very few negative votes, but that the others, which were amendments to the Constitution, should lie over for ratification at the next meeting. This was accepted by the mover, and was unanimously adopted.

Dr. G. H. Rohé, Secretary of the Rush Monument Committee, read the

REPORT OF THE RUSH MONUMENT COMMITTEE.

Report of the Chairman.—On the part of the Rush Monument Committee, I beg to report progress made in furtherance of the great project, which has been entrusted to them. Since its inception, they have been gratified by the concurrent testimony of many of the ablest members of the profession, and by the enthusiastic endorsement of numerous State and other Medical Societies as to the pre eminent claim of Benjamin Rush to be commemorated as proposed. Without ascribing to him excellence above criticism, it must be admitted that he was so prominent a figure in his profession and in public affairs during our Revolutionary period, and filled so many parts and all so well in the early history of the Republic, that at this day he stands among the fathers of the Nation, the unquestioned peer of the heroes of that time, whatever their vocation.

The Committee are aware that there were many other noble and patriotic men in the ranks of our profession, who have deserved the grateful recognition of their country, but it is doubtful whether in the instance of any other individual so many reasons do exist for preference for this intended distinction. These were set forth in the earlier report of the original committee, [*vide* JOURNAL OF AMERICAN MEDICAL ASSOCIATION, Vol. IV, No. 21, p. 581.] and in the later circular addressed to the members of the profession of medicine in the United States, but the present Committee may be permitted to again remind their professional brethren that Benjamin Rush was a physician who was eminent as a practitioner, both in private life and on the hospital staff, who fearlessly combatted the pestilential diseases that were common in his day and by one of which he lost his life; who was eminent as a teacher, having assumed the office of professor at the age of 24, and retained that dignity almost half a century, his private pupils having numbered about 2000; who was eminent as a writer, his printed works filling seven volumes, of which his treatise on Insanity in its medical and medico legal relations was for seventy years the standard authority on that subject in Europe as in our own country; who, with all the demands of his busy professional life, was also eminent, as a philanthropic, patriotic citizen, the exemplar of the physician's proper office in public life, an active participator in the events of the memorable period of the Nation's birth, a signer of the Declaration of Independence, a member of the Convention which framed the Constitution of the United States, a general officer of the Revolutionary Army, the Surgeon General and Physician General of the Middle Department; who, in later years, filled many offices of public trust, having been the first Treasurer of the United States Mint and the Port Physician of Philadelphia; who was a leader in every project of social reform, and as alive to the importance of public health questions as any modern sanitarian, the first President of the Society for the Abolition of Slavery, the advocate of the higher education of women, of the establishment of public schools, of the abolition of the death penalty, of legislation against the abuse of alcohol, of the amelioration of the treatment of the insane, etc.

Dr. Thomas G. Morton on the 17th of December, 1885, addressing the Association of Resident Physicians of Pennsylvania Hospital, of which Dr. Rush

was a physician for thirty years, extols him as "one of the most notable men of his time," and attributes to him the expression of views, "which were half a century in advance of the times."

Especially noticeable, because of the occasion, was the tribute to Dr. Rush's fame by Dr. Weir Mitchell, President of the College of Physicians of Philadelphia, in his classic and eloquent commemorative address on the 4th of January, of the present year, at the centennial anniversary of the institution of that distinguished body. Dr. Mitchell emphasized Rush as "the greatest physician this country has produced." "He was a statesman, a scholar, an army surgeon, a punctual and careful physician, an actively religious man, a far seeing and courageous philanthropist, and a sanitarian far in advance of his day. There are what I might call four careers, in all of which he excelled unaided by secretaries or modern means of condensing and relegating labor; one such suffices most men. He was a member of every important political assembly which met in this State while he lived. When timid men fell out of the Continental Congress, he was elected to that body, that he might sign the Declaration of Independence, and he was the only practising physician whose name is on that energetic arraignment of the Crown."

In the words of Dr. Charles K. Mills, President of the American Neurological Association, in his recent address before the Medico Legal Society of New York, on "Benjamin Rush and American Psychiatry:" A Rush renaissance now seems to be imminent, and it is a strange commentary upon patriotism that the leaders in this movement are two Englishmen, who have recently given us excellent biographical sketches. The first of these appeared in October, 1885, from the pen of Dr. Benjamin Ward Richardson, in his Asclepiad—in which Rush's position in medecine is carefully analyzed and asserted, and in which also attention is directed to his standing as patriot, politician, philanthropist, orator, teacher, and man of letters. The second is contained in the recent monograph of Dr. D. Hack Tuke, on "The Insane in the United States and Canada," who calls him the American Fothergill, saying that he resembled the latter in the independence of his medical practice, in acuteness of observation, in his enthusiastic love of the art of healing, in his incessant labor, in popularity as the leading physician of the day in a great city, but above all, in uniting with the functions of a physician, the philanthropy which manifested itself in innumerable practical suggestions for the benefit of his kind, and in the daily exemplification of Terence's immortal axiom. "Rush has been called the American Sydenham, first by Lettsom, who said of him that he approached, if not exceeded Sydenham in grandeur and compass of thought. By his American admirers and eulogists he has often been spoken of as the American Hippocrates," but adds Dr. Nutts, "perhaps it is unjust to compare him with anyone. He was a character, peculiar, striking, unique."

With such a man to honor, the profession of medicine would neglect a sacred duty in failing to do this honor, and the Committee, accordingly, earnestly appeal to the physicians and medical students of America to make the modest individual contribution of $1 apiece, which from their numbers, will swell to an amount sufficient to make their memorial the most imposing at the National Capital. The great National medical library and museum, which under the auspices of the Medical Department of the Army will soon be completed, offers a fitting locality for the proposed monument. As the statue of Professor Henry stands at the approach to the Smithsonian Institution, which was so honored by his charge, and that of Chief Justice Marshall at the ascent to the Supreme Court of the United States, over which he had so long presided, what more appropriately could first meet the physician, who visits this great depository of medical literature, science and art than the benevolent features of so great a Master in Medicine as Benjamin Rush?

All which, with the reports of the Secretary and Treasurer, is respectfully submitted.

ALBERT L. GIHON, M.D.,
Chairman Rush Monument Committee.

Report of the Secretary.—The Secretary of the Rush Monument Committee reports that he has endeavored to faithfully perform the duties of his office during the past year. In a book procured for the purpose, he has kept a succinct and accurate history of the Committee and its proceedings.

Since the last meeting of the Association an appeal to the medical profession, in aid of the fund, has been printed and distributed through the local chairmen, in all parts of the United States. The power of the press, both professional and popular was invoked, and the response of this mighty engine of public opinion was prompt and generous.

In the instructions issued to local committees, the method of collecting funds was left to their discretion. The wisdom of this action has been demonstrated by the good results achieved. In the opinion of the Secretary this policy should be continued as the most likely to accomplish the object of the committee's endeavors.

The medical profession of this country has resolved, through its representative organization, the American Medical Association, *that this memorial shall be built.* The committee to whom the labor of collecting the necessary funds has been entrusted, will be diligent in the performance of its duty. It now devolves upon every physician having the honor and dignity of his profession at heart, to give the trifle asked. If every one who hears or reads this report will send his first succeeding fee to the treasurer, the desired result will soon be attained. If there is love of patriotism, of philanthropy, of learning and of self-sacrifice in the hearts of the physicians of this country, the noble example of Benjamin Rush in each of these spheres of a well rounded life, should stir up such enthusiasm that in one year from this time the committee's work would be accomplished.

The contribution asked from each is but small. Every one can give it. Let us all then say, with King Henry at Agincourt:

"A very little let us do,
And all is done."

GEORGE H. ROHÉ,
Secretary Rush Monument Committee.

Report of Treasurer.—The treasurer of the Rush Monument Committee begs leave to submit, this, his first report on the financial condition and prospects of the enterprise. The president of the committee, Dr. Gihon, in his report, which I have had the opportunity of reading, has graphically presented the history and purpose of the project and shows the eminent propriety there is in the medical profession placing a statue at the National Capital to honor the foremost medical man that our country has produced. This view which had become quite general found expression in the appointment of a standing committee by the American Medical Association, at its meeting in 1885, charging it with the special duty of raising funds and erecting in Washington city a suitable monument to Dr. Benjamin Rush, whose learning, professional eminence and patriotic services easily place him at the head of the many worthies of our noble profession in America.

That the monument may, as far as practicable, represent the universal esteem in which the memory of Dr. Rush is held by the medical profession everywhere, it was deemed advisable to invite the medical men in every State and Territory of the United States to aid, by small contributions, in this testimonial.

The secretary of the Rush Monument Committee, Dr. Rohé, in his report, which I have also seen, shows how through the agency of a member of this committee resident in each State and Territory, the Army, Navy, and Marine Hospital Service, the profession has been everywhere solicited to join in this work. Responses making partial returns to the treasurer from the members of the committee in the following States have been received: Arkansas, California, Colorado, Connecticut, Indiana, Kansas, Maryland. New Hampshire, New Jersey, New Mexico, New York, Ohio, Pennsylvania, Vermont, West Virginia, U. S. Army, U. S. Navy and U. S. Marine Hospital Service. The States and Territories not named have not made returns to this date, June 2, 1887, although some of them, we hear, are at work in the matter. The information received from the members of the committee in the several States is to the effect that the project meets the hearty approbation of the medical men of their section, and that contributions will in time become so general as practically to include every physician of note in the country.

To the end that the profession may know with what degree of prudence the money raised for the Rush Monument is being husbanded, I deem it proper to refer briefly to the rules adopted by the committee when it organized for business, touching this important matter. They require that the names of all contributors, with the amounts given, shall be entered in a book kept for the purpose, and that a receipt, or certificate, for the same, signed by the treasurer, be transmitted to the donor.

That all moneys received shall be deposited by the treasurer in the bank of Riggs & Co., in Washington, to the credit of the Rush Monument Committee. That no debts shall be contracted by individual members of the committee, not authorized by a vote of the committee, except the necessary expenses of postage and printing, and these must have the concurrent sanction of the President, Secretary and Treasurer. And that no moneys shall be drawn from the treasury except upon vouchers bearing the endorsement of the President and Secretary of the committee. These regulations have all been observed. The register of the names of contributors, the bank book of deposits, and all vouchers for expenses thus far incurred, are herewith submitted for such action as the Association may deem proper to take.

The total sum which has been sent to the treasurer amounts to $389.

The total amount disbursed, as per vouchers, numbered from 1 to 8, inclusive, amounts to $143.08.

The ratio of expense in future will not be so great, as the printing of blanks will serve for a year or more. It is possible that the amount received by the treasurer may be less than the Association and the public might reasonably have expected. The fact, however, should be kept in mind, that the committee has just begun work, and that this report embraces returns from but about one half the States and but partial returns from any.

Appended to this report is an alphabetical list of the names of all contributors, with their post office address, and the amounts given by each. All of which is respectfully submitted.

J. M. TONER,
Treasurer Rush Monument Committee.

The following was received from Dr. D. Hack Tuke:

LYNDON LODGE, HANWELL.

My Dear Doctor:—Allow me to wish success to your Rush monument. You know, from my short biography of him in my book on your asylums, how much I venerate and desire to perpetuate his memory. I should have felt it an honor to send a trifle to the subscription list as a sign of my appreciation of your labors, but I believe donations are confined to your own country. Very truly, D. HACK TUKE, M.D.

DR. TONER, Washington, D. C.
May 25, 1887.

Young, J. D., Stockton, Cal.; Young, J. K. Philadelphia, Pa.

On motion of Dr. W. B. Atkinson, the report was accepted and referred to an auditing committee, consisting of Drs. E. Grissom, A. B. Palmer, and A. Garcelon.

This Committee subsequently reported that they had examined the vouchers and found the accounts correct.

Dr. Jno. Morris, of Maryland, on behalf of Dr. Jas. M. Keller, Chairman of the Committee, read the

REPORT ON CREMATION

as follows:

The Committee on Cremation, appointed at the last meeting of the Association, beg leave to report:

That no facts of a practical character, in addition to those so forcibly presented by the former Committee, have come to their notice during the year. A report made to the American Public Health Association at Toronto, last October, largely embodies the views of the Committee. In that report it is stated that it is only in the case of sudden and violent eruptions of disease or a great epidemic that the failure of the ordinary modes of burial can be realized or properly brought to the notice of the people. That as long as such outbreaks do not occur, no particular attention is given to the matter by the profession or the laity; that inasmuch as cremation has not met with popular acceptance, a modified form of cremation, called by Liebig cremacaucus, might be adopted. This looks to the adoption of municipal and State laws, compelling the use of destructive agents to bring about the rapid disintegration of the dead body. Caustic lime or chloride of zinc are especially fitted for this office. This process of immediate destruction of the dead body is particularly desirable in cases of persons dying of zymotic diseases. The burial of persons dying by these diseases should be placed by law in the hands of the health authorities. The old fashioned triple coffin and vault should be entirely discarded. Earth to-earth burial should, as far as possible, be encouraged. As our cities increase, as our populations thicken, the evils of our present mode of burial will increase. In the end it will be discovered that cremation is the purest, safest means of escape from the evils incident to decomposition of the dead.

The report closed with the following resolution:

Resolved, That it is the judgment of the American Medical Association that the burial of all persons dying of zymotic diseases should be placed by law under the control of the health authorities, and that in all such cases of disease chemical agents should be used by such authorities to bring about a rapid disintegration of the dead body.

The report was referred to the Section on State Medicine at the request of the special committee.

Dr. J. McF. Gaston, of Georgia, Chairman of the Special Committee on the

PREVENTION OF YELLOW FEVER BY INOCULATION,

offered the following:

WHEREAS, An appropriation has been made by Congress for investigating yellow fever inoculation, and an eminent bacteriologist has been appointed to examine the data presented in Mexico and Brazil,

Resolved, That it is desirable that two other members of the medical profession should be associated in this work, one having practical and clinical acquaintance with yellow fever, and the other being qualified to communicate with the population of the respective localities;

Resolved, That a committee of three be appointed by the President of this Association to communicate this action to President Cleveland, setting forth the grounds for such recommendation.

A motion by Dr. G. H. Rohé to lay it on the table was lost, and the resolutions were adopted. Dr. Rohé moved a reconsideration, which was lost.

On motion of Dr. N. S. Davis, it was agreed to proceed with the regular order, as the By-laws require that new and miscellaneous business of this kind should be considered only on the first and fourth days of the session.

The Address in Obstetrics was read by Dr. F. M. Johnson, of Missouri, Chairman of the Section.

The Address in State Medicine was read by Dr. G. H. Rohé, of Maryland, Chairman of the Section.

The Address on Diseases of Children was read by Dr. J. S. Knox, of Illinois, Chairman of the Section.

These addresses were referred for publication.

The Permanent Secretary read the

REPORT OF THE TREASURER.

I have the honor to report that the receipts to the treasury of the Association during the interval between the two annual meetings have amounted to the sum of $21,723.22; the expenditures to $20,319.45, leaving a balance in the treasury at this time of $1,403.77. There is nothing further of interest to report or suggest at this time. All of which is respectfully submitted. RICHARD J. DUNGLISON,
Treasurer.

June 9, 1887.

He also read the report of the Librarian, which asked an appropriation of $10 to the *Index Medicus*. On motion, this was granted.

He next read a communication from the Chairman of the Committee on Finance of the Ninth International Medical Congress, asking aid.

Dr. Davis moved to appropriate $500. An amendment was offered to make it $1,000. This was adopted.

Dr. Davis announced two resolutions which he asked should be considered on Friday morning. On motion of Dr. J. F. Hibberd, they were made the special order after the Addresses.

Dr. J. H. Hobart Burge, of Brooklyn, offered the following resolutions, which were adopted:

Resolved, That the Committees of Arrangements of the American Medical Association be expected hereafter to adopt efficient means to prevent conversation and loitering in the vestibule and all ante-rooms or the hall in which the general meetings of the Association are held.

Resolved, That it be the duty of the Permanent Secretary to place a copy of this resolution in the hands of each succeeding Committee of Arrangements.

The Association adjourned until Friday, at 10 A.M

FRIDAY, JUNE 10—FOURTH DAY.

The President called the Association to order at 10 A.M., and prayer was offered by Rev. W. H. Vibbert.

The Committee of Arrangements announced two charges against members; they were referred to the Judicial Council.

The final report of the Nominating Committee was read. The following physicians were appointed to deliver addresses at the next meeting: On General Medicine, Dr. R. Beverly Cole, San Francisco, Cal.; Surgery, Dr. E. M. Moore, New York; Public Medicine, Dr. James L. Cabell, Virginia.

A committee consisting of Drs. J. M. Toner, Eugene Grissom, and Darwin Colvin, was appointed to notify those selected to deliver addresses, and in case of declination or death, to fill the vacancy.

Surgeon-General Hamilton, of the U. S. Marine Hospital Service at Washington, offered the following resolution, in relation to the investigation of the prevention of yellow fever by inoculation:

WHEREAS, The President of the United States has appointed George M. Sternberg, Surgeon U. S. Army, to proceed to Mexico and Brazil for the purpose of investigating the method there practiced for the prevention of yellow fever by inoculation;

WHEREAS, This report will be accompanied by photo-micographic illustrations of the appearance of the principal organs of the body affected by yellow fever: therefore, be it

Resolved, That the Senate and House of Representatives be requested to cause such number of copies of Dr. Sternberg's report to be printed as may be needed by the profession of medicine of the United States; be it further resolved, that the resolution on this subject passed yesterday be rescinded.

Dr. J. McF. Gaston objected that it was not in order. After some discussion, the previous question was demanded by the proper number. It was decided in the affirmative by a large vote, and the resolution of Dr. Hamilton was then adopted.

The Address on Dental and Oral Surgery was read by Dr. J. S. Marshall, of Illinois, Chairman of the Section.

The Address on Medical Jurisprudence was read by Dr. I. N. Quimby, Chairman of the Section.

On motion of Dr. A. N. Bell, it was agreed that the Committees should be appointed as requested in this Address.

The President appointed them as follows:

Criminality of Fœticide and Measures for its Prevention—I. N. Quimby, N. J., W. B. Atkinson, Pa., W. H. Byford, Ill.

Duties Commonly Exercised by Coroners—H. O. Marcy, Mass, J. H. H. Burge, N. Y., W. W. Dawson, Ohio.

Dr. J. M. Toner reported that the necrological notices had been published as before.

The report of the Auditors was presented and accepted:

The undersigned, Auditing Committee of the accounts of the Treasurer of the American Medical Association, and also of the Treasurer of the Board of Trustees, report that they have carefully examined the accounts of said officers, and find them correctly cast and properly vouched, and that the balances are as reported by said officers to the Association. In behalf of the Auditing Committee,

ALONZO GARCELON, *Chairman*.

Dr. Davis, of the Committee on Meteorological Investigations, etc., reported progress. On motion of Dr. Brodie, the report was accepted and the Committee continued.

Dr. Davis offered the following:

Resolved, That the regular graduates of such dental and oral schools and colleges as require of their students a standard of preliminary or general education, and a term of professional study equal to the best class of the medical colleges of this country, and embrace in their curriculum all the fundamental branches of medicine, differing chiefly by substituting practical and clinical instruction in dental and oral medicine and surgery, in place of practical and clinical instruction in general medicine and surgery, be recognized as members of the regular profession of medicine, and eligible to membership in this Association on the same conditions and subject to the same regulations as other members.

This was adopted by a large majority.

Dr. N. S. Davis read the following:

Resolved, That the Committee of Arrangements are hereby directed at each annual meeting of the Association, to so arrange the programmes regarding entertainments and receptions, that the evening of the third day be reserved for a regular annual dinner under the following general regulations: The chief registration officer shall provide for each registration table a paper headed, "Annual Dinner of the American Medical Association," with two columns for names, one headed tickets without wines or liquors at a specified sum; the other tickets with wines, etc., at a specified sum; that each member when registering can have the opportunity to take a ticket for the dinner if he desires it, and can be entirely free to enjoy the dinner not only without using wines, but also without being required to assist in paying for that drank by others; while those who desire the addition of wines will enjoy the same liberty. It shall be the duty of the Committee of Arrangements to select a proper place for the dinner, to ascertain the cost per plate on the plan already indicated, that the price paid for the tickets will pay the entire cost of the dinner, leaving no part to be paid either by the local profession or by the Treasurer of the Association.

This was also adopted by a large majority.

Dr. A. H. Wilson, Mass., offered a resolution appropriating an honorarium of $300 to the Permanent Secretary. After some discussion, Dr. Davis offered an amendment to strike out all after the word resolved, and insert the following:

WHEREAS, It has been the unswerving policy of the Trustees for the publication of THE JOURNAL, to enlarge and increase the value of THE JOURNAL as fast as the income of the Association will permit, therefore

Resolved, That said Board of Trustees be a Standing Committee on Finance to which all propositions for the appropriation of money, made hereafter, shall be referred and reported upon before final action on the same by the Association.

This was adopted. The vote was then taken on the resolution as amended, and it was adopted.

Dr. D. J. Roberts offered a resolution on Medical Education, which, on motion of Dr. Brodie, was referred to the Section on State Medicine.

Dr. J. M. Toner offered a resolution that the Presidents of each State or Territorial Medical Society be an Honorary Vice-President of this Association. On motion of Dr. D. J. Roberts, this was laid upon the table.

On motion of Dr. E. A. Wood, of Pa., the President was requested to appoint a committee of three to report on Dietetics. The President appointed as such committee Drs. E. A. Wood, of Pittsburgh, Pa., J. S. Whittaker, Cincinnati, O., and F. Woodbury, Philadelphia, Pa.

Dr. T. E. Woodbridge, of Ohio, offered a resolution to appoint a committee to examine and report upon Sanitary Locations. On motion this was referred to the Section on State Medicine.

The Permanent Secretary read a telegram from the President, Dr. A. Y. P. Garnett, thanking the Association for the honor conferred upon him.

On motion of Dr. Brodie, the thanks of the Association were tendered to the citizens and profession of Chicago, to Drs. R. N. Isham, N. S. Davis, C. Gilman Smith, and S. J. Jones, and to Mr. and Mrs. S. M. Nickerson and Mr. and Mrs. Rosenberg, and to the many who had so courteously invited the Association to enjoy their hospitalities, to the officers of the Association, and to all who had contributed to make this session a grand success.

After some pleasant remarks from the retiring President, he declared the Association adjourned to meet on the second Tuesday of May, 1888, in Cincinnati.

WM. B. ATKINSON,
Permanent Secretary.

INDEX VOLUME VIII.
